Before dealing squarely with the remaining inequities in food distribution and access, as well as the environmental damage often associated with the provision of food, the first and foremost fact is that our ability to provide sufficient food and to do so in increasingly cost-effective ways has been a major human and humanitarian achievement. It is all the more remarkable given that the past 50 years have seen the global population double, adding more mouths to be fed than existed on the planet in 1950. And according to most projections, it appears likely that growing food needs can be met in the foreseeable future, notwithstanding a growing list of technological, distributional, food safety, and health issues that require serious attention and action (Bruinsma 2003; Runge et al. 2003).

Figure 8.1 illustrates the trend in a number of key indicators of food provision. The most significant trend is the growth in food output from 1961 to 2003, increasing by over 160%, or 1.7% per year. As a consequence, average food production per capita also increased by around 25% during the period. Fueling this output growth in many parts of the world were long-term investments in the generation and distribution of new seeds and other farming technologies, and in infrastructure such as irrigation systems and rural roads. This allowed farm productivity to increase and marketing margins to decrease, reducing the price of many foods. Figure 8.1 shows that following significant spikes in the 1970s caused primarily by oil crises, there have been persistent and profound reductions in the price of food globally. It is *well established* that past increases in food production, at progressively lower unit costs, have improved the health and well-being of billions of people, particularly the poorest, who spend the largest share of their incomes on food.

Despite rising food production and falling food prices, more than 850 million people still suffer today from chronic undernourishment, and the absolute number of hungry people is rising. In 1970 there were an estimated 959 million people suffering from hunger, or about one quarter of the world's population. By 1998 that number had been reduced to 815 million, but progress has been slow. And in sub-Saharan Africa, there are now many more hungry people than there were in 1970. There have also been recent declines in food security in South Asia and the transition economies. In 2000–02, the total number of 852 undernourished people globally was up 37 million from 1997–99. Of this total, 815 million people were in developing countries, up by around 38 million from the 777 million in 1997–99 (FAO 2001, 2004a). In industrial countries, approximately 1.6% of children under five are underweight (WHO 2004d).

This chapter provides insights into the structure and distribution of food provision, with particular emphasis on the relative contribution of various ecological systems. It examines trends in the core food sources (crops, livestock, and fisheries), some of the key linkages to ecosystems and ecosystem service provision, and the drivers of those trends. Examining the drivers of change is particularly important, since some are amenable to intervention so as to bring about improved outcomes, particularly with regard to greater provision of (or fewer trade-offs with) other ecosystem services. Finally, the chapter addresses linkages between human well-being and food access and use. The chapter does not dwell on the important issue of the specific ways in which food is cultivated or harvested, and how those ways affect ecosystem capacity and the provision of other services. These topics are the core focus of specific systems chapters, of which cultivated systems (Chapter 26), drylands (Chapter 22), inland waters (Chapter 20), coastal (Chapter 19), and marine (Chapter 18) systems are the ones most directly relevant. Key related service chapters are those on biodiversity (Chapter 4), fresh water (Chapter 7), and nutrient cycling (Chapter 12).

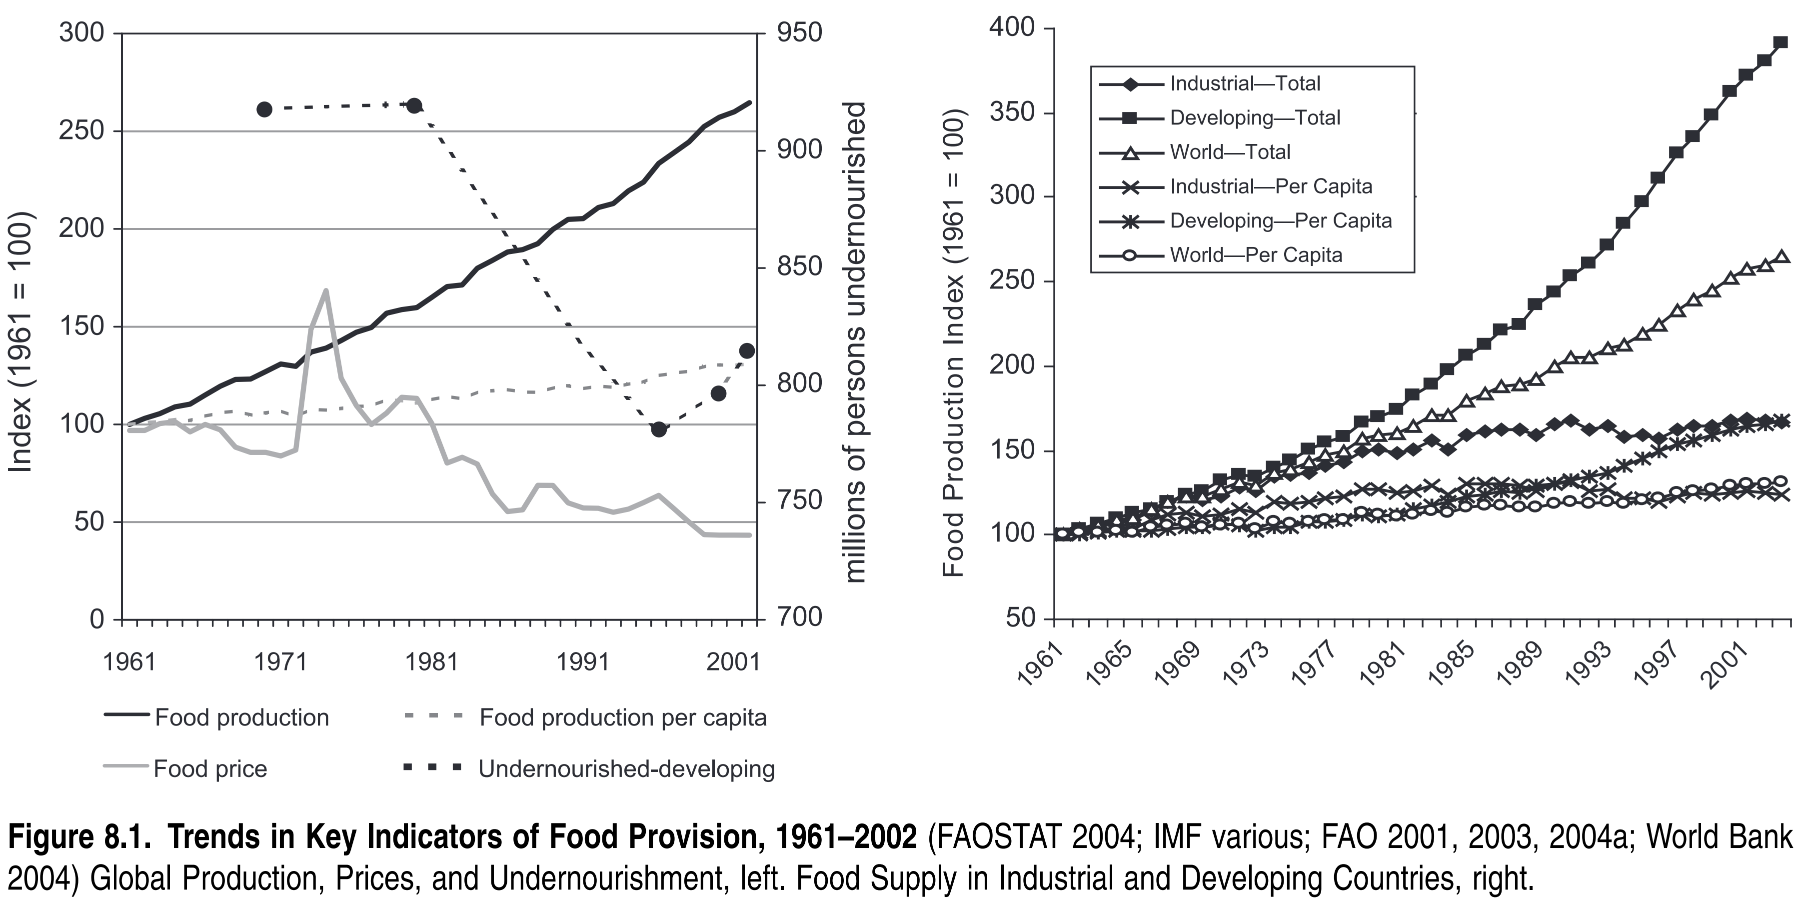

Figure 8.1. Trends in Key Indicators of Food Provision, 1961–2002 (FAOSTAT 2004; IMF various; FAO 2001, 2003, 2004a; World Bank 2004) Global Production, Prices, and Undernourishment, left. Food Supply in Industrial and Developing Countries, right.

8.2 Magnitude, Distribution, and Structure of Food Provision

This section has two main subsections. First, a contemporary perspective of the structure of food provision is presented, focusing both on major food groups and on a breakdown of food provision by system types. An assessment of the spatial distribution of global food production by value for crops, livestock, and fisheries is also presented. Second, a review in more depth is provided of the specific regional and food group trends for crops, livestock, and fisheries.

8.2.1 Structure and Distribution of Food Provision

The overall distribution of food production by MA system type and by major food group is presented in Table 8.1. Care must be taken in interpreting the Table for several reasons. First, the MA systems are neither mutually exclusive nor fully exhaustive of all terrestrial ecosystems. For example, a single cropland area might simultaneously be counted as belonging to several MA systems, since it is a *cultivated system* in a *dryland* area, situated in the *coastal* zone. Second, it is very difficult to obtain any reliable information on the quantity and value of wild sources of food (apart from commercial fisheries), even though they are extremely important in many parts of the world.

All crop production is considered to take place in cultivated systems. (See Chapter 26.) Dryland systems account for about 38% of total crop production, with forest and mountain ecosystems each accounting for about 25%, and coastal systems around 12%. Table 8.1 shows both annual and perennial crop production, irrigated and rain-fed production proportions, and an assessment of the food and feed utilization of crops. On average, about 53% of food crops find their way into food and 21% are used for feed. The remaining 26% is categorized as used for seed, waste, or other industrial processing. Only a small share of perennial crop production is used for feed. However, a significant quantity of wild fisheries capture is used for feed—for aquaculture and, to a lesser extent, livestock. Aquaculture production is roughly split evenly between inland/fresh and coastal/brackish waters. Wild fish catches from freshwater systems are extremely difficult to estimate, as most go unreported. Some 63% of wild marine fish catches are from marine systems and 37% from coastal systems.

Figure 8.2 (in Appendix A) shows the spatial distribution of the total value of food production summarized in Table 8.1, indicating where the major calorie and protein sources of the world are concentrated. Figure 8.3 (in Appendix A) shows a detail for Asia, highlighting the importance of coastal zone systems in providing high values of both marine and terrestrial food sources. This dual pressure on coastal zones poses particular management challenges. (See Chapter 19.)

8.2.2 Distribution of and Trends in Domesticated and Wild Food Production

8.2.2.1 Domesticated Species

As domestication of plant and animal species favored for food production has evolved, the species base supporting food provision has been eroded. Of the estimated 10,000–15,000 edible plants known, only 7,000 have been used in agriculture and less than 2% are deemed to be economically important at a national level. Only 30 crops provide an estimated 90% of the world population's calorific requirements, with wheat, rice, and maize alone providing about half the calories consumed globally (Shand 1997; FAO 1998; FAOSTAT 2004).

There is a large potential for the improvement and greater use of neglected and underutilized species (FAO 1996; Naylor et al.

Table 8.1. The Global Structure of Food Provision by Food Category and MA Ecosystem (2000 production)

Food/Feed Types		Total Value	Share By Use (percent)		Value by Selected MA System (billion 1989–91 dollars)							
			Food	Feed	Dryland	Forests	Cultivated Systems	Mountains	Polar	Inland Waters	Coastal	Marine

Total value of food production		**1,557**			**608**	**300**	**1,089**	**345**	**2**	**32**	**210**	**57**

Production values derived from 2000 production estimates weighted by 1989–91 global average international dollar prices for individual products in each food type group (FAOSTAT 2004; FAO Fishstat 2003; FAO 1997). The 1989–91 prices are the most recent set of complete and comparable prices covering all FAO crop and livestock products. Fisheries prices based on landed values by group of species. Production values by MA system and irrigated/rain-fed split derived by authors from GIS analysis of cropland, irrigated area, and pasture and livestock distribution. Non-food agricultural products were excluded from the analysis. Note that total value for each food group is not the sum of individual MA system values since MA systems overlap and not all MA systems are included in the table.

[a] Fisheries totals do not include wild inland water catches.
n.a. = data not available.

2004). In addition, along with traditional crop varieties, wild relatives of crop plants have been used to supply specific traits that have been introduced into crop plants using conventional breeding techniques, and, increasingly, using modern biotechnology (FAO 1998). There is also a large potential for the domestication and improvement of new crops, especially fruits, vegetables, and industrial (or cash) crops (Janick and Simon 1993), but the probability of developing new major staple crops is probably rather limited (Diamond 1999). With regard to livestock, of the estimated 15,000 species of mammals and birds, only some 30–40 (0.25%) have been used for food production, with fewer than 14 species accounting for 90% of global livestock production.

Since the origins of agriculture, farmers—and, more recently, professional plant and animal breeders—have developed a diverse range of varieties and breeds that contain a high level of genetic diversity within the major species used for food. For some crop species, there are thousands of distinct varieties (FAO 1998). Similarly, there are many breeds of livestock that originate from a single species. However, as larger and larger areas are planted with a smaller and smaller number of crop varieties, and as livestock systems are intensified, many of these varieties and breeds are at risk of being lost in production systems and increasingly are found only in ex situ collections. (See Chapter 26.) For example, FAO estimates that in Europe 50% of livestock breeds that existed 100 years ago have disappeared (Shand 1997).

Plant breeders have achieved yield increases through changing plant physiology and number of grains; increasing the oil, protein, and starch content of specific crops; shortening the maturity period for annual and perennial crops; and increasing drought resistance and nutrient use efficiency. Plant breeding per se has been complemented by deliberate programs of genetic enhancement or ''base broadening'' in order to incorporate genetic variation into plant breeders' stocks. Generally, there has been insufficient investment in such ''pre-competitive'' crop improvement activities (Simmonds 1993; FAO 1996; Cooper et al. 2000).

8.2.2.1.1 Crops

Over the 40 years from 1964 to 2004, the total output of crops expanded by some 144% globally, an average increase of just over 2% per year, always keeping ahead of global population growth rates. As shown in Table 8.2, output growth varied by region and over the period as a whole.

Despite a resurgence of crop output in the early to mid-1990s in response to both the decline in outputs from countries in transition and a surge in food prices, many middle-income and richer countries have seen a gradual slowing down in the growth of crop output in line with the deceleration of population growth and the attainment of generally satisfactory levels of food intake. Decelerating growth patterns in crop output have been most evident in industrial countries and in Asia more widely.

Table 8.2. Global and Regional Growth Rates in Crop Output (Bruinsma 2003)

Region	1969–99	1979–99	1989–99
		(percent per year)	
Sub-Saharan Africa	2.3	3.3	3.3
Near East/North Africa	2.9	2.9	2.6
Latin America and Caribbean	2.6	2.3	2.6
South Asia	2.8	3.0	2.4
East Asia	3.6	3.5	3.7
Developing countries	3.1	3.1	3.2
Industrial countries	1.4	1.1	1.6
Transition economies	–0.6	–1.6	3.7
World	**2.1**	**2.0**	**2.1**

Output in the transition economies fell by about 30% between 1990 and 1995 from its fairly stable level in the mid to late 1980s. While output has since steadied around a lower level, a significant drop in average food energy intake and an increase in the incidence of malnutrition have been documented during the 1990s, as described elsewhere in this chapter.

In response to growing affluence and shifting dietary patterns that increased demand for both food and feed crops, growth of food output in Asia has been consistently high, at 3% a year or more since the early 1960s. The feed market is important not only for intensive livestock production, but increasingly for aquaculture, as seen in the rapid increase in soybean demand for carp cultivation in China.

While growth in overall crop output in sub-Saharan Africa has been relatively strong over the past two decades, beverage and fiber crops, predominantly for export, still represent a significant share of that production. Since food crop production has not grown as markedly, and population growth rates remain high, sub-Saharan Africa remains the only region in which per capita food production has not seen any sustained increase over the last three decades, and this has recently been in decline. In North Africa and the Middle East, growth in crop output has been both moderate and often erratic.

The past 40 years have also seen some considerable shifts in crop production, driven by changes in consumption. Figure 8.4 shows the trends in crop production by major crop group on a per capita basis. There have been four general trends exhibited by oilcrops; fruits and vegetables; cereals and sugar crops; and roots, tubers, and pulses.

Growth in output of oilcrops and vegetable oils between 1961 and 2001was consistently strong at just over 4% per year, largely propelled by a rapid growth in palm oil (8.2% per year), rapeseed oil (6.9% per year), and soybeans (4.1% per year). The principal commodities included in this category (and their global production quantities in million tons in 2001) include soybeans (177), oil palm (128), coconuts (52), groundnuts (36), and rapeseed (36). Cottonseed (37 million tons) is usually often part of this group, but it is excluded here as it is not considered a food product.

Food use of oil and vegetable oil crops, expressed in oil equivalent, grew from 6.3 kilograms per capita per year in 1964/66 to 11.4 kilograms in 1997/99. Demand has grown more in developing countries (5.0% per year) than in industrial ones (3.2%), stimulated by rising incomes and urbanization that have increased consumption of cooking oil, processed foods, and snacks. More than for any other crop (and excluding pastures), it is the global area expansion of oilcrops over the past 40 years that has driven cropland expansion. (See Box 8.1.)

Fruit and vegetable production grew in line with population during the 1960s and 1970s, when growing demand lead to increased per capita output. The principal commodities in this category, and their 2001 production in million tons, are tomatoes (106), watermelons (81), bananas (65), cabbages (61), grapes (61), oranges (60), apples (58), and dry onions (51). While per capita output growth was modest during the 1980s, it accelerated during the 1990s. Between 1961 and 2001, production of vegetables grew from 72 kilograms per capita on average per year to 126 kilograms, and that of fruits from 56 to 77 kilograms per year.

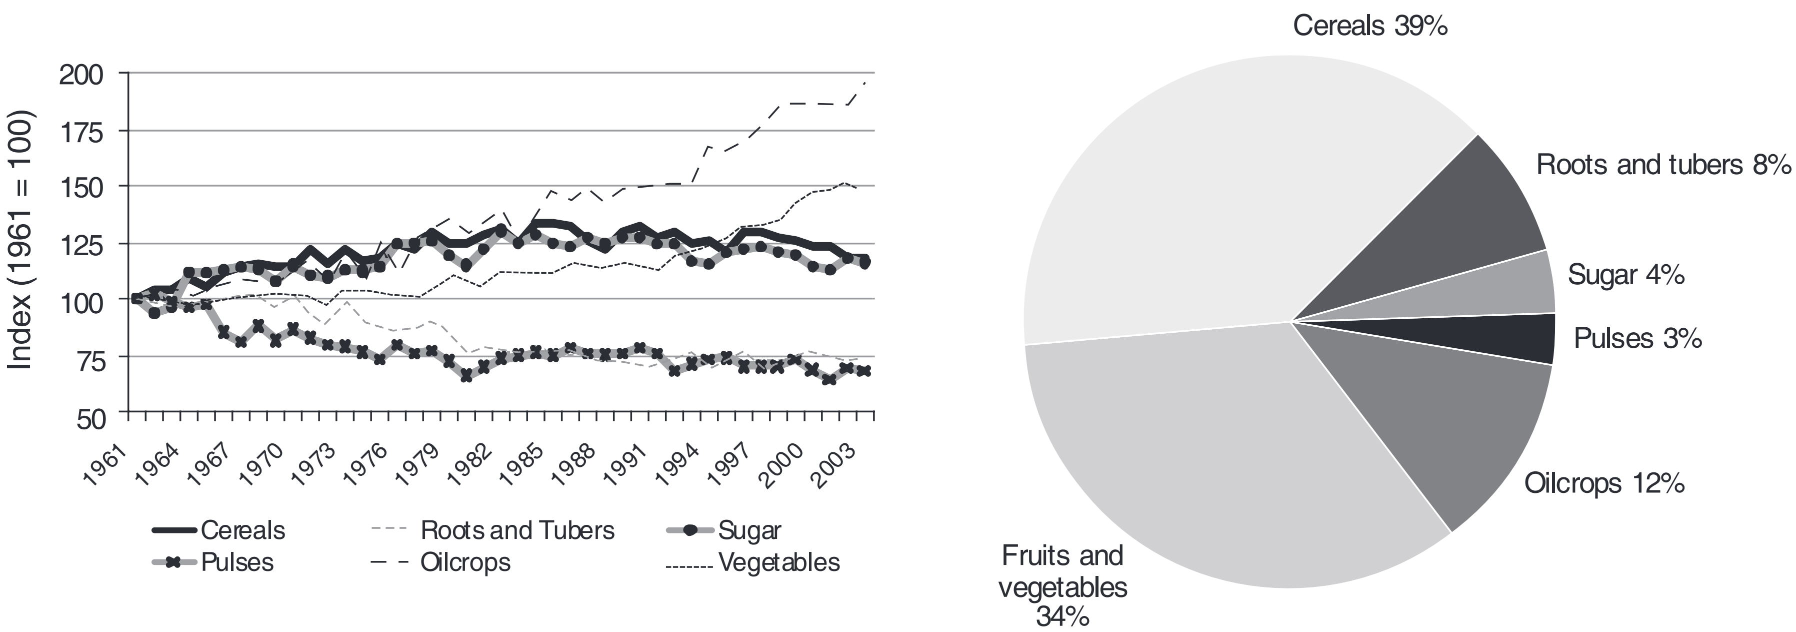

Figure 8.4. Aggregate Structure of Per Capita (1961–2003) and Total Food Crop Output by Group (2001–03 averages) (Calculated from FAOSTAT 2004)

BOX 8.1

Cropland Dynamics: The Case of Oil Crops (Bruinsma 2003: 101–03)

In 1961 the harvested areas of cereals and oilcrops stood at 648 million and 113 million hectares respectively. Over the past 40 years, output of oilcrops expanded dramatically, and by 2001 their harvested area stood at 233 million hectares compared to 674 million hectares for cereals. The harvested area of soybean alone expanded by some 50 million hectares. Most of the oilcrop expansion took place in land-abundant countries (Brazil, Argentina, Indonesia, Malaysia, the United States, and Canada).

The big four oil crops have been responsible for a good part of the expansion of cultivated land under all crops in developing countries and the world as a whole. In terms of harvested area, land devoted to the world's principal crops (cereals, roots and tubers, pulses, fibers, sugar crops, and oilcrops) expanded by 59 million hectares (or 6%) since the mid-1970s. (Increases in harvested area arise from a physical expansion of cultivated land, an expansion of land under multiple cropping (a hectare of arable land is counted as two if it is cropped twice in a year), or both. Therefore, the harvested area expansion under the different crops discussed here could overstate the extent to which physical area in cultivation has increased. This overstatement is likely to be more pronounced for cereals (where the arable area has probably declined even in developing countries) than for oilcrops, as the latter include also tree crops (oil and coconut palms and olive trees).)

A 105-million-hectare increase in harvested area in developing countries was accompanied by a 46-million-hectare decline in industrial countries and transition economies. The expansion of land under the big four oil crops was 63 million hectares—that is, they accounted for all the increase in world harvested area, and more than compensated for the drastic declines in the area under cereals in industrial countries and transition economies. In these countries, the expansion of oilseed area (25 million hectares) substituted and compensated for part of the deep decline in the area sown to cereals. But in developing countries, it seems likely that it was predominantly new land that came under cultivation, as land under the other crops also increased.

These numbers illustrate the dramatic changes in cropping patterns that occurred, particularly in industrial countries, as a result of policies (such as EU support to oilseeds) and of changing demand patterns toward oils for food in developing countries and toward oilcakes/meals for livestock feeding everywhere. They also demonstrate that land expansion still can play an important role in the growth of crop production. The 200% increase in oilcrop output between 1974/76 and 1997/99 in developing countries was brought about by a 70% (50-million-hectare) expansion of land under these crops at the same time as land under other crops increased by an almost equal amount.

Particularly notable is the rapid expansion of the share of oil palm products (in terms of oil palm fruit) from Southeast Asia (from 40% of world production in 1974/76 to 79% in 1997/99) and the dramatically shrinking share from Africa (from 53 to 14%). Africa's share in terms of actual production of palm oil (9% of the world total, down from 37% in the mid-1970s) remained well below that of its share in oil palm fruit production. This denotes the failure to upgrade the processing industry, but also the potential offered by more-efficient processing technology to increase oil output from existing oil palm areas. The contrast of these production shares with the shares of land area under oil palm is even starker: Africa still accounts for 44% of the world total, three quarters of it in Nigeria.

Cereal and sugar crop production grew at an accelerated rate in the 1960s and 1970s, increasing their total per capita output by around 25% by 1980. The principal cereal crops, according to their 2001 production in million tons, are maize (615), paddy rice (598), wheat (591), barley (114), sorghum (60), millet (29), and oats (27).

Per capita cereal production peaked in the mid-1980s and has been in slow decline ever since. Sugar crop production followed broadly the same pattern as that for cereals. The per capita production of roots, tubers, and pulses declined by around 25% between the early 1960s and the early 1980s, with pulses declining more rapidly at first. Since then production has roughly kept pace with population growth.

Overall, these trends suggest that higher-value cereals, fruits, and vegetables have tended to displace pulses and roots and tubers.

The cereal sector remains particularly important in several ways. Cereals provide almost half of the calories consumed directly by humans globally (48% in 2001) and will continue as the foundation of human food supply into the foreseeable future because of their high yields, nutrient density, and ease of cooking, transport, and storage compared with other staples such as root and starch crops. Cereal production accounts for almost 60% of the world's harvested crop area and an often disproportionately larger share of the usage of fertilizer, water, energy, and other agrochemical inputs. The cereal sector therefore is especially important from the perspective of ecosystem services and trade-offs between services both locally and globally. Chapter 7 in the MA *Scenarios* volume describes the technological and humanitarian successes of the cereal-based Green Revolution, as well as the subsequent and continuing controversy about the scale and longevity of its environmental and equity implications. At the heart of this debate lie many questions of trade-offs among ecosystem services and among elements of human well-being. One part of that debate has focused on the relative economic, social, and environmental costs of intensification versus expansion strategies for meeting global (cereal) food needs (Evenson and Gollin 2003; Conway 1997; Green et al. 2005) as well as on key assumptions regarding the scientific opportunities for improving future crop yield potential (Cassman 1999; Cassman et al. 2003).

Aggregate cereal consumption and production patterns are influenced by three major, codependent forces. The first force is a two-stage income effect in which cereal consumption increases in proportion with incomes as they grow from low levels, but a reversal in this behavior (technically, a reverse in the ''income elasticity'') is witnessed as incomes continue to rise and as basic energy and other dietary needs are met. At this stage most consumers tend to replace food staples like cereals with higher-value foods, such as animal protein and fruits and vegetables. The second force is urbanization, which often brings a shift in cereal preferences toward wheat and rice at the same time as an overall decline in the share of cereals in a more diverse diet. And the third force is the increasing role of coarse grains (maize, sorghum, millet) but also wheat and, to a lesser extent, rice as livestock feed. These forces, all at various stages of evolution in different parts of the world, have resulted in a net increase in per capita cereal consumption globally from 135 to 155 kilograms per year between 1961 and 2001, even though cereals now constitute a slightly lower proportion of total energy intake (down from 50% to 48%).

The trends are clearer if industrial- and developing-country groupings are distinguished. In industrial countries, per capita consumption of cereal as food fell from 148 to 130 kilograms per year (representing 38% and 31% respectively of dietary energy supply), while in developing countries per capita consumption increased from 129 to 162 kilograms per year (representing 59% and 53% respectively of DES). (See Box 8.2 for a description of trends in cereals for feed.)

Following a peak in food prices in 1996, there was strong growth in crop output in 1999 in both industrial and developing countries, but since then the general pattern of growth deceleration has resumed. In industrial countries, output actually declined in both 2001 and 2002. In the case of cereals, global output levels have stagnated since 1996, while grain stocks have been in decline. The area devoted to the major cereals has been decreasing at about 0.3% annually since the 1980s. These trends are likely to continue if real cereal prices continue to fall, causing farmers to switch to more profitable crops, such as vegetables and fruits. Loss of highly productive cereal-growing land is particularly acute in areas of rapid urban expansion, a common feature of development in many countries. Although there has been some cereal price recovery since 2001, prices still stand at some 30–40% lower than their peak in the mid-1990s (FAO 2004b).

Growth in the yield of the major cereals has been virtually constant for the past 35 years since the release of the first miracle varieties of wheat and rice and of the single-cross maize hybrids. And in many of the world's most important cereal production areas, there has even been a plateauing of yields in the past 15–20 years as average farm yields reached about 80–85% of the genetic yield potential (Cassman 1999). Such stagnation is evident in key rice-growing provinces in China, Java and other parts of Indonesia, Central Luzon in the Philippines, the Indian Punjab, Japan, and South Korea (Cassman et al. 2003), as well as for irrigated wheat in the Yaqui Valley of Mexico. However, yield growth rates will have to increase to meet future food demand unless more land area is devoted to cereal production. While in many low-productivity areas there is still considerable scope (and pressing need) for raising yields through the use of improved technologies and management practices, in high-productivity areas future yield growth will depend increasingly on raising genetic yield potential and more fine-tuned crop and soil management practices to allow consistent production near the yield potential ceiling.

Despite the potential contribution of genomics and molecular biology, as well as substantial research investments to improve photosynthesis during the 1970s and 1980s, there is as yet limited evidence that biotechnology approaches can help raise the yield potential ceiling. Indeed, there has been little progress toward increasing maximum net assimilation rates (photosynthesis minus respiration) in crop plants, and the determinants of yield potential are under complex genetic control that result in trade-offs between different options for increasing seed number, seed size, partitioning of dry matter among different organs, crop growth duration, and so forth (Denison 2003; Sinclair et al. 2004). Consideration of these issues has led to calls for caution in projecting forward past achievements in yield growth as a basis for assessing future food security, as well as for greater urgency in the key scientific challenges involved (Denison 2003; Cassman 2001).

8.2.2.1.2 Livestock

Livestock and livestock products are estimated to make up over half of the total value of agricultural gross output in industrial countries, and about a third of the total in developing countries, but this latter share is rising rapidly (Bruinsma 2003). The global importance of livestock and their products is increasing as consumer demand in developing countries expands with population growth, rising incomes, and urbanization. This rapid worldwide growth in demand for food of animal origin, with its accompanying effects on human health, livelihoods, and the environment, has been dubbed the ''Livestock Revolution'' (Delgado et al. 1999). Livestock production has important implications for ecosystems and ecosystem services, as it is the single largest user of land either directly through grazing or indirectly through consumption of fodder and feedgrains (Bruinsma 2003). Industrial livestock production, the most rapidly growing means of raising livestock, poses a range of pollution and human health problems. (See Chapter 26.) At the same time, livestock production can promote linkages between system components (land, crops, and water) and enables the diversification of production resources for poor farmers (Devendra 2000).

The overall annual growth rates for livestock product outputs are summarized by region and by time period in Table 8.3. The global growth rate is currently just over 2% per year and is declining over time, but this masks the true dynamics of the sector (and highlights the potential pitfalls of interpreting global-scale data), as there are large regional disparities. While growth rates in industrial countries, where people already enjoy adequate supplies of

BOX 8.2

The Growing Use of Crops as Feed (Delgado et al. 1999)

Crops are used both as feed inputs for intensive livestock systems and for direct or processed sources of food. Global use of cereals as feed increased at only 0.7% per year between 1982 and 1994 despite rapid increases in meat production. Growth rate in cereal use in industrial countries was negligible, while it increased by about 4% a year in the developing countries. Despite the higher growth rate, developing countries still use less than half as much cereal for feed as industrial countries do. During the early 1990s, concentrated cereal feed provided between 59% and 80% of the nutrition given to animals in the industrial world. By contrast, cereals accounted for only 45% of total concentrate feed in Southeast Asia, the developing region with the most intensive use of feed grains.

For the world as a whole, it is estimated that 660 million tons (in 1997) of mainly coarse grains, making up 35% of all cereal use, are fed to animals. Most of these are used in the United States and other industrial countries. Nevertheless, increasing amounts are being fed to intensive livestock in developing countries, as poultry and pig production increased. Over the last decade, the increase in cereal use for feed has been more gradual than expected, partly because of a reduction in intensive livestock production in the transition economies, partly because of high cereal prices in the EU, and partly because of increasing efficiency of feed conversion.

Poultry are very efficient feed converters, requiring only 2–2.5 kilograms of feed per kilogram of meat produced and even less per kilogram of eggs. Pigs require 2.5–4 kilograms of dry matter per kilogram of pig meat, while concentrate-fed ruminants require much more feed per kilogram of meat.

The use of cereals as feed has been fastest in Asia, where output growth has risen the most and land is scarce. In Other East Asia, Southeast Asia, and Sub-Saharan Africa, cereal use as feed grew faster than meat production, indicating that those regions are intensifying their use of feed per unit of meat output. Most of Asia, West Asia–North Africa, and Sub-Saharan Africa lack the capacity to produce substantial amounts of feed grain at competitive prices. The growing amounts of feed grains imported into these regions attest to this deficiency. Given that many developing countries cannot expand crop area, two possibilities remain: intensification of existing land resources and importation of feed. Because much of the gain from intensification will probably go toward meeting the increasing demand for food crops, substantially more feed grains will have to be imported by developing countries in the future.

Alternatives to crops in the way of feed include household waste products and crop residues. In developing countries, household food waste, such as tuber skins, stems, and leaf tops, has traditionally been an important feed source for backyard monogastric production in particular. But small-scale backyard operations are disappearing because of low returns to labor and increased competition from large-scale producers. Although each backyard operation is small, at the aggregate level such systems act as major transformers of waste into meat and milk. Because large operations are unlikely to find it cost-effective to collect small amounts of waste from many households, this source of animal feed may be underused in industrial systems.

Trends and Projections in the Use of Cereal as Feed. Figures are three-year moving averages centered on year shown. The 2020 projections are from the July 2002 version of the IMPACT model. (Delgado et al. 2003, calculated from data in FAOSTAT 2004)

	Total Cereal Use as Feed

[a] Ranges show high and low estimates based on data from various sources.

animal protein, have remained at just over 1% for the past 30 years, growth rates in developing countries as a whole have been high and generally accelerating. The trends in East Asia (and particularly China) are particularly strong, with livestock product growth rates of over 7% a year over the last 30 years, albeit from a low base. South Asia and the Middle East and North Africa have maintained long-term growth in livestock product output of over 3% per year.

As with crops, two regions have lagged behind in livestock production: the countries in transition and sub-Saharan Africa. The transition economies exhibit the same pattern as for crops—slow long-term shrinkage of output, followed by collapse in the early 1990s. Sub-Saharan Africa, faced with the world's highest stresses of poverty, hunger, and population growth (see Chapters 3, 6, and 7) and with continuing insecurity, particularly in pastoral areas within the subcontinent, has made slow progress; per capita livestock output has hardly increased at all in the past 30 years (Ehui et al. 2002).

With regard to the product structure of growth, Figure 8.5 presents the trends in growth of global output for each of the major livestock food product categories, expressed in per capita terms. Three broad groupings of trends are shown; for poultry meat; for pigmeat and eggs; and for bovine, mutton, and goat meat and milk. Poultry meat production has expanded almost ninefold, from some 2.9 to 11.2 kilograms per capita per year between 1961 and 2001. In developing countries, this entailed a production expansion from 1.0 to 7.7 kilograms per capita per year as population in those countries increased from 2.1 billion to 4.8 billion. In industrial countries, the equivalent figure was from 6.7 to 24 kilograms as population increased from 980 million to 1.3 billion. This quite remarkable growth in output has been achieved through rapid expansion of industrial (''landless'') chicken rearing and processing facilities located in peri-urban areas throughout the world. (See Chapter 26.) These enterprises in turn depend on supplies of quality grain-based feedstuffs from national or international markets.

Table 8.3. Global and Regional Growth in Livestock Output (Bruinsma 2003)

World	**2.2**	**2.1**	**2.0**

While growth in the poultry meat sector has been relatively consistent since the early 1960s, the output of eggs and pork was slower both in its takeoff and in its subsequent growth, with higher and more sustained growth starting only in the early 1980s. Per capita production of both eggs and pork almost doubled between 1961 and 2001. Total production of eggs rose from 15.1 million to 57.0 million tons, and pork from 24.7 million to 91.3 million tons. In developing countries, annual per capita production of eggs and pork increased from 1.6 and 2.1 kilograms, respectively, in 1961 to 7.0 and 11.3 kilograms in 2001. In industrial countries, growth has been more modest, however, from 10.8 to 12.7 kilograms per capita in the case of eggs, and from 20.5 to 24.0 kilograms per capita in the case of pork during the same time period. Pig and poultry meat each now account for about a third of all meat produced worldwide, and more than one half of total pig production is in China.

Growth in milk (cattle and buffalo), beef, and mutton and goat meat production has, on the whole, kept pace with population growth rates, and average per capita global production has stayed relatively constant over the last 40 years. The 1961 global production of 344 million, 29 million, and 6 million tons of milk, beef, and mutton and goat meat, respectively, increased to 590 million, 59 million, and 11 million tons in 2001. Milk production has risen faster in developing than in industrial countries, from 32 to 50 kilograms per capita per year, but still lies far below the 264 kilograms per capita per year of industrial countries. Annual per capita production of beef increased in developing countries from 4.6 to 6.2 kilograms between 1961 and 2001, while in industrial countries, despite the large-scale switch to poultry meat, annual per capita beef production edged up from 19.6 kilograms in 1961 to 22.4 in 2001.

Looking back at the trends in the evolution of livestock systems, three points can be made: First, almost the entire expansion in output from poultry and pigs, globally, and from beef and milk cattle in industrial countries, has taken place in intensive, industrial production systems. Second, while providing food in relatively safe, reliable, and progressively cheaper ways, there have been many examples in both industrial and developing countries of a wide range of soil, water, and odor pollution problems, as well as potential large-scale health risks from the more intensive production of livestock. (See Chapter 26.) Third, the expansion of extensive beef production systems, primarily in South and Central America, has been associated with high rates of deforestation (Mahar and Schneider 1994; Kaimowitz 1996; Vosti et al. 2002).

Livestock productivity (output per head of livestock) continues to be higher in industrial than in developing countries, with the largest difference in the case of milk production, which is more than six times higher. In 2001, for example, milk yield was 3,075 and 480 kilograms per animal in industrial and developing countries, respectively. In general, sub-Saharan Africa and South Asia have the lowest output per animal compared with other parts of the world. In sub-Saharan Africa, milk production per animal has been declining since 1961, and in 2001, while production of beef per animal was about 65% of the world average, production of milk per animal was only 14% of the world average.

This low productivity level can be attributed to the types of production systems prevailing in sub-Saharan Africa. Generally, three phases of the income-herd relationship in smallholder producers can be distinguished, which coincide with the process of commercialization of the livestock sector: emergence, expansion, and contraction. Poor farmers raise few livestock, but as development begins to take place poor rural households are able to gradually expand their livestock holdings. The herd size gradually

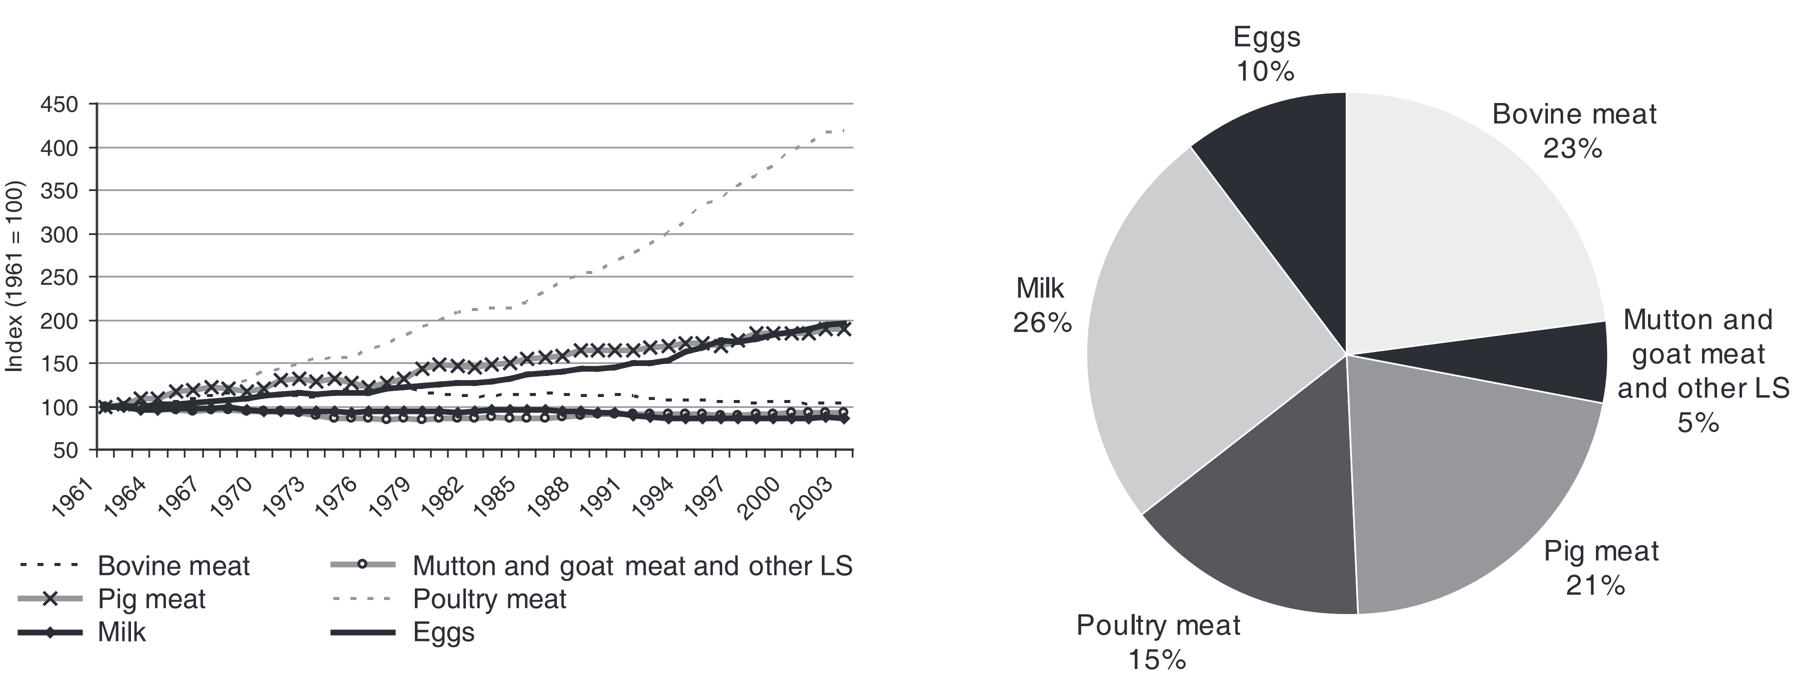

Figure 8.5. Aggregate Structure of Per Capita (1961–2003) and Total Livestock Output by Group (2001–03 averages) (Calculated from FAOSTAT 2004)

expands with further development, but there is a point of development in many rural economies after which most farmers choose to stop raising livestock. Beyond a certain income level, herd size for most households falls as productivity increases, and only a few specialized households evolve toward larger-scale commercial operations (McIntire et al. 1992).

To date, overall growth in livestock production has been sufficient to meet increases in demand without significant price increases, and relative to the long-term downward trend in prices for cereals, oils, and fats, the prices for livestock products have remained relatively stable. However, there are considerable differences between continents and countries in production and consumption, and international trade between surplus and deficit producers has increased. Developing countries, as a group, have become net importers of livestock products from industrial countries. Between 1990 and 2000, net imports of meat and milk to developing countries grew by more than 6% a year, while net imports of eggs declined by a little over 16%.

8.2.2.2 Wild Food Sources: Fisheries

Biodiversity provides a diverse range of edible plant and animal species that have been and continue to be used as wild sources of food, including plants (leafy vegetables, fruits, and nuts), fungi, bushmeat, insects and other arthropods, and fish (including mollusks and crustaceans as well as finfish) (Pimbert 1999; Koziell and Saunders 2001). Many types of wild food remain important for the poor and landless, especially during times of famine and insecurity or conflict, when normal food supply mechanisms are disrupted and local or displaced populations have limited access other forms of nutrition (Scoones et al. 1992). Even in normal times, these wild land-based foods are often important in complementing staple foods to provide a balanced diet, and plants growing as weeds may often be important in this respect (Johns and Staphit 2004; Cromwell et al. 2001; Satheesh 2000).

About 7,000 species of plants and several hundred species of animals have been used for human food at one time or another (FAO 1998; Pimbert 1999). Some indigenous and traditional communities use 200 or more species for food (Kuhnlein et al. 2001). The capacity of ecosystems to provide wild food sources is generally declining, as natural habitats worldwide are under increasing pressure and as wild plant and animal populations are exploited for food at unsustainable levels.

This section focuses on freshwater and marine fisheries, as they are globally significant sources of wild food, and it also covers aquaculture.

During the past century, the production and consumption of fish (including crustaceans and mollusks) has changed in important ways. Three trends are notable: average per capita consumption has increased steadily; the proportion of fish consumed at considerable distances from where it is harvested is growing; and an increasing number of fish stocks have been critically depleted by catch rates that exceed, often considerably, any commonly understood measure of maximum sustainable yield.

During the last four decades, the per capita consumption of fish as seafood increased from 9 to 16 kilograms per year. Table 8.4 shows fish production and utilization over the last half of the 1990s.

8.2.2.2.1 Trends in trade, commercialization, and intensification

Ninety percent of full-time fishers conduct low-intensive fishing (a few tons per fisher per year), often in species-rich tropical waters of developing countries. Their counterparts in industrial countries generally produce several times that quantity of fishing output annually, but they are much fewer, probably numbering about 1 million in all (FAO 1999), and their numbers are declining. In industrial countries, fishing is seen as a relatively dangerous and uncomfortable way to earn an income, so as a result fishers from economies in transition or from developing countries are replacing local fishers in these nations.

Nearly 40% of global fish production is traded internationally (FAO 2002). Most of this trade flows from the developing world to industrial countries (Kent 1987; FAO 2002). Many developing countries are thus trading a valuable source of protein for an important source of income from foreign revenue, and fisheries exports are extremely valuable compared with other agricultural commodities. (See Figure 8.6.)

Although fish are consumed in virtually all societies, the levels of consumption differ markedly. Per capita consumption is generally higher in Oceania, Europe, and Asia than in the Americas and Africa. Small island countries have high rates of consumption; land-locked countries often low levels. Fish is eaten in almost all social strata, due to the large variety of fish species and products derived from them, ranging from the very exclusive and expensive and rare to the cheap and currently still plentiful.

8.2.2.2.2 Overfishing and sustainability

After 50 years of particularly rapid expansion and improving technological efficiency in fisheries, the global state of the resources is causing widespread concern. Between 1974 and 1999, the number of stocks that had been overexploited and were in need of urgent action for rebuilding increased steadily and by 1999 stood at 28% of the world's stocks for which information is available. While the percentage of overexploited stocks appears to have stabilized since the late 1980s, the latest information indicates that the number of fully exploited stocks has been increasing in recent years while the number of underexploited stocks has been decreasing steadily—from an estimated 40% in 1970 to 23% in 2004. The most recent information available from FAO suggests that just over half of the wild marine fish stocks for which information is available are fully or moderately exploited, and the remaining quarter is either overexploited or significantly depleted.

The Atlantic Ocean was the first area to be fully exploited and overfished, and fish stocks in the Pacific Ocean are almost all currently fully exploited. There still seems to be some minor potential for expansion of capture fisheries in the Indian Ocean and the Mediterranean Sea, although this may be due to environmental changes including eutrophication. Phytoplankton plumes near densely populated areas and riverine plumes have been associated with higher levels of fisheries productivity (Caddy 1993).

At the beginning of the twenty-first century, the biological capability of commercially exploited fish stocks was probably at a historical low. FAO has reported that about half of the wild marine fish stocks for which information is available are fully exploited and offer no scope for increased catches (FAO 2002). Of the rest, 25% are underexploited or moderately exploited and the remaining quarter are either overexploited or significantly depleted.

Although information on catches from inland fisheries is less reliable than for marine capture fisheries, it appears that freshwater fish stocks are recovering somewhat from depletion in the Northern Hemisphere, while the large freshwater lakes in Africa are fully exploited and in parts overexploited. Some fish species exhibit more dramatic threshold effects, appearing less able to recover than others.

Accentuating the ecological implications of the increase in capture fisheries production is an important trend in catch com-

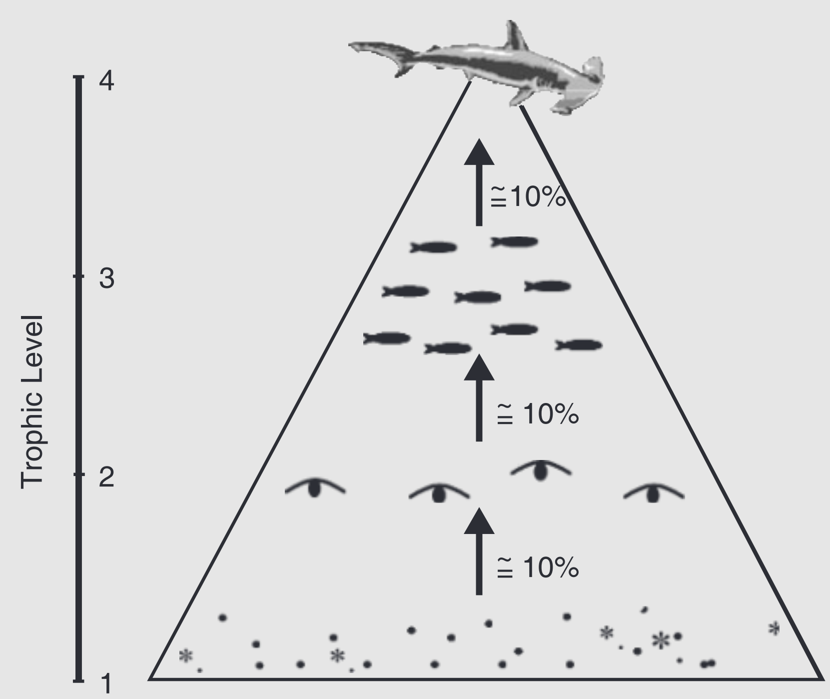
position—over the past 30 years the average trophic level of fish landed from marine and freshwater ecosystems has declined. (See Box 8.3.) Trophic level decline is the progressive change in catch composition, in the case of marine systems, from a mixture of top predatory fish such as sharks and saithe, mid-trophic level fish such as cods and herrings, and a few lower trophic level animals such as shrimp to a catch of a few mid-trophic species such as whiting and haddock and many low-trophic species such as shrimp. This change is a result of three phenomena: the expansion of fisheries from benthic coastal production areas to the pelagic open ocean; the expansion of fisheries from the Northern Hemisphere (dominated by large shelves and bottom fish) to the Southern Hemisphere (dominated by upwelling systems and pelagic fish); and overfishing, possibly leading to a local replacement of depleted large predators by their smaller preys. This change in catch composition is sometimes called "fishing down marine food webs."

BOX 8.3

Trophic Level

One way to understand the structure of ecosystems is to arrange them according to who eats what along a food chain. (See Figure.) Each link along the chain is called a trophic level. Levels are numbered according to how far particular organisms are along the chain—from the primary producers at level 1 to the top predators at the highest level. Within marine systems, large predators such as sharks and saithe are at a high trophic level, cod and sardines are in the middle, and shrimp are at a low trophic level, with microscopic plants (mainly phytoplankton) at the bottom sustaining marine life (Pauly et al. 2003).



8.2.2.2.3 Freshwater fisheries and food security

Approximately 10% of wild harvested fish are caught from inland waters, likely a smaller proportion than in the early twentieth century. However, it is more difficult to measure freshwater fisheries catches than marine catches. They may be underreported by as much as a factor of two because informal fisheries activities, such as subsistence fisheries, are not accurately accounted for in national statistics (Coates 1995). Fish production from inland waters is almost entirely finfish, with negligible amounts of crustaceans or mollusks, except in localized areas. As shown in Figure 8.7, the mean tropic level of freshwater fisheries landings tends to be lower than that of marine catches.

The socioeconomic value of freshwater fish catches is especially high. Freshwater fish tend to be consumed in their entirety, with minimal wastage, providing key sources of protein for local communities. And in addition to their nutritional value, freshwater fisheries provide livelihoods for low-income and resource-poor groups. The high level of artisanal and informal activity, relying on labor-intensive catching methods, contributes to food security for vulnerable groups, including women and children.

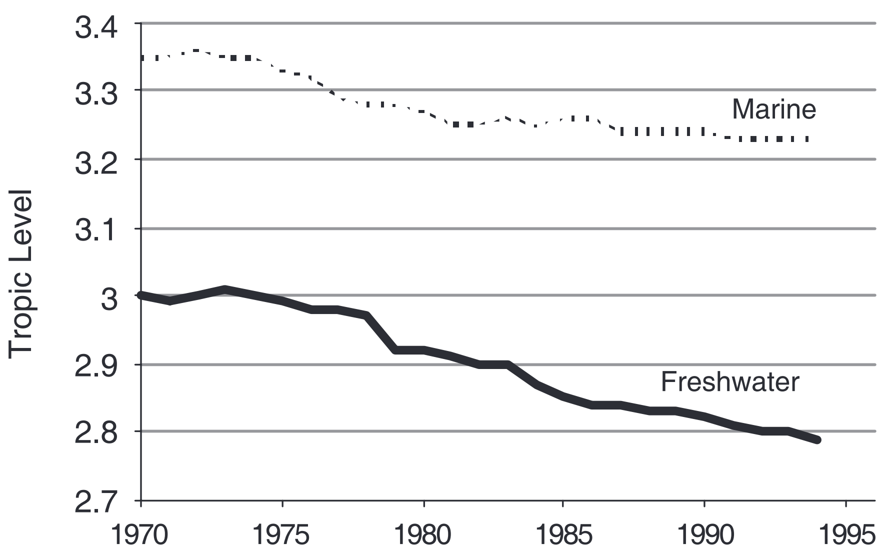


Figure 8.7. Decline in the Trophic Level of Fishery Catch, 1970–95 (Pauly et al. 1998)

8.2.2.2.4 Aquaculture

Although aquaculture is an ancient activity, it is only during the past 50 years that it has become a globally significant source of food. In 2002 it contributed approximately 27% of fish harvested and 40% (by weight) of all fish consumed as food. However, the variety of supply from aquaculture is well below that of capture fisheries: only five different Asian carp species account for about 35% of world aquaculture production, and inland waters currently provide about 60% of global aquaculture outputs.

The distinction between capture fisheries and aquaculture in fresh waters can be unclear. For example, extensive aquaculture in China includes catches from stocked rivers and lakes (which are substantial). While expanding aquaculture production can take the pressure off wild fisheries resources in some cases, in other cases the opposite is true (Naylor et al. 2000), as cultivation of carnivorous species can require large inputs of wild fish for feed. Overall, catches of wild fish for non-food uses are increasing faster than catches for food.

8.3 Food Provision and Biodiversity

This section reviews some of the key impacts of the provision of food on biodiversity. Since food provision involves the purposive management or exploitation of ecosystems to enhance food productivity, there are often trade-offs involved with other ecosystem services. In the past, when food production activities affected a smaller share of Earth's land and ocean bodies, and overall demand for ecosystem services supported by biodiversity was less than today, many of these trade-offs were not recognized or were not considered to be important. Now cultivated systems account for about 27% of the world's land surface and for a much higher share of habitable land (Wood et al. 2000).

The most direct impact of food provision on biodiversity has been through habitat conversion: around 43% of tropical and subtropical dry and monsoon forests and 45% of temperate broadleaf and mixed forests globally have been converted to croplands. Huge areas of the world are now planted to a small number of crop species or covered by modified pastures. In addition, rapid increases in coastal aquaculture have lead to the loss of mangrove ecosystems. Though future rates of conversion are expected to be much lower in absolute terms than historically, the major locations of agricultural expansion have frequently coincided with remnants of natural habitats with high biodiversity value (Myers et al. 2000). And the construction of roads and other infrastructure (such as irrigation canals), which are seen as key to promoting agricultural development and meeting the Millennium Development Goals, tends to dissect the landscape and to further limit the movement of wildlife and the dissemination of plant species.

Second, food provision affects wild biodiversity through its demand for inputs other than land, most notably water and nutrients, and through the pollution of ecosystems with pesticides and excess nutrients. Irrigated agriculture is a major user of fresh water (see Chapter 7), which, together with the direct loss of wetland habitats from conversion and the pollution of inland waters from excess nutrients, has a major negative impact on inland water biodiversity. (See Chapter 20.) As a consequence, wild fish populations in inland waters can be greatly reduced, often having the greatest negative impacts on the poor (Bene et al. 2003). Despite increases in water use efficiency, total water demand for agriculture is increasing and in many regions is projected to outstrip sustainable supplies over the coming decades. (See Chapter 7.)

Agriculture is the major consumer of reactive nitrogen, but only a fraction this is used in plant growth and retained in food products. The excess leads to biodiversity loss and reduced water quality in inland waters and coastal systems through eutrophication and to terrestrial plant diversity losses through aerial deposition. (See Chapters 12, 19, and 20.) Despite modest increases in nitrogen use efficiency, demand for fertilizer is projected to increase by 65% by 2050, leading to a doubling of current rates of N aerial deposition and N loading in waterways (Galloway et al. 2004).

Of the pesticides in widespread use, the most important effects on biodiversity are from persistent organic pollutants, since these have effects on large spatial and temporal scales. (See Chapter 25.) Many of the most persistent chemicals are being phased out through appropriate legislation and replaced by ones with fewer environmental impacts. However, the total use of pesticides is still increasing, and the poor regulatory environments in many countries mean that highly toxic chemicals continue to be used unsafely.

A third aspect of the impact of food provision on biodiversity concerns the effects within agricultural production systems and landscapes. Since agricultural landscapes (areas containing a significant share of cropland and pasture) now occupy 38% of Earth's land area, the maintenance of biodiversity within them is an important part of any overall strategy for biodiversity conservation. Even in relatively intensely farmed areas, cultivated crop production typically only covers a portion of the actual land areas, and much of the rest of the land can serve as habitat for wild species, if appropriately managed. However, in many agricultural landscapes wild biodiversity appears to be declining. For example, the pan-European bird index for farmland birds shows a declining trend since 1980 (see Chapter 26), in contrast to the situation for overall pan-European bird index.

One positive landscape-wide impact noted in sub-Saharan Africa, South Asia, and Southeast Asia is the trend of growing more trees in agricultural landscapes, for a wide variety of purposes. Trees stabilize and enhance soils, contribute in themselves to biodiversity, but also play host to a variety of birds and insects. Management practices can have major impacts on such biodiversity and the services that it provides for nutrient cycling, pest control, and pollination (Chapter 26), with positive spillovers for agricultural production.

The spread of invasive alien species is a fourth way that food provision affects biodiversity. While most of the world's major crops species are "alien" in the sense that their main production areas are outside their areas of origin (with notable exception of rice, the world's most important crop), none of the major crop plants are invasive. The greatest ecological risks probably arise from the spread of alien aquatic species. (See Chapter 20.) The introduction of the Nile perch in Lake Victoria, for example, led to the extinction of a large number of cichlid fish species.

Tilapia is the second most important fish species for aquaculture. Like carp, tilapia is vegetarian, and therefore tilapia-based aquaculture avoids many of the negative effects of carnivorous species. However, escapes into surrounding freshwater ecosystems may disrupt local species populations. Besides the direct use of alien species for food production, trade in food products is a major potential pathway for the introduction of pests and diseases, and most countries have quarantine systems to address this threat (FAO/NACA 2001).

Finally, when food provision is from wild sources, overexploitation and certain fishing practices can have major impacts on species composition. Overexploitation has been implicated as the leading threat to the world's marine fishes and has led to a decline in the average trophic level of catches, as described earlier. Overfishing affects not only the target species but also habitats, food webs, and non-target species. High-impact fishing (including bottom trawling, long-lining, gill netting, and dynamite fishing) causes damage to the biodiversity of sensitive habitats, such as cold-water reefs, tropical coral reefs, and seamounts, and to migratory seabirds (Pauly et al. 1998, 2003; Jackson et al. 2001). (See Chapter 18.)

Historically, many terrestrial species have become extinct due to hunting, and there are currently 250 mammal species, 262 bird species, and 79 amphibian species listed as threatened due to overexploitation for food (Baillie et al. 2004). In some groups of species and in some ecosystems, overexploitation is a particularly serious threat. In eastern and southeastern Asia, for example, almost all species of turtles and tortoises are in serious decline as a result of harvesting for human consumption and medicine, mainly in China (Baillie et al. 2004). In some cases overexploitation of plants, particularly medicinal plants, is also threatening many populations.

Food insecurity can have very severe consequences for local biodiversity. Famines, conflict, civil unrest, floods, and other natural disasters can decimate local food production and break food supply chains. In such cases, people are often forced to resort to exploitation of local wild plant and animal sources of food, often unsustainably.

8.4 Drivers of Change in Food Provision

The MA defines a driver as "any natural or human-induced factor that directly or indirectly causes a change in an ecosystem." (See Chapter 3.) In this section, that definition is limited to factors causing change in a specific ecosystem service: food provision.

Increased understanding of the drivers of change in food provision can generate insights into potential intervention opportunities for accelerating desired change and mitigating or adapting to less welcome trends. The discussion of drivers here is organized around two key dimensions. The first is the distinction recognized by the MA conceptual framework between indirect and direct drivers of ecosystem change. The second is the distinction between factors influencing food demand as opposed to those shaping food supply.

Assessing the impact of drivers for both demand and supply is particularly important in the case of food. The demand for food has long since outstripped the capacity of nature to provide it unaided, and for several millennia humans have transformed natural ecosystems for the singular purpose of obtaining more accessible, reliable, and productive sources of food to meet growing demands (Evans 1998; Smith 1995). The factors driving these changing demands must therefore be examined as a proper context for examining drivers of change in food provision.

Emerging patterns of food consumption provide early signals of the shifts in stresses on specific ecosystems in specific locations. In subsistence-oriented food production systems there is strong geographical coincidence of food consumption and ecosystem stress. In the increasingly globalized commodity trade and food industry sectors, the consumption-driven footprint of production on ecosystems might be several continents or oceans removed from the sites where consumption takes place.

Chapter 3 in this volume and Chapter 7 in the *Scenarios* volume contain information that is complementary to this section, particularly with regard to the treatment of indirect drivers such as technology, demographic trends, and economic growth. Chapter 26 in this volume also provides a brief summary with regard to the agricultural sector in exemplifying the important role of science and technology as a driver of change. That material is not repeated here, but appropriate cross-references are made.

Table 8.5 presents an assessment of the key indirect drivers of food provision, using separate grouping of drivers for food demand and supply. Table 8.6 presents the key direct (supply-side) drivers. For each driver the Tables provide a qualitative assessment of its rate of change and a judgment of its relevance in terms of influencing food provision. These variables are assessed both retrospectively over the past 50 years and for current and projected trends (up to 2015). Finally, to provide a slightly more nuanced perspective, these driver-specific assessments are provided for both industrial (In) and developing (Dg) regions in two adjacent rows. In the subsections that follow, every driver is not described in detail, but the key drivers where some relevant data exist are dealt with selectively. Trends in some important drivers are shown in Figure 8.8.

8.4.1 Indirect Drivers

8.4.1.1 Drivers of Food Demand

Eight factors are identified here that shape the demand for food. The first four of these (population growth, urbanization, economic growth, food prices) encompass the major demographic and economic trends that condition the demand for food and specific types of food in the aggregate. The remaining four factors (food marketing, food-related information, consumer attitudes to

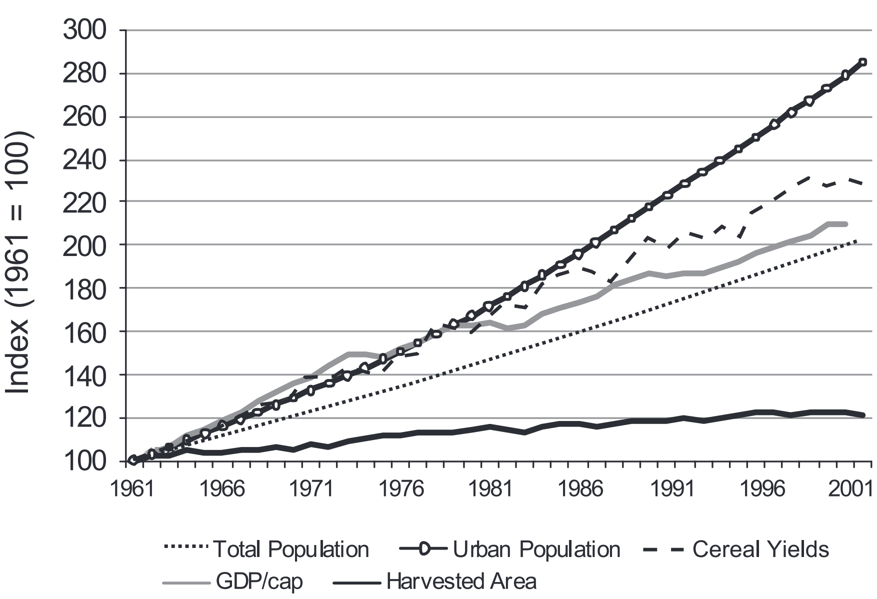

Figure 8.8. Trends in Selected Drivers of Food Provision Worldwide, 1961–2001 (FAOSTAT 2004; World Bank 2003)

production practices, and diet and lifestyle preferences) are often more subtle expressions of the interplay of the previous three drivers but are increasingly shaping the structure of food consumption. Finally, these trends are drawn together in the paradigm of the ''diet transition'' (Popkin 1993, 1998; WHO 2003b).

8.4.1.1.1 Population growth and age structure

Between 1961 and 2001 the major driver of growth in total food consumption was population growth. Global population doubled in this time period, from just over 3 billion to 6.1 billion, while the apparent consumption of calories per person increased on average by around 24% (FAOSTAT 2004). But from a global perspective the central role of population growth as a driver of food demand has started to decline, significantly in some regions of the world. Population growth rates, which peaked at 2.1% per year in the late 1960s, had fallen to around 1.35% (or 78 million additional people) per year by the turn of the millennium (UNDP 2003). This still represents a daunting food security and humanitarian challenge, as approximately 90% of this increase is taking place in developing countries. Around half of the total population increase in developing countries will occur in sub-Saharan Africa and South Asia, where the incidence of hunger is already high and, according to estimates for 2000–02, increasing in absolute terms (FAOSTAT 2004; Bruinsma 2003; FAO 2004a).

By contrast, in Western Europe, transition countries, and East Asia, population growth is extremely low and in some cases negative. As a consequence of lower fertility rates and increased life expectancy, typical of richer countries, the average age of individuals in such countries is increasing. Conversely, countries with higher fertility rates, which are also often poorer, have younger age structures. (See Chapter 3.)

While population size and growth rates have direct consequences for food needs and the required resilience of food production systems, age structure has more subtle impacts. One such impact is that energy and diet diversity requirements are age- (and sex-) dependent and, for example, increase for mothers during pregnancy and lactation. Furthermore, there is evidence of differences in food consumption according to age in the United States (Blisard and Blaylock 1993) and Japan (Mori and Gorman 1999). For example, U.S. and Japanese studies found older people to be consuming more fruit, as well as eating more meals at home.

8.4.1.1.2 Urbanization

Urbanization has proceeded at such a pace that globally, urban dwellers will outnumber rural populations by around 2007. High-income countries currently have populations that are 70–80% urban, and the same pattern is being seen as development progresses elsewhere (such as in Latin America and the Caribbean). The proportion of those in developing countries who live in cities has doubled since 1960 from 22% to over 40%. This share is expected to grow to almost 60% by 2030 (UN 2004). Developing countries now account for around 80% of the world's urban population. In 2001, 13 of the world's 17 "megacities" were in developing countries, and by 2015 it is expected that figure will have risen to 17 (UN 2001). (See also Chapter 27.)

Urbanization affects many dimensions of food demand. First, food energy requirements of urban populations are generally less than those in rural areas because of more sedentary lifestyles (Clark et al. 1995; Delisle 1990). Urban consumers generally have higher incomes as well as access to a more diverse array of both domestic and imported foods. Urban lifestyles often mean less time at home, and more meals eaten away from home (Popkin 1993). As a consequence, urban consumers eat more processed and convenience foods. This raises issues of food cost, quality, and safety in terms of the use of appropriate inputs, especially safe water in food processing.

Empirical evidence shows that urban diets are more diversified and contain more micronutrients and animal proteins but with a considerably higher intake of refined carbohydrates as well as of saturated and total fats and lower intakes of fiber (Popkin 2000). Data for China, Indonesia, and Pakistan at two points in time show reduced consumption of cereals and roots and tubers and increased consumption of fruits and vegetables and meats among urban populations (Regmi and Dyck 2001). The greater diversity, including of fruits and vegetables, generally available to urban populations does not necessarily translate into increased diversity of consumption (Popkin et al. 2001; Johns and Shtapit 2004).

A widely observed trend in urban diets is the switch away from traditional staples (locally produced millet, sorghum, root crops, and plantains, for instance) and toward consumption of rice and wheat, even though cereal diet shares decline overall. Often the rice and wheat needs are met through imports. Rice is particularly attractive because its preparation is quick and simple relative to other cereals. Wheat gains popularity through increased consumption of bread, noodles, pasta, dumplings, and so on. Given the scale and speed of urbanization, particularly in developing countries, these dietary shifts amount to significant changes in the structure of food demand at the national and regional scale. While importing rice and wheat for urban markets requires foreign exchange and can undercut the market potential for domestic suppliers, it can increase the food security of urban populations (usually a politically important social group) by tapping into sources of food supply that are often more reliable and of higher quality than domestic sources. Because of domestic infrastructure constraints and related high transaction costs, it may also be more economical to import food even when local and foreign production costs are similar.

There are other impacts of urbanization apart from structural changes in food consumption. One is the loss of prime agricultural land as a consequence of urban expansion, often displacing food production into less productive land elsewhere. Another is the major changes in nutrient flows associated with the flow of food from rural to urban areas. Whereas organic matter residues were once recycled locally, this nutrient export from rural to urban areas can deplete soil nutrient content in the production areas and can concentrate nutrients in human wastes and other residues in and around cities. The latter incurs effluent treatment and disposal costs and often causes pollution of water courses or coastal waters. A good example is the depletion of soil fertility in the banana-growing regions of Uganda due to the high demand for cooking bananas in Kampala, which involves shipping complete stems for processing in the city. There are also significant other, often negative, effects associated with the continuous need for food transportation (such as the contribution of increased exhaust emissions to local particulate matter as well as to greenhouse gases).

8.4.1.1.3 Income growth

It is *well established* that income is the single most important factor determining the amount and quality of food consumption. The relative share of budget spent on food is significantly higher among the poor but decreases rapidly as incomes increase and basic nutritional needs are met (Engel's law) (Tomek and Robinson 1981). At higher levels of income, high-value, more nutritious, or more culturally prestigious foods, such as fresh seafood or imported specialty foods, replace less-valued food sources (as described earlier regarding the transition to high-value meat, fish, vegetables, and fruits in East Asia since the late 1980s). In particular, the extra demand for meat is driving the "Livestock Revolution."

The most widely used proxy of income derived from aggregate statistics is the national measure of GDP per capita. (See Chapter 2.) At a macroeconomic scale there is strong evidence of the association between national average energy supply (kilocalories per person per day) and national economic growth as measured by GDP. (See Figure 8.9.)

8.4.1.1.4 Food advertising, information, consumer power, and changing food preferences

The previous drivers have played and will continue to play key roles in shaping the overall quantity and structure of food consumption in generally predictable ways: more people, urban migration and urban lifestyles, higher incomes, and lower food prices. This second group of drivers acts to influence the food consumption decisions of individuals in more subtle ways. They are often factors that come increasingly into play as incomes rise and basic food needs are met, but far from exclusively so.

Consumers in industrial and developing countries, particularly in the urban environment, are exposed to advertising for food, and poor consumers are often the specific targets of food-related information and safety-net programs. Such advertising and information can directly alter food preferences. And as a variety of obstacles have slowly been removed, opportunities for providing consumers with information, particularly about food safety, nutri-

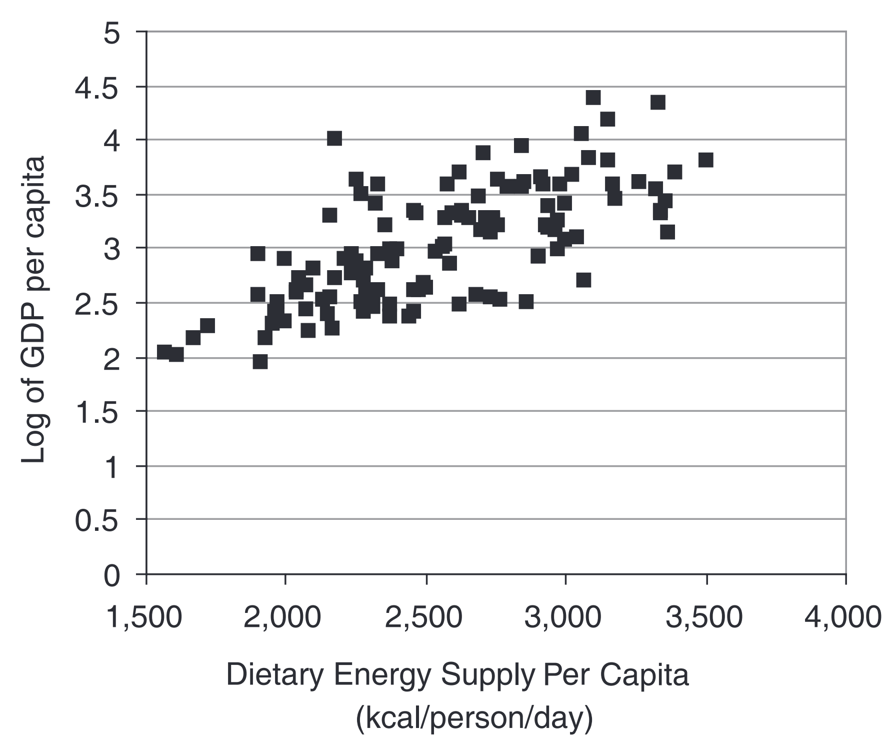

Figure 8.9. Association between National Average Dietary Energy Supply and GDP, Per Capita (Arcand 2001)

tion, and health have increased. At the same time, however, local and traditional knowledge that underpin traditional diets and cuisine is often in decline (Johns and Sthapit 2004).

Public information media—radio stations, newspapers, and television channels as well as public service access points such as clinics, schools, churches—are increasingly being used as cost-effective means of providing food and nutrition information to the public. Messages are varied, from direct commercial advertising to important public health information, such as the advantages of breast-feeding or the existence of contaminated food supplies locally. In richer countries, this phenomenon is most apparent with regard to the high levels of consumer interest and credence in information concerning health-related or weight-control-related attributes of food. While the latter are often passing fads, they do have significant impacts on food production. The current attention being given to low-carbohydrate diets for weight loss, for example, has had a measurable increase in demand for white meats, fish, and eggs and a measurable reduction in demand for wheat-flour based products and, in the United States, tomatoes (a large share of which are grown for tomato paste in pastas and pizzas).

In the transition to lifestyles more characteristic of industrial societies, retaining a strong traditional food system in which diet has recognized health, cultural, and ecological roles has allowed some countries to reduce the often concomitant increases in chronic noncommunicable diseases (Popkin et al. 2001). Asian and Mediterranean diets (Trichopolulou and Vaasiloppoulou 2000) provide the clearest examples. Traditional societies often see food, medicine, and health as interrelated. Food may have strong symbolic and religious value and is highly associated with cultural identity and social well-being (Etkin 1994; Johns 1990; Johns and Sthapit 2004).

Trade liberalization and the increased role of transnational food companies, urbanization, and migration, combined with the equalizing effects of rising incomes, has led to convergence between diets internationally. Yet cultural and religious factors appear to limit such convergence and to help retain dietary diversity (Bruinsma 2003).

8.4.1.1.5 The "diet transition"

Excessive consumption, particularly of some food types, has been associated with the growing phenomena of excessive body weight and obesity and with the associated health risks. Urbanization and socioeconomic changes have resulted in diets that are higher in energy and lower in diversity of fruits and vegetables than those consumed historically. As a consequence, many countries now face a "double burden" of diet-related disease: the simultaneous challenges of increased morbidity and susceptibility to communicable diseases among undernourished populations and increased incidence of chronic diseases associated with the overweight and obese (WHO 2003a; Ezzati et al. 2002). The pathway from traditional rural diets to those of increasingly urban and affluent societies and its attendant implications for nutrition and health has been dubbed the nutrition transition or the diet transition (Popkin 1993; Smil 2000; Receveur et al. 1997). (See Box 8.4.) The diet transition can be viewed as the integration of many of the individual consumption-related drivers just described, having both significant human and ecosystem health outcomes.

8.4.1.2 Drivers of Food Supply

8.4.1.2.1 Investments in agricultural research and development

It is *well established* that technological innovation is a major driver of increased agricultural productivity and in many cases is now the major source of increased productivity (Evenson et al. 1999; Acquaye et al. 2003; Roe and Gopinath 1998; Ruttan 2002). In turn, a major indirect driver of changes in food production systems has been the flow of innovations arising from investments in agricultural research and development. Worldwide, public investments in agricultural research nearly doubled in inflation-adjusted terms, from an estimated \$11.8 billion (in 1993 dollars) in 1976 to nearly \$21.7 billion in 1995. (See Table 8.7.) Developing countries account for just over half of the world's public agricultural research (Pardey and Beintema 2001). (See Table 8.8.)

Regional totals fail to reveal, however, that the public spending was concentrated in only a handful of countries. Just four countries—the United States, Japan, France, and Germany—accounted for two thirds of the \$10.2 billion of public agricultural research done by rich countries in 1995. Similarly, China, India, and Brazil dominate the spending on agricultural research in developing countries. By the mid-1990s, about one third of the annual \$33-billion investment in agricultural research worldwide was done by private firms, including those involved in providing farm inputs and processing farm products. The overwhelming majority (\$10.8 billion, 94% of the global total) of this privately funded research was conducted in industrial countries (Pardey and Beintema 2001).

Chapter 7 of the *Scenarios* volume discusses the historical evolution of the impacts of investments in agricultural productivity. A meta-study of quantitative evidence on the economic payoffs from improved productivity attributable to agricultural research, which included 1,845 data points from evaluation studies published between 1950 and 1995, revealed that the mean average economic rate of return on investment was 30.4% per year, though the range was wide; there appeared not to have been, as was popularly believed, any observable decrease in the rate of return to research investment over time; nor was there any significant regional bias in payoffs—that is, the economic returns to research investments in sub-Saharan Africa were not statistically different from those in Asia (Alston et al. 2000). One persistent finding has been the importance in agricultural research of spillover of knowledge and technologies between different locations. Indeed, evaluation studies that have specifically taken account of knowledge and technology spillovers have shown that this has accounted for a large share, and in many cases more than half, of the overall economic benefits (Alston 2002). Nonetheless, local R&D is necessary to facilitate spillover, and the lower levels of local R&D in Africa as opposed to Asia help account for the former's lower level of productivity growth (Masters 2005).

8.4.1.2.2 Agricultural policy and trade: producer subsidies and import tariffs

One of the most important and controversial set of drivers conditioning food provision globally are agricultural production and trade policies, and especially the producer subsidy and tariff protection measures supported, in particular, by the European Union, the United States, and Japan. By subsidizing food production and exports, while keeping in place high import tariffs, particularly on semi-processed or processed foods, these OECD countries drive down food prices on the world market, undercutting the potential profitability of developing-country producers in their own markets while simultaneously limiting their export opportunities (Watkins and von Braun 2003).

In 2002, some \$235 billion of the over \$300 billion spent by OECD countries on their agricultural sectors (some six times the amount they allocate to overseas development aid) went to support agricultural producers. This support is paid for by higher

BOX 8.4

Diet and Nutrition Drivers: The "Diet Transition"

Popkin (1998) has described five broad nutrition patterns (see Figure), not restricted to particular periods of human history but presented as historical developments. "Earlier" patterns are not restricted to the periods in which they first arose, but continue to characterize certain geographic and socioeconomic subpopulations.

Pattern 1: Collecting Food. This diet, which characterizes hunter-gatherer populations, is high in carbohydrates and fiber and low in fat, especially saturated fat. The proportion of polyunsaturated fat in meat from wild animals is significantly higher than in meat from modern domesticated animals. Activity patterns are very high and little obesity is found among hunter-gatherer societies.

Pattern 2: Famine. The diet becomes much less varied and subject to larger variations and periods of acute scarcity of food. During the later phases of this pattern, social stratification intensifies, and dietary variation increases according to gender and social status. The pattern of famine has varied over time and space. Some civilizations have been more successful than others in alleviating famine and chronic hunger. The types of physical activities changed, but there is little change in activity levels associated with this pattern.

Pattern 3: Receding Famine. The consumption of fruits, vegetables, and animal protein increases, and starchy staples become less important in the diet. Many earlier civilizations made great progress in reducing chronic hunger and famines, but only in the last third of the last millennium have these changes become widespread, leading to marked shifts in diet. However, famines continued well into the eighteenth century in portions of Europe and remain common in some regions of the world. Activity patterns start to shift and inactivity and leisure becomes a part of the lives of more people.

Pattern 4: Nutrition-related Noncommunicable Disease. A diet high in total fat, cholesterol, sugar, and other refined carbohydrates and low in polyunsaturated fatty acids and fiber, and often accompanied by an increasingly sedentary life, is characteristic of most high-income societies (and increasing portions of the population in low-income societies), resulting in increased prevalence of obesity and contributing to the degenerative diseases that characterize Omran's final epidemiologic stage.

Pattern 5: Behavioral Change. A new dietary pattern appears to be emerging as a result of changes in diet, evidently associated with the desire to prevent or delay degenerative diseases and prolong health. Whether these changes, instituted in some countries by consumers and in others also prodded by government policy, will constitute a large-scale transition in dietary structure and body composition remains to be seen. If such a new dietary pattern takes hold, it may be very important in increasing disability-free life expectancy.

The focus is increasingly on patterns 3 to 5, in particular on the rapid shift in much of the world's low- and moderate-income countries from pattern 3 to pattern 4, commonly termed the "diet transition" or "nutrition transition."

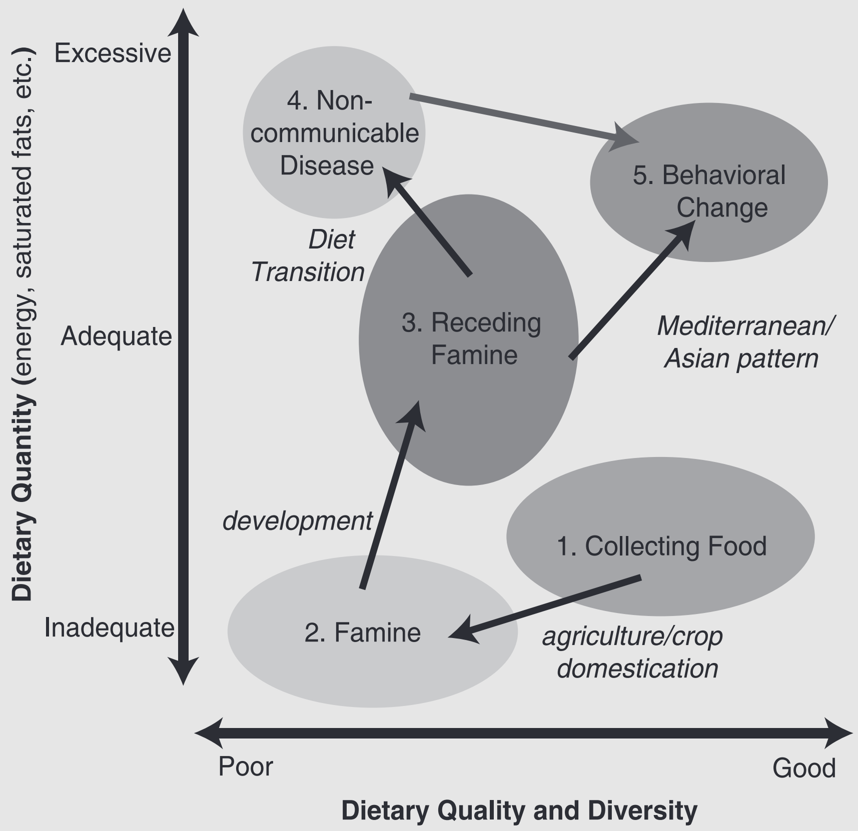

Table 8.7. Global Agricultural Research Spending, 1976–95. Figures in parenthesis indicate number of countries. (Pardey and Beintema 2001)

Region	1976	1985	1995
	(thousand 1993 dollars)

	(thousand 1993 dollars)		
Developing countries	11,469	672	12,141
Industrial countries	10,215	10,829	21,044
Total	21,692	11,511	33,204

domestic food prices and by taxes ($100 billion in the EU, $44 billion in Japan, and $31 billion in the United States). And it represents around 31% of average farm income (18% in the United States and 36% in the EU). For individual commodities that OECD countries target for support (wheat, maize, cotton, dairy, beef, sugar, rice, and oilcrops), the levels of support can be much higher (OECD 2003a; Watkins and von Braun 2003). Government support in Japan has consistently represented around 85% of farmers' rice production revenues, while U.S. rice support has declined from around 50% in 2002 (OECD 2004). The economic losses to developing countries due to these policies has been estimated as some $24 billion a year in lost agricultural production and incomes of farm households and about $40 billion a year in lost access to markets in OECD countries (Diao et al. 2004).

Fisheries are another area of food production where subsidies have become controversial. In the early 1990s it was established that subsidies had probably contributed to an excessive buildup of fishing fleets worldwide during the preceding decade. (See Chapter 18.) Since then, it has proved difficult to limit the fishing of existing fleets, and fish stocks continue to be overexploited as illegal, unreported, and unregulated fishing spreads. Subsidies to the fishing industry are regulated through WTO agreements; however, the international community has agreed that existing WTO rules are not sufficient to ''discipline'' their use, and efforts are now being made to seek improved measures under the so-called Doha round of trade talks (Chang 2003).

From an ecosystem perspective, these market distortions have two major effects. In countries where subsidies are paid, food output increases to levels that would be uneconomic in the absence of subsidies, drawing proportionately more land, labor, and other resources into production and creating higher levels of agricultural pollution. While other factors such as increasing productivity have caused the net amount of agricultural land to grow more slowly or even to decline in some OECD countries, those effects would have been more significant in the absence of subsidies. Recently, the OECD reported that while nitrogen runoff, pesticide use, and agricultural greenhouse gas emissions have fallen since the mid-1980s in most OECD countries, they have increased in the United States (OECD 2003b).

The other major impact of producer subsidies is the reduction of production and income opportunities in other parts of the world where subsidies are not paid, although these impacts can be ambiguous. While it could be argued that reduced production incentives might conserve more habitat and reduce demands on local natural resources, it also can make poor people even poorer by limiting productivity enhancement incentives on existing lands, thus accelerating land degradation and further increasing pressure to convert more land.

International processes and agreements under the World Trade Organization have a major bearing on these drivers, particularly WTO's Agreement on Agriculture. This provides a framework for removing the ''amber box'' trade biases induced by producer subsidies and import tariffs, as well as for agreeing on a broader set of ''green box'' provisions dealing with support to producers for improving the environmental and landscape dimensions of farming through a range of ''set-aside,'' ''conservation,'' ''countryside stewardship,'' or similar programs. The espoused intent of ''green box'' measures is to provide incentives to farmers to follow less polluting, more environmentally sensitive production practices. However, such provisions have become highly contentious as they are seen by many, including most developing countries, as a way of legitimizing existing rich-country producer support in another guise.

There are other ecosystem-relevant dimensions of the Agreement on Agriculture, including the notion of decoupling support to producers from the quantity of production so as to limit perverse incentives to overproduce food, use more agricultural land, use more potentially polluting agricultural inputs, and generate more wastes. The impacts of the WTO on agriculture are still emerging and developing, but its potential ramifications will likely grow, bringing with it a significant change in food production incentives globally. Through the WTO, for example, developing countries are becoming increasingly effective at asserting demands for more liberal agricultural trade policies.

8.4.1.2.3 Food industry commercialization and integration

Just as agriculture has witnessed a gradual industrialization of the production process, so too have there been sweeping changes in food marketing, processing, and retailing practices. Even where industrialization of the production process has not taken place, the concentration and formalization of marketing is having significant repercussions on production decisions and on the need for improved smallholder collective action in order to stay engaged in food markets. Several forces at work are leading to the integration and formalization of food marketing and supply chains: growing economies of scope and scale in the transportation, processing, and retailing subsectors; falling food prices that have reduced profit margins and further encouraged consolidation in the post-harvest sector; a growing need to respond to consumer demands for specific type and quality of product that provides incentives to shorten the marketing ''chain,'' such as vertical integration; a growing need for transparency and accountability in the certification of food sources, such as organic foods, and to satisfy appropriate (regulated or self-imposed) standards and food safety requirements; and the enormous expansion in the role of supermarkets, even in developing countries (Berdegue et al. 2003).

Thus an increasing share of food production is being contracted for before planting, with contracts that often involve producer obligations relating to minimum quantities, product quality, and delivery dates. Such stringent criteria are very difficult for smallholders to meet, and farmer associations and marketing groups are increasingly being formed to help respond to these needs. For example, in the United States there has been massive consolidation of farms due to the economic pressures to improve economies of scale for both production and marketing purposes (as well as, in recent times, to fully reap the benefit of production subsidies). In the 1920s and 1930s there were more than 6 million farms of around 40 hectares each. By the late 1990s, there were fewer than 2 million farms and they averaged 200 hectares each (Bread for the World 2003).

8.4.2 Direct Drivers

8.4.2.1 Climate Change and Climate Variability

Although there is a relatively rich literature on the potential impacts of long-term climate trends on future food production (see, for example, Rosenzweig and Parry 1996; Sombroek and Gommes 1996; Parry et al. 2004), evidence on the impacts of historical and recent climate change on food production is relatively sparse. Although climate is a major uncontrollable factor influencing food production (especially in areas of rain-fed agriculture), it is extremely difficult to reliably isolate the influence of climate from other factors such improved seeds, the use of irrigation, fertilizer, pesticides, crop and land management.

However, some data do exist. For example, based on over 80 years of crop yield and climate data in five central Corn Belt states in the United States, Thompson (1998) developed relationships describing the influence of monthly average temperature and total precipitation on corn yields. These suggest that 40 millimeters above normal precipitation in July would lead to a corn yield increase of 316 kilograms per hectare above the long-term average. It has also been suggested that U.S. corn and soybean yields could drop by as much as 17% for each degree that the growing season warms (Lobell and Asner 2003), although the level of certainty in such findings remains low (Gu 2003). Weather variability in China has been shown to have a measurable effect on year-to-year national grain output (Carter and Zhang 1998), and a study of the temperature and wine quality in the world's top 27 wine regions over the past 50 years reveals that rising temperatures have already affected vintage quality (Jones et al. 2004).

Global-scale cyclical weather patterns have also strongly influenced food production. This includes the impact of, in particular, the El Niño-Southern Oscillation and the North Atlantic Oscillation. Carlson et al. (1996) found that a negative Southern Oscillation Index (a measure of pressure difference in an ENSO event) can result in a corn yield that is 10% above trend line in U.S. Corn Belt states, and ENSO-based climate variability has significant impact on cereal production in Indonesia (Naylor et al. 2002), where year-to-year fluctuations in the August sea-surface temperature anomaly explain about half the interannual variance in paddy production during the main (wet) growing season. The North Atlantic Oscillation has also been shown to significantly correlate to vegetation productivity in northern Asia, with a surprisingly long lag time of one-and-a-half years (Wang and You 2004).

8.4.2.2 Area Expansion and Intensification

There have been two main direct drivers of growth in food production: the increase in the area extent of cultivation, grazing, or fishing and the intensity of production or exploitation within cultivated areas. Figure 8.8 showed increasing trends in both harvested area (area expansion) and cereal yields (a proxy of increased intensification). It is clear that, for crops, it is intensification rather than area expansion that has mainly driven increased food output. Over the past 40 years cropland area has expanded globally by some 15%—from 1.3 billion to 1.5 billion hectares (see Chapter 26), the area of pasture has grown some 11% from 3.14 billion to 3.48 billion hectares (FAOSTAT 2004), and practically all corners of the world's oceans are now accessible to the world's fishing fleet (given the capacity of modern fishing vessels to stay at sea for extended periods and the large amounts of catch in refrigerated holds).

While physical expansion in the area dedicated to food provision has been important in the past, rates of growth are now relatively low—and in some places in decline (for instance, in the European Union and Australia). This slowdown reflects both the slowing growth in global food demand and the more limited opportunities for area expansion. Just as with the large growth in crop yields per hectare of cropland, there has also been substantial increase in livestock production per animal; however, intensive livestock systems are dependent on inputs from a significant land area for feed production. (These trends are described in more detail in Chapter 26.)

Investments in agricultural research and the resulting flow of innovation have been key to the intensification process. Technical change and increased use of external inputs such as irrigation, fertilizer, and mechanical power contribute to changes in productivity—the formal means by which changes in intensification can be measured. Increased productivity can also come from the introduction of less capital-intensive food-feed systems, whereby both the main crops as well as the introduction of legumes can enhance the cropping system. The complementary advantages of both food and feed enable intensification of mixed crop-livestock systems and can increase total factor productivity (Devendra et al. 2001).

8.5 Food Provision and Human Well-being

The MA defines five dimensions of human well-being—basic material for a good life, security, health, good social relations, and freedom and choice (MA 2003)—into which the production and consumption of food maps in several ways. Food production, distribution, processing, and marketing provide employment and income to a large share of the world's population. About 2.6 billion people depend on agriculture for their livelihoods, either as actively engaged workers or as dependants (FAO 2004b). (The exact number of people dependent on food processing, distribution, and marketing for their livelihoods is not certain.) Food consumption contributes directly to health and is an important aspect of cultures and social relations, and indirectly supports improved security and freedom and choices.

There are several attributes of food that have a major bearing on its potential impact on human well-being—quantity and price, diversity and quality of its nutrient content, and safety. The actual impact of food depends on local food availability and the ability of consumers to gain access to and properly use it, as well as on individual food preferences. The dimensions of food availability, access, and utilization are integrated in the notion of food security, defined as "access by all people at all times to enough food for an active, healthy life" (Reutlinger and van Holst Pellekan 1986). For the poor, the price of food (as well as access to wild sources of food) is key to determining the value of incomes, and for many such people the relationship between wage rates and food prices is a critical determinant of human well-being. It is *well established* that a productive food and agriculture sector not only benefits individual farmers and food consumers but also provides a platform for economic growth (Mellor 1995; Hazell and Ramasamy 1991).

8.5.1 Health and Nutrition

The most direct and tangible benefit of food is its role in enabling individuals to pursue active, healthy, productive lives as a consequence of adequate nutrition. For these reasons, access to adequate, safe food has been recognized as a basic human right. The 1948 Universal Declaration of Human Rights proclaimed that "everyone has the right to a standard of living adequate for the health and well-being of himself and his family, including food." Nearly 20 years later, the International Covenant on Economic, Social and Cultural Rights (1966) developed these concepts more fully, stressing "the right of everyone to . . . adequate food" and specifying "the fundamental right of everyone to be free from hunger." These rights were specifically embodied in the 1989 International Convention on the Rights of the Child and have found further expression and practical interpretation through subsequent confirmation at the 1996 and 1999 World Food Summits (UN/SCN 2004).

Proper nutrition has many benefits for human, physical, and mental development. Better-fed children show improved educational performance, and better-fed adolescents and adults are able to lead more economically productive lives. Good nutrition also reduces neonatal and child mortality, helping to slow population growth by increasing birth intervals and reducing demand for large families. Well-nourished mothers are also more likely to survive childbirth themselves and to deliver healthier babies (ACC/SCN 2002).

Inadequate consumption of protein and energy as well as deficiencies in key micronutrients such as iodine, vitamin A, and iron are key factors in the morbidity and mortality of children and adults. An estimated 55% of the nearly 12 million deaths each year among children under five in the developing world are associated with malnutrition (UNICEF 1998). Malnourished children also have lifetime disabilities and weakened immune systems (UNICEF 1998). Moreover, malnutrition is associated with disease and poor health, which places a further burden on households as well as health care systems.

A commonly used measure of the impact of ill health on human well being is disability-adjusted life years. This is a measure of the burden of disease, reflecting the total amount of healthy life lost, to all causes, whether from premature mortality or from some degree of disability during a period of time. Table 8.9 summarizes the available evidence regionally and globally on the burden of nutrition-related health impacts measured in terms of DALYs.

While the human health consequences of undernourishment, since they arise largely out of conditions of poverty and marginalization, legitimately dominate global humanitarian concerns, health problems associated with overconsumption of (certain types of) food have grown alarmingly over the past 40 years. The health-related aspects of nutrition are examined in three steps. First, micronutrient deficiency is considered, since although this is most often associated with undernourishment, it can arise even in diets with adequate or excessive protein and energy content. Second, undernourishment-related aspects are looked at, largely acute and communicable diseases. And third, the evidence on overnourishment-related noncommunicable diseases is reviewed.

The constituents of good nutrition are fairly well understood, but dietary needs vary according to a range of context- and individual-specific characteristics, including climate, metabolism, and occupation. Guidelines indicate that a healthy adult diet includes a daily intake of 2,780 kilocalories for males and 2,235 kilocalories for females. Recommended daily allowances for protein are 37 grams for males and 29 grams for females (FAO/WHO/UNU 1985); however, these recommendations vary by country. Recommended daily intakes have also been established for a number of vitamins, minerals, and other micronutrients. For example, daily intakes have been established of 750 micrograms of vitamin A for both males and females, 130 micrograms of iodine for males, and 110 micrograms for females (FAO/WHO 2002). In addition, components of foods may have functions that include antibiotic, immuno-stimulation, nervous system action, anti-inflammatory, antioxidant, anti-glycemic, and hypolipidemic properties (Johns and Sthapit 2004).

Figure 8.10 presents a simplified schematic summary of the principal pathways of impact of food on human well-being, as mediated through nutrition. The following sections describe some of these pathways and, as far as available evidence permits, quantify the scale and intensity of specific nutrition, health, human development, and economic outcomes. But first the major trends in key measures of nutrition over the past 40 years are reviewed.

8.5.1.1 Diet Quantity: Dietary Energy Supply

The most commonly used proxy of food availability is the gross availability of food, as proxied by the average per capita availability of calories from food products, the dietary energy supply. Figure 8.11 shows levels and trends in DES over the period 1961 to 2001 for industrial and developing countries and for the world. Expansion of food production, coupled with declining real prices for food, increased DES by 24% globally over that period (an

Table 8.9. Regional and Global Burden of Nutrition-related Disease Risk Factors. The Table shows the estimated disease burden for each risk factor considered individually. These risks act in part through other risks and act jointly with other risks. Consequently, the burden due to groups of risk factors will usually be less than the sum of individual risks. The disability-adjusted life year is a measure of the burden of disease. It reflects the total amount of healthy life lost to all causes, whether from premature mortality or from some degree of disability, during a period of time. (Adapted from Ezzati et al. 2002; Ollila n.d.; and WHO 2002a)

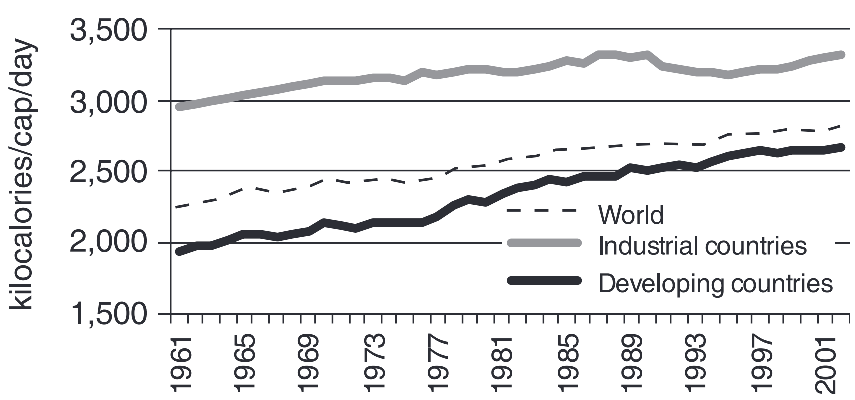

Figure 8.11. Dietary Energy Supply, 1961–2001 (FAOSTAT 2004)

11% and a 39% average increase, respectively, in industrial and developing countries). In 1961, with a world population of around 3 billion, the average DES was around 2,250 kilocalories per capita per day. By 2001, average DES had reached 2,800 kilocalories per capita despite a doubling of world population to 6.1 billion (FAOSTAT 2004).

But there have been, and remain, large geographic and socioeconomic differences in DES. Such disparities largely arise from differences in income, in the disposition of and access to food and to lands favorable for food production, and in dietary preferences and food utilization practices. Figure 8.12 depicts an obvious twin peak structure—one peak for developing countries and another for industrial ones. From the 1960s through to and especially during the 1980s, there was a progressive shrinking of the DES gap between these two groups (Wang and Taniguchi 2003). Although the average DES of developing countries increased from 1929 to 2,675 kilocalories per day over 40 years, it is still lower than the DES in industrial countries in 1961, some 2,947 kilocalories per day. And during those 40 years the figure in industrial countries increased to 3,285 kilocalories a day (FAOSTAT 2004).

The progress of individual countries varies more markedly. Over the same 40 years Indonesia's average DES grew by 68% from a very low 1,727 to 2,904 kilocalories per day, Uganda's average figure barely increased from 2,318 to 2,398, while in the United States average DES grew by some 31%—from 2,883 to 3,766 kilocalories a day. With regard to overall shares of food consumption, industrial countries—with 24% of the world's population—consumed 29% of global calories, 34% of global protein, and 43% of global fat in 2001 (FAOSTAT 2004). (Trends in hunger are discussed in further detail later.)

Of particular concern in Figure 8.12, however, is that the trend of improvement was reversed during the 1990s, when a noticeable leftward shift (lower DES) became apparent in several parts of the distribution (Wang and Taniguchi 2003). The figure suggests that the nutritional status of at least some developing and middle-income countries worsened during the 1990s.

8.5.1.2 Dietary Quality and Diversity

There are many other dimensions of good nutrition besides dietary energy supply. In addition to quantity, key elements of good nutrition are diet quality and diversity. A healthy diet comprises both sufficient quantities and a proper mix of carbohydrates, proteins, fats, fibers, vitamins, and micronutrients, as well as components with health-mediating functional properties (Johns and Sthapit 2004). These can be derived from a diverse range of crop and livestock products as well as wild and cultivated fisheries products and other wild sources of food. (See Box 8.5.)

A handful of epidemiological studies from the United States and Europe, along with a few case studies from Africa and Asia, uphold the conventional wisdom concerning the benefits of a varied diet, particularly in fruits and vegetables. Nutritional status and child growth improve with consumption of greater food diversity, as do measures of functional properties of dietary components likely to play an important role (Johns and Sthapit 2004; Johns 2003).

Micronutrients are needed, as the term suggests, in only minuscule amounts; the consequences of their absence are severe, however, and contribute significantly to the burden of disease. Micronutrients enable the body to produce enzymes, hormones,

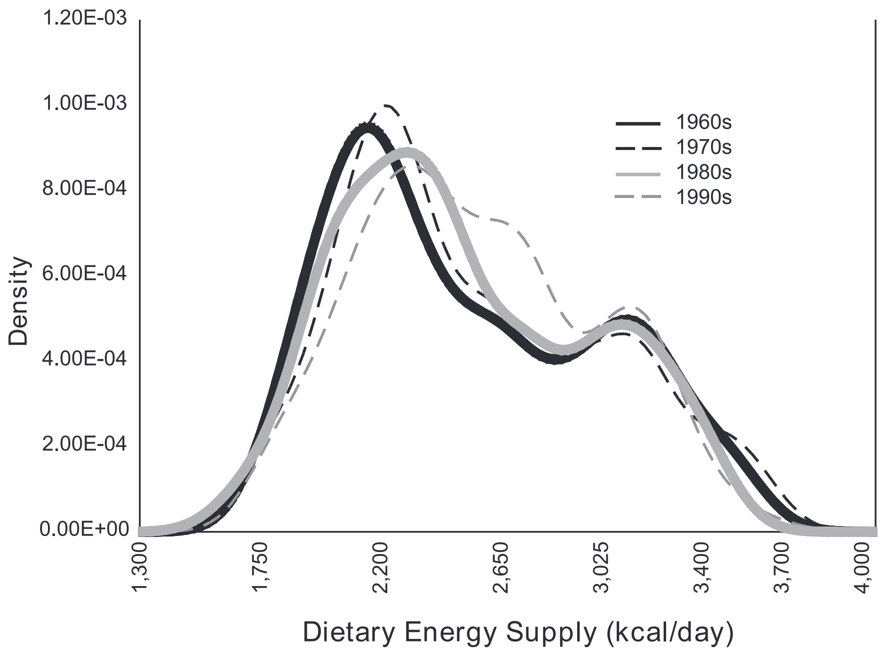

Figure 8.12. Distribution of Per Capita Dietary Energy Supply by Decade (Wang and Taniguchi 2003)

BOX 8.5

Biofortification (IFPRI/CIAT 2002)

It is now possible to breed plants for increased vitamin and mineral content, making "biofortified" crops a promising tool in the fight to end malnutrition and save lives. An estimated 3 billion people suffer the effects of micronutrient deficiencies because they lack money to buy enough meat, fish, fruits, lentils, and vegetables. Women and children in sub-Saharan Africa, South and Southeast Asia, and Latin America and the Caribbean are especially at risk of disease, premature death, and impaired cognitive abilities because of diets poor in crucial nutrients, particularly iron, vitamin A, iodine, and zinc.

We have the ability today to further improve and disseminate more widely iron-rich rice, quality protein maize, high-carotene sweet potato, and high-carotene cassava. The potential advantages of biofortification are that it does not require major changes in behavior by farmers or consumers, can directly address the physiological causes of micronutrient malnutrition, can readily be targeted to the poorest people, uses built-in delivery mechanisms, is scientifically feasible and cost-effective, and can complement other ongoing methods of dealing with micronutrient deficiencies.

The potential disadvantages are that biofortification may not benefit small-scale and poor farmers; it undermines dietary diversity and creates possible conflict with distinctive food cultures; nutrient traits (except (-carotene) are difficult to verify without advanced technology; public investment is needed where infrastructure, including formal seed systems and marketing , and economies are weak; evaluations will be time-consuming; and resistance to and ethical issues related to transgenic crops are found in some regions.

and other substances essential for proper growth and development. Different micronutrients interact: there is a correlation, for example, between iron deficiency and deficiency in other vitamins and minerals (WHO 2004b). In addition, the content of specific micronutrients in foods can affect the absorption of other minerals.

Iodine, vitamin A, iron, and zinc are the most important individual micronutrients in global public health terms; their lack represents a major threat to the health and development of populations the world over, particularly to preschool children and pregnant women in low-income countries. Vitamin A deficiency and iron deficiency (related to anemia) alone affect as many as 3.5 billion people (WHO 2004b). Micronutrients with high bioavailability that are provided from animal-source foods include minerals, calcium, iron, phosphorus, zinc, magnesium, and manganese, along with the vitamins thiamine B1, riboflavin B2, niacin, pyridoxine B6, and B12 (CAST 1999). Several other nutrients are known to be inadequate in developing countries, including B12, folate, and vitamin C. This section describes the four micronutrients most important for public health at present.

Vitamin A is derived from animal sources as retinol and from fruits and vegetables (such as dark leafy vegetables and yellow and orange non-citrus fruits) as carotene, which is converted into vitamin A in the body. Plant-derived vitamin A is more difficult to absorb than that from animals. Vitamin A deficiency significantly increases the risk of blindness and of severe illness and death from common childhood infections, particularly diarrheal diseases and measles. In communities where vitamin A deficiency exists, children are on average 50% more likely to suffer from acute measles.

Improvements in vitamin A status have been demonstrated to lead to a 23% reduction in mortality among children aged one to five (Rahmathullah 2003), so preventing between 1.3 million and 2.5 million deaths each year and saving hundreds of thousands of children from irreversible blindness. Vitamin A therapy is a standard treatment in children with measles infection in developing countries. Measles infection itself causes a transient immunosuppression. Measles as an acute catabolic disease is thought to use up body reserves of nutrients, making the child more vulnerable to disease in the first instance and unable to counter the effects of the disease. The risk of dying from diarrhea, malaria, and measles was increased by around 20–24% in Vitamin A–deficient children (Rice et al. 2003).

Iron is readily available in many foods, especially meat, fish, and poultry, as well as in some leafy vegetables such as spinach. WHO estimates that 4–5 billion people worldwide, many of them women of reproductive age and children under 12 (as many as half of all such women and children in developing countries), are affected by iron-deficiency-induced anemia. Iron deficiency is associated with malaria, intestinal parasitic infestations, and chronic infections. One strategy to mitigate iron deficiency has been to promote the use of home gardens with small animals. Other strategies include food fortification and the eradication of infections.

Iodine deficiency is the world's most prevalent—yet easily preventable—cause of brain damage. Iodine deficiency disorders jeopardize children's mental health. They affect over 740 million people, 13% of the world's population; 30% of the remainder are at risk. Chronic iodine deficiency causes goiter in adults and children. Serious iodine deficiency during pregnancy may result in stillbirths, abortions, and congenital abnormalities such as cretinism—a grave, irreversible form of mental retardation that has affected people living in iodine-deficient areas of Africa and Asia (Aquaron et al. 1993; Hsairi et al. 1994; Foo et al. 1994; Yusuf et al. 1994). Global rates of goiter, mental retardation, and cretinism are all falling, attributed in varying degrees to the increased use of iodized salt (WHO 2004b). Of far greater global and economic significance, however, is iodine deficiency disorder's less visible yet more pervasive level of mental impairment that lowers intellectual development.

The consequences of severe human zinc deficiency have been known since the 1960s, but only more recently have the effects of milder degrees of zinc deficiency, which are highly prevalent, been recognized. Trials have shown that zinc supplementation results in improved growth in children; lower rates of diarrhea, malaria, and pneumonia; and reduced child mortality. In total, about 800,000 child deaths per year and, through deaths and increased rates of infectious diseases in affected areas, some 1.9% of DALYs are attributed to zinc deficiency. The incidence of diarrhea is increased around 20% in zinc-deficient children and that of pneumonia around 10–40% (Black 2003).

8.5.1.3 Hunger

Undernutrition can be broadly categorized into protein energy undernutrition (the result of a diet lacking enough protein and calorie sources) and (specific) micronutrient deficiencies. PEM is probably the most important factor contributing to nutrition-related mortalities (Habicht 1992).

FAO estimates that 852 million people worldwide did not have enough food to meet their basic daily energy needs in 2000–02. This includes 9 million in industrial countries, 28 million in countries in transition, and 815 million in developing countries (FAO 2004a). Some 519 million hungry people live in Asia and the Pacific and 204 million in sub-Saharan Africa, around 60% and 24% respectively of the global total of undernourished people. Viewed as a share of regional population, this means that some 16% of Asians and 33% of sub-Saharan Africans are undernourished. The two most populous countries in the world—China and India—alone account for almost 43% of the global total of hunger, but the highest incidence rates, ranging from 40% to 55% of the population, are found in Eastern, Southern, and Central Africa (FAO 2004a).

The latest hunger estimates signal a disturbing reversal of trends reported since around 1970 of a gradual decline in both hunger incidence and the absolute number of hungry people. Between 1969–71 and 1995–97, the absolute number of hungry people in developing countries had fallen from around 959 million to 780 million people. During the period 1995–97 to 2000–02, however, while the proportion of undernourished in developing countries fell by 1%, the number of hungry increased by some 18 million people to a total of 815 million.

This trend reversal reported by FAO (2003) confirms the analysis of overall DES patterns globally undertaken by Wang and Taniguchi (2003). The regional trends in the number of undernourished in developing countries for the early to mid-1990s and from the mid-1990s to around 2000 are clearly shown in the upper panel of Figure 8.13. The progress in hunger reduction in the early 1990s occurred predominantly in China and India. But in the second half of the decade, progress in China slowed and in India reversed, while in the Near East and Central Africa the numbers of hungry increased throughout the 1990s. The large-scale humanitarian crisis existing in Central Africa has escalated unabated.

Chronic child hunger, in particular, is measured using anthropometric measures for height-for-age or stunting. Using cross-sectional data from 241 nationally representative surveys, de Onis et al. (2000) have shown that the prevalence of stunting in children has fallen in developing countries from 47% in 1980 to 33% in 2000 (by 40 million). Progress has not been uniform, however. Stunting has increased in East Africa but decreased in Southeast Asia, South Central Asia, and South America. Stunting has moderately improved in North Africa and the Caribbean. West and Central Africa show little progress. Despite the average decrease, child undernutrition remains a major public health problem.

Undernutrition has a huge global impact on morbidity and mortality due to infectious diseases. In spite of a general understanding that undernutrition increases susceptibility to infectious diseases, good estimates of etiological fractions for the influence of hunger on infectious disease mortality predominantly exist for children under five, where being underweight confers about 50% of the mortality risk for the main infectious diseases in the developing world like diarrhea, malaria, pneumonia, and measles (Schelp 1998; Cebu Study Team 1992). Child growth (also in utero, resulting in low birth weight) has again a very strong effect on morbidity and mortality. Birth weight alone is the single most important predictor of mortality in early life.

Evidence suggests that PEM is linked with higher malaria morbidity/mortality (Caulfield et al. 2004). Both malaria and chronic hunger have effects on child growth. Undernutrition is highly prevalent in many areas in which morbidity and mortality from malaria is unacceptably high. The global burden of malaria is associated with various nutrient deficiencies as well as underweight status. Although the association is complex and requires additional research, improved nutritional status lessens the severity of malaria episodes and results in fewer deaths due to malaria. Deficiencies in vitamin A, zinc, iron, and folate as well as other micronutrients are responsible for a substantial proportion of malaria morbidity and mortality. It is recommended that nutrition programs should be integrated into existing malaria intervention programs.

Diarrheal diseases are an important cause of mortality and morbidity in children, leading to more malnutrition but also being a consequence of undernutrition, as susceptibility to diarrheal diseases is increased in malnourished children (Lanata and Black 2001). There is ample evidence that giving formula and the early introduction of solids increases susceptibility to diarrhea, which emphasizes the importance of access to clean water.

Disease affects a person's development from a very early age. Gastroenteritis, respiratory infections, and malaria are the most prevalent and serious conditions that can affect development in the first three years of life. It is estimated that children under the age of five in developing countries suffer from 3.5 episodes of diarrhea per year and between four and nine respiratory tract infections in their first two years of life (Mirza et al. 1997). Infections affect children's development by reducing their dietary intake, by causing a loss of nutrients, or by increasing nutrient demand as a result of fever.

Undernutrition also plays a significant role in morbidity among adults. The link between morbidity from chronic disease and mortality, on the one side, and a high body mass index, on the other side, has been recognized and analyzed in industrial countries primarily for the purpose of determining life insurance risk. These relationships have also been studied in developing countries. A study on Nigerian men and women has shown mortality rates among chronically energy-deficient people who are mildly, moderately, and severely underweight to be 40%, 140%, and 150% greater than rates among non-chronically energy-deficient people (ACC/SCN 2000).

There are also linkages between food provision and HIV/AIDS. Not only does good nutrition of afflicted individuals help maintain the quality of their life, but in a rural environment there are implications for the feasibility of continued engagement in food production activities. One challenge is to minimize demands on a household labor pool that is severely depleted by the incapacitation of the afflicted family member and the time devoted to care giving by other family members (Gillespie and Haddad 2002).

8.5.1.4 Obesity and Overweight

Obesity has become a global epidemic. At present over 1 billion adults are overweight, with at least 300 million considered clinically obese, up from 200 million in 1995 (WHO 2003a). Obesity

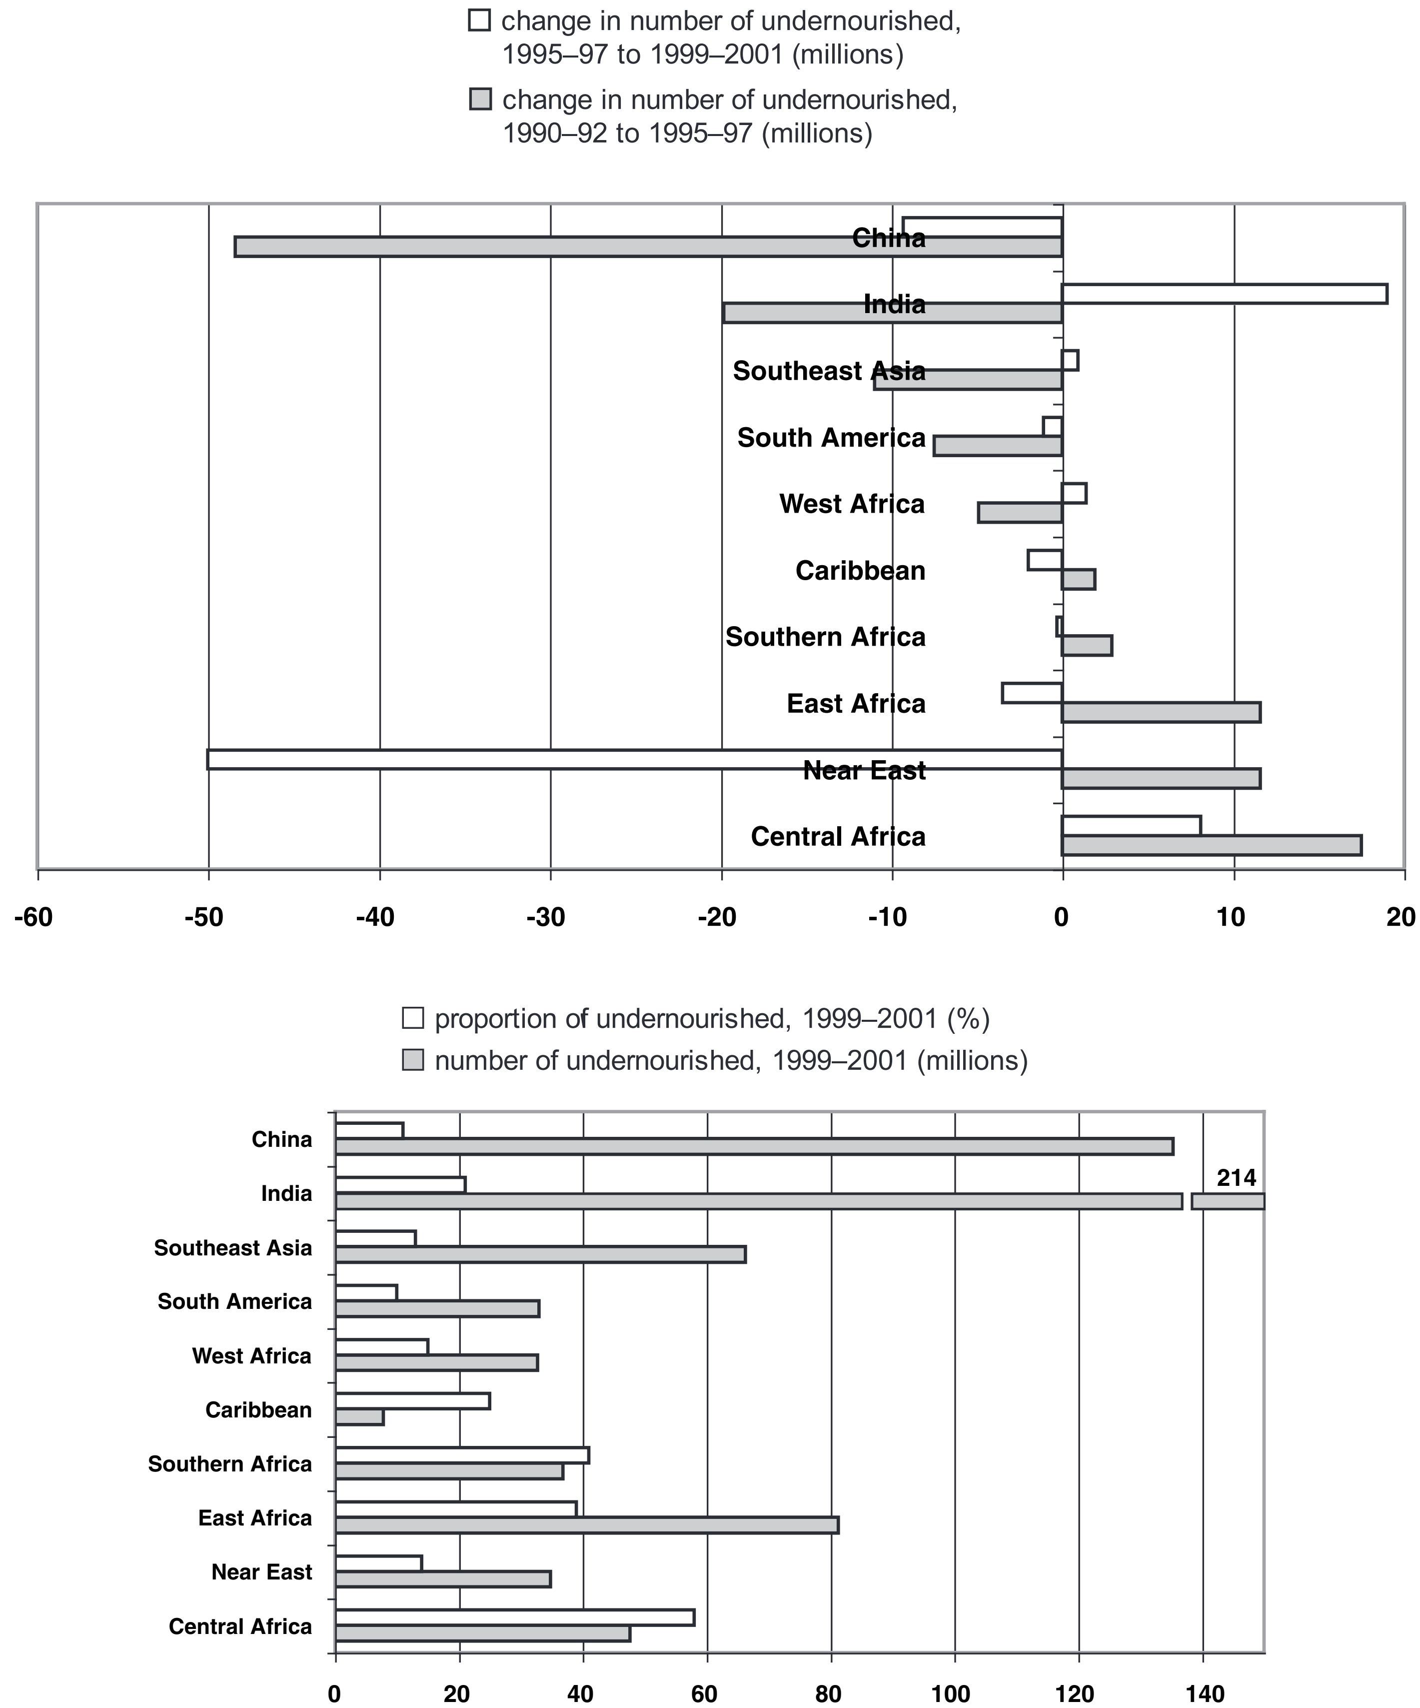

Figure 8.13. Status and Trends of Hunger, 1990–2001 (FAO 2003)

is now a major determinant of the global burden of chronic disease and disability. In many countries, significant incidence of both obesity and undernutrition may co-exist. (See Figure 8.14.) Obesity is a complex condition, with serious social and psychological dimensions, and can be found across almost all ages and socioeconomic groups (WHO 2003a). The prevalence of overweight and obesity is commonly assessed using the body mass index, which is defined as the weight in kilograms divided by the square of the height in meters (kilograms per square meter). A BMI of over 25 kilograms per square meter is defined as overweight, and a BMI of over 30 kilograms per square meter as obese (WHO 2003a).

Rising rates of obesity and overweight are due to both reduced physical activity and increased consumption of more energy-dense, nutrient-poor foods with high levels of sugar and saturated fats. Obesity rates often increase faster in developing countries than in industrial ones (Chopra 2002; WHO 2003a). The underlying causes of these trends include urbanization, income growth, changing lifestyles, and globalization of and convergence of "western" diets, the "diet transition." This transition is generally associated with an epidemiological transition in which disease patterns shift over time so that infectious and parasitic diseases are gradually but not completely displaced, and noncommunicable diseases become the leading cause of death (Uusitalo et al. 2002). WHO reports that NCDs now account for 59% of the 57 million deaths annually and 46% of the global burden of disease. There is a *well-established* link between an unhealthy diet and several of the most important of these NCDs, including coronary heart disease, cerebrovascular disease, various cancers, diabetes mellitus, dental caries, and various bone and joint diseases (WHO 2003b). Low levels of physical activity exacerbate dietary causes of increased risk of NCDs (WHO 2003b).

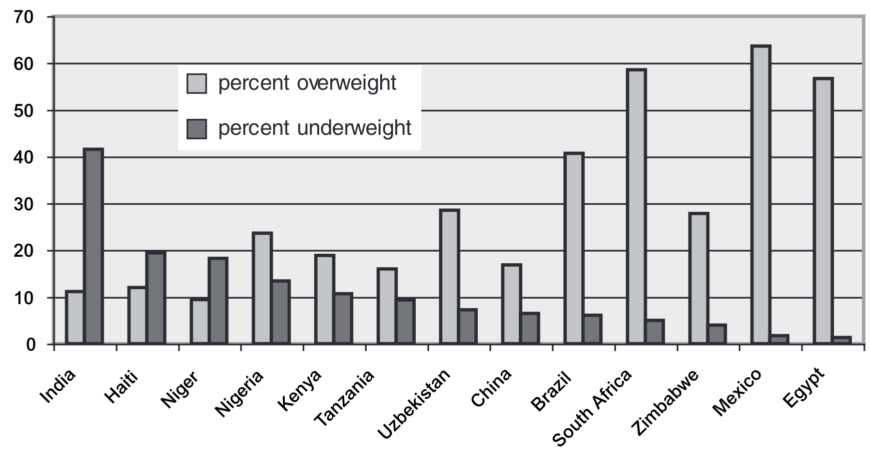

Figure 8.14. Double Burden of Undernutrition and Overnutrition among Women Aged 20–49 for Selected Developing Countries. A calculation of body mass index, BMI, can determine if a person is not eating enough, or is consuming too much. Many developing countries are facing both problems simultaneously. Note: data for each country are from the most recent year available. (Mendez et al. 2005)

Obesity rates have tripled or more since 1980 in some areas of North America, the United Kingdom, Eastern Europe, the Middle East, the Pacific Islands, Australasia, and China. Current obesity levels range from below 5% in China, Japan, and certain African nations to over 75% in urban Samoa. But even in relatively low prevalence countries like China, rates are almost 20% in some cities (WHO 2003a). A study by the Centers for Disease Control and Prevention in the United States found that almost 65% of Americans are overweight and around one quarter are obese (Flegal et al. 2002).

Child obesity is a growing concern and is already an epidemic in some areas. Based on an analysis of 160 nationally representative cross-sectional surveys from 94 countries, the global prevalence of overweight among pre-school children was assessed at 3.3%, representing, in developing countries, some 17.6 million children (de Onis et al. 2000). According to the U.S. Surgeon General, the number of overweight children in the United States has doubled and the number of overweight adolescents has tripled since 1980 (WHO 2003a).

Overweight and obesity lead to adverse metabolic effects on blood pressure, cholesterol, triglycerides, and insulin insensitivity (Rguibi and Belahsen 2004). Non-fatal health problems include respiratory chronic musculoskeletal problems, skin problems, and infertility. The more life-threatening problems are cardiovascular disease, conditions associated with insulin resistance such as type-2 diabetes, and certain types of cancers, especially the hormonally related and large-bowel cancers and gall bladder disease (WHO 2003b). Four out of the 10 leading global disease burden risk factors for NCDs identified by WHO (2002a) were diet-related: high blood pressure, high cholesterol, obesity, and insufficient consumption of fruits and vegetables.

An estimated 16.7 million deaths, or almost 30% of the global total, result from various forms of cardiovascular disease (WHO 2004c). Many of these are preventable by action on the major primary risk factors: unhealthy diet, physical inactivity, and smoking. Cancer accounts for about 7.1 million deaths annually (12.5% of the global total). Dietary factors account for about 30% of all cancers in western countries and approximately up to 40% in developing countries. Diet is second only to tobacco as a preventable cause (WHO 2004c). And up to 2.7 million lives could potentially be saved each year with sufficient global fruit and vegetable consumption (WHO 2004c). Fruits and vegetables as part of the daily diet could help prevent major NCDs such as cardiovascular disease and certain cancers.

A number of concerns have been raised concerning the convergence of diets that accompanies globalization, in addition to the negative effects on health and nutrition. These are loss of cultural identity and increased resource use in food production and transportation (Bruinsma 2003). It is estimated, for example, that an average American diet requires about three times as much nitrogen fertilizer per capita as the average Mediterranean diet (Howarth et al. 2002).

The simplification of diets in terms of food sources as a consequence of the nutrition transition has also had implications on demand for certain types of food and hence on the structure of crop, livestock, and aquaculture production systems as well as the genetic diversity they embody (Johns 2003). Although an increasing number of processed foods are available, particularly in urban and higher-income markets, the species and intra-species diversity of food sources is narrowing (Johns 2003).

Conversely, agricultural intensification and the simplification of agricultural landscapes can limit the availability of and access to wild foods and to food plants growing as weeds that may be of nutritional importance, especially to landless poor people and to vulnerable groups within households (Scoones et al. 1992). Similarly, the decline of traditional fisheries (following commercial exploitation of coastal fisheries and damage to inland water ecosystems due to water extraction and diversion) can have severe negative nutritional consequences for poor artisanal fishers (DFID 2002).

8.5.2 Food Safety

Illness as a result of contaminated food is a widespread health problem and an important factor in reduced economic productivity. The global incidence of food-borne disease is difficult to estimate, but it has been reported that in 2000 alone 2.1 million people died from diarrheal diseases, and it is estimated that 70% of the 1.5 billion global episodes of diarrhea are due to biologically contaminated food (WHO 2002b). Additionally, diarrhea is a major contributor to malnutrition in infants and young children. In industrial countries, up to 30% of people reportedly suffer from food-borne diseases each year (WHO 2002b). In the United States, for example, around 76 million cases of food-borne diseases, resulting in 325,000 hospitalizations and 5,000 deaths, are estimated to occur each year (Mead et al. 1999).While the situation in developing countries is less documented, they bear the brunt of food safety problems due to the presence of a wide range of food-borne diseases, including those caused by parasites. For example, cholera is a major public health problem in developing countries (WHO 2002b).

Food contaminants can occur naturally or as a result of poor or inadequate production, storage, and handling. Hazardous agents include microbial pathogens, zoonotic disease agents, parasites, myco- and bacterial toxins, antibiotic drug residues, hormones, and pesticide residues. Genetically modified organisms and their potential to contain allergens or toxins have also begun to receive attention (Unnevehr 2003). Food safety risks vary with climate, diet, income level, and public infrastructure, and food-borne pathogens are more prevalent in developing countries, where food safety may be as important as food security for health and nutrition. Consumption of contaminated food may cause children to be stunted, underweight, and more susceptible to infectious diseases in childhood and later in life.

In addition to food safety risks associated with uncontrolled endemic diseases found in developing regions, there are also food safety risks that appear in highly developed production systems when animal concentrations are high, feeds contain contaminants, or meat and milk are improperly handled. There have been outbreaks of several zoonotic diseases (those naturally transmitted from animals to humans) recently in people, including avian influenza, severe acute respiratory syndrome, and Creutzfeldt-Jakob Disease. Of 1,709 human pathogens, 832 are zoonotic, and of 156 emerging diseases, 114 are zoonotic. Overall, zoonotic pathogens are more than three times more likely to be associated with emerging diseases than non-zoonotic pathogens. Examples include influenza, brucellosis, bovine spongiform encephalopathy, tuberculosis, and rabies (Kaufmann and Fitzhugh 2004).

Genetically modified foods are increasingly receiving attention in the food safety debate with regard to toxicity, allergenicity, stability of the modified genetic composition, nutritional effects associated with genetic modification, and unintended effects as a result of gene insertion (WHO 2005). Outcrossing (the movement of genes from GM plants into conventional crops or related species in the wild), as well as the mixing of crops derived from conventional seeds with those grown using GM crops, may have an indirect effect on food safety and food security if the gene products are toxic. The risk of seed mixing is real, as was shown when traces of a maize type that was only approved for feed use appeared in maize products for human consumption in the United States (WHO 2005).

GM foods currently available on the international market have passed risk assessments and are not likely to present risks for human health (WHO 2005). In the developing world, the approval and cultivation of GM crops is largely limited to soybean, maize, and cotton in Argentina, Brazil, China, India, Mexico, and South Africa (James 2004). Consumption of GM foods has not shown any adverse effects on human health in the general population in the countries where they have been approved. Nevertheless, food safety assessments are essential to GM approvals and thus need to be started early in the process of GM crop development (Unnevehr 2003).

Pesticide residues on food are also of growing concern. In the United States, for example, the Environmental Protection Agency has set maximum legal limits for pesticide residues on food commodities for sale domestically. In the most recent U.S. Food and Drug Administration studies, dietary levels of most pesticides were less than 1% of the acceptable daily intake established by the FAO and WHO (Bessin 2004). Consumption of pesticide residues in food remains a significant problem in most developing countries, however, especially for food that is produced and consumed locally (Dasgupta et al. 2002). Pesticides, especially organochlorides, are expected to increase in importance as a health concern, particularly in the context of multiple pesticide exposure. Although the long-term effects of pesticide exposure remain uncertain, evidence suggests that toxins may increase carcinogenic and neurotoxic health risks in susceptible sub-groups (Alavanja et al. 2004; Maroni and Fait 1993).

8.5.3 Household Economic Impacts

Consumption of food is also linked to cognitive development and labor productivity. Nutrition has a dynamic and synergistic relationship with economic growth through the channel of education, and the evidence shows that the causality works in both directions: better nutrition can lead to higher cognitive achievement and increased learning capacity, and thus to higher labor productivity as well as higher incomes. And higher levels of education lead to better nutrition.

8.5.3.1 Nutrition and Cognitive Development

This dual causality between nutrition and cognitive development is complex and varies over the life cycle of a family. In utero, infant, and child nutrition can all affect later cognitive achievement and learning capacity during school years, ultimately increasing the quality of education gained as a child, adolescent, and adult. Parental education affects in utero, infant, and child nutrition directly through the quality of care given (principally maternal) and indirectly through increased household income. Human capital development, primarily through education, has received merited attention as a key to economic development (Verner 2004), but early childhood nutrition has yet to obtain the required emphasis as a necessary facilitator of education and human capital development.

Despite the limited evidence demonstrating a causal link between poor nutrition and cognitive achievement, systematic evidence supports the argument that policy interventions in early childhood nutrition are crucially important for cognitive achievement, learning capacity, and, ultimately, household welfare. Specifically, available studies (Horton 1999) have shown that:

- PEM deficiency, as manifested in stunting, is linked to lower cognitive development and educational achievement;
- low birth weight is linked to cognitive deficiencies;
- iodine deficiency in pregnant mothers negatively affects the mental development of their children;
- iodine deficiency in children can cause delayed maturation and diminished intellectual performance; and
- iron deficiency can result in impaired concurrent and future learning capacity.

Children are most vulnerable to malnutrition in utero and before they reach three years of age, as growth rates are fastest and they are most dependent on others for care during this period. However, nutrition interventions, such as school feeding programs, among children of school age are also important for strengthening learning capacity.

Yet there remains significant uncertainty surrounding estimates of the monetary costs associated with the impact of hunger and malnutrition on school performance. Nevertheless, Behrman (2000) cites three studies suggesting that, by facilitating cognitive achievement, child nutrition and schooling can significantly increase wages. Micronutrients from animal-source foods are especially important in the health of women of reproductive age and in the cognitive development and school performance of children (Neumann and Harris 1999). Behrman (2000) concludes that while the link between health and educational attainment is not as robust as most studies suggest, and specific cost-benefit analysis is difficult to carry out, policies supporting nutrition make good sense, and the empirical basis for this is as sound as that of many other conventional assumptions in economics.

8.5.3.2 Nutrition and Labor Productivity

Much of the empirical work linking economic outcomes to nutrition to date has focused on agriculture, and it attempts to link farm output, profits, wages, or labor allocation choices to indicators of nutritional intake such as calories or to nutritional outputs such as weight-for-height, BMI, and height. Widely cited work by Strauss (1986) links the average calorie intake per adult in a household to the productivity of on-farm family labor in Sierra Leonean agriculture. For this sample, on average, a 50% increase in calories per consumer equivalent increased output by 16.5%, or 379 kilograms. For an increase of 50% in hours of family labor or in the area of cultivated land, this compares with an output response of 30% and 13%, respectively. Significantly, Strauss's findings show that the lower the calorie intake is, the more significant the output response is to increased calorie intake. For example, based on a daily intake of 1,500 calories per consumer equivalent, a mere 10% increase in calorie intake would increase output by nearly 5%.

Findings from Ethiopia, presented in Croppenstedt and Muller (2000), show that a 10% increase in weight-for-height and BMI would increase output and wages by about 23% and 27%, respectively. They also find that height, an indicator of a person's past nutritional experience, is a significant determinant of wages in Ethiopia, with a person who is 7.1 centimeters above the average height earning about 15% more wages. These findings have to be contrasted with the effect of other productivity-augmenting investments, such as education. Nutrition would appear to compare well with the 4% increase in cereal output attributed to an additional year of schooling in a rural Ethiopian household.

Poor nutritional status not only reduces a person's output, it may also prevent them from carrying out certain tasks. A study in Rwanda found that those who are poorly fed have to choose activities that are physically less demanding—and less well paid (Bhargava 1997). A low BMI and poor nutritional status may also limit productivity indirectly through absenteeism and reduced employment opportunities. Moreover, to carry out certain activities, undernourished people may have to put their muscle mass and heart rate under much greater strain than well-nourished people do, requiring more energy to produce the same output, which may lead to health problems in the long term.

There is also an increasing awareness of the role of micronutrients in people's nutritional status, as described earlier. For example, iron deficiency in adults negatively affects productivity as well as contributing to absenteeism. Basta et al. (1979) found that productivity among Indonesian rubber plantation workers with anemia was reduced by 20% compared with non-anemic workers. There is also some evidence that iodine deficiency during adulthood reduces productivity and work capacity (Hershman et al. 1986).

8.5.4 Macroeconomic Growth

There is clear evidence of an association between improvements in nutrition and improvements in macroeconomic growth, but the nature and strength of the association is sensitive to the context and time frame (Easterly 1999; Arcand 2001; Wang and Taniguchi 2003). Overall, inadequate nutrition is estimated to cause losses of between 0.23% and 4.7% per year in per capita GDP growth rates worldwide (Arcand 2001). Improved nutrition affects economic growth directly through its impact on labor productivity and indirectly through improvements in life expectancy. The reverse is also true, and analysis using 81 indicators found that a 1% increase in per capita GDP raises per capita calorie intake by approximately 540 kilocalories a day (Easterly 1999). Differences in economic growth explained 40% of cross-country differences in improved mortality rates over the last three decades (Pritchett and Summers 1996), while in a separate study covering some 65 countries between 1970 and 1995, half of the decline in child malnutrition from 1970 to 1995 could be attributed to income growth (Smith and Haddad 2000). Half of the economic growth that occurred in the United Kingdom and France in the eighteenth and nineteenth centuries has been attributed to improvements in nutrition and health (Fogel 1994).

More recent and comprehensive analysis of 114 countries over the period 1961–99 found that, on average, the GDP growth rate increased by 0.5% per capita for each 500 kilocalorie-per-day increase in dietary energy supply (Wang and Taniguchi 2003). However, the results differed significantly between country groups and short-term and long-term perspectives. For some groups (East and Southeast Asia), GDP growth was up to four times higher, while in others (sub-Saharan Africa) GDP growth was absent or negative. Furthermore, short-term GDP impacts were also ambiguous (a mix of positive, neutral, and negative impacts). This is explained on the basis of a "nutrition trap" for some countries, particularly—and persistently—in sub-Saharan Africa. In such countries, significant increases in DES often translate into an expansion in short-term population growth rates that depress both per capita DES and GDP. To overcome this, nutrition and income need to attain levels at which further increases in DES do not promote population expansion, or DES increases need to be large and sustained (Wang and Taniguchi 2003).

8.5.5 Cultural Aspects

Food is not just an economic good and a requirement for good health, but also a centerpiece of culture. It is no coincidence that the word "company" stems from *com,* meaning together and *panis* meaning bread. Recalling the quasi-mystical status of the yam in much of African culture, Wole Soyinka, the Nigerian Nobel laureate for literature, speaking on the role of cultural leaders in changing attitudes and behaviors related to food and nutrition, said "Food is allied to culture in the most organic, interactive way, and one may be brought to the aid of, in enhancement of, or in celebration of the other" (IFPRI 2004).

Cultural aspects of food and acquired tastes (a type of "food bias") can be significant determinants of both physical and economic well-being. For example, in drought-prone southern Zambia, some drought-resistant crops, such as millet and sorghum, are not cultivated because southern Zambians have not acquired a taste for them despite the fact that these foods could provide food security during times of drought.

Food is so integral to the formation of cultural identities and global unity that 2004 was declared "The International Year of Rice" by FAO, to commemorate rice as a life force having "enormous impact on human nutrition and global food security" (FAO 2004). A grain of rice is compared with a grain of gold in Southeast Asia, and many Japanese perceive rice as the "heart" of their culture. Rice, along with many other foods, is used for consumption by people every day, as well as to celebrate religious and social holidays, festivals, and other special occasions.

Indeed, food rituals form the core of many religious rituals, and inadvertently affect markets and trade. Taboos associated with different types of food also set apart cultures, sects, and denominations. Not only do these taboos and rituals help promote social solidarity and maintain cultural boundaries, they also promote "food bias" and, thereby, contribute to the kinds of food trade a culture will initiate and promote. For example, religious beliefs associated with pigs in the Judaic and the Muslim traditions are not likely to initiate any pork trade in these regions. Similarly, Hinduism's taboo of beef, due to the sacred allegiance to the cow, can adversely affect the beef trade in certain regions of India. In North America, the turkey has become a cultural symbol associated with Thanksgiving, and more broadly is associated with Christmas, generating a large turkey trade during these seasons.

Recognizing that the enjoyment of wholesome food is important in the pursuit of happiness and, in part, as a backlash to the rapidly growing western/urban culture of fast food, a small but rapidly growing grassroots movement has been established that seeks to maintain the cultural significance of food and its consumption (Jones et al. 2003).

8.5.6 Distributional Dimensions

In low-income countries, most of which are characterized by a relatively large share of agriculture in the economy and a high proportion of rural population, food production has critical distributional impacts in the form, for example, of income or health inequalities. It has impacts on poverty alleviation, reduced inequalities in food consumption, improved nutrition and health, low commodity and food prices, and direct and indirect employment and income generation. The size and pattern of these impacts depend on a number of factors: the rate of growth of agricultural and food production across regions and types of crops, agriculture's share in the economy, the proportion of the population that is rural, asset (mainly land) distribution, rural infrastructure, well-functioning markets, availability of agricultural inputs and credit to the poorer farmers and in remote areas, and adequate research and extension (von Braun 2003).

Thus a whole set of factors combine to have a broad and equitable impact from increased food productivity. This explains the continued food distributional inequalities despite food production per capita increasing globally. Increased local food production remains critical to alleviating poverty and providing food security. In general, the experience of the last few decades shows that the higher the food (and agricultural) output (especially when it is due to higher labor and land productivity), the more equal the land distribution, the better the small farmer's access to inputs and markets, and the less suppression of agricultural prices, the greater is the positive impact on income and consumption distribution, poverty alleviation, and food security for the poor (von Braun 2003). Further, the more ''distribution friendly'' variables that are present, the stronger is their synergistic impact.

Livestock are also a significant source of income and consumption in low-income countries. Often they provide a supplementary source of income and income stability. However, in many cases livestock are a vital, even the sole, source of income for the poorest, the landless, pastoralists, sharecroppers, and widows. They are one of the few assets available to these groups. Livestock also allow the rural poor to exploit common property resources, such as open grazing areas, in order to earn incomes and reduce income variability, especially in semiarid areas.

Main Messages

Global timber harvest has increased by 60% in the last four decades and will continue to grow in the near future, but at a slower rate. The growth rate of timber harvest has slowed in recent years and is likely to continue to grow more slowly in the foreseeable future. (In this chapter, "timber" is used to denote standing trees and their immediate products). The portion of harvested wood that was used for pulp increased threefold since 1961, reflecting a major shift in demand for timber products as pulpwood demand greatly outpaced the increased demand for sawn wood products.

Timber supplies for common industrial wood products appear to be ample for the near future, but there will be shortages of high-value species and premium quality woods due to past overharvesting. Timber production from both forest and agricultural plantations will increase over the near future, providing wood for pulp and common sawtimber. Premium woods from large and old trees of highly valuable species are scarce in most regions. They may be restored through protection and sustainable forest management in the longer term but will remain in short supply for the foreseeable future.

Plantations are providing an increasing proportion of timber products. In 2000, plantations were 5% of the global forest cover, but they provided some 35% of harvested roundwood, an amount anticipated to increase to 44% by 2020. The most rapid expansion will occur in the mid-latitudes, where yields are higher and production costs lower. Gains in production will also come from insect and disease-resistant trees, genetically improved trees with higher yields and improved fiber characteristics, improved planting techniques, and improved management. The net effect will increase the amount of products available to satisfy timber, fuel, and fiber needs, but with a reduced harvest from natural forests in most regions.

Major shifts in the location of timber production have resulted from a combination of globalization, economic stress, and changing national policies, and the future for sustainable timber supplies varies across areas and regions. In general, recent production shifts have been from north to south. In the northern boreal and temperate regions, forest-growing stocks have increased in the recent past, as overall annual growth has exceeded mortality and harvest. This trend will continue into the foreseeable future (*medium certainty*). In the low latitudes, deforestation and degradation continue to diminish natural forests. Contributing to this are examples of destructive, exploitive, and illegal logging practices. These combine with a complex of other drivers, including fuelwood extraction, agricultural expansion, development policies, and population pressures to contribute to forest degradation. The associated production losses are partially offset by plantation expansion, but premium species are seldom replaced, either in regrowing forests or in plantations.

International trade in forest products has increased at a rate much faster than the increase in production. The global value of timber harvested in 2000 was around $400 billion, and around one quarter of that entered into world trade, representing some 3% of total merchandise trade. In constant-dollar terms, global exports increased almost twenty-five-fold between 1961 and 2000. Five countries—the United States, Germany, Japan, the United Kingdom, and Italy—imported more than 50% of world imports in 2000, while Canada, the United States, Sweden, Finland, and Germany accounted for more than half of exports. During the past decade, China has increased its imports of logs and wood products by more than 50% and, if unabated, this rate of increase will put significant pressure on wood supplies in many regions, particularly Russia and Southeast Asia.

International moves toward sustainable forest management and forest certification have expanded rapidly in recent years. To date they have been used primarily in industrial countries, and only locally in developing countries, and they do not seem to be affecting timber production or trade significantly. They are, however, affecting forest management where certification is involved. Their broad future effectiveness remains uncertain, but they could become more important in some regions, such as Europe.

The global forestry sector annually provides subsistence and wage employment of 60 million work years, with 80% taking place in the developing world. While timber is processed mainly by industrial firms, the management of forests, including harvesting and transport, is dominated by individuals, families, and small companies. In the industrial world, the forestland is both privately (in Europe and the United States, for example) or publicly (as in Canada) owned and managed. In the developing world, most of the forest is a public resource. These ownership factors create very different and diverse opportunities for people to interact with and benefit from forest products and services. As production moves South in the near future, the trend indicates increasing forest employment opportunities in sub-tropical and tropical regions, with declining employment in temperate and boreal regions. Labor requirements per unit of output in all regions will continue to shrink due to technological change.

Illegal logging is a significant factor that skews timber markets and trade, particularly in tropical forest regions and countries with weak or transitional governments. It is estimated that up to 15% of global timber trade involves illegal activities, and the annual economic toll is around $10 billion. Addressing this problem will require a major effort by both governments and private industry.

On a global basis, the recorded value of fuelwood production per capita has fallen in recent years, and earlier concerns about a "wood energy crisis" have eased. Fuelwood is the primary source of energy for heating and cooking for some 2.6 billion people, and 55% of global wood consumption is for fuelwood. While populations in developing regions will continue to grow, estimates from FAO indicate that global consumption of fuelwood appears to have peaked in the 1990s and is now believed to be slowly declining. Accurate data on fuelwood production and consumption are difficult to collect, since much of it is produced and consumed by households in developing countries. It is also difficult to relate trends to ecosystem condition, since fuel is harvested from woody plants wherever they occur. Localized fuelwood shortages in Africa impose burdens on people who depend on it for home heating and cooking. The impact on people may be high prices in urban areas or lengthy and arduous travel to collect wood in rural areas.

The burning of wood fuel without appropriate smoke venting creates significant health hazards, and where wood shortages force poor families to shift to dung or agricultural residues for heating and cooking, the problems are exacerbated. An estimated 1.6 million deaths and 39 million disability-adjusted life years are attributed to indoor smoke pollution, with women and children most affected. Where adequate fuel is not available, the consumption of cooked food may decline, leading to adverse effects on nutrition and health. Human well-being can be enhanced in many developing regions through efforts to assure adequate and accessible fuel supplies, as well as to promote more-efficient stoves and more-effective smoke venting.

Wood and forest biomass, agricultural crops and residues, manure, municipal and industrial wastes, and many other non-fossil organic materials can produce renewable energy and fuel supplies through a variety of modern industrial processes. These renewable energy technologies are being rapidly developed throughout the world, but examples of full commercial exploitation are still fairly modest. Competition from low-cost and widely available fossil-based fuels currently limits the expansion of successful research and pilot projects into widespread commercial production. Biomass-based energy production, while likely to expand slowly in the near future, offers great promise for the mid- and long-term future, as the nonrenewable nature of fossil fuels, particularly natural gas and petroleum crude oil, begins to affect energy economics because of shortages and supply disruptions.

Global cotton production has doubled and silk production has tripled since 1961, accompanied by major regional shifts in the production areas. Production of other agricultural fibers such as wool, flax, hemp, jute, and sisal has declined. While cotton production has doubled, the land area on which it is harvested has stayed virtually the same. Major area expansion of cotton production in India and the United States has been offset by large declines in Pakistan and the former Soviet Union. These shifts have important impacts on limited water resources, since much of the cotton crop is irrigated, and on agricultural land use patterns, as cotton competes with food crops for arable land. There have also been significant impacts of the use of fertilizer and pesticides for the increased production of cotton. Silk production also experienced a major shift in production area, from Japan to China, due to lower labor costs.

There are still instances where species are threatened with extinction due to the trade in hides, fur, or wool, in spite of international efforts to halt poaching and trade. On the other hand, there are instances, such as for crocodiles, where international conservation efforts have restored species and established sustainable production of valuable commodities.

9.1 Introduction

This chapter on timber, fuel, and fiber covers a wide range of ecosystem services provided by an equally wide range of ecosystems. The major focus is on timber that is linked most closely with forest ecosystems and forest-related communities and industries, but it extends to fuel and fibers as well. Information about recent trends in supply and consumption of those products is presented and assessed in terms of the impact of that consumption on ecosystems and human well-being, and efforts are made to identify and assess the important drivers of change in each resource area. Trends in the condition of the ecosystems from which these services are derived are found in other chapters of this volume (particularly Chapters 21, 22, and 26).

Forests cover about 30% of the ice-free land area of Earth, but global forest cover has declined considerably through history (FAO 2001a; Williams 2003). (See also Chapter 21.) While there are copious statistics for the timber and wood products that enter into world trade, assessing the connection between production and forest ecosystems is complicated by the fact that the production statistics are reported by country rather than by biome or ecosystem.

The most complete and comparable statistics are maintained by the U.N. Food and Agriculture Organization, and its publications and databases are widely cited in this chapter. It should be noted that all statistics on wood production, whether for fuel or commercial purposes, have some limitations. Regional data are reported by FAO, but the regions are geographic or geopolitical, making their direct use in reflecting effects on forest ecosystems of limited value. For this assessment, FAO country data have been regrouped to approximate the dominant forest systems affected by the production trends reported. Table 9.1 lists the countries that were grouped into the seven major forested regions chosen for

this assessment. Figure 9.1 (in Appendix A) indicates where these seven regions are.

In addition to timber, fuels derived from biomass are also considered in this chapter. More than 2 billion people worldwide rely on biomass for their main energy source (IEA 2003). Although wood and charcoal are the primary energy sources in many societies, particularly developing ones, the data for assessing the impacts of this use and consumption on ecosystem sustainability are largely unavailable. This is due to several factors, including the difficulty of monitoring the supply and consumption of wood fuels accurately, as much of it is done outside the market economy.

The last section of the chapter discusses some of the general trends in the production and consumption of important fibers derived from forest or agricultural crops, domestic animals, wildlife, and other sources. These products, each of which could be the subject of a major assessment, are treated sparingly due to limitations of space and time.

The ownership of forests varies on the basis of legal and cultural traditions and history. In some nations, central governments claim vast areas of forest but do little to enforce those claims. Poor administration and corruption allow illegal logging and other forms of resource extraction, including within protected forests. In other areas, highly developed property rights systems exist, and resource extraction is often tightly regulated as a result. More wood per hectare is generally harvested from private forests than public ones, because of more-intensive management and more-focused forest production objectives. While some private forests produce multiple benefits, many are managed mainly for timber. (See Table 9.2.)

For forests in protected areas, timber harvest may or may not be one of the management objectives. Even where forests are protected from harvesting in some protected areas, resource extraction (for commercial or local use) continues unabated owing largely to poor governance and corruption (WWF 2000; Khan et al. 1997; Smith et al. 2003; and see MA *Policy Responses,* Chapter 5).

In both temperate and tropical forests, many local communities have decision-making rights for the management of public forestlands. Such community forest management systems include joint forest management in India (TERI 2000) and nascent concession systems in Bolivia and Peru. In order to foster long-term maintenance of forest resources, communal forest management arrangements generally allocate all or part of the forest production revenues to the local community. While the amount of forest products produced under such arrangements remains negligible as a fraction of total global output, community management can produce significant positive local economic impacts.

9.2 Timber and Related Products

While forests produce a wide range of services that are essential to human well-being, their major financial output consists of timber that can be used for a variety of manufacturing, building, fuel, and other materials. Timber is harvested from forest ecosystems (both intensively and extensively managed), forest and agricultural plantations, and trees outside forests. It should be noted that there is not always a clear distinction in the data and discussion of these issues between "planted forests" and "plantations." (See Chapter 21.)

9.2.1 Industrial Roundwood

According to FAO, industrial roundwood includes wood for the following commodities: sawlogs, veneer logs, pulpwood, other industrial roundwood (used for tanning, distillation, match blocks, poles, piling, posts, pitprops, and so on) and, in the case of trade, also chips and particles and wood residues. Although the title "industrial roundwood" suggests that this is wood harvested by industrial companies, the majority of the timber harvested in the world is still harvested by individuals, families, and small operations using a variety of traditional and modern methods. This use of the term "industrial" is better understood to mean wood that is produced for sale into commercial channels for processing or end use.

9.2.1.1 Production

Production of industrial roundwood increased between 1961 and 1980 in nearly all regions, but the increase, which was slowing gradually before 1980, slowed considerably between 1980 and 2000. (See Table 9.3.) Some of this decline in the rate of increase reflects the demise of the Soviet Union and the associated dramatic reduction in timber production. Russian and other former Soviet Union timber production, in excess of 300 million cubic meters a year in Soviet times, declined to one fourth of previous levels.

As the former centrally planned economy moved toward greater use of markets, the subsidies received by the transport sector were largely eliminated and with it, the subsidy that allowed

Table 9.2. Some Key Differences Affecting Forest Product Derivation from Public and Private Forests

Category	Public Forest	Private Forest
Management regime	extensive	intensive

timber transport from the forests to distant processing facilities. In addition, the large declines experienced in Russian Federation GDP further depressed timber demand and production. A growing Russian economy together with new export markets, such as China, should revive some of the demand for Russian Federation wood products, and indeed timber production increased in the late 1990s. The transport subsidy is unlikely to return, however, and Russian timber production in the next decade will likely be substantially lower than in Soviet times.

9.2.1.1.1 Illegal logging

It should be noted that the FAO data (and Table 9.3) consist primarily of legally produced wood as reported to national governments, and so in regions where illegal logging is significant, the data may underreport the actual volume of timber harvested. It is difficult to estimate the magnitude of illegal removals, and quantitative estimates vary. But the amount of timber involved is both locally and globally significant. Contreras-Hermosilla (2002) estimates that as much as 15% of global timber trade involves illegalities and corrupt practices, amounting to annual losses in assets and revenues in excess of $10 billion. Curry et al. (2001) conclude that ''illegal logging is rife in all the major tropical timber producing countries,'' citing studies showing that 70% of log production in Indonesia (50 million cubic meters per year) is derived from illegal sources; 80% of logging in the Brazilian Amazon during 1998 was illegal, and half of all timber in Cameroon is sourced through illegal logging (WRI 2000b).

Illegal logging takes many forms, including logging timber species protected by national or international law; logging in protected or prohibited areas; logging without authorization; extracting more timber than authorized; timber theft and smuggling; and fraudulent transfer pricing and other corrupt accounting practices. Its negative impacts include the impoverishment of forest landscapes, governments and local communities that are deprived of significant forest revenues, the strengthening of organized criminal enterprises, and inducements for the corruption of law enforcement and other officials (Contreras-Hermosilla 2002).

National and local governments, being unable to appreciably reduce illegal logging, often play down its extent. In Russia, for example, according to government figures illegal logging over the past decade has amounted to 1% of legally permitted logging. Independent NGO and scientific assessments, however, estimate illegal logging to constitute some 20% of the total, with illegal exports of particularly valuable species in border areas being double the legally permitted volumes (Sheingauz 2001). In other areas too, weak or poorly enforced legislation has been ineffective in protecting forests from illegal logging (for example, in the Congo basin) (Global Witness 2002).

9.2.1.1.2 Forest plantations

All the following statistics refer to forest plantations as opposed to planted forests, with the distinction being, for the latter, the application of planting as one of several normal silvicultural techniques used to reforest harvested areas. Plantations, in contrast, are intensively managed, regularly spaced stands, often monocultures, often of exotic species, and usually with the production of wood as the main product (FAO 2000c). Forest plantations covered 187 million hectares in 2000, with Asia accounting for 62% (FAO 2001a). This total represented a tenfold increase (from 17.9 million hectares) since 1980 (FAO 2001a). In 2000, the annual rate of new planting was estimated at 4.5 million hectares, of which 79% was in Asia, and much of this in China and India. (See Chapter 21 for a more complete description of trends in plantation forests.)

Yields from tropical plantations are high—often in the range of 10–30 cubic meters per hectare per year for *Eucalyptus* and *Pinus,* with some species on favorable soils reaching yields as high as 50–60 cubic meters per hectare. Given the amount of research that has gone into improving yield from planted stocks, these yields are likely to continue to increase. Because of high yields and increasing area, plantations provide a continuously increasing portion of the world's timber supply. According to FAO (2001a), plantations were only about 5% of global forest cover in 2000, yet provided some 35% of global roundwood, an amount anticipated to increase to 44% by 2020.

Plantation growth rates and wood quality are likely to improve with each successive rotation, as trees embodying new genetic improvements are increasingly being used to replace the old technology embodied in the prior harvest. Thus far the genetic improvements have come primarily through conventional breeding techniques. However, there are substantial efforts under way to apply modern biotechnology, including genetic engineering, to industrial trees and plantation forests (Sedjo 2004). The degree of acceptance of genetically engineered (transgenic) trees remains uncertain. But based on experience with genetically engineered crops, there is reason to believe that the adoption of transgenic technology for trees will be variable.

9.2.1.1.3 Agricultural plantations

Plantations of agricultural and industrial crops such as rubber, coconut, and oil palm are increasingly important sources of industrial wood for the forest industries of Asia. It is estimated that there are some 27.4 million hectares of these crops in the region. Changing technology and markets are resulting in the conversion of formerly wasted by-product logs to products such as plywood, particleboard, paper, and lumber for furniture and other uses (Durst et al. 2004).

Rubberwood (*Hevea brasiliensis)* is estimated to cover some 9 million hectares, primarily in Indonesia, Thailand, and Malaysia. Planted originally for the production of latex, the trees mature at about age 30 and are then replaced. Prior to the emergence of milling technology in the late 1970s, the wood was either used for energy or disposed of in open burning. Today, it is estimated that over 6.5 million cubic meters are processed into sawn lumber, largely for furniture (Durst et al. 2004). Rubberwood is also used for manufacturing a variety of wood panels. This production, which eases pressure on many formerly used native species, is currently the basis for exports of almost $1.5 billion annually from Malaysia and Thailand (Durst et al. 2004).

Coconut palm (*Cocos nucifera*) is another agricultural crop with emerging value for the forest products industry. Its primary use is for coconut oil, but after age 60, when yields begin to decline, the palms are generally felled and replaced. Removing the downed stems from the plantation is important for controlling disease, and selling them for lumber production increases plantation revenues.

It is estimated that, throughout Asia, palm wood production rates of around 5 million cubic meters per year will be available for at least 20–30 years. After that time, the existing plantations will be replaced by higher-yielding dwarf varieties that produce less valuable lumber, but which may be useful for products such as panels (Durst et al. 2004).

Oil palm (*Elaeis guineensis)* plantations cover an estimated 6.5 million hectares in Asia and are grown on a 25- to 30-year rotation (Durst et al. 2004). While this is a huge potential in terms of biomass, research and development are needed to overcome limitations in the use of this species for wood products. That research is under way, and if the experience in developing and using other formerly "unusable" species is any guide, increasing industrial use is likely in the future.

9.2.1.2 Consumption

Between 1961 and 1991, the market value of global wood consumption more than doubled in real terms, growing at 2.7% per year (FAO 1999). In terms of processed wood products, sawnwood increased by 20%, wood panels by 600%, and paper by 350% between 1961 and 1991. These increases were achieved, in large part, through improved production efficiencies, recovery of wood residues for use in wood panels, and paper recycling (FAO 1999).

An increasing supply of wood products has begun to flow into China as that economy continues to develop rapidly. China is now importing 107 million cubic meters of wood, which represents an increase of more than 50% during the period 1997–2003 (Sun et al. 2004). The demand for imported wood has developed in part as a result of policies limiting domestic harvest levels. Imports are made up of raw pulp and paper largely coming from Canada and Russia and sawn lumber and logs from Russia, Malaysia, and Indonesia (Sun et al. 2004). Imports from Russia have resulted in continued forest loss in there through rapid logging of mature forests. (See Chapter 21.) Demand from China is expected to continue to grow, resulting in increased social, environmental, and economic effects, particularly in Russia and Southeast Asia.

The substitution of a variety of other materials for wood has contributed to relatively slow growth in global timber consumption in recent years. Steel studs (with up to one-third recycled content) are replacing wood in some markets of industrial countries, and vinyl has largely replaced wood as a siding material in North America. Plastics have replaced wood in some specialty applications—for example, to a large extent in the European window frame market. The use of metal roofing is growing rapidly in many parts of the developing world and, along with other products, it has largely replaced wood as a roofing material.

As premium quality and specialty woods have become scarce due to high-grading and other forms of unsustainable harvesting, there has been considerable replacement of traditional wood products by new products. Solid hardwood furniture has been replaced in many situations by a thin veneer of hardwood glued to a manufactured panel. Solid boards for sheathing buildings have been replaced, first by plywood and then by composite oriented strandboard. Solid wood joists for flooring systems are being replaced by engineered I-joists fabricated from smaller pieces of wood from widely available second-growth trees that often do not produce the large and high-strength pieces needed for solid wood structural timbers. These I-joists offer a flatter floor, greater strength, and longer spans. These manufactured wood products are so far largely confined to markets in industrial countries.

In many parts of the world, newly engineered forms of wood flooring, often with sturdy artificial overlays, are gaining wide acceptance. Other new products include engineered panels for nonstructural uses such as furniture, flooring, and moldings. These are often constructed using sawdust, shavings, and other residuals from sawmills or plywood mills. Viet Nam has a plan to build as many as nine particleboard plants to support its growing furniture industry. Non-wood fibers are increasingly being tapped for these products; examples include panels from wheat straw in the North American wheat belt, and medium density fiberboard produced from oil palm stalks in Malaysia and Indonesia. Like many new technologies, the agri-fiber panels have had difficulties with some early testing. However, the technology seems well adapted for fiber-short nations with growing economies, such as China.

In the paper industry, plastics and other materials have replaced some paper bags, packing papers, and paperboard. Increasing use of recycled fiber has caused roundwood use for paper in the United States to decline significantly since the mid-1990s. Markets for many paper products in North America are saturated, and low economic growth in areas like Europe and Japan, driven by sluggish economic growth and declining birth rates, contributes to the demand weakness.

9.2.1.3 Trade

While FAO (2003c) indicates that total roundwood harvest across the world has increased some 60% since 1961, the constant-dollar value of forest products exported has increased almost twenty-five-fold. (See Table 9.4.) Much of this is due to the increasing proportion of finished and semi-finished products in trade, as opposed to unprocessed logs or chips.

About one quarter of global timber production enters into international trade, according to FAO, and paper alone makes up about 2% of all global trade (IIED 1996). With a total value of around $100 billion in 1991 (FAO 1995), wood products constituted about 3% of total world trade. This trade is growing rapidly, particularly in industrial countries. By 1996–98, import value was estimated at almost $43 billion and export value was $135 billion (WRI 2000a). Five countries—the United States, Germany, Japan, the United Kingdom, and Italy—accounted for more than 50% of international imports in 2000, while Canada, the United States, Sweden, Finland, and Germany accounted for more than half of international exports (FAO 1999).

Much of the total global trade is within regions. Flows between the United States and Canada, between northern and central Europe, and within Southeast Asia dominate world trade (TMFWI 2001). Where these trade patterns have resulted in shifting timber production to more productive regions (as described later), total timber production has increased more rapidly than the area of forest harvested.

9.2.1.4 Employment

In recent decades there has been a decline in the labor inputs required by the forest products industry, where employment has experienced similar declines as many other extractive and manufacturing industries (U.S. Bureau of Labor Statistics 2004).

For example, from 1955 to the mid-1990s, labor productivity in logging in the United States increased an average of 1.45% annually (Perry 1999). Since output increased at about the same rate, however, employment levels remained relatively steady. Employment in forest product processing has declined in many countries in recent years due to increasing labor productivity. In the United States, for example, over the period 1997–2003 employment in the paper and paperboard production fell by one third while total production barely declined (U.S. Bureau of Labor Statistics 2004).

9.2.1.5 Future Availability

Estimates of future wood demand must be approached with some caution, as past assessments have regularly overestimated needs (Clawson 1979; Sedjo and Lyon 1990). More-recent estimates by FAO (1998b) suggest that the global wood demand by 2045/50 will be about 2 billion cubic meters a year and that supply should

Table 9.4. Forest Product Exports and Imports, 1961–2000 (Data from FAO 2003c)

Total	**7**	**63**	**153**		

be about the same, with Asia contributing about 700 million cubic meters and North America about 1 billion cubic meters.

Ultimately, the future availability of wood supplies is likely to be related more to growth and productivity of managed and planted forests than to the area of natural forests or gross forest stock. Production from natural forests will continue to be replaced by production from plantation forests, especially in tropical and sub-tropical forests (as described later). The same trend seems likely in many temperate forest areas. In the United States, for example, the harvest of softwood timber on non-plantation native forests is forecast to decline by 25% over the next 50 years, and standing stocks on non-plantation forests are expected to increase significantly (USDA Forest Service 2003).

Although the amount of forest cover is changing differently by region, other factors also contribute to timber supply and availability. (See Chapter 21.) The forest available for timber production has been declining in some parts of the world (in Europe, North America, Taiwan, and Japan, for instance) due to increasing emphasis on non-timber services such as nature conservation and wilderness. For example, some 21 million hectares of productive forestland have been set aside in conservation reserves (parks, wilderness, and so on) in the United States (USDA Forest Service 2001). This area has more than doubled since 1953, reflecting the increased emphasis on non-timber forest values in the latter half of the twentieth century (USDA Forest Service 2001).

In many areas of the world, suburban sprawl and the fragmentation of ownerships are having an effect on the availability of forests for harvesting, management, and recreational access. In addition, the resulting land use patterns create significant problems for land management and wildfire management in the rural-urban interface (Sampson and DeCoster 2000; Gordon et al. 2004). Large areas of land that meet the definition of forest for inventory purposes are not available for timber production due to the small size of the ownerships or reduced access due to isolation from road networks by other ownerships (Tyrrell et al. 2004). Few national forest inventories effectively account for this factor.

In spite of increasing timber harvests, the reclassification of productive forest to non-timber use, and forest fragmentation, the forests available for timber production in Europe and North America have increased in terms of total standing timber stock. In Europe, it is estimated that annual growth in standing timber is around 700 million cubic meters while timber removals in 2000 were around 418 million cubic meters (FAO 2003b). In the United States, softwood sawtimber stocks in 1997 were 8% higher than in 1963, and hardwood sawtimber stocks had nearly doubled (up 95%) in the same period (USDA Forest Service 2001). With both regions tending to reduce harvesting intensity, particularly on publicly owned lands, the prospects for the near future are for continued growth in the standing stock of timber in both Europe and North America.

One potential factor that can deplete these timber stocks in the future is the threat of alien invasive species, which move more freely as a result of increased global trade. For example, recent infestations in central North America by several invasive insects have resulted in the mortality of large numbers of deciduous trees, especially maples and ashes. In the past, such invasives as Dutch elm disease (*Ophiostoma lumi* and *O. novo-ulmi*) have virtually eliminated individual tree species in some areas.

In addition to the volume of standing timber, the quality of the timber resource is also important. For example, North American eastern hardwood forests, while doubling in standing stock in recent decades, are often dominated by species such as red maple (*Acer rubrum*) that are not as valuable for timber as the original forests that were, in many areas, dominated by species such as oaks, hickories, and chestnuts. In many areas of the world, the premium quality trees and most valuable species have been unsustainably harvested, and supplies of those high-value woods are increasingly limited (FAO 2003b).

The uncertainties in this future prospect include political decisions affecting land use and access to the land for timber harvest, changing trade policies, and the uncertain effects of climate change on net forest growth rates. There are indications that the uncertainty of future access to forests for timber harvest is currently discouraging investment in the forest products industry in some regions.

9.2.2 Wood Pulp

Pulpwood is one component of industrial roundwood production, and the production of pulpwood from forest ecosystems is often tightly integrated with the production of other solid wood products. Pulpwood is derived from a variety of wood sources, ranging from the harvest of fast-growing young trees in plantations managed specifically for pulp production, to the small or lower-quality stems removed from managed forests to improve forest quality or health, to the shavings, trimmings, and other wood produced in the manufacture of sawn wood products. Pulpwood accounts for about a third of the roundwood harvested (including fuelwood) (IIED 1996).

In 1995, about 17% of the wood for paper came from primary forests (mostly boreal), 54% from regenerated forest, and 29% from plantations (IIED 1996). This is expected to change as increased output from plantation forests, many of which will mature in the next decade, reaches world markets.

The global production of wood pulp has almost tripled in the past 40 years. (See Table 9.5.) Regional experience is uneven, with the most rapid expansion occurring in the tropical regions, for a variety of reasons described later in the chapter. The rate of expansion has slowed significantly in recent years, and the current global market in pulp and paper products is marked by overcapacity in the industry and low prices. This has resulted in an unprecedented decline in U.S. pulp and paper production and capacity after 1999, for example (*Economist* 2000). Since late 2003, prices for pulp have rebounded, perhaps aided by high demands in the expanding Chinese economy. This current situation does not, however, change the outlook for further structural change and regional shifts in these industries, especially with increased production from plantations globally.

These factors suggest that the prospect for the near future is a continued leveling off of wood pulp production, with continued decline of major pulp mills in the mature production areas of Europe, Japan, and North America. Those impacts, if they occur, will not affect all regions similarly. The industry continues to shift both mill locations and wood supply contracts to regions of lower-cost production, such as South America and Asia. Such shifts are also tied to increased demand in Asia, especially China.

The rapid increase in wood pulp production over the past four decades was tied to several trends, such as increased population and literacy, leading to increased consumption of paper and paper products and increased use of packaging and packing materials as trade in manufactured consumer goods has grown. The slowdown of the rate of growth in wood pulp production, however, indicates a maturation of these markets and the impact of competing materials. Nevertheless, the International Institute for Environment and Development (1996) predicts continued increased consumption of paper globally, with most of the increase in Asia.

Even so, there appears to be little evidence to suggest that changes in forest ecosystem condition will materially affect the availability of wood pulp globally in the foreseeable future. In fact, the evidence suggests that the increased harvest of young plantations will continue to keep supplies ample and prices low. Since most of the end products of wood pulp (packaging, paper, and so on) are traded in market economies, it is unlikely that changes in the supply will affect consumer well-being, since these societies are generally less vulnerable to modest price changes, and world trade is active in most of these items.

The use of non-wood fiber in pulp supply is expected to remain low and concentrated in Asia. Non-wood materials made up 5.3% of global pulp in 1983 and 11.7% in 1994, and they are expected to reach 12–15% by 2010 (Pande 1998). Most of the non-wood fiber is used in ''small-scale pulp mills'' (less than 30 tons a day), many of which are currently being closed as a result of poor pollution controls and increasingly stringent standards (e.g., FAO 1998a). This industry has not been well supported by research and development of improved technology or pollution controls (Hunt 2001). Two scenarios are likely for the small-scale non-wood pulp sector. Either most small mills will eventually be replaced by larger regional mills that use wood fiber, or cost-effective pollution abatement will be developed, in which case the projected 10–15% of global production of paper from non-wood fibers may be realized.

9.2.3 Craft Wood

The use of wood as a basis for local crafts is common in forested and wooded regions. The products range across a wide variety—from musical instruments to special furniture, toys, and fixtures

and to artistic and decorative objects. The woods prized for many of these objects are often culled from commercial timber production lines.

While wood crafting is often a significant local economic or cultural activity, there are few data to address the importance of these wood products at the ecosystem, country, or regional level, and few reliable data at the global level to assess the condition and trends of the production of craft wood products. From the limited information available, Bali exports about $100 million of wood carvings a year, suggesting an important contribution to local economies. A study done by CIFOR (2002) indicated that the African craft wood industry is not sustainable, with a declining availability of preferred tree species in most African countries.

9.2.4 Carbon Sequestration in Wood Products

The international community has increased its focus on the issue of climate change due to the buildup of atmospheric carbon dioxide and other greenhouse gases. One topic receiving significant attention has been the ability of forests to sequester atmospheric CO_2 in the process of photosynthesis. (See Chapter 21.)

The harvesting of forest products from sustainably managed forests leads to medium-term carbon sequestration in the form of stable wood products that remain in use for decades or centuries (Skog and Nicholson 1998). Functions for quantifying the rate of retirement or turnover of a wide variety of forest products have been developed, allowing analysts to calculate the carbon fate of harvested wood products (Skog and Nicholson 1998).

At this time, there have been no carbon offset payments or credits recognized for wood product storage, and the national reporting guidelines under the United Nations Framework Convention on Climate Change have treated wood products as though the carbon contained was released in the same year that it was harvested (Houghton et al. 1997). This would be a reasonable assumption if the amount of wood products in use were stable, but it has been estimated that the total amount of wood stored in products was increasing globally at a rate equivalent to about 139 million tons of carbon per year in 1990 (Winjum et al. 1998). Continuing research and international negotiations are seeking practical ways in which this carbon sequestration can be appropriately documented and credited to countries under the UNFCCC and the Kyoto Protocol.

9.2.5 Drivers of Change in Production and Consumption of Timber Products

Increased production of wood products is associated with the growth in human population, improved literacy, increased industrial development, and the associated greater demand. Most of predicted future human population growth is expected to occur in developing countries and to place more demands on forest resources.

Nevertheless, as noted earlier, there are many factors affecting use of wood products that have resulted in reduced demand for some products, with changes in structural products and recycling; at the same time, other factors are leading to increased consumption, including increased literacy and the development of the Chinese economy. Still other factors are influencing how products are produced, where supplies come from, and which nations are importers and exporters of wood products. Aside from production and demand factors, climate change will have an impact on the forests of many nations in the future and will likely result in the increased use of plantations to sequester carbon to mitigate change (Gitay et al. 2001). In spite of difficulty in quantifying clear cause-and-effect relationships, some causal factors can be identified and assessed, at least in a general manner. These are discussed briefly in this section. (See also MA *Scenarios,* Chapter 7.)

9.2.5.1 Globalization

The trend toward globalization of timber trade has significantly affected the forest products industries in recent decades. As markets become more globalized, companies tend to rely more on plantation forests than on natural ones, particularly in the southern temperate and Asian countries, where labor and materials tend to cost less. Technological advances have helped to enable long-distance operations. Information and communications technologies allow companies and traders to manage activities and processes across the world. Falling transportation costs, spurred in part by increased trade in manufactured commodities, help lower shipping costs for relatively low-value material, such as wood chips or other unprocessed fibers.

Market competition encourages firms to relocate production facilities or to buy production inputs in regions where lower labor costs, easier access to resources, higher timber yields, good governance, political stability, functioning logistics and service, availability of recycled fiber, or any combination of these factors exist that can bring costs down and increase profits. In 1999, for example, the production costs for bleached pulp in Chile was estimated at $330 per ton, compared with $420 per ton in northern industrial countries (*Financial Times* 1999).

During the 1970s and 1980s, world trade in wood chips emerged as a growing factor in the paper industry. At present a fleet of more than 100 specialized chip vessels operates under charter, hauling chips long distances. Increasingly, chip exports are being based on plantation forests in sub-tropical and tropical regions instead of primary forests or low-value secondary forests in temperate regions.

9.2.5.2 Supply Shifting

Shifting timber production is in part a function of globalization and the lower cost of fiber from plantations in regions of the Southern Hemisphere, but it is also a function of political decisions to protect forests from harvest (Berlik et al. 2002). When affluent regions use more wood products than they produce, the harvest is often shifted to regions that have less capability or desire to enforce oversight on such matters as environmental impact or worker safety and health. The result is greater negative impact than would arise if consumption were reduced, or production increased, in the affluent region (Berlik et al. 2002). Both depletion of supply and shifting technologies also result in changes among the species harvested.

High-quality veneer and sawn wood continue to be produced largely from primary or secondary natural-origin forests as opposed to plantations. A major exception is the management of plantations in northern and central Europe on long rotations for high quality sawlogs. Pulkki (1998) suggested that sustainable forest management techniques could ensure the long-term provision of valuable species from most tropical areas as well, but that is not a prospect for the near-term future. Teak offers a particularly good example of a high-quality hardwood species that can be grown to sawlog size in about 30–40 years in tropical areas. Little teak is now derived from natural origin forests (Pandey and Brown 2000), and the future of the species as a commercial product depends on plantations (Rasmussen et al. 2000).

Traditionally valued rare tropical hardwoods have seen shifting patterns of sourcing over the centuries as early supplies were depleted and replacement species emerged, often from other continents. Given the nature of the species, the trends in deforestation, and weak institutional capacity in producing areas, many valuable tropical species will decline markedly in availability in future decades (Adams and Castano 2002).

9.2.5.3 Increase in Plantations

The recent increase in plantations is forecast to continue into the foreseeable future, even if the rate of expansion proceeds more slowly than in the recent past. FAO estimates that the plantation share of roundwood production will grow from the current one third to almost half of total global production by 2040. Roundwood production from plantation forests is likely to provide 906 million cubic meters by 2045 compared with 331 million cubic meters in 1995 (FAO 2000c, 2001a).

There is considerable debate over the appropriate role of plantations in relation to sustainable forest management (UNFF 2003). Oliver (1999) estimates that plantations growing 12.5 cubic meters per hectare per year on 8% of the world's forested lands could satisfy current global wood consumption, easing pressure on natural forests. Others argue that the competition from plantations can render the long-term management of many forests uneconomical, thus increasing the incentives to exploit and abandon them or to sell them off for development or other land uses (TMFWI 2001). Investments in plantation forestry will only be made under good governance (Rice et al. 1997). Most plantation investment is in countries with stable political systems, high availability of land, and climate and soil conditions that promote high yields. Whether that concentration can continue for long without controversy over conflict with other land uses, traditional users, or environmental impact is highly uncertain (Durst and Brown 2002).

In the near future, the production from plantations will significantly increase due to the age structure of the current plantations. In 1995, it was estimated that some 55 million hectares of plantations were younger than 15, and some 22 million hectares were in the 0–5 year age class (Brown 2000). Many of those plantations will be coming into harvest age between 2005 and 2010, and to the extent that they reflect the enhanced yields being pursued through improved varieties, fertilization, and other management improvements, their impact on markets will be significant.

There is a large body of research available to enable plantation managers to improve yields from their lands by selecting specific stock or improved stock from various genetic improvements, depending on species. For example, Newton (2003) suggested that volumes in planted northern conifers can be improved by 7–26% at rotation age through genetic improvement, Matziris (2000) suggested an observed volume increase of 8–13% in Aleppo pine (*Pinus halepensis*) in Greece, and Li et al. (2000) estimated volume improvement in loblolly pine of 12–30% through tree improvement.

Planted forests supply less than 7% of wood used for fuels (FAO 2000c), but the opportunities to expand various forms of agroforestry in community settings, reducing travel times to obtain fuelwood and supplying livestock fodder, are immense and could have large impacts on the quality of life in many parts of the world (Sanchez 2002).

9.2.5.4 Mechanization and Utilization Technology

Mechanization of timber harvesting has reduced employment in the forestry sector, particularly in the tasks of felling trees and transporting logs. However, mechanization has been key to improving forest management and has led to reduced injury and mortality in the sector.

The output of forest products has risen faster than the production of industrial roundwood over the last 20 years. Conversion efficiency, recycling, and waste reduction are all contributing factors. In developing countries, however, efficiency is still low and improvements will increase fiber availability (Chen 2001). For example, while mills in the industrial world produce about 70% product from the wood received, mills in the developing world reach only 30% (WWF n.d.). Closing this "efficiency gap" through technology transfer and other means offers a significant opportunity for meeting future commodity demands without increasing pressure on forest ecosystems.

Engineered wood products are becoming increasingly common as a result of reductions in the availability of high-quality structural wood, competition from steel products, and cyclical wood prices. These products, derived as a result of new technologies, essentially turn low-quality wood and wood residues into products valuable for construction and furniture (Enters 2001). The use of engineered wood products in the North American market, for example, has grown at a rate of 20% per year since 1992, reaching more than 29 million cubic meters in 1997 and projected to rise to over 45 million cubic meters by 2005 (Taylor 2000). If the use of these technologies continues to spread, the pressure on some ecosystems and high-quality species will be eased.

9.2.5.5 Global Energy Sources and Costs

As nonrenewable fossil energy supplies decline and new sources of renewable energy are sought, the implications for the supply and consumption of forest products are significant. They are not, however, all pressing in one direction, so the potential effect is mixed and difficult to discern at this point.

To the extent that the cost of energy rises in response to fossil supply changes, forest product technologies that are energy-intensive will become less competitive. Whether this will affect some of the new engineered wood products is unclear. In addition, field production methods that rely on mechanization may suffer competitively against those that use more traditional means of growing, harvesting, and processing timber, and trade could be affected if transportation costs rise significantly.

On the other hand, increasing prices for fossil fuels are likely to encourage more-rapid development of biomass-based fuels, and their emergence could provide outlets for low-grade timber products that currently lack markets. On managed natural forests, in particular, the sale of low-grade timber could provide the financial support needed to invest in thinning, weeding, and other management practices that result in improved forest health and the production of higher-quality timber products. Such markets could also provide economic incentives for the establishment of agriculture or forest plantations devoted to woody crops grown specifically for energy production.

9.2.5.6 Sustainable Forest Management

Appropriate forest management can improve yields and permit long-term sustainable timber production from extensively managed forests. However, managing forests in a sustainable manner may create short-term reductions in timber harvest as managers seek to replace production goals with sustainability goals. (See Chapter 21.)

Although there are still significant differences in the national interpretations of sustainable forest management progress, FAO reports that in 2000 some 89% of forests in industrial countries were subject to a formal or informal management plan (FAO 2001a). Although reports from developing countries were less complete, about 6% of those forests were reported to be subject to a formal management plan covering at least five years. These efforts may be too new to assess the ultimate impact on timber harvest levels, and there is no international assessment of their effect at this time.

There is a clear efficiency gap in logging methods between forests in many tropical and sub-tropical areas and sustainably managed forests elsewhere. The result is considerable waste of wood, loss of forests, forest degradation, and soil damage in unsustainable operations. The Tropical Forest Foundation suggests that 50% less stem damage during operations would increase productivity on a given land base by 20%. The application of sustainable management practices in developing countries (that is, reduced impact logging) would go a long way toward improving long-term fiber yields and the effective and efficient use of extracted resources, while conserving forests as systems (FAO 2003b). Improved infrastructure, reduced corruption, and independent certification may all be required for improved forest management to become a reality in many developing nations.

9.2.5.7 Forest Certification

Forest certification has been developed as a means of helping demonstrate that specific forests are being managed in a sustainable manner under a defined set of standards as wood products are harvested (see MA *Policy Responses,* Chapter 8). It is described by proponents as a market-based instrument, with the implicit assumption that consumers will prefer certified forest products and be willing to pay a price premium sufficient to cover the cost of the certification process and the associated management techniques. Timber producers that have adopted certification have done so primarily to reduce pressure from environmental NGOs and to satisfy customers such as merchants and retailers who are at risk from NGO campaigning.

By 2000, several certification schemes had emerged, and some 80.7 million hectares, or about 2%, of the global forest area was certified (FAO 2001a). Virtually all of this land (92%) was in the industrial regions of North America and Europe. The movement has continued to expand rapidly, and by 2003 some 124.1 million hectares were reported certified on the Web sites of three large certification systems—the Programme for Endorsement of Forest Certification Schemes (formerly the Pan-European Forest Council), the Forest Stewardship Council, and the Sustainable Forestry Initiative—and the Canadian Standards Association added another 14.4 million hectares. By 2004, the estimate of certified forests in those four systems had grown to 164 million hectares (van Kooten et al. 2004). However, certification is still largely a phenomenon of industrial countries.

The implications of certification for the future production of timber remain uncertain. The costs of achieving certification are significant, and the extent to which those costs might create competitive imbalances is still uncertain. The hope that certified products would command a price premium that could cover the additional costs has not yet been realized, and it seems unlikely in the foreseeable future. It is possible that market pressures (particularly access to specialized markets in regions such as Europe) could create new and significant pressures for companies to undergo certification.

9.2.5.8 Deforestation

Deforestation and the loss of forests reduces the land's capacity to produce wood and other services. (See Chapter 21.) Loss of forests has a long history throughout Europe and western Asia, but during the last four decades the highest deforestation rates have been in tropical forests in Africa, Southeast Asia, and South America, where it is currently estimated that over 100,000 square kilometers per year are deforested (FAO 2001a).

Where deforestation continues in tropical forest regions, producers may be unable to maintain past production levels because forests are converted to other land uses or lands become too degraded to recover to forests. One example is in Africa, where producers in Ghana and Côte d'Ivoire are losing forest to large-scale conversion to coffee and cocoa plantations (TMFWI 2001). Certain forest types, particularly dry tropical forests, are especially subject to land use change.

9.2.5.9 Political and Economic Change

Political and economic changes occur regularly, and most create largely local or regional impacts on the production or consumption of timber products. Some, however, such as the collapse of the Soviet Union, the decision to eliminate timber harvest in major areas of China, or increased corruption (Smith et al. 2003) create impacts on the forest products industry around the globe. Given the increasing trend toward globalization and supply shifting described earlier, political decisions that once created mainly local or national impacts may now affect global supply and demand dynamics.

One dynamic that exists but is difficult to assess is the uncertainty associated with public policy. Investors who fear that public pressure will reduce access to timber supplies, or force new costs on production processes, may hesitate to make investments or may move their operations to locations perceived to be less risky. This raises the specter of extractive industries concentrating on the least restrictive areas, where public pressures for effective pollution controls or sustainable management are lower and the resulting environmental and social impacts are higher.

9.2.6 Environmental and Social Impacts of Timber Extraction

9.2.6.1 Environmental Impacts

Poorly planned or excessive timber harvesting can increase road access into remote forest areas, leading to a reduction in forest interior and increasing the ''edge'' effects associated with forest fragmentation (Kremsater and Bunnell 1999). This has resulted in wildlife population declines and reduced species richness (FWI/GFW 2002). Increased access to forests promotes illegal logging as well as poaching of wildlife resources and hunting of bushmeat. The trade in illicit bushmeat has become so widespread that in 2002 the signatories to the Convention of Biodiversity adopted a resolution and a program of action to deal with this issue at their Sixth Convention of the Parties, and the Convention on International Trade in Endangered Species of Wild Fauna and Flora has established a special working group to deal with this issue.

Environmental concerns over single-species plantation forests compared with managed natural forests include reduced biodiversity, degradation of soils, reduced water conservation, increased susceptibility to pest invasion, and impacts of genetic modifications on natural gene diversity (Nambiar and Brown 1997; Estades and Temple 1999; Lindenmayer and Franklin 2002; Thompson et al. 2002; Cossalter and Pye-Smith 2003; SCBD 2003). However, under many situations, when plantations are established on degraded lands and are appropriately managed they can increase local biodiversity through re-establishment of native species in the understory (Lugo et al. 1993; Allen et al. 1995).

9.2.6.2 Social Impacts

The importance of wood products to domestic industries, employment, building materials, and energy supplies can be estimated by several measures. Wood products facilities at all scales provide employment that can be important to local communities. Harvesting trees, hauling logs and products to market, and handling shipments at ports engage additional workers. In some instances, the cycle of work is dictated by weather, creating seasonal employment, for example in the Amazon region, where the flooding cycle halts logging and milling for months at a time.

FAO estimates that the global forestry sector provides subsistence and wage employment equivalent to 60 million work years, with 80% in developing countries (FAO 1999). Much of this involves people who work in an ''informal'' economy. One estimate is that for every job reported in the official surveys, there could be as many as two jobs that go unreported (TMFWI 2001). In addition, timber products and fuelwood are critical portions of many subsistence economies.

The number of people involved is significant, but the data for evaluation of trends and impacts on human well-being are scarce. For example, European enterprises with fewer than 20 employees are not included in formal employment surveys (EU 1997). Yet in the European Union it is estimated that over 90% of all firms have fewer than 20 employees (Hazley 2000). One database lists 7,000 Indian workers in furniture making, when it seems more likely that there could be several hundred thousand thus employed in this country of 1 billion people (TMFWI 2001). The FAO estimate of 60 million work years is likely to be an underestimate of the true figure.

The impacts of economic change and development strategies fall unevenly on different portions of society. Conversion of forests into timber production as a primary objective may reduce access and availability for non-timber resources and values, often at the expense of indigenous populations that were unable to profit from the increased industrial output. In many developing countries, forests are a primary source of energy, food, and medicine for some segments of society—often the poor. Forest sources of food are often most critical as buffer supplies to help subsistence societies through periods of crop shortages or seasonal famines, and medicines derived from forest plants are used by some three quarters of the world's people, with thousands of medicinal plants identified as important sources, particularly in tropical forest ecosystems. Where forests are converted to intensive timber production or plantations, the resulting loss of biological diversity is mainly of these non-timber species, with a resulting decline in well-being for the people dependent on them.

Public policy decisions that alter timber harvests also have important impacts on people. It is estimated that China's decision to restrict timber harvest due to concerns for the flooding caused by improper harvesting methods will reduce employment by up to 1 million jobs (*China Green Times* 2000). This is now having major impacts on regional wood markets as Chinese industry turns to international sources for logs and fiber.

Replacement of managed natural forests by plantations at large scales may affect local and indigenous communities, either through displacement or through the loss of the natural forest biodiversity that formerly provided sources of food, medicine, fuelwood, fodder, and small timber on which these communities depend for their livelihoods.

9.3 Non-wood Forest Products

A great number of non-wood forest products are of importance to people in virtually every forest ecosystem and elsewhere. These products contribute directly to the livelihoods of an estimated 400 million people worldwide and indirectly to those of more than a billion. They include foods, medicinal products, dyes, minerals, latex, and ornamentals among others. This section, however, considers only those that are fiber-based and serve as inputs to construction or craft purposes.

9.3.1 Bamboos

There are approximately 1,200 species of woody and herbaceous bamboos, the former being most important from the socioeconomic perspective (Grass Phylogeny Working Group 2001). Many woody bamboos grow quickly and are highly productive. For example, the shoots of *Bambusa tulda* elongate at an average rate of 70 centimeters per day (Dransfield and Widjaja 1995). Annual productivity values range between 10 and 20 tons per hectare per year, and bamboo stands may achieve a total standing biomass that is comparable to some tree crops (of the order of 20–150 tons per hectare) (Hunter and Junqi 2002). It is estimated that bamboo makes up about 20–25% of the terrestrial biomass in the tropics and sub-tropics (Bansal and Zoolagud 2002). A substantial amount of bamboo timber comes from plantations, although natural forests are also important.

Bamboos are multipurpose crops, with more than 1,500 documented uses. As a construction material, bamboo is widely used in all parts of the world where it grows, and because of its high strength-weight ratio, bamboo is the scaffolding material of choice across much of Asia. The tubular structure of the plant is optimally ''engineered'' for strength at minimum weight. In many places, its use is restricted almost exclusively for low-cost housing, usually built by the owners themselves. For this and other reasons, bamboo is often regarded as the ''poor man's timber'' and used as a temporary solution to be replaced as soon as improved economic conditions allow. However, architects' interest in working with bamboo has also led to this becoming a common building material for the wealthy. Modern manufacturing techniques allow the use of bamboo in timber-based industries to produce flooring, board products, laminates and furniture.

Despite its importance, very little is known about the worldwide distribution and resources of bamboo, especially in natural forests, although some preliminary regional assessments are available (Bystriakova et al. 2003, 2004). As a non-wood forest product, and one that is often harvested in non-forest settings, bamboo is not routinely included in forest inventories. According to FAO, statistical data on bamboo timber are only available for 1954 to 1971 (FAO 2001a). Today, very few countries monitor non-wood forest product supply and use at the national level, although program efforts in some countries (such as India) are beginning to occur.

Although reported figures on the area of bamboo forests are inconsistent, it is widely accepted that China is the richest country in the world in terms of bamboo resources. China's bamboo forests cover an estimated area of 44,000 to 70,000 square kilometers, mostly of *Phyllostachys* and *Dendrocalamus* species. Their standing biomass is estimated at more than 96 million tons (Feng 2001). Asia ranks first in bamboo production, and Latin America is second. It is estimated that bamboo in Latin America covers close to 110,000 square kilometers (Londoño 2001).

Worldwide, domestic trade and subsistence use of bamboo are estimated to be worth \$8–14 billion per year. Global export of bamboo generates another \$2.7 billion (INBAR 1999). Bamboo is increasingly being used as a substitute for wood in pulp and paper manufacturing, and currently India uses about 3 million tons of bamboo per year in pulp manufacture and China about 1 million tons, although China is set to increase the use of bamboo for paper to a target of 5 million tons per year.

In many countries in Asia, Africa, and Central and South America, bamboo products are used domestically and can be very significant in both household and local economies. In parts of Africa, for example, the majority of rural families depend entirely on raw bamboo for construction, household furniture, and fuel. Since the products are traded locally, statistics do not enter the national accounting systems. Thus the real value of bamboo products, as well as the impact of changing supplies on human well-being, is difficult to estimate.

9.3.2 Rattans

Rattan is a scaly, fruited climbing palm that needs tall trees for support. There are around 600 different species of rattan, belonging to 13 genera; the largest of which is *Calamus,* with some 370 species (Sunderland and Dransfield 2000). It is estimated that only 20% of the known rattan species are of any commercial value. The most important product of rattan palms is cane from the stem stripped of leaf sheaths. This stem is solid, strong, and uniform, yet highly flexible. The canes are used either in whole or round form, especially for furniture frames, or split, peeled, or cored for matting and basketry. Rattans require considerable treatment, including boiling and scraping to remove resins and dipping in insecticides and fungicides prior to drying. The range of indigenous uses of rattan canes is vast—from bridges to baskets, fish traps to furniture, crossbow strings to yam ties.

Rattans are almost exclusively harvested from the wild tropical forests of South and Southeast Asia, parts of the South Pacific (particularly Papua New Guinea), and West Africa. Much of the world's stock of rattan grows in over 5 million hectares of forest in Indonesia. Other Southeast Asian countries, such as the Philippines and Laos, have less rattan but have been relatively self-sufficient due to the appropriate size of their processing sector. No rattans grow naturally elsewhere, and even in these locations deforestation can lead to local extinction of rattans due to their dependence on mature forests.

In the last 20 years, the international trade in rattan has undergone rapid expansion. The trade is dominated by Southeast Asia, and by the late 1980s the combined annual value of exports of Indonesia, Philippines, Thailand, and Malaysia had risen to almost $400 million, with Indonesia accounting for 50% of this trade (Sunderland and Dransfield 2000). The net revenues from the sale of rattan goods by Taiwan and Hong Kong, where raw and partially finished products were processed, totaled around $200 million a year by the late 1980s (Sunderland and Dransfield 2000).

Worldwide, over 700 million people trade in or use rattan. Domestic trade and subsistence use of rattan are estimated to be worth $2.5 billion per year. Global exports of rattan generate another $4 billion (INBAR 1999).

9.3.3 Drivers of Change in Bamboo and Rattan Products

9.3.3.1 *Increased Trade*

Traditionally, bamboo was used domestically and supplies were extracted based on local requirements. Contemporary additional applications of bamboo have propelled it into new domestic and international markets, increasing profits and income for many participants in the sector. Bamboo generates substantial export income for several countries, such as China ($329 million in 1992) and the Philippines ($241 million in 1994) (INBAR 1999).

Indonesia has a clear advantage over other countries, with its overwhelming supply of wild and cultivated rattan (80% of the world's raw material), and rattan contributes about $300 million to Indonesia's foreign exchange and is an important vehicle for rural development. It also raises the value of standing forests, as rattan is the most valuable of the non-wood forest products in the country, earning 90% of total export earnings from such products (INBAR 1999).

Much of Indonesian wild production was diverted from the international market to the domestic market as a ban on export of unprocessed rattan was phased in between 1979 and 1992. Other major rattan products manufacturers, such as the Philippines and China, are augmenting domestically produced supplies with imports from other rattan producers such as Myanmar, Papua New Guinea, and Viet Nam (often based on unsustainable harvesting), along with continued illicit supplies of Indonesian cane.

9.3.3.2 *Depletion of Resource Base*

Most bamboo-processing countries are facing a shortage of raw material. The causes of this range from overharvesting and conversion of bamboo forestland to settled agriculture or shifting cultivation. Restoring productive agricultural land to bamboo production is often difficult, as is seen in parts of Nepal, where farmers' concerns for food security are more pressing.

In Indonesia, Laos, and the Philippines, parts of the rattan resource base are becoming scarce. In Indonesia, large-diameter rattans are becoming scarce; in Laos, the rate of exploitation from accessible areas is unsustainably high; and the Philippines has recently become a rattan importer (INBAR 1999). In all cases, loss of forest cover is a main contributor to reduced supply of rattans. As a result of limited supplies of rattan in China and the Philippines, wood is now regularly used in place of large-diameter rattan as a main structural element in "rattan" furniture.

9.3.3.3 *Biological Cycles*

Many species of bamboo flower simultaneously at long intervals, then set seed and die. Where large areas of bamboo forest are involved, these area-wide disturbances are significant. India, for example, is currently experiencing a bamboo flowering that is expected to affect more than 10 million hectares and peak in 2007 (FAO 2004). The impacts are enormous. The amount of dead woody product vastly exceeds harvesting and storage capacity, leading to serious economic losses. Soils unprotected from erosion are damaged before vegetation is re-established, and local employment suffers. The huge influx of seed leads to a population explosion of rats that, when the seed supply is largely eaten, move out to compete with people for food in regional communities. The last flowering cycle in India (1911–12) led to serious famines, and research and policy measures are under way to mitigate the damage of the current flowering cycle (FAO 2004).

9.3.3.4 *Plantations*

While a few countries, such as China and India, have successfully promoted bamboo plantations, far more struggle with providing the needed technical and financial support. Potentially adverse effects of bamboo monoculture, such as possible depletion of soil, low biodiversity, and loss of genetic diversity, are largely uncertain.

Private-sector cultivation of rattan, from both large and small-scale plantations, has fallen below expectations and failed to respond to local raw material scarcities. The traditional rattan cultivation system in Kalimantan appears to be under threat, with reduced rattan garden establishment and some conversion of existing rattan gardens to other uses owing to low prices for the main cultivated species and new competing land use opportunities (Belcher 1999).

9.3.3.5 Technological Development and Substitution

Industrial use of bamboo has increased dramatically due to new developments in bamboo processing technology. Laminated bamboo board, bamboo mat plywood, bamboo particleboard, bamboo-fiber molds, floorings, and engineered timber (all called ''composites'') from bamboo fiber are currently available for building construction, architecture decorating, and other applications. In the pulp and paper industry, some bamboo species can be substituted for timber.

9.4 Fuel

In 2000, the world used approximately 1.8 billion cubic meters of fuelwood and charcoal (FAO 2003b). Energy use from fuelwood and charcoal accounts for 0.7–1.1 terawatts out of a global total energy use from all sources of 14.6 terawatts (Gonzalez 2001b). Although these statistics combine fuelwood and charcoal, this chapter discusses the two forms separately because of their different environmental and social impacts.

Although they account for less than 7% of world energy use, fuelwood and charcoal provide 40% of energy used in Africa and 10% of energy used in Latin America (WEC 2001), and 80% of the wood used in tropical regions goes to fuelwood and charcoal (Roda 2002). In Africa, 90% of wood use goes to fuelwood and charcoal, the highest of any region in the world (FAO 2003a). On the other hand, fuelwood and charcoal account for only 20% of wood use in temperate regions (Roda 2002).

The International Energy Agency projects that, by 2030, renewable energy sources will provide some 53% of residential energy consumption in developing countries as a whole, compared with 73% in 2000. In that projection, an estimated 2.6 billion people will continue to rely on traditional biomass for cooking and heating, and virtually all of that will be produced and consumed locally (IEA 2002a).

FAO (2001b) analyses since 1970 indicate that as certain regions in Asia and Latin America have industrialized—particularly China and Brazil—people have switched from fuelwood and charcoal to fossil fuels. Consequently, total global fuelwood use seems to have peaked somewhere around 2000, although total global charcoal use continues to rise (Arnold et al. 2003).

In recent projections of global energy use, the IEA indicates that with continuation of present government policies and no major technological breakthroughs, the use of combustible renewables and waste will grow by 1.3% a year, compared with an overall growth in energy use of 1.7% annually over the next decade (IEA 2002a). The projections reflect the conclusion that the growth of combustible renewables and waste will slow as people in developing countries (which presently use about 73% of world renewables) gain more disposable income and switch to using fossil fuels. A counter-trend may, however, result as the cost of fossil fuels rise and people are forced to use less convenient fuels. With the volatility of international oil prices, these trends will be highly irregular and difficult to predict.

9.4.1 Fuelwood

People harvest fuelwood by cutting or coppicing shrubs, by lopping branches off mature trees, or by felling whole trees. In many rural areas, local people prefer fuelwood from shrub species that will regenerate after coppicing (Gonzalez 2001a). Cooking and heating are the major end uses of fuelwood and charcoal. In some developing nations, wood and charcoal are important for commercial applications such as bakeries, street food, brick-making, smoking foods, and curing tobacco and tea, and fuelwood is an important source of income and employment in many rural areas.

Since developing societies tend to shift from wood fuels to other sources for home heating and cooking, the change in fuelwood production and consumption reflects both a change in economic condition and a change in ecosystem impact. Fuelwood is often produced and consumed largely outside the market system, in subsistence societies, and its value to human well-being is therefore not captured in unadjusted national economic statistics, such as GDP.

9.4.1.1 Production and Consumption

FAO provides the most consistently developed estimates over time for the use of fuelwood. (See Table 9.6.) It should be noted, however, that these data were developed from a fairly small sample, and in many countries the historical data were estimated from models based on population change and average consumption rates. These FAO country data have been grouped according to the forest regions established as being reflective of large forest biomes, but care must be taken in inferring that trends in use of fuelwood translate directly into impacts on forest ecosystems. While charcoal is largely produced from forests in the developing world, fuelwood is produced from woody plants wherever they are found on the landscape. Note, for example that the ''other areas'' category in Table 9.6, which reflects production outside the identified major forest areas, represents a significant amount of fuelwood production. To the extent that agroforestry grows in importance, more of these energy resources will be derived from agricultural and grazing systems.

The African tropical forest region experienced a near-doubling (91% increase) in rural population between 1960 and 2000, but recorded fuelwood value per capita declined, although the decline slowed only in the latter two decades. (See Table 9.7.) On the other hand, the Asian tropical region, which also experienced a doubling of rural populations (98% increase) in the period saw per capita fuelwood values decline at a far more rapid rate, particularly since 1980. This indicates that the dependence on wood as a rural energy source disproportionately declined in Asia relative to Africa (and other regions). This may indicate a shift away from wood fuel as Asian rural populations experienced more rapid development during the period. Nevertheless, FAO predicts an increased demand for wood in central and eastern Asia of about 25% by 2010 over the amount used in 1994 (RWEDP 1997).

Using FAO price data and adjusting for inflation to portray a constant-dollar value of fuelwood production, the average value of fuelwood produced per rural person has declined significantly (with the exception of the Southern temperate region) since 1980. While published prices may stem largely from urban economic transactions, rural populations were chosen for this comparison because of the importance of fuelwood to rural societies, particularly poor rural people.

FAO (2003a) projects that total fuelwood use in Africa will increase by 34% to 850 million cubic meters by 2020, but at a rate less than the rate of population growth. Local forest departments throughout Africa have continued to record locally severe problems of overharvesting to provide wood and charcoal for urban areas (Arnold et al. 2003; FAO 2003a). (See Box 9.1.) Declining local availability of fuelwood is also a problem in areas of India, Haiti, the Andes, and Central America, especially near large cities.

9.4.1.2 Future Availability

Although in the 1970s there was increasing concern that the exploding demand on fuelwood resources, driven by population increases,

BOX 9.1

Fuelwood Supply Analysis in Southern Africa

A multiscale analysis of fuelwood availability in the Southern Africa region, done as part of the Southern Africa Millennium Assessment, demonstrates a method of identifying localized conditions that would otherwise be masked in a large-scale assessment (Scholes and Biggs 2004). The analysis utilizes a geographic model to compare the local biomass production rate to the local harvest rate. Where harvest exceeds production the stock will inevitably decline, and, despite some regrowth in the depleted area, the zone in which harvesting occurs expands until the effort required to transport the wood or charcoal exceeds its value.

At the scale of the entire Southern Africa region, much more wood is grown than is consumed as fuel (Scholes and Biggs 2004 Fig 7.1). Thus a regional analysis would lead to the conclusion that fuelwood supply is not a problem. A more fine-grained analysis, however, reveals several very clearly defined areas of local insufficiency that indicate unsustainable use:

- Western Kenya, southeast Uganda, Rwanda, and Burundi;
- Southern Malawi;
- the area around Harare in Zimbabwe and Ndola and Lusaka in Zambia;
- Lesotho; and
- locations in the former homelands in South Africa—in KwaZulu, Eastern Cape and Limpopo provinces, and around Gauteng.

SAfMA local studies confirm that fuelwood shortages are experienced at the last two locations, with the exception of the Gauteng spot. The generalized "rural Africa" model that predicts per capita woodfuel use clearly breaks down in this highly urbanized situation where electricity and coal are well established and relatively cheap energy sources. Conversely, SAfMA local studies in the Richtersveld and Gorongosa-Marromeu confirm that in areas indicated by the regional model to have a fuelwood sufficiency, this is indeed the case.

Checks with local experts and personal experience in the team confirmed that the fisrt three locations currently experience severe fuelwood deficiencies. Therefore, it seems that the regional-scale assessment correctly identified problem areas at a local scale. The authors attribute this to the fact that the underlying wood production models and fuel demand models are working at a resolution of 5 kilometers, slightly smaller than the typical radius of fuelwood depletion around population concentrations.

would have devastating effects on forest ecosystems, currently available evidence suggests that fuelwood demand has not become a major cause of deforestation (Arnold et al. 2003). There are local situations of concern, such as areas near settlements, where an income can be earned by cutting and carrying wood to buyers, but it appears that fuelwood supply is not important enough in most places, with the possible exception of some regions in Africa, to attract national policy intervention to reduce deforestation. The predicted supply for South and East Asia is well above the projected demand.

Recent estimates developed by FAO indicate that global consumption of fuelwood appears to have peaked in the late 1990s and is now believed to be slowly declining. Global consumption of charcoal appears to have doubled between 1975 and 2000, largely as a result of continuing population shifts toward urban areas (Girard 2002; Arnold et al. 2003). Since the production of charcoal entails a net loss of energy and is highly concentrated in forest areas of the developing world, increased charcoal consumption signals pressure on wood supplies.

9.4.1.3 Impacts on Human Well-being

Fuelwood is the main source of household energy for an estimated 2.6 billion people, and in urban areas of developing countries families may spend 20–30% of their income on wood and charcoal fuels (FAO 1999). In terms of impact on their well-being, the main problem for the ever-increasing number of urban dwellers may be price rather than availability of fuelwood.

In rural villages that rely on hand-gathered wood, local shortages may impose serious time constraints on women, whose task it usually is to collect fuelwood, as well as increased energy use and risk of injury associated with lengthy travel with heavy loads. While it is usually women who search for and carry wood on their heads and backs for rural use, many rural people load animals and carts to transport wood for sale in urban areas. Thus, urban demand translates into local economic opportunities. In areas where the demand exceeds the sustainable supply, this can result in serious impacts on local forests.

The lack of reliable and consistent data limits the ability to assess the impact of fuelwood trends on human well-being. People make fuel choices for a variety of reasons, including convenience, price, and reliability of supplies. For example, it has been found that price, availability, and ease of use are very important in affecting fuel choice among urban people, while the price of stoves and the level of pollution from the fuel did not seem to matter as much (Gupta and Kohlin 2003).

A 1996 survey of rural energy in six Indian states found that wood was becoming more scarce and difficult to obtain (ESMAP 2000). As a result, some poorer households were using less efficient fuels like straw and dung, while wealthier households were shifting up the "energy ladder" to purchase charcoal or fossil fuels. The most common response, however, was for households to increase their collection time to compensate for reduced availability and access (Arnold et al. 2003). This and other studies reinforce the conclusion that, in many rural areas, gathered supplies of fuelwood still constitute the main source of domestic energy, making these users more vulnerable to changes that affect their ability to get wood supplies. Reduced access may arise from resource shortages, from changes in land tenure (such as increased privatization), or increased distance to common property. In all circumstances, the result is a reduction in well-being for affected families.

FAO (2000a) estimates that about half the world's households cook daily with biomass fuels and that most of this cooking is done indoors with unvented stoves. Pollutants found in biomass smoke include suspended particulates, carbon monoxide, nitrogen oxides, formaldehyde, and hundreds of other organic compounds such as polyaromatic hydrocarbons. In many parts of the world, for all or part of the year these pollutants are released from stoves in poorly ventilated kitchens and homes. Women, infants, and young children who spend more time in the home suffer the highest exposures.

Several studies have suggested that domestic smoke pollution is responsible for respiratory diseases, low birth weight, and eye problems. The evidence is overwhelming in the case chronic obstructive pulmonary disease in adults and acute respiratory infection in children. There is also evidence to suggest a relationship with perinatal conditions, blindness, tuberculosis, and lung disease. It has been suggested that domestic smoke pollution may also be related to asthma and cardiovascular disease (FAO 2000a), and in total an estimated 1.6 million deaths and 39 million disability-adjusted life years are attributed to indoor smoke, primarily in Africa, Southeast Asia, and the Western Pacific (WHO 2002).

There could be additional impacts in local areas experiencing a shortage of fuelwood. One is the increase in crop residues and dung that are used for cooking and heating in the absence of available wood. These fuels are less efficient and produce more smoke, and the burning of crop residues and dung reduces their availability for enhancing soil structure and fertility, leading to reduced food production. Where adequate fuels are not available, the consumption of cooked food may decline, leading to adverse effects on nutrition and health.

The conclusion to be drawn is that there are important human benefits to be gained from targeted efforts to improve fuelwood availability and accessibility in localities where it is now in short supply. The adoption of improved stoves, with higher efficiency and improved venting, would have important human well-being benefits across wide regions but has often proved more difficult than anticipated, for reasons of affordability and cultural acceptability.

9.4.2 Charcoal

Charcoal consists of the remnants of wood that has been subjected to partially anaerobic pyrolysis (decomposition under heat). Conversion of wood to charcoal creates a product with double the energy per unit mass that is less bulky and more convenient for transport, marketing, and sale than fuelwood. The major domestic end uses of charcoal are cooking and heating, often in the urban areas of developing countries where people are able to purchase, rather than gather, their home energy supplies. Charcoal is not as convenient as petroleum fuels, so as incomes rise people tend to shift from charcoal to coal, gas, or oil. Thus, charcoal consumption has tended to peak, then diminish, as development proceeds. Other large users of charcoal include light industrial users, such as blacksmiths and ceramic and brick makers, and Brazil alone produces approximately 6 million tons of charcoal annually for steel production (WEC 2001).

In Africa, there is a general trend to replace fuelwood with charcoal (Girard 2002). For example, in Bamako, Mali, the proportion of households that use charcoal has risen from nothing in 1975 to 50% in 1996, while the proportion using fuelwood has declined at the same rate (Girard 2002). This trend is expected to continue throughout Africa.

Converting wood to charcoal provides employment and has the advantage of using wood remnants and sawdust that are often otherwise wasted. Nevertheless, much of the charcoal is produced in low-efficiency "cottage industries," resulting in a net loss of energy of as much as two thirds of the energy contained in the original wood, although some of that lost energy is offset by the reduced energy required in transport to markets. Charcoal production, particularly if low-efficiency techniques are used, is a significant source of air pollutants and greenhouse gases.

Charcoal production is declining significantly in Europe and the southern temperate region. (See Table 9.8.) Where charcoal production is increasing to provide fuel for some urban areas, and where inefficient charcoal production methods are common, this may be a local concern for forest sustainability, although there is limited information available to assess these situations (Arnold et al. 2003). Certainly at the regional and global level, trends for charcoal production and use do not suggest broad threats to forest ecosystems.

9.4.3 Industrial Wood Residues

In many modern wood industries, residues that were formerly waste products now provide a portion of the electricity and heating needs of the mill or paper plant. For example, in the mid-1990s, it was estimated that the pulp and paper industry in the United States produced about 56% of its energy needs by burning the unused wood components removed in the pulping process (Klass 1998). In the United States, 98% of the bark, saw dust, and wood trimmings from sawmill operations, and the black liquor produced in the pulping process, are currently used as fuel or to produce other fiber products (Energy Information Administration 1994). Enters (2001) indicates that on average, only half the wood harvested in Asia is used and the rest is unused residue that goes to waste.

As industrial wood processing and paper-making residues have become increasingly used to generate energy, the main impact on local communities has been the associated reductions in air and water pollution. Historically, many mill communities tolerated smoke, chemical aerosols, and degraded stream reaches as a necessary part of maintaining the jobs and economic impact of the mill. Today, the communities that benefit from modern mills have fewer associated pollution burdens.

9.4.4 Biomass Energy

The world currently relies heavily on nonrenewable fossil energy sources such as coal, petroleum, and natural gas, and although long-term forecasts for declining supply of fossil fuels entail a high degree of uncertainty, Klass (1998) estimates that the gradual depletion of oil and natural gas reserves will become a major problem by 2050. As the availability of fossil fuels declines, the only renewable carbon resource large enough to substitute for or replace fossil resources for the production of fuels and electricity is biomass. Policy implications include the opportunity to encourage more efficient and modern biomass systems through technological development and diffusion.

Industrial biomass includes energy systems generating electricity, heat, or liquid fuels from fuelwood, agricultural crops, or manure. In 2000, biomass other than fuelwood and charcoal may have provided 5% of global world energy (WEC 2001). Biogas produced from dung and other carbohydrate-based agriculture products like nonedible oil cake is another major source of energy in Asia, particularly in India and China (Deng 1995).

Current technologies for converting biomass into electricity and fuels include thermochemical and microbial processes such as combustion, gasification, liquefaction, and fermentation (Klass 2002). Biogas is most commonly produced using animal manure, mixed with water, stirred and warmed inside air-tight digesters that range in size from around 1 cubic meter for a small household unit to as large as 2,000 cubic meters for a commercial installation (Ramage and Scurlock 1996). The biogas can be burned directly for cooking and space heating or used as fuel in internal combustion engines to generate electricity.

Examples of thermochemical processes include wood-fueled power plants in which wood and woody wastes are combusted to produce steam that is passed through a turbine to produce electricity; the gasification of rice hulls by partial oxidation to yield fuel gas, which drives a gas turbine to generate electricity; and the refining of organic oils to produce diesel fuels. Another example is the alcoholic fermentation of corn to produce ethanol, which is then used in a variety of formulations in motor fuels (Klass 2002).

Soybeans and oil palms produce oil crops that can be processed directly into biodiesel. The combination of different biomass sources and conversion technologies can produce all the fuels and chemicals currently manufactured from fossil fuels. The major obstacle is the price competition from fossil fuels. While most analysts foresee the economic gap narrowing and reversing as fossil fuel prices rise in response to dwindling supplies, there are varying opinions as to when this may have a significant effect, with estimations up to the middle of the twenty-first century (Klass 2003), and some predicting that peak petroleum production may occur well within the first quarter (IEA 2002b).

The data on production of biomass-based liquid fuels and electricity are limited. One major source, the International Energy Agency (IEA 2003), pools estimates for all renewable sources, including energy generated from solar, wind, biomass, geothermal, hydropower and ocean resources, and biofuels and hydrogen derived from renewable resources.

Table 9.8. Charcoal Production 1961–2000 (Data from FAO 2003c)

Region	1961	1980	2000	1961–80	1980–2000
	(million cubic meters)			*(percent change)*	
Africa tropical	2.6	5.6	12.0	114	114
America temperate		0.5	0.9		70
America tropical	6.0	8.7	13.7	45	58
Asia temperate	0.3	0.3	0.5	8	43
Asia tropical	1.6	2.8	3.4	71	25
Europe temperate	0.3	0.4	0.2	24	–39
Southern temperate	0.6	0.6	0.3	4	–48
Other areas	2.9	4.7	8.3	60	76
Total	**14**	**24**	**39**	**64**	**67**

As noted earlier, fuels and electricity can be produced from almost any biomass resource, but commercial production has been limited. A few examples are power and steam production via the combustion of municipal solid wastes, of fuel gas recovered from landfills, and of biogas produced in wastewater treatment plants. Steam and hot water are produced in the gasification of wood and wood wastes to produce fuel gas for use in commercial buildings and the combustion of black liquor in the pulp and paper industry. Liquid fuels for internal combustion engines come from lipids and fuel oxygenates come from fermented grains. In the United States, production of fuel ethanol from corn has been commercialized, but it relies on federal subsidies and policies requiring the use of organic oxygenates in gasoline to reduce pollution in some areas of the country. A major research and development effort is in progress to displace corn with low-cost cellulosic feedstocks such as crop residues and non-merchantable wood produced through fuel reduction projects aimed at reducing the intensity and severity of forest fires (Sampson et al. 2001).

On a energy content basis, existing global standing biomass is estimated to be about 100 times the total annual consumption of coal, oil, and natural gas in the 1990s, and net annual production of biomass is 10 times annual energy consumption (Klass 1998). Incremental new biomass growth on carefully designed sustainable plantations that produce dedicated energy crops could eventually have large potential uses in meeting global energy demands.

There is considerable variation in the estimates of the biomass in agricultural wastes that might be available for energy production. For example, one study estimates that the potential amount of rice straw and husks available for energy might range from about 300 million to 1,900 million tons (Koopmans and Koppejan 1998). The range involves different assumptions about production as well as the extent to which available crop residues will be used for fuel, fodder, fertilizer, fiber, or feedstock. One of the issues in using crop residues for commercial energy production is that their use may depend on storage for prolonged periods after harvest. Also, the scale of biomass electric plants may exceed locally available feedstock supplies.

Taking into account the net primary productivity of the world's ecosystems and conventional energy technology, global biomass could provide energy at a theoretical rate of 9 terawatts (WEC 2001) to 26 terawatts (Holdren 1991), compared with the current rate of global energy use of 15 terawatts (Gonzalez 2001b). Some regional studies show significant supplies available. (See Table 9.9.) Realistic estimates of supply, however, need to be tempered by several factors:

- Much biomass, such as crop residues and logging wastes, are widely dispersed; making their collection for commercial use difficult and costly.
- The removal of organic material from producing crop and forestlands may compromise their ability to sustain productivity. Organic material returns are essential for maintaining soil quality, so only a portion of the waste biomass can be safely removed.
- The environmental impacts of increased biomass energy production, both positive and negative, need to be considered (Sampson et al. 1993).

An increasing role for biofuels in the world energy system would have significant local economic implications. Growing, harvesting, and transporting these fuels could provide new crop and employment opportunities for rural residents.

Because biofuels are produced from renewable sources, their use does not involve a net transfer of carbon dioxide into the atmosphere. As a result, where they replace fossil sources they can be counted as a positive benefit in attempts to address climate change. To the extent that they become a significant force, the benefits accrue across all nations and societies. For example, the use of bagasse in Australia is estimated to reduce net emissions of CO_2 into the atmosphere by 226,000 tons per year (Ramage and Scurlock 1996).

The benefits of clean, renewable energy and fuels are evident, but the slow rate of their growth in relation to the growth in fossil fuel use reflects the difficult obstacles that biofuels face. An integrated, large-scale biomass energy industry has yet to emerge despite the major expenditures made to develop new technologies and scale them from research to production levels. In most of the industrial world, the lack of financing for first-time production facilities, the difficulty in assuring growers of adequate prices and producers of adequate supplies in the absence of market experience, and the lack of an energy infrastructure geared to dispersed, decentralized production facilities have all deterred industrial development of biomass fuel. The competition from fossil fuels has also contributed to the slow growth in biomass-based production of modern fuels, despite the steady advances from research and technological development.

9.4.5 Drivers of Change in the Use of Biomass Fuels

9.4.5.1 Fossil Fuel Availability

The near-term prospects for the future of biomass fuels remain one of slow growth. If fossil fuel prices continue to rise in the coming decades, the longer-term prospects (2030–50) for biofuels look very positive. The combination of drivers, including concern over global climate change, pollution, and fossil fuel depletion, appears poised to drive government policies and market forces toward an increased role for biomass-based modern energy sources.

9.4.5.2 Income and Development Levels

As incomes rise and development proceeds, people tend to shift from low-cost, heavy, or inefficient fuel sources to those that cost more but require less effort to obtain and use. If development efforts succeed in raising incomes and living standards, pressures on local ecosystems for fuelwood will diminish as people move up the energy ladder to other sources.

9.4.5.3 Technology Development and Transfer

Programs that successfully introduce more efficient cooking and heating stoves, modern renewable sources (such as solar, geothermal, and wind), or other energy innovations can reduce pressure on local sources of biomass fuels. The result can be improved human well-being by lowering the time and effort spent gathering fuel, lowering health impacts from smoke, and supporting improved diets.

Increased use of biomass for commercial energy production will require continued major investment in research, development, and technology transfer.

9.4.5.4 Resource Availability

Lack of accessible fuelwood supplies can be an important localized problem with serious impacts, particularly on rural or low-income people. This can be the result of an imbalance between population levels and local biomass production capability, as described in Box 9.1, in the absence of affordable or accessible energy options. Policy options may include efforts to increase local fuel production (through increased agroforestry), introduce technology innovation, or improve fuel transport.

Table 9.9. Consumption and Potential Supply of Biomass Fuels for 16 Asian Countries[a] (RWEDP 1997)

Consumption/Supply	1994 Area (million hectares)	1994 Mass (million tons)	1994 Energy (petajoules)	2010 Area (million hectares)	2010 Mass (million tons)	2010 Energy (petajoules)

9.5 Fiber

9.5.1 Agricultural Plant Fibers

A wide variety of crops are grown for fiber production. Flax, hemp, and jute are generally produced from agricultural systems, while sisal is produced from the fiber contained in the leaves of the *Agave* cactus, which is widely cultivated in tropical and subtropical areas. (See Chapter 22.) Silk is a special case, produced by silkworms fed the leaves of the mulberry tree, grown in an orchard-like culture. The production of all the listed fibers except silk has declined in recent decades. (See Table 9.10.)

Competition from non-cellulosic fibers has increased significantly in recent years. (See Table 9.11.) According to the U.S. Department of Agriculture (whose data varies slightly from that of FAO in Table 9.10), total world fiber production has grown by 63% in the last two decades, while the proportion of natural (cellulosic) fibers has declined from almost two thirds to under one half (USDA-ERS 2003).

9.5.1.1 Cotton

Cotton is the single most important textile fiber in the world, accounting for over 40% of total world fiber production. It is an unusual crop, in that it is an oil crop grown for its fiber, which develops as elongated surface cells on the seedcoat. The cotton seed itself constitutes about 65% of the harvested crop and contains about 17% oil and 24% protein (Gillham et al. 2003).

While some 80 countries around the world produce cotton, China, the United States, India, Pakistan, and the former Soviet Union have dominated global production since 1961, although their relative share of the global total has changed over time. (See Table 9.12.) Over 70% of the world's cotton is produced in the United States (above 30° north latitude), China, the former Soviet Union countries, and southern Europe (Gillham et al. 2003). The water and fertilizer requirements for high yields of cotton under intensive production are high, and it is this that leads to concentrated production in so few regions.

Cotton is produced on both irrigated and rain-fed cropland, and cotton demand has been the basis for major irrigation projects over the past century. In Uzbekistan, for example, major irrigation developments were constructed in the 1940s to convert the region into the primary cotton producer for the Soviet Union (Gillham et al. 2003). The resulting diversion of water, along with the intensive use of agrochemicals, resulted in disastrous environmental deterioration of the Aral Sea. (See Chapter 20.)

Global production of cotton has about doubled in the past 40 years, while the land harvested has stayed virtually the same (FAO 2003c). However, those global totals mask significant shifting of cotton growing. For example, a major area expansion in Pakistan has been offset by large declines in the rest of the world. FAO

Table 9.10. World Production of Selected Agricultural Fibers, 1961–2000 (FAO 2003c)

Item	1961	1980	2000	1961–80	1980–2000

data show some inconsistency in yields, with China's year 2000 yield of over 1 ton per hectare being significantly higher than the global average.

Although the rate of increase in cotton production has slowed since 1980, further growth in cotton production is set to continue through either additional planting or irrigation or through increased yields from improved varieties, management techniques, or pest protection. The reasons for declining production in some regions vary and include increased competition for available irrigation water, loss of productive soils to salinization, or declining markets and prices due to continued or increased competition from synthetic fibers.

In one major cotton-producing region—Uzbekistan—the area planted to cotton has declined steadily from a peak of 2.1 million hectares in 1987 to a reported 1.44 million hectares in 2000 (FAO 2003c). Since the demise of the Soviet Union, the ability of the region to trade cotton for food has diminished, and the need to become more self-sufficient in food is contributing to the decline in the area devoted to cotton production. In addition, the collapse of the economy contributed to a lack of fertilizer and other inputs due to the shortage of foreign exchange (Gillham et al. 2003).

Cotton plays a major role in the economies of many developing countries. In India, over 60 million people derive income from cotton and textiles. In Pakistan, textiles employ over one third of the industrial labor force, and in Uzbekistan 40% of the workforce relies on cotton (Gillham et al. 2003). In China, an estimated 50 million families grow cotton, illustrating that much of the world's cotton is produced by smallholders relying primarily on family labor. In these situations, the crop competes with food crops for available land, water, time, and energy, and strong markets or government policies that encourage expanded cotton production may create difficulty in meeting food production needs.

One of the major challenges in cotton production is the management of crop pests. The most widely known pest, the cotton bollworm (*Helicoverpa armigera*), causes millions of dollars worth of damage annually. One estimate suggests that India alone suffers over $300 million in annual damages from this pest (www.nri.org/work/bollworm.htm). This has led to major research efforts around the world to develop improved pest management techniques. One approach, genetically modified cotton, is being tested in many regions but has raised significant controversies.

Smallholders face significant competitive disadvantages in growing cotton, lacking the mechanical implements for timely operations, the inputs to raise yields or protect against pests, and the marketing ability to produce commercial amounts for sale. It has been estimated that it would take 75–150 smallholders, averaging a quarter to a half hectare each, to produce 100 bales of cotton—a common amount needed to attract a commercial contract (Gillham et al. 2003). Thus, many of the world's cotton producers need significant technical and marketing support to maintain cotton production as a viable agricultural option.

Significant changes in the supply of agricultural fibers can have an impact on those craftsworkers, artisans, and local producers who rely heavily on one or more of them for their livelihood. Slow gradual changes, which seem far more likely, will not be as disruptive, as they provide time for adaptation. Although changes in the production of cotton in any one region would not appear to have significant impact on the well-being of consumers, due to the extent to which the fiber is traded on world markets, such changes will affect local food supplies due to the competition of cotton production with food production.

While the controversy surrounding genetically modified organisms extends well beyond cotton, this crop is one where the issues are both current and particularly important. Media reports estimate that some 1.5 million hectare of GM cotton were planted in China in 2001 and some 100,000 hectares were grown in India in 2003 after the country approved testing in 2002 (Reuters 2002, 2004). To date, there are no official data on these crop varieties, but their use is growing rapidly, along with the associated controversies.

GM cotton is the result of genetic engineering that introduces genetic material from the Bt (*Bacillus thuringiensis*) organism into the cotton plant. This protein makes the crop more resistant to pests such as the cotton bollworm. Proponents of the technology point to evidence of increased yields and profits to growers, particularly small growers who lack the capital and equipment to control pests effectively. They also argue that the technology reduces the use of pesticides and lowers associated environmental impacts. Critics of the technology assert that early pest resistance is likely to vanish as pests evolve the capability to overcome the new defenses and that there are dangers of releasing genetic material into the environment that may not be subject to natural controls. They also express concerns that farmers may end up using more pesticide rather than less, as the need to control pests other than the target pests becomes more important.

These are issues of great importance to the future of many crops, and an adequate assessment of the technology and its implications is beyond the scope of this chapter. Such an assessment will be increasingly important as the world grapples with the implications of GMO crops, including cotton.

9.5.1.2 Silk

Silk has long been highly prized for the manufacture of fine cloth. It is produced primarily in Asia, where silkworm culture (sericulture) has been under way for centuries. Originally developed in China, silkworms and their host, mulberry trees, have been exported widely around the world. Although commercial sericulture has been tested in many areas of Europe, northern Africa, and the Americas in the past, world production is now heavily centered in China, which accounted for 73% of reported world production in 2000 (FAO 2003c).

Silk production has tripled and the center of production has shifted from Japan to China over the last 40 years. In 1961, Japan produced 57% and China produced 20% of a total world supply of 32 million tons (FAO 2003c). By 2000, China was producing 73% and India was producing 14% of a world supply that had tripled to 110 million tons (FAO 2003c). China's silk production in 2000 (78 million tons) exceeded total world output in 1980 (68 million tons). The movement of silk production from Japan to China over the recent past appears to be linked primarily to lower labor costs in the very labor-intensive production process.

9.5.1.3 Flax, Hemp, Jute, and Sisal

FAO data contain statistics on several of the world's important fiber crops, including flax, hemp, jute and jute-like fibers, and sisal.

Flax is obtained from the stems of several varieties of *Linaceae usitatissimum,* an annual herb that has been cultivated since prehistoric times. The crop has been transported from its native Eurasia to all the temperate zones with cool, damp climates. It is also grown for oilseed production in many parts of the world and was the major source of cloth fiber (linen) until the growth of the cotton industry. Flax fiber cultivation on agricultural land involves dense plantings to prevent the annual plant from branching, then harvesting before maturity.

The total area devoted to flax production has declined from over 2 million hectares in 1961 to less than 450,000 hectares in 2000. The most significant decline was in the former Soviet Union, where the area devoted to flax went from over 1.6 million to about 200,000 hectares. During that same period, the most significant increase in production was reported from China, where production has grown fivefold to some 215,000 tons. In 2000, the three largest flax producers (China, France, and Russia) produced almost two thirds of total global output (FAO 2003c).

Hemp is the common name for *Cannabis sativa,* an annual herb that was native to Asia but is now widespread around the world due to its history of cultivation for bast fiber and drugs. The fiber, taken from the stem, was once widely used to produce various kinds of cordage, paper, cloth, oakum, and other products. Hemp production has declined dramatically since 1961, particularly in the former Soviet Union. In 2000, the two largest producers (China and North Korea) reported over half of total global production (FAO 2003c).

Jute is the common name for the tropical annuals of the genus *Corchorus.* Many species yield fiber, but the primary sources of commercial jute are two species (C. *capsularis* and C. *olitorius*) grown in the Ganges and Brahmaputra valleys of India. Jute is used primarily for coarse fabrics used in burlap, twine, and insulation. Total world production of these fibers declined between 1980 and 2000, particularly in China, Thailand, and Myanmar, and jute and jute-like fibers are now produced almost entirely in India and Bangladesh, where some 89% of total global production originated in 2000 (FAO 2003c).

Sisal is extracted from the leaves of the Agave cactus *(Agave sisalana* and *A. fourcroyides*), which is widely grown in dry tropical regions. The fibers are strong and used primarily for cordage, such as binding twine for hay bales. Over 70% of the sisal fiber production in 2000 was in Brazil and Mexico (FAO 2003c). The major decline between 1961 and 2000 was reported by Tanzania, where production fell from 200,000 to 20,000 tons in that period (FAO 2003c).

Fibers from *Musa* (banana and abaca), *Ciba, Patendra,* and *Bomba* species and coir from coconut palm are also used in many countries for local crafts, cloth, and other uses.

9.5.2 Wood Fibers

Fibers made of almost pure cellulose derived from wood pulp have been manufactured since the late 1800s. Rayon, the most widely known, was developed in France in the 1890s and was originally called ''artificial silk'' (Smith 2002). It has been commercially produced in the United States since 1910 (Fibersource 2004). In rayon production, purified cellulose is chemically converted into a soluble compound that is then passed through a ''spinneret'' to form soft filaments that are chemically treated or ''regenerated'' back into almost pure cellulose. The fibers are then used to produce cloth, cord, or other products. High-performance cords, such as those used in tires, were developed in the 1940s (Fibersource 2004).

At one time, rayon and cotton competed for similar end uses, but cotton's lower price gives it a competitive advantage. Rayon is moisture-absorbent, breathable, and easily dyed for use in clothing. It has moderate resistance to acids and alkalis and is generally not damaged by bleaches. As a cellulosic fiber, rayon will burn, but flame-retardant finishes can be applied. It is now manufactured primarily in Europe and Japan (Smith 2002), although production has declined almost 50% since 1980.

Lyocell is a more recently developed cellulosic fiber, which entered the consumer market in 1991 and was designated as a separate fiber group from rayon due to its unique properties and production processes. Lyocell is both biodegradable and recyclable, and virtually all of the chemicals used in production are reclaimed, making it a very environmentally friendly fiber (Smith 1999). Lyocell is stronger than cotton or linen both when dry and wet. These characteristics make it highly useful for a variety of clothing and similar uses. Since it is a manufactured fiber, the diameter and length of the fibers can be varied according to the desired end use, allowing the fiber to be substituted (or blended) for cotton- or silk-like appearances (Smith 1999). Industrial uses for lyocell include conveyor belts (due to its strength), cigarette filters, printers blankets, abrasive backings, carbon shields, specialty papers, and medical dressings (Smith 1999).

9.5.3 Animal Fibers

9.5.3.1 Domestic Animals

Animal skins and fibers such as wool and mohair are a staple in many societies' clothing and shelter. Most domesticated livestock provide multiple products such as milk, meat, and fiber. Ranching and herding occur largely in agricultural and dryland systems, and excessive grazing pressure is often cited as a driving force for degradation of those systems. As competition from synthetic fabrics has reduced the demand for wool in recent decades, wool production declined 16% between 1980 and 2000, after rising between 1960 and 1980. (See Table 9.13.) The number of live sheep declined 4.4% in that same period, but since the available FAO (2003c) data list all live animals together and do not differentiate those from which wool is harvested, the decline in wool animals is not clear.

The increase in hide production appears to reflect both increased population (associated with increased consumption of leather goods) and the growth of animal agriculture. FAO (2003c) reports, for example, that the world population of live goats more than doubled between 1961 and 2000.

Skins and hides from domestic livestock are generally produced as a by-product of animals slaughtered for meat, so the trends in Table 9.13 are a reflection of the growth in animal agriculture, as well as increased demand. Wool production has stayed virtually unchanged over the last four decades, showing only a slight decline between 1961 and 2000. This appears to reflect the rough balance between increasing populations and reduced per capita wool usage as other fibers have replaced it in some markets.

9.5.3.2 Wildlife

Skins, furs, wools, and hairs from many species of wild mammals, reptiles, and even birds and fish are traded in the international market to make products ranging from clothing and accessories such as footwear, shawls, and wallets to ornaments and furnishings such as charms, rugs, and trophies. Consumers of these products range from local people in Southeast Asian communities using small pieces of tiger skin as magic amulets to ward off evil and illness, to the world's wealthy, wearing fashionable shahtoosh shawls made from the endangered Tibetan antelope.

The skins, hair, and furs from wild animals have been an important source of clothing and shelter for people throughout human history. In some cases today, this trade is putting further pressure on some of the world's most endangered species. For example, progress made over the years in stemming the demand for tiger bone medicine is being thwarted by what appears to be, in some countries, increased poaching of tigers for their skins. Despite their legal protection, the estimated illegal harvest of tens of thousands of Tibetan antelope annually for their wool has reduced populations to fewer than 75,000 animals, compared with an estimated 1 million at the beginning of the twentieth century. (See Box 9.2.)

For some species, the trade and use of skins and furs can be made sustainable. The revival of crocodilian populations in the wild is considered one of the great conservation success stories of the last quarter-century, demonstrating the effectiveness of the Convention on Trade of Endangered Species and sustainable use management programs. In 1969, all 23 species of crocodilians were threatened or had declining populations. Today, one third

BOX 9.2

Shahtoosh

The wool of the Tibetan Antelope (*Chiru Pantholops hodgsonii*), known as shahtoosh, is a valuable and widely traded commodity, despite the animal's protected status and a 23-year-old international trade ban. Unfortunately, the wool is not collected by combing or brushing the animal but by killing it, so that individual hairs can be plucked from the skin (www.traffic.org/25/wild4_3.htm).

Known as Chiru in its home range on the remote Qinghai-Tibetan Plateau of China, the Tibetan antelope lives at altitudes between 3,700 and 5,500 meters, with some animals venturing into the Ladakh region of India. More closely related to sheep and goats than to other antelope species, Tibetan antelope have developed a super-fine layer of hair to protect against the harsh plateau environment. IUCN classifies the Tibetan antelope as vulnerable to extinction.

Because items made from shahtoosh bring extraordinarily high prices, there is widespread poaching and smuggling of hides and wool. The harsh, remote region and the existence of well-armed and organized poaching gangs make law enforcement difficult and dangerous.

Table 9.13. World Production of Hides, Skins, and Greasy Wool, 1961–2000 (FAO 2003c)

Item	1961	1980	2000	1961–80	1980–2000
	(thousand tons)			*(percent change)*	
Cattle hides, fresh	4,070	5,655	7,389	39	31
Buffalo hides, fresh	322	488	811	52	66

Sheepskins, fresh	929	1,106	1,598	19	45
Total	**5,582**	**7,639**	**10,638**	**37**	**39**
Greasy wool	2,619	2,794	2,346		

of crocodilians can sustain a regulated commercial harvest and only four species are critically endangered.

The most likely cause of changes in wildlife-derived skins and fibers will be the ability of governments to control the poaching and trade in the skins and fibers from animals threatened with extinction. Where successful conservation efforts can result in a sustainably harvested supply, production will be maintained. Demand for particular animal products (and the resulting prices) may, in some instances, be driven more by fashion trends or cultural demands than by ecosystem conditions.

9.6 Sustainability of Timber, Fuel, and Fiber Services

While there are local and regional exceptions, the global production and consumption of most timber, fuel, and fiber goods over the last four decades has increased significantly, although the rate of increase has slowed during the past decade. In the process, the continents have become more interconnected through international trade, the value of which has grown much faster than global wood products output.

The impacts on forest ecosystems due to this increased production are difficult to generalize. In some cases, timber harvesting has directly contributed to degrading and deforesting forest ecosystems, most recently in tropical areas. This is particularly true where institutional controls are weak and where destructive and often illegal logging practices are common. In other situations, where modern forest technologies and effective governance occur, forest area and measures of condition are holding steady or improving in the face of increased production. While many negative impacts can be seen immediately, the full impacts on forests (either positive or negative) from particular harvesting practices may not be evident for many years.

For the near future, total global wood supplies are predicted to remain adequate for most market demands, if not in surplus. Increases in demand for forest products in the near future are likely to be met by increases in supply and are unlikely to create significant price increases that would create hardship on consumers. That does not apply to premium species or the high-quality woods that have been overharvested in the past. For the near future, those will be in short supply and will need to be replaced by other species or manufactured products or substitutes.

Fuelwood is a special case, largely because it is so important to the people who depend on it for heating and cooking. It is produced, harvested, and consumed locally in the regions where it is a critical factor in family well-being. Local assessments of fuelwood and its relationship to both ecosystems and communities are feasible and needed, as national or regional assessments of overall fuelwood adequacy mask critical community shortages.

In most parts of the world, changes in the production of the timber, fuel, and fiber in the near future (10–15 years) will be caused primarily by political, social, and economic forces rather than changes in the capacity of ecosystems to produce these services. Exceptions may be the capacity of local ecosystems to meet fuelwood demands in some rural subsistence economies, particularly in Africa, and the reduction in availability of some wildlife skins and fibers due to population declines. Where institutional capacity is weak, significant increases in industrial production of wood or fibers such as cotton can cause adverse impacts on local environments or disadvantage traditional users who relied on the ecosystem for food, shelter, medicines, or other nonindustrial products.

Due to increasing globalization of investments and trade, some of the more important policy impacts on the supply of forest products may come in the form of trade or transportation policies; subsidies or taxes for production, transportation, or manufacturing; economic development; or monetary policy. These policies are made outside the forestry and agricultural sectors, often for vastly different reasons of national interest.

The search for a sustainable future involves important challenges in the provision of timber, fuel, and fiber. Some of those challenges include:

- the skillful management of planted and natural forests to supply wood crops, employ local people, and support improvements in literacy, housing, nutrition, and health;
- the application of wise policy decisions that consider industrial production, environmental quality, and local communities and are supported by sufficient governance to achieve their objectives;
- the development and dispersal of science and technology to improve efficiencies in wood and fiber production and use, to protect important biodiversity, watershed, and social values, and to contribute to the alleviation of poverty; and
- reduced pressure on remaining natural forests to provide habitat for wild species and people whose future is threatened by the loss of those forest types.

These challenges include, but go beyond, science, management, technology, and laws. They are fundamental social issues that each society and nation will have to tackle.

In terms of the assessment made in this chapter, as noted earlier, global generalizations tend to mask local dynamics. Since policy is made locally, nationally, and regionally, the need to understand and assess local and regional conditions is a critical precursor to informed policy-making, and it is hoped that the global context illustrated here will contribute to those efforts.

Main Messages

Global freshwater use is estimated to expand 10% from 2000 to 2010, down from a per decade rate of about 20% between 1960 and 2000. These rates reflect population growth, economic development, and changes in water use efficiency. Projections that this trend will continue have a high degree of certainty. Contemporary water withdrawal is approximately 3,600 cubic kilometers per year globally or 25% of the continental runoff to which the majority of the population has access during the year. If dedicated instream uses for navigation, waste processing, and habitat management are considered, humans then use and regulate over 40% of renewable accessible supplies. Regional variations from differential development pressures and efficiency changes during 1960–2000 produced increases in water use of 15–32% per decade.

Four out of every five people live downstream of, and are served by, renewable freshwater services, representing 75% of the total supply. Because the distribution of fresh water is uneven in space and time, more than 1 billion people live under hydrologic conditions that generate no appreciable supply of renewable fresh water. An additional 4 billion (65% of world population) is served by only 50% of total annual renewable runoff that is positioned in dry to only moderately wet conditions, with concomitant pressure on that resource base. Only about 15% live with relative water abundance.

Forest and mountain ecosystems serve as source areas for the largest amounts of renewable freshwater supply—57% and 28% of total runoff, respectively. These ecosystems each provide renewable water supplies to at least 4 billion people, or two thirds of the global population. Cultivated and urban ecosystems generate only 16% and 0.2%, respectively, of global runoff, but because of their close proximity to human settlements, they serve 4–5 billion people. Such proximity is also associated with nutrient and industrial water pollution.

From 5% to possibly 25% of global freshwater use exceeds long-term accessible supply. Overuse implies delivery of freshwater services through engineered water transfers or nonrenewable groundwater supplies that are currently being depleted. Much of this water is used for irrigation with irretrievable losses in water-scarce regions. All continents record overuse. In the relatively dry Middle East and North Africa, non-sustainable use is exacerbated, with current rates of freshwater use equivalent to 115% of total renewable runoff. In addition, possibly one third of all withdrawals come from nonrenewable sources, a condition driven mainly by irrigation demand. Crop production requires enormous quantities of fresh water; consequently, many countries that aim at self-sufficiency in food production have entrenched patterns of water scarcity. Alternatively, crops can be traded on global food markets, with some countries accruing substantial benefits from importing "virtual water" that would otherwise be required domestically to irrigate crops.

The water requirements of aquatic ecosystems in the context of expanding human freshwater use results in competition for the same resources. Changes in flow regime, transport of sediments and chemical pollutants, modification of habitat, and disruption of migration routes of aquatic biota are some of the key consequences of this competition. In many parts of the world, competition for fresh water has produced impacts that fully extend to the coastal zone, with effects including oxygen depletion, coastal erosion, and harmful algal blooms. Through consumptive use and interbasin transfers, several of the world's largest rivers (the Nile, the Yellow, and the Colorado in the United States) have been transformed into highly stabilized and in some cases seasonally nondischarging river channels.

The supply of fresh water continues to be reduced by severe pollution from anthropogenic sources in many parts of the world. Over the past half-century, there has been an accelerated release of artificial chemicals into the environment. Inorganic nitrogen pollution of inland waterways, for example, has increased substantially, with nitrogen loads transported by the global system of rivers rising more than twofold over the preindustrial state. Increases of more than tenfold are recorded across many industrialized regions of the world. Many anthropogenic chemicals are long-lived and transformed into by-products whose behaviors, synergies, and impacts are for the most part unknown as yet. As a consequence of pollution, the ability of ecosystems to provide clean and reliable sources of fresh water is impaired. Severe deterioration in the quality of fresh water is magnified in cultivated and urban systems (high use, high pollution sources) and dryland systems (high demand for flow regulation, absence of dilution potential).

The demand for reliable sources of fresh water and flood control has encouraged engineering practices that have compromised the sustainability of inland water systems and their provision of freshwater services. Prolific dam-building (45,000 large dams and possibly 800,000 smaller ones) has generated both positive and negative effects. Positive effects on human well-being have included flow stabilization for irrigation, flood control, drinking water, and hydroelectricity. Negative effects have included fragmentation and destruction of habitat, loss of species, health issues associated with stagnant water, and loss of sediments and nutrients destined to support coastal ecosystems and fisheries.

Water scarcity is a globally significant and accelerating condition for 1–2 billion people worldwide, leading to problems with food production, human health, and economic development. A high degree of uncertainty surrounds these estimates, and defining water scarcity merits substantial further analysis in order to support sound water policy formulation and management. Rates of increase in a key water scarcity measure—water use relative to accessible supply—from 1960 to present averaged nearly 20% per decade globally, with values of 15% to more than 30% per decade for individual continents. Inequalities in level of economic development, education, and governance result in differences in coping capacity for water scarcity.

The annual burden of disease from inadequate water, sanitation, and hygiene totals 1.7 million deaths and the loss of at least 50 million healthy life years. Some 1.1 billion people lack access to safe drinking water and 2.6 billion lack access to basic sanitation. Investments in drinking water supply and sanitation show a close correspondence with improvement in human health and economic productivity. Each person needs only 20 to 50 liters of water free of harmful contaminants each day for drinking and personal hygiene to survive, yet there remain substantial challenges to providing this basic service to large segments of the human population. Half of the urban population in Africa, Asia, and Latin America and the Caribbean suffers from one or more diseases associated with inadequate water and sanitation.

The state of freshwater resources is inadequately monitored, hindering the development of indicators needed by decision-makers to assess progress toward national and international development commitments. Substantial deterioration of hydrographic networks is occurring throughout the world, increasing the difficulty of making an accurate assessment of global freshwater resources. The same is true for groundwater monitoring, standard water quality monitoring, and freshwater biological indicators. New techniques make it possible to identify literally thousands of chemicals, including long-lived synthetic pharmaceuticals, in freshwater resources. But universal application of these techniques is lacking, and there are no systematic epidemiological studies to understand their impact on long-term human well-being.

Trade-offs in meeting the Millennium Development Goals and other international commitments are inevitable. It is *very certain* that the condition of inland waters and coastal ecosystems has been compromised by the conventional sectoral approach to water management, which, if continued, will jeopardize human well-being. In contrast, the implementation of the established ecosystem-based approaches adopted by the Convention on Biological Diversity, the Convention on Wetlands, the Food and Agriculture Organization, and others could substantially improve the future condition of water-provisioning services by balancing economic development, ecosystem conservation, and human well-being objectives.

7.1 Introduction to Fresh Water as a Provisioning Service

This chapter provides a picture of the recent history and contemporary state of global freshwater provisioning services. It documents a growing dependence of human populations on these services, which has resulted in a variety of activities aimed at stabilizing and delivering water supplies. So effective has been the ability of water management to influence the state of this resource, in terms of both its physical availability and chemical character, that anthropogenic signatures are now evident across the global water cycle. Much of this influence is negative due to overuse and poor management. The capacity of ecosystems to sustain freshwater provisioning services is thus strongly compromised throughout much of the world and may continue to remain so if historic patterns of managed use persist.

7.1.1 Fresh Water in the MA Context

Within the MA conceptual framework (see Chapter 1), water is treated as a service provided by ecosystems as well as a system (inland waters). Because the water cycle plays so many roles in the climate, chemistry, and biology of Earth, it is difficult to define it as a distinctly supporting, regulating, or provisioning service. Precipitation falling as rain or snow is the ultimate source of water supporting ecosystems. Ecosystems, in turn, control the character of renewable freshwater resources for human well-being by regulating how precipitation is partitioned into evaporative, recharge, and runoff processes. Together with energy and nutrients, water is arguably the centerpiece for the delivery of ecosystem services to humankind (Falkenmark and Folke 2003).

While recognizing the role of water in supporting and regulating services, the placement of this chapter among other provisioning services is done from a practical point of view, in part because water resources are the most tangible and well-documented aspect of this broader spectrum of freshwater services. This chapter assesses the condition and recent trends in global freshwater resources, examining the amount and condition of renewable and nonrenewable surface and groundwater supplies, changes in these supplies over time and into the near future, and the impacts on human well-being of changes in the service. Chapter 20 examines the role of inland water ecosystems that provide a multitude of services, including water, fish, habitat, cultural and aesthetic values, and flood prevention. Because fresh water is so essential to life on Earth, its assessment overlaps with services and ecosystem chapters across the MA.

Throughout this chapter reference is made to summary statistics on the fresh water associated with specific ecosystems. While ecosystems are strongly dependent on the water cycle for their very existence, at the same time these systems represent domains over which precipitation is processed and transferred back to the atmosphere as ''green water'' (through evapotranspiration drawn from soils and plant canopies in natural ecosystems and rain-fed agriculture). The remainder runs off as ''blue water'' which constitutes the renewable water supply that can pass to downstream users—both aquatic ecosystems and humans such as farmers who irrigate. These water flows can be tabulated across ecosystems to identify areas that are critical to human well-being as well as those that require particular attention in designing strategies for environmental protection. Box 7.1 defines key terms used in this analysis.

7.1.2 Setting the Stage

Prior to the twentieth century, global demand for fresh water was small compared with natural flows in the hydrologic cycle. With population growth, industrialization, and the expansion of irrigated agriculture, however, demand for all water-related goods and services has increased dramatically, putting the ecosystems that sustain this service, as well as the humans who depend on it, at risk. While demand increases, supplies of clean water are diminishing due to mounting pollution of inland waterways and aquifers. Increasing water use and depletion of fossil groundwater adds to the problem. These trends are leading to an escalating competition over water in both rural and urban areas. Particularly important will be the challenge of simultaneously meeting the food demands of a growing human population and expectations for an improved standard of living that require clean water to support domestic and industrial uses.

Meeting even the most basic of needs for safe drinking water and sanitation continues to be an international development priority. Some 1.1 billion people lack access to clean water supplies and more than 2.6 billion lack access to basic sanitation (WHO/UNICEF 2004). Reducing these numbers is a key development priority. By adopting the initial targets of the Millennium Development Goals, governments around the world have made a commitment to reduce by half the proportion of people lacking access to clean water supply and basic sanitation between 1990 and 2015.

The ministerial declaration from the 2nd World Water Forum in The Hague in 2000 captured the essence of the goals and challenges faced (see Box 7.2), including articulation of the importance of ecosystems in sustaining freshwater services. Water continues to rise in importance in major policy circles, with 2003 declared the International Year of Fresh Water, release of the first World Water Development Report (UN/WWAP 2003) by a collaboration of 24 U.N. agencies through the World Water Assessment Programme, and proclamation by the UN General Assembly of the International Decade of Action ''Water for Life'' in 2005–15.

Societies have benefited enormously through their use of fresh water. However, due to the central role of water in the Earth system, the effects of modern water use often reverberate throughout the water cycle. Key examples of human-induced changes include alteration of the natural flow regimes in rivers and waterways, fragmentation and loss of aquatic habitat, species extinction, water pollution, depletion of groundwater aquifers, and ''dead zones'' (aquatic systems deprived of oxygen) found in many inland and coastal waters. Thus, trade-offs have been made—both explicitly and inadvertently—between human and natural system requirements for freshwater services.

The challenge for the twenty-first century will be to manage fresh water to balance the needs of both people and ecosystems, so that ecosystems can continue to provide other services essential for human well-being. Human impacts on the capacity of ecosystems to continue delivering freshwater services are assessed in

BOX 7.1

Operational Definitions of Key Terms on Fresh Water

The global water cycle involves major transports that link Earth's atmosphere, land mass, and oceans, though the emphasis in this chapter is on the continental hydrologic cycle. The Figure here outlines the major fluxes of fresh water, which help to define the renewable supplies on which humans and ecosystems depend. The water cycle can be divided into a portion that is accessible to humans and that which is not. The portion of the global water cycle that is accessible to humans is shown in the diagram. The following nomenclature is used throughout this chapter.

Total Precipitation (P_t). This term is equivalent to the total sustainable water supply falling as rain and snow over the terrestrial portion of Earth. P_t represents the ultimate source of fresh water for recharge into soils, evaporation, and transpiration by plants in natural and cropped ecosystems, recharge into groundwaters, and, eventually, runoff and discharge through river corridors. For the purposes of this study, P_t represents climatic means, unless otherwise noted. P_t can be divided into precipitation that is accessible (P_a) or inaccessible (P_i) to humans on the land mass. Ocean precipitation is denoted as P_o.

Total Blue Water Flow (B_t). This term represents the global renewable water supply computed as surface and sub-surface runoff. "Total" here refers to "blue water" that is both accessible and inaccessible to humans. It is a subcomponent of P_t, representing the net fresh water remaining after accounting for evapotranspiration (ET) losses to the atmosphere from the soils and vegetation of natural ecosystems and rain-fed agriculture, known as "green water" (G_t). Blue water represents the sustainable supply of fresh water that emanates from ecosystems and is then transferred through rivers, lakes, and other inland aquatic systems. These downstream ecosystems evaporate and consume water (C_{iws}) and reduce blue water flows. In basins occupied by humans, accessible blue water (B_a) is further reduced (B_a') through consumptive losses (C_a) from water resource management, such as irrigation.

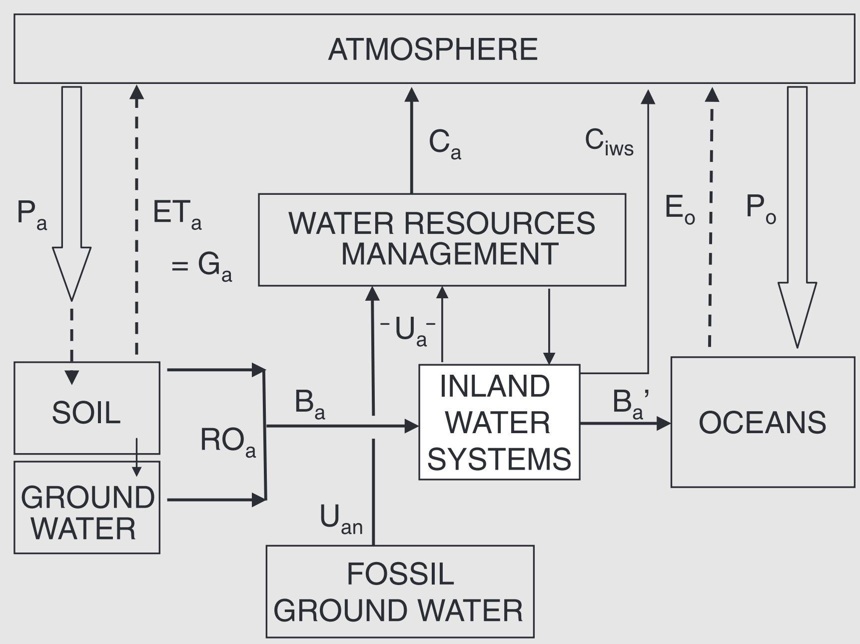
Water Use (U_a). This represents water withdrawn or used by humans. U_a is derived from either accessible blue water flows (B_a) or nonrenewable sources, predominantly fossil groundwater mining, which constitutes a non-sustainable water use. Use is divided into domestic (D_a), industrial (I_a), and agricultural (A_a) applications, a part of which can be returned to inland water systems, though sometimes degraded in its quality in such return flows.

Water Consumption (C_a). The portion of water that is lost as net evapotranspiration after being withdrawn from an accessible supply source (U_a). Such losses are associated predominantly with irrigation, and emerge from both renewable and nonrenewable freshwater supplies. C_a is also referred to as irretrievable losses. While humans "consume" water directly for drinking, this is not termed water consumption but simply a component of domestic water use tabulated under U_a.

Non-sustainable Water Use (U_{an}). This is computed by comparing total water demand or withdrawals for human use (U_a) to the available renewable water supply (B_a). Where U_a exceeds B_a at the point of extraction, non-sustainable use is tabulated. For most parts of the planet, this will refer to the "mining" of groundwaters, especially in arid and semiarid areas, where recharge rates to the underground aquifer are limited. U_{an} can also embody the interbasin transport of fresh water from water rich to water poor areas.

Environmental Flows. These are the water requirements needed to sustain freshwater ecosystems.

Water Abundance and Scarcity. The conjunction of renewable freshwater supply, withdrawals, consumptive losses, and level of development can be used to define quantitative measures of water abundance or scarcity. The number of people supported on a unit of renewable freshwater flows (the "water crowding" index) will define thresholds of chronic water scarcity, as will use-to-supply ratios (U_a /B_t or U_a / B_a).



Chapter 20. Some options on balancing human and ecosystem water requirements are discussed in Chapter 7 of the MA *Policy Responses* volume.

Before describing the details of this chapter's assessment, a word is in order on the quality of information on which it is based. Monitoring the continental water cycle in a timely manner at the global scale using traditional discharge gauging stations—the mainstay of water resource assessment—continues to challenge the water sciences (IAHS 2001; NRC 1999; Kanciruk 1997). Data collection is now highly project-oriented, yielding often poorly integrated time series of short duration, restricted spatial coverage, and limited availability. In addition, there has been a legal assault on the open access to basic hydrometeorological data sets, aided in large measure by commercialization and fears surrounding piracy of intellectual property. Delays in data reduction and release (up to several years in some places) are also prevalent. Much information has yet to be digitized, and exists in difficult-to-use book and report formats.

Based on available global archives at the WMO Global Runoff Data Center, to which member states contribute voluntarily, there was arguably a better knowledge of the state of renewable surface water supplies in 1980 than today. Such statements apply to many parts of the world, including otherwise well monitored countries like the United States and Canada (IAHS 2001; Shiklomanov et al. 2002), though most marked declines are in the developing world. Our understanding of groundwater resources is even more limited, since well-log, groundwater discharge/recharge, and aquifer property data for global applications are only beginning to be synthesized (Foster and Chilton 2003; UNESCO-IHP 2004). Information on water use and operation of infrastructure has never been assembled for global analysis (IAHS 2001; Vörösmarty and Sahagian 2000).

While remote sensing and models of the water cycle can be used to fill some data gaps, these approaches themselves produce a range of outputs arising from differences in their input data streams and detailed calculation procedures (e.g., Fekete et al.

BOX 7.2

Ministerial Declaration from the 2nd World Water Forum

The ongoing series of World Water Forums (Marrakech 1997, Hague 2000, Kyoto 2003, Mexico 2006), organized by the World Water Council and its partners, brings together a broad array of thousands of stakeholders to discuss strategies for sustainable development with respect to water. While there have been three such gatherings to date, outputs from the affiliated Ministerial Conference of the 2nd Forum are most relevant to the MA. This Ministerial Declaration captures the interconnections among ecosystem integrity, human actions affecting water supply, and human well-being. It is precisely these interactions that define the contemporary conditions and trends and that are suggestive of responses that foster water stewardship, sustainable water use, and progress toward development. These fundamental goals highlight the need for well-functioning ecosystems. They also reflect strongly the Millennium Development Goals:

- meeting basic human needs—that is, access to safe and sufficient water and sanitation, which are essential to health and human well-being;
- securing the food supply to enhance food security through a more efficient mobilization and use of water for food production;
- protecting ecosystems and ensuring their integrity through sustainable water resources management;
- sharing water resources to promote peaceful cooperation and develop synergies between the different uses of water within and between the states concerned;
- managing risks to provide security from floods, droughts, pollution, and other water-related hazards;
- valuing water to manage it in a way that reflects economic, social, environmental, and cultural values for all its uses; and
- governing water wisely to ensure good governance, including public participation.

2004). Without a sustained international commitment to baseline monitoring, global water assessments will be difficult to make and fraught with uncertainty. Box 7.3 gives the range of current estimates used in global water resource models, an uncertainty that in part arises from these data problems.

7.2 Distribution, Magnitude, and Trends in the Provision of Fresh Water

While it is true that there is an abundance of water across blue planet Earth, only a small portion of it exists as fresh water, and even a smaller fraction is accessible to humans. Nearly all water on Earth is contained in the oceans, leaving only 2.5% as fresh water. (See Table 7.1.) Of this small percentage, nearly three quarters is frozen, and most of the remainder is present as soil moisture or lies deep in the ground. The principal sources of fresh water that are available to society reside in lakes, rivers, wetlands, and shallow groundwater aquifers—all of which make up but a tiny fraction (tenths of 1%) of all water on Earth. This amount is regularly renewed by rainfall and snowfall and is therefore available on a sustainable basis.

Global averages fail to portray a complete picture of the world's water resource base, however. The basic climatology of the planet dictates that fresh water will be distributed unevenly around the globe, with abundant supplies across zones like the wet tropics and absolute water scarcity across the desert belts and in the rain shadow of mountains. For this assessment, both locally available runoff and water transported though river networks is considered (Vörösmarty et al. 2005). River corridor flows convey essential water resources to those living on the banks of large rivers, such as along the lower Nile. Figure 7.1 (in Appendix A) shows the broad range of sustainable water resources (blue water flows), which varies from essentially zero in many arid and semiarid regions to hundreds and thousands of cubic kilometers per year as major river corridor flow. Such regional differences in the quantity of available fresh water establish the diverse patterns of water supply across the globe.

The supply of fresh water is conditioned by several additional factors, which amplify the patterns of abundance and scarcity. These factors include the distribution of humans relative to the supply of water (that is, access to water), patterns of demand, presence of water engineering to stabilize flows, seasonal and interannual climate variations, and water quality. The following sections assess the state of global freshwater supplies, demands (withdrawals or use), and water quality. The time domain covered here is the last several decades and into the near future of 2010–15.

7.2.1 Available Water Supplies for Humans

Estimates of global water supply are imprecise and complicated by several factors, including differences in data and methodologies used, loss of hydrographic monitoring capacity, alternative time frames considered, and distortions from land cover, climate, and hydraulic engineering that are increasingly a part of the water cycle. The renewable resource base expressed as long-term mean runoff has been estimated to fall between 33,500 and 47,000 cubic kilometers per year (Korzoun et al. 1978; L'vovich and White 1990; Gleick 1993; Shiklomanov and Rodda 2003; Fekete et al. 2002; Nijssen et al. 2001; Döll et al. 2002). Within-year variations also define the basic nature of water supply. At the continental scale, maximum-to-minimum runoff ratios vary between 2:1 and 10:1 (Shiklomanov and Rodda 2003), with individual rivers experiencing ratios far higher, such as in snowmelt-dominated basins or episodically flooded arid and semiarid river systems. These variations necessitate flow stabilization through hydraulic engineering for either protection (for example, from floods) or seasonal supply augmentation (for example, for dry-season agriculture or hydroelectricity).

Water supply can also be assessed from the standpoint of societal access to renewable runoff and river flow, from which humans can secure provisioning services. By one estimate (Postel et al. 1996), one third of global renewable water supply is accessible to humans, when taking into account both its physical proximity to population and its variation over time, such as when flood waves pass uncaptured on their way to the ocean. Such accessibility is considered as part of this assessment later in this chapter.

Groundwater plays an important role in water supply. It has been estimated that between 1.5 billion (UNEP 1996) and 3 billion people (UN/WWAP 2003) depend on groundwater supplies for drinking. It also serves as the source water for 40% of self-supplied industrial uses and 20% of irrigation (UN/WWAP 2003). For certain countries this dependency is even greater; for example, Saudi Arabia meets nearly 100% of its irrigation requirements through groundwater (Foster et al. 2000). Two important classes of groundwater can be identified. The first is renewable groundwater resources, closely linked to the cycling of fresh water, through which the ground is periodically replenished when sufficient precipitation is available to recharge soils or when floodplains become inundated. The second, fossil groundwater, is

BOX 7.3

Uncertainties in Estimates of Contemporary Freshwater Services, Use, and Scarcity

All entries are ranges in the units indicated and represent near-contemporary conditions.

Geographic Region	Renewable Water Supply[a]	Total Withdrawals	Mean Water Crowding	Mean Use-to-Supply (U_a/B_t) Ratio	Population with U_a/B_t Ratio Greater than 40%
	(cu. km. per year)		*(people/mill. m³/yr)*	*(percent)*	*(million)*
Asia	7,850–9,700	1,520–1,790	320–384	16–22	712–1,200
Former Soviet Union	3,900–5,900	270–380	48–74	6–8	56–110
Latin America	11,160–18,900	200–260	25–42	1–2	84–160
North Africa/Middle East	300–367	270–370	920–1,300	74–108	91–240
Sub-Saharan Africa	3,500–4,815	60–90	115–160	2–2	16–140
OECD	7,900–12,100	920–980	114–129	8–12	164–370
World Total	**38,600–42,600**	**3,420–3610**	**133–150**	**8–9**	**1,123–2,100**

[a] For the purpose of this intercomparison, supply is total supply (B_t). See also Box 7.1 and Table 7.2.

The ranges reported here are from three global-scale water resource models, two of which were used directly in the MA: University of New Hampshire (Vörösmarty et al. 1998a; Fekete et al. 2002; Federer et al. 2003) for the Condition and Trends Working Group assessment and Kassel University (Alcamo et al. 2003; Döll et al. 2003) used in the Scenarios Working Group. A third model from the University of Tokyo and Global Soil Wetness Project (Oki et al. 2001, 2003b; Dirmeyer et al. 2002) was also compared.

The global-scale correspondence for total supply, withdrawals, water crowding, and demand-to-supply ratio is high, but masks continental-scale differences. Such disparities can be large, as for water supply in Latin America, where large remote tropical river systems have proved difficult to monitor systematically. Substantial differences at the continental scale are noted for population living under severe water scarcity (use-to-supply >40%). The order-of-magnitude range apparent for sub-Saharan Africa can be linked in part to the distribution of sharp climatic gradients that are difficult to analyze geographically. The result is also a function of the assumptions made regarding access to water. Because of such uncertainties, the current state-of-the-art in global models put 1–2 billion people at risk worldwide arising from high levels of water use. The MA models predict a much smaller range, from 2.0–2.1 billion.

Large uncertainties surround current estimates of water consumption by the largest user of water, agriculture. Recent estimates vary from 900 (Postel 1998) up to 2000 cubic kilometers per year (Shiklomanov and Rodda 2003). A value of 1200 cubic kilometers per year is reported in this assessment (Table 7.4).

Table 7.1. Major Storages Associated with the Contemporary Global Water System (Shiklomanov and Rodda 2003)

Type	Volume	Fraction of Total Volume	Fraction of Fresh Water
	(thous. cu. km.)	*(percent)*	*(percent)*
World ocean	1,338,000	96.5	–
Groundwaters	23,400	1.7	–

Total fresh water	**35,029**	**2.53**	**100**

typically locked in deep aquifers that often have little if any long-term net recharge. Whenever this is extracted, it is functionally "mined," a particularly acute problem in arid regions, where replenishment times can be on the order of thousands of years (Margat 1990a, 1990b).

Establishing the contribution of groundwater to the global supply of freshwater inserts a substantial element of uncertainty into the overall assessment. Problems of poor data harmonization, incomplete and fragmentary inventories, and methodological difficulties are well documented (Revenga et al. 2000; UN/WWAP 2003; Morris et al. 2003). As a result, there is large uncertainty in estimates of fresh groundwater resources, ranging from 7 million to 23 million cubic kilometers (UN/WWAP 2003; Morris et al. 2003). While abundant, their use can be severely restricted by pollution (Foster and Chilton 2003) or by the cost of extracting water from aquifers, which rises progressively in the face of extraction rates exceeding recharge (Dennehy et al. 2002).

Another important water supply is represented by the widespread construction of artificial impoundments that stabilize river flow. Today, approximately 45,000 large dams (>15 meters high or between 5 and 15 meters high and a reservoir volume of more than 3 million cubic meters) (WCD 2000) and possibly 800,000 smaller dams (McCully 1996; Hoeg 2000) have been built for municipal, industrial, hydropower, agricultural, and recreational water supply and for flood control. Recent estimates place the volume of water trapped behind documented dams at 6,000–7,000 cubic kilometers (Shiklomanov and Rodda 2003; Avakyan and Iakovleva 1998; Vörösmarty et al. 2003). In drainage basins regulated by large reservoirs (>0.5 cubic kilometers) alone, one third of the mean annual flow of 20,000 cubic kilometers is stored (Vörösmarty et al. 2003). Assuming seasonal six-month low flows constitute roughly 40% of annual discharge (Shiklomanov and Rodda 2003), this impounded water represents a global potential to carry over an entire year's minimum flows.

Desalinization constitutes a renewable water supply using distillation and membrane techniques to withdraw salt from otherwise unusable water. While the technology continues to improve, desalinization remains the most costly means of supplying fresh water and is highly energy-intensive (Gleick 2000). Costs range between $1 and $4 per cubic meter, placing it well above the most expensive traditional sources (Gleick 2000). Despite this, in 2002 there were over 10,000 desalinization plants in 120 countries supplying more than 5 cubic kilometers per year, with a global market of $35 billion per year (UN/WWAP 2003). Collectively, these plants provide for much less than 1% of global freshwater use.

More than 70% of global installed desalinization capacity is in the oil-rich states of the Middle East and North Africa (UN/WWAP 2003). While its use may be difficult to justify for high-water-consumptive activities like irrigation, investments in desalinization technologies are likely to improve efficiency and bring down costs, creating a potentially important source at least for domestic drinking water (Gleick 2000), and the annual supply of desalinized water could double in 15 years (UN/WWAP 2003). The unresolved issue of adequately managing brine waste from the desalinization process to protect nearby coastal ecosystems requires special attention.

Finally, rainwater harvesting through traditional methods or modern technology is another way in which humans augment freshwater supply. Rainwater harvesting can directly increase the soil water content or be stored for later application as supplemental irrigation during dry periods. This is particularly important in places like India, which relies heavily on a short period of intense rainfall (WWC 2000). The groundwater authorities in India, for instance, have made it mandatory for multistoried buildings in New Delhi and several other states to have a rooftop rainwater harvesting system (Hindustan Times, Patna, September 2002). Rainwater harvesting can also be an appropriate technology for maintaining groundwater base flow and reducing flood peaks. (See MA *Policy Responses,* Chapter 7, for further discussion.)

7.2.1.1 Total Flows of Fresh Water

Ecosystems vary greatly in their exposure to precipitation and hence as source areas for renewable runoff that emerges as part of the hydrologic cycle. (See Table 7.2.) The proportional contribution of each ecosystem to global runoff is generally equivalent to the fraction of precipitation to which it is exposed. Forests therefore are associated with slightly more than half of global precipitation and yield about half of global runoff, while mountains represent one quarter of both global precipitation and runoff. Cultivated and island systems are the next most important source areas, each constituting about 15% of global runoff. All other systems contribute 10% or less. Paradoxically, dryland ecosystems, due to their large aerial extent, receive a nearly identical fraction of global precipitation as mountains do, yet because of substantial losses from the system due to evapotranspiration, they are a relatively minor contributor to global renewable water supply (<10%). Urban systems, because of their restricted extent (<<1% of land area), receive only 0.2% of global precipitation and provide the same very minor proportion of global runoff.

From a regional perspective, Latin America is most water-rich, with about one third of global runoff. Asia is next, with one quarter of global runoff, followed by OECD (20%), and sub-Saharan Africa and the former Soviet Union, each with 10%. The Middle East and North Africa is clearly driest and most water-limited, accounting for only 1% of global runoff.

7.2.1.2 Freshwater Flows Accessible to Humans

Ecosystems constitute the ultimate source areas for freshwater provisioning services. The accessibility of renewable water supply can be estimated through an index measuring the proportion of total annual renewable runoff generated locally that eventually flows through river corridors and encounters downstream human populations. The importance of upstream ecosystems as source areas for freshwater supply is demonstrated in Table 7.2. Cultivated, coastal, and urban systems, with sizable fractions of the global population, have from 90% to 100% of their renewable runoff accessible. Drylands also show high accessibility, likely reflecting the propensity of humans to settle near scarce freshwater resources. Mountains, forests, and inland waters each show 70–80% of total runoff as accessible to downstream populations. The exception is polar systems, which yield less than 20% of total runoff as accessible, reflecting their remote and generally uninhabited environment.

Populations served by accessible runoff emerging from individual ecosystems are typically in the billions. Cultivated systems, forests, inland waters, and mountains each serve at least 4 billion people. Four fifths of the world lives downstream of runoff from cultivated lands, followed by a nearly identical fraction downstream from forests. Inland waters and mountains provide water to two thirds of global population and drylands to one third. Remote islands and polar systems serve the fewest people. Runoff from urban systems, nearly all generated in close proximity to densely settled areas, serves nearly three quarters of the world's population.

The large fractions of total runoff expressed as accessible runoff indicate that, by and large, human society has positioned itself into areas with identifiable local sustainable water supplies or river corridor flows. A geographic distribution of human settlement thus is linked to the availability of fresh water (see also Meybeck et al. 2001). The global geography of accessible runoff, expressed in units of dependent population per unit of delivered flow, was shown in Figure 7.1. Mountains serve 3 times, forests 4 times, and inland waters 12 times as many people downstream through river corridors as they do through locally derived runoff. Urban areas nearly double the total service when tabulating downstream populations. Remaining ecosystems show more-limited importance in transferring precipitation as accessible runoff to downstream populations. For drylands, this is due to a lack of substantial quantities of runoff, while for coastal or island systems it is a consequence of short flow pathways to the ocean. Each of these systems still supplies 15–30% of global population with renewable and accessible runoff.

From a regional perspective, Latin America and Asia constitute the largest proportion (together nearly 60%) of global accessible runoff. And while the OECD, sub-Saharan Africa, and the former Soviet Union generate a large portion of the global runoff, substantial quantities are remote and inaccessible particularly in the former Soviet states (see also Postel et al. 1996). The Middle East and North Africa generates less than 1% of renewable accessible runoff.

Overall, the global fraction of total annual runoff that is accessible to humans is 75%, with slightly more than 80% of world

Table 7.2. Estimates of Renewable Water Supply, Access to Renewable Supplies, and Population Served by the Provision of Freshwater Services, Year 2000 Condition (computed based on methods in Vörösmarty et al. 2005; renewable water supply estimates from Fekete et al. 2002 from simulated water budgets using climatology data from 1950–96)

population (4.9 billion people) being served by these renewable and accessible water flows. However, while providing an estimate of long-term water supply, these figures overstate the effective availability of fresh water. Given that approximately 30% of annual runoff is uncaptured flood flow (Shiklomanov and Rodda 2003), the world's population has its access reduced from 75% to 53% of total runoff.

Globally, renewable freshwater services reflect the geographic distributions of both water supply and human populations. Four out of every five people live downstream of and are served by renewable freshwater services. (See Figure 7.2.) Thus, while the human population is generally well organized with respect to the availability of fresh water, 20% of humanity remains without any appreciable quantities of sustainable supply or must gain access to such resources through costly interbasin transfers from more water-rich areas. (See also Table 7.2.) These people are highly reliant on unsustainable water resources. For those with access to renewable supplies, a total of 65% of the world's population is served by the 50% of total annual renewable runoff that is positioned in dry to moderately wet conditions, with concomitant pressure on that resource base. Only 15% live with relative water abundance—that is, in conjunction with the remaining 50% of total runoff (represented by the high runoff-producing regions shown in the upper part of the curve in Figure 7.2). If uncaptured flood flow is incorporated into these calculations, for the 80% of

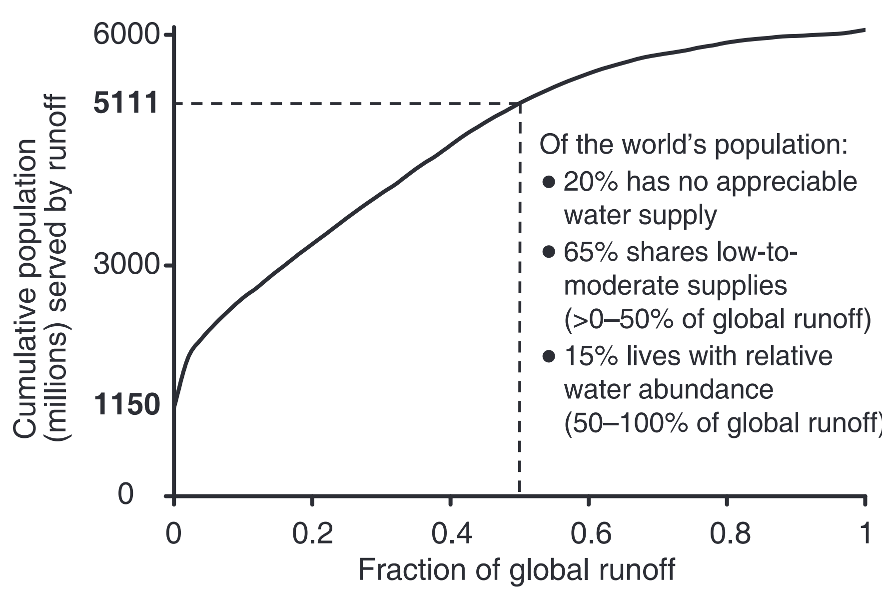

Figure 7.2. Cumulative Distribution of Population with Respect to Freshwater Services, 1995–2000. Fraction of runoff is ranked from low to high based on mean annual conditions. This distribution is also affected by seasonal variations in available runoff.

world population who reside in the lower half of the water availability spectrum in Figure 7.2 (65% plus 15% with no appreciable renewable freshwater flows), the effective supply is reduced from 50% to 35% of total runoff.

7.2.2 Water Use

Over the last few centuries, global water use has shown roughly an exponential growth and been linked closely to both population growth and economic development. There was a fifteenfold increase in global water withdrawals between 1800 and 1980 (L'vovich and White 1990), when population increased by a factor of four (Haub 1994). Since the 1900s, the overall increase has been sixfold (WMO 1997). Global consumptive water losses, primarily from evapotranspiration through irrigation, increased thirteenfold during this same period. A major, recent feature of human water use is the reduction in per capita use rates, dropping as of around 1980 from about 700 to 600 cubic meters per year, though the aggregate global withdrawal continues to increase (Gleick 1998; Shiklomanov and Rodda 2003).

While the general features of a historical rise in freshwater demands are clear, there are substantial uncertainties surrounding water use estimates, reflecting the current state of knowledge, assumptions (or lack thereof) on potential efficiency changes and reuse potential, number of years projected into the future, and interactions with market forces (Gleick 2000; Shiklomanov and Rodda 2003). The summary statistics from three global tabulations provided earlier, in Box 7.3, demonstrate the current degree of uncertainty.

Global water withdrawals today total about 3,600 cubic kilometers per year, with a wide range of use over individual continents. (See Table 7.3.) The largest user is Asia, accounting for nearly half of the world total, with OECD next, using about one third. The remaining continents each represent less than 10% of global use. Water use today is dominated by agricultural withdrawals (70% of all use), followed by industrial and then domestic applications. Withdrawals in agriculture are fundamentally defined by irrigation. In Asia, the Middle East and North Africa, and sub-Saharan Africa, agriculture accounts for 85–90% of all withdrawals. Driven by irrigation demand, overall withdrawals across MENA constitute 120% of renewable accessible supplies, meaning that this region relies on nonrenewable supplies for food production. Agricultural water use in the former Soviet Union and the OECD is proportionally much lower, reflecting the water needs of other sectors in these industrial economies. In contrast, industrial water use is only 4% in sub-Saharan Africa, reflecting a low level of economic development.

Table 7.3. Freshwater Services Tabulated as Withdrawals for Human Use over MA Regions and the World, 1995–2000 (WRI et al., 1998, updated using Shiklomanov and Rodda 2003, as in Vörösmarty et al. 2000; resampled to MA reporting units)

MA Geographic Region	Domestic Water Use D_a	Industrial Water Use I_a	Agricultural Water Use A_a	Total Use (Withdrawals) U_a
		(cu. km. per year)		
Asia	80	99	1,373	1,550
Former Soviet Union	34	115	188	337
Latin America	33	31	205	269
North Africa/ Middle East	22	15	247	284

OECD	149	489	384	1,020
Global Total	**328**	**753**	**2,480**	**3,560**

Water lost from groundwater and surface water sources to the atmosphere through net evaporation (such as from irrigation, cooling towers, or reservoirs) is termed water consumption or irretrievable losses, which today represent a substantial fraction of water use. Contemporary irretrievable losses through irrigation, computed as the evapotranspiration component of agricultural withdrawals, are assessed here. (See Table 7.4.) Irretrievable losses from irrigation represent one third of all water use globally. The efficiency computed for irrigated agriculture (the ratio of water withdrawn to water consumed or lost through evapotranspiration on irrigated cropland) is on average 50% globally and varies from 25% (in Latin America) to 60% (in Asia). Additional losses from evaporation from reservoirs, irrigation ditches, and so on are difficult to estimate accurately but could total over 500 cubic kilometers per year (Postel 1998), thus indicating the conservative nature of the consumption estimates in Table 7.4. (See Box 7.3 earlier in this chapter for the range in current estimates of consumptive loss from irrigation.)

Non-sustainable water use could be a substantial component of total withdrawals. Earlier work based on documentary evidence showed approximately 200 cubic kilometers per year of global aquifer overdraft (Postel 1999; WWC 2000), though the estimate is regarded as highly uncertain (Foster 2000). This assessment of water supply and use (based on Vörösmarty et al. 2000, 2005; Fekete et al. 2002) using a geospatial framework (about 50-kilometer resolution) enables calculations to be made of the degree to which water withdrawal exceeds locally accessible supplies—in other words, non-sustainable water use (U_{an}). Worldwide, non-sustainable withdrawals can be computed using two endpoints: crop evaporative demands or water use statistics, which include both consumption and transport losses, some unknown fraction of which reenters the surface-groundwater system for potential reuse (Molden 2003). These endpoints give a calculated non-sustainable use of about 400–800 cubic kilometers per year. In terms of total freshwater withdrawals, 10–25% could represent nonrenewable use. When the earlier estimate of 200 cubic kilometers per year is also included, a large degree of uncertainty results, and from 5% to 25% of freshwater withdrawals could represent nonrenewable use.

Nevertheless, each of these estimates reflects a high dependence on existing water services, especially in areas where induced, chronic water stress necessitates costly water engineering remedies, groundwater depletion, or curtailment of water-using activities. Each continent shows a heavy reliance on such nonrenewable extraction, ranging up to one third of total use based on the high estimates. Asia and MENA show the greatest level of such dependence; OECD, the least. In MENA, 30% of all water use is from non-sustainable sources, and this use is equivalent to over one third of accessible renewable supplies.

Figure 7.3 (in Appendix A) shows the contemporary geography of such non-sustainable use and demonstrates the much larger impacts that arise at subcontinental scales. The summary in Table 7.4 may thus understate the true degree of this overconsumption locally. The spatial pattern of overuse is broadly consistent with previously reported regions of use exceeding supply, major water transfer schemes, or groundwater overdraft: Australia, western Asia, northern China, India, North Africa, Pakistan, Spain, Turkey, and the western United States (Muller 2000; Shah et al. 2000;

Table 7.4. Consumptive and Non-sustainable Freshwater Use over MA Regions and the World, 1995–2000. Renewable supplies calculated as for Table 7.2. Irrigated water consumption was computed over irrigation-equipped land (Döll and Siebert 2000) within the cropland domain depicted by Ramankutty and Foley (1999). Evapotranspiration losses from irrigated cropland (Vörösmarty et al. 1998; Federer et al. 2003) relative to available local runoff or, when available, river corridor flows determine non-sustainable use. See Figure 7.3 for geography of non-sustainable use.

[a] Range represents crop demand alone (low estimate) versus reported withdrawals (high estimate, which includes delivery loss; Table 7.3). Recycling within river basins of irrigation withdrawals that are not consumed by crops reduces, to some unknown degree, the high estimate (see Molden 2003). Calculations assume a maximum 75-kilometer buffer around river corridors from which irrigation areas can secure fresh water.

Vörösmarty and Sahagian 2000; Dennehy et al.2002; EEA 2003; MDBC 2003; NLWRA 2004).

Non-sustainable use expressed as a proportion of irrigated agricultural withdrawals shows an even higher degree of dependency on nonrenewable supplies. Globally, about 15–35% of irrigation withdrawals are computed to be non-sustainable. Individual continental areas show percentages ranging from less than 10% to 40%, as in the case of Asia. Such high rates indicate an increasing degree of food insecurity. Given projections showing no major expansion in global cropland area (Bruinsma 2003), increasing pressure will be placed on irrigated cropland, which today provides nearly 40% of crop production (Shiklomanov and Rodda 2003; UN/WWAP 2003). By its very nature, this water use cannot persist indefinitely, and many regions of the world have well-documented cases of aquifer depletion and abandonment of irrigation, adding constraints to irrigated crop production arising from rising development costs, soil salinization, and competition for water required by sensitive ecosystems and commercial fisheries (Postel and Carpenter 1997; Postel 1998; Foster and Chilton 2003).

7.2.3 The Notion of Water Scarcity

The assessment thus far has shown a growing dependence of human society on accessible freshwater resources. To assess the state of these provisioning services more comprehensively, the supply of renewable water must be placed into the context of interactions with people and their use of water. A set of relative measures can be used in this regard.

One measure of dependence on fresh water is the population served per million cubic meters per year of accessible runoff (renewable supply). This is known as the ''water crowding'' index, with levels on the order of 600–1,000 people per million cubic meters per year (that is, 1,000–1,700 cubic meters per year supply per person) showing water stress, and above 1,000 people (that is, less than 1000 cubic meters per year per person) indicating extreme water scarcity (Falkenmark 1997). Another measure is the relative water use or water stress index (WMO 1997; UN/WWAP 2003), expressed as the ratio of water withdrawals to supply. More sophisticated indicators are available that incorporate social and economic dimensions of water use (Raskin 1997; Sullivan et al. 2003), and these will be described in the section on water and human well-being. A major water scarcity indicator effort is under way through the World Water Assessment Programme (UN/WWAP 2003).

Worldwide, a substantial quantity of renewable freshwater supply—nearly 30,000 cubic kilometers per year—is accessible to humans. Thus contemporary use represents slightly more than 10% of annual supply. However, there is a substantial range in the share of accessible runoff used by humans across different continents as well as a rapidly changing picture over the last few decades. Time series of use indicate increasing pressures on the freshwater resource base.

Between 1960 and 2000, world water use doubled from about 1,800 to 3,600 cubic kilometers per year, a rate of about 17% per decade, with a slower (10%) increase projected to 2010. (See Table 7.5.) Individual continents show increases over the 1960–2000 timeframe from 15% up to 32% per decade. MENA has historically shown a great dependence on its freshwater supply, using well over half as early as 1960 and exceeding all renewable supplies shortly after 1980. Today its withdrawals represent 120% of accessible sustainable supply, and these are projected to rise to >130% by 2010. Asia, the former Soviet Union, and OECD countries show intermediate levels of use relative to supply over this period. In sub-Saharan Africa, substantial contributions of fresh water from river basins in the wet tropics coupled with rela-

Table 7.5. Indicators of Freshwater Provisioning Services and Their Historical and Projected Trends, 1960–2010. Water use, "water crowding" (population supplied per unit accessible renewable supply), and use relative to accessible supply, by region, are shown. These figures are based on mean annual conditions. The values for the relative use statistics shown rise when the sub-regional spatial and temporal distributions of renewable water supply and use are considered. (Population from Vörösmarty et al. 2000; demand estimates from WRI et al. 1998, updated using Shiklomanov and Rodda 2003, as in Vörösmarty et al. 2000; resampled to MA reporting units)

MA Geographic Region	Population	Water Use U_a	Water Crowding on Accessible Renewable Supply[a]	Use Relative to Accessible Renewable Supply[1] (U_a/B_a)

[a] Renewable supply calculated as for Table 7.2, and refers to accessible blue water flows (B_a). Index uses full regional population.

tively poor water delivery infrastructure and restricted development mean that only 2% of renewable supply is tapped. In water-rich Latin America, relative use rates also remain low, at less than 5%.

The contemporary water crowding index is modest in almost all regions. Only MENA shows a value reflective of its well-known position as a highly water-scarce region. Over the last four decades there has been a sustained and substantial increase in the water crowding index with respect to accessible runoff, reflecting directly the impact of population growth. Worldwide, the number of people served per unit of supply has doubled during this period, at an average rate of 20% per decade. Several regions show even greater rates of increase—a tripling for MENA and sub-Saharan Africa and a more than doubling for Asia and Latin America. Globally, an additional 13% crowding in renewable supply is predicted between 2000 and 2010, with greatest regional increases expected in sub-Saharan Africa (30%) and MENA (20%). A slight slowing in rate of increase is noted globally, with near stability in the index for OECD and the former Soviet states.

Several cautionary notes are needed in interpreting these trends. The statistics are based on mean annual flows and access computed for 100% of individual continental and global populations. In the context of the 50% of continental runoff generated in dry to moderately wet climate zones (19,800 cubic kilometers per year) that serves the majority of global population, contemporary use represents nearly 20% of the mean annual supply. When seasonal variations in runoff are considered (reducing supplies to 13,900 cubic kilometers per year), withdrawals exceed 25% of the renewable resource. In addition, if dedicated instream uses of about 2,000 cubic kilometers per year for navigation, waste processing, and habitat management are considered (based on Postel et al. 1996), humans then use and regulate 40% or more of renewable accessible supplies.

Further, the crowding index does not take into account different countries' abilities to deal with water shortages. For example, high-income countries that are water-scarce may be able to cope to some degree with water shortages by investing in desalination or reclaimed wastewater. The study also discounts the use of fossil water sources because such use is unsustainable in the long term.

In addition, while the global numbers are well below the extreme scarcity threshold of 1,000 people per million cubic meters per year of renewable supply, they mask important local and regional differences and thus understate the true degree of stress (Vörösmarty et al. 2000, 2005). Prior assessments (Revenga et al. 2000) show that as of 1995 some 41% of the world's population, or 2.3 billion people, were living in river basins under water stress, with some 1.7 billion of these people residing in river basins under conditions of extreme water scarcity. From a river basin perspective, the Volta, Nile, Tigris and Euphrates, Narmada, and Colorado in the United States will show ongoing pressure through 2025 (Revenga et al. 2000). Another 29 basins will descend further into scarcity by 2025, including the Jubba, Godavari, Indus, Tapti, Syr Darya, Orange, Limpopo, Yellow, Seine, Balsas, and Rio Grande. Indicators based on mean annual conditions also mask important supply limits imposed by seasonal and inter-annual variability. For example, in India most of the annual water supply is generated as a result of the monsoons, which in many cases means both flooding downstream as well as seasonal drought.

Another measure of adequacy of the freshwater supply is the mean use-to-supply ratio. A set of thresholds for water stress was given by the United Nations in a recent global analysis that used this ratio based on mean annual conditions (WMO 1997): low (<10%), moderate (10–20%), medium/high (20–40%), and high (>40%). Using this classification and a grid-based approach necessary to capture the high degree of spatial heterogeneity (see Vörösmarty et al. 2000), the contemporary global-scale ratio is from low-to-moderate, as seen in Table 7.5, although entire continents are under a moderate (Asia, former Soviet Union, and OECD) to high (MENA) state of scarcity. This is in stark contrast to the situation in 1960, when uniformly low levels of scarcity were noted (with the exception of MENA). Globally, it has been shown that 2.5 billion people suffer from at least moderate levels of chronic water stress (Vörösmarty et al. 2000) and from 1–2 billion people suffer high levels of scarcity even when tabulations are made conservatively on total renewable supplies. Calculating the population at risk through a ratio based on accessible supplies would increase the overall exposure to stress.

Water scarcity as a globally significant problem is a relatively recent phenomenon, evolving only over the last four decades. Rates of increase in the relative use ratio from 1960 to the present averaged about 20% per decade globally, with values from 15% to more than 30% for individual regions. A slowing in the rate of increase in use is projected between 2000 and 2010, to 10% per decade globally. With anticipated population growth, economic development, and urbanization, a further increase in the relative use ratio for some continents is likely to remain high (MENA at 14% per decade, Latin America at 16%, and sub-Saharan Africa at 20%).

7.2.4 Environmental Flows for Ecosystems

In light of the expanding use of fresh water by humans and several indicators of growing water stress, an important issue emerges with respect to the sustainability of water provisioning services—that is, being able to continue providing water for human use while also meeting the water requirements of aquatic ecosystems so as to maintain their capacity to provide other services. ''Environmental flows'' refers to the water considered sufficient for protecting the structure and function of an ecosystem and its dependent species. These flow requirements are defined by both the long-term availability of water and its variability and are established through environmental, social, and economic assessment (King et al. 2000; IUCN 2003).

Determining how much water can be allocated to human uses or distorted through flow stabilization (such as dam construction) without loss of ecosystem integrity is central to an understanding of how freshwater ecosystems support human well-being through the range of provisioning, supporting and regulating services. Assessment of water availability, water use, and water stress at the global scale has been the subject of on-going research. However, water requirements of aquatic ecosystems are only now being estimated globally and considered explicitly in these assessments (Smakhtin et al. 2003). Flow requirements can range globally from 20% up to 80% of mean annual flow, depending on the river type, its species composition, and the river health condition objectives sought (for instance, pristine, moderate modification from natural conditions, minimum flows), indicating the high degree of potential conflict with river regulation and human uses should the environment be preserved.

If human systems are viewed as being embedded within natural systems, human water use can expand to a ''sustainability boundary'' beyond which a substantial degradation of ecosystem services results (King et al. 2000; Postel and Richter 2003). Determining the location of the sustainability boundary is critical to successful management and rests on clearly defining what constitutes a degraded ecosystem. Environmental flows should consider both the quantity and timing of flow to maintain ''naturally variable flow regimes'' (Poff et al. 1997), whereby seasonal flow patterns are maintained with the aim of retaining the benefits provided by low and high flows. (See Figure 7.4.) Naturally low flows, for example, help exclude invasive species while high flows, especially floods, shape channels and allow the delivery of nutrients, sediments, seeds, and aquatic animals to seasonally inundated floodplains. High flows may also provide suitable migration and spawning cues for fish (Poff et al. 1997; Baron et al. 2002).

7.2.4.1 Global Trends in Water Diversion and Flow Distortion

While global trends in altered water regime are difficult to assemble with certainty due to incomplete information, they reflect an overall increase in regulation of the world's inland river systems (Revenga et al. 2000; Vörösmarty and Sahagian 2000). Tables 7.4 and 7.5 provided an indication of the scope of such changes. Water withdrawals show a doubling between 1960 and 2000, by which time irretrievable losses from irrigation alone totaled 34% of all global use.

One third of all rivers for which contemporary and predisturbed discharges could be compared in a compendium (Meybeck and Ragu 1997) showed substantial declines in discharges to the ocean. Long-term trend analysis (more than 25 years) of 145 major world rivers indicated more than one fifth with declines in discharge (Walling and Fang 2003). From 1960 to 2000 there was a near quadrupling of reservoir storage capacity and more than a doubling of installed hydroelectric capacity (Revenga et al. 2000). Worldwide, large artificial impoundments (storing each 0.5 cubic kilometers or more) now hold two to three months of runoff, capable of significant hydrograph distortion, with several major basins showing storage potentials of greater than a year's runoff (Vörösmarty et al. 2003). Much of this regulation occurred over the last 40 years.

Through consumptive use and interbasin transfers, several of the world's largest rivers (Nile, Yellow, Colorado) have been transformed into highly stabilized and in some cases seasonally nondischarging river channels (Meybeck and Ragu 1997; Kowalewski et al. 2000). In the case of the Yellow River, improved water management since 2000 has helped to restore flows (MWR 2004).

7.2.4.2 Recent History of Governance and Management for Environmental Flows

Over the last decade, policy solutions to developing environmental flows have taken several forms, depending on social and historical context, degree of scientific knowledge, water infrastructure,

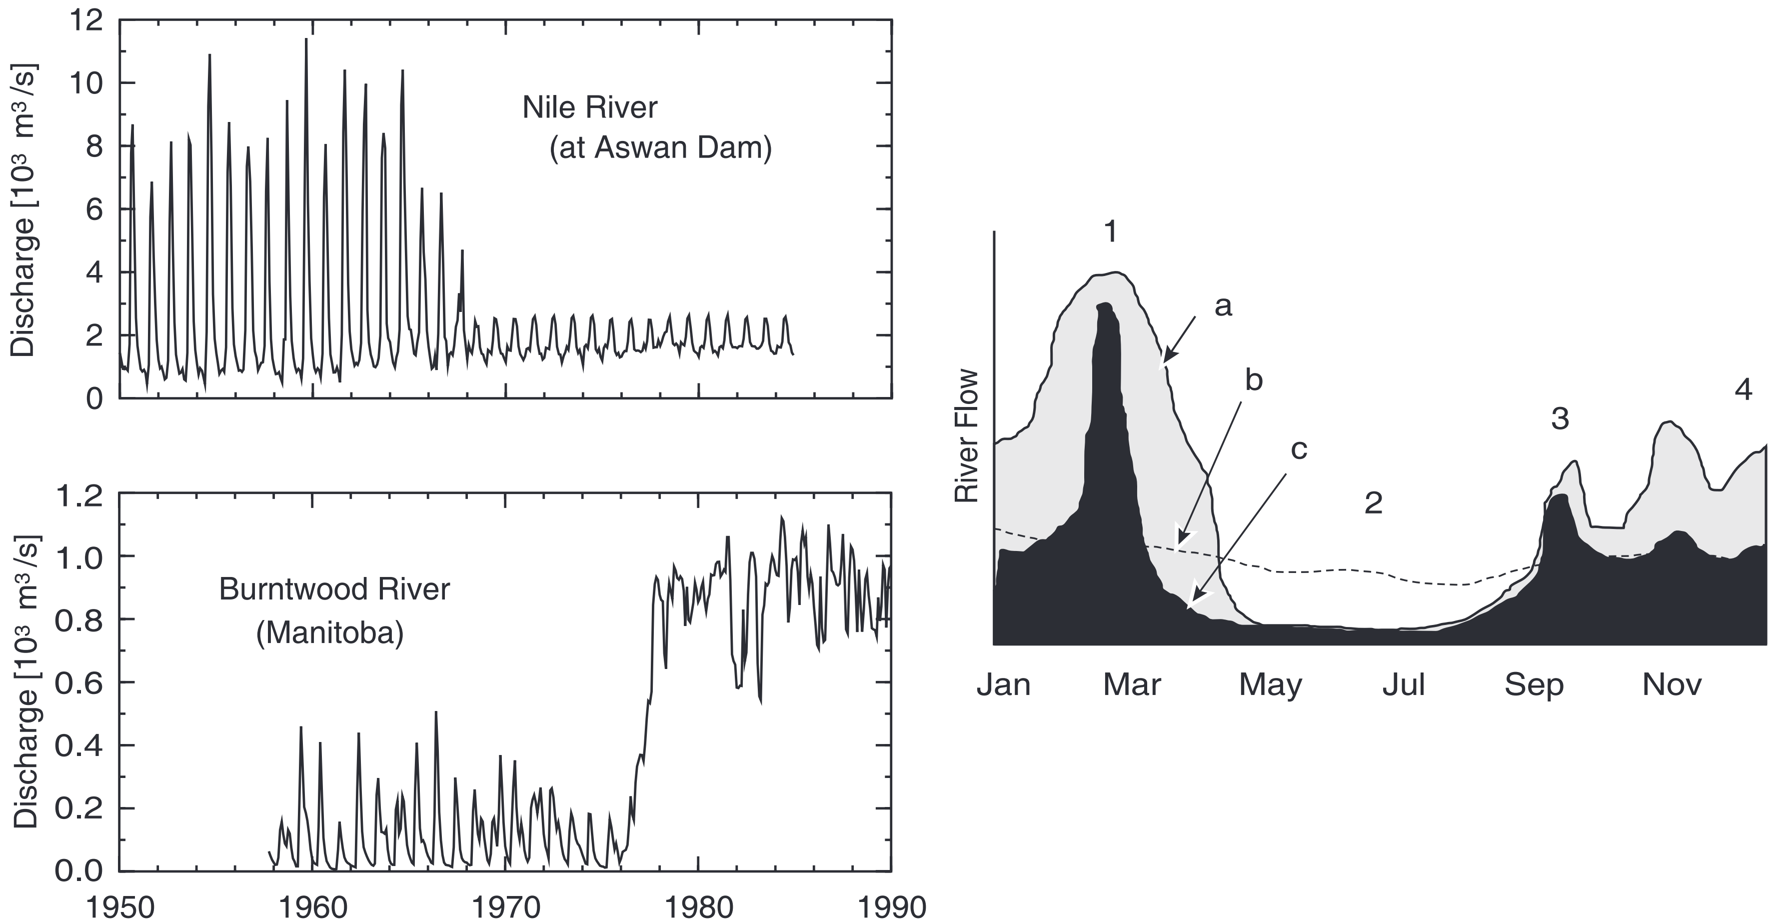

Figure 7.4. Managing for Environmental Flows: Contrasts among Natural, Reservoir-affected, and Reconstituted River Discharge Regimes. Observed alteration of natural flow regimes (left) arises from the provision of freshwater services, as through impoundment on the Nile River and interbasin transfer to optimize hydropower on the Burntwood River (Vörösmarty 2002). Environmental flow management attempts (right) to preserve key facets of the (a) natural flow regime in light of (b) typical 20th century flow distortion after damming. Condition (c) represents a partially "re-naturalized" flow regime, which retains important hydrologic characteristics: 1) peak wet season flood, 2) baseflow during the dry season, and 3) a "flushing" flow at the start of the wet season to cue life cycles, and 4) variable flows during the early wet season. Flow regime (b) shows many more negative effects than (c), even though both regulate similar volumes of water annually. (Right panel adapted from Tharme and King 1998)

and local ecosystem conditions. These approaches include managing the quantity and temporal pattern of water withdrawals or releases (Poff 2003; Postel and Richter 2003), developing water markets, and preemptively managing land use to protect watersheds.

Water allocation for environmental flows to sustain functioning freshwater ecosystems is practiced in parts of Australia, Europe, New Zealand, North America, and South Africa. However, there appears to be very little consideration of this matter anywhere in Asia, despite aggressive water extraction from many rivers during the dry season across the continent. But there is cause for cautious optimism. The calculation, adoption, and implementation of environmental flows are under consideration in other parts of the world. In addition, more than 2,000 river, lake, and floodplain restoration projects in at least 20 countries, particularly in Europe but also in Africa and Asia, are being carried out (DRRC 1998; UKRRC 2004; Richter et al. in prep.). Some key examples include the restoration of the Diawling delta in Mauritania (Hamerlynck and Duvail 2003), the Waza Logone floodplain in Cameroon (Loth 2004), the Danube and Rhine Rivers, and the South Florida Everglades—one of the largest ecosystem restoration projects ever attempted (Baron et al. 2002).

The shift toward management for natural flow regimes is also reflected by parallel shifts in public policy from laws favoring private interests and prior appropriations (as in much of the American West) to protecting water rights and environmental flows as part of the "public trust." In 1998, South Africa passed landmark legislation to aid decision-making on all or part of any significant water resource (National Water Act 1998). One of the most progressive aspects of this act was establishment of a Reserve to support both essential human needs (water for drinking, food preparation, personal hygiene) and aquatic ecosystem integrity. Notably, this two-part Reserve—with human and environmental components—takes priority over other uses such as irrigation and industrial withdrawal. In Burkina Faso, a new water framework law (Loi d'Orientation sur L'eau), adopted in 2001, establishes the legal and institutional framework for promoting integrated basin management, equitable access, water for nature, and international cooperation. The legislation recognizes that "infrastructures which are built on a water course must maintain a minimal flow that guaranties aquatic life" (MEE 2001).

For many highly regulated river systems in North America (e.g., Colorado, Columbia, Missouri, Savannah), recent changes in dam operations and adaptive management plans are now fostering conditions that improve fish habitat, river-floodplain connectivity, and estuarine ecosystems, often at the cost of hydroelectric generation or navigability to barges (Postel and Richter 2003; Richter et al. in prep.). In addition, the decommissioning and removal of some dams has begun in the United States (Hart et al. 2002). In Australia, water allocation reforms have led to limits on future withdrawal (that is, a "water cap") in the Murray-Darling River basin, subsequent development of a water market where allocations are traded, and creation of incentives to increase water productivity and efficiency (Blackmore 1999; MDBC 2004). Similarly, water markets developed in Mexico, Chile, and some western states in the United States have been used to secure flows for ecosystems (Thobani 1997).

Watershed management strategies that integrate ecological principles have been used to prevent water supply crises from developing. An often-cited example is the New York City water supply management strategy, which includes protection of riparian habitat in the nearby source area of the Catskills Mountains, thus eliminating the need to construct a water filtration plant at an estimated cost of $6 billion. The ~400,000-hectare Pinelands National Reserve in nearby New Jersey is regulated under a Comprehensive Management Plan developed at the local, state, and federal level in 1978–79 (Good and Good 1984). The plan permits a wide spectrum of land use development categories, ranging from intensive development to full protection, and it successfully redirected human activities to areas deemed appropriate while protecting a large core area, which is ecologically sensitive, drought-prone, and nutrient-poor and which harbors a unique community of wildlife with a large number of endemic species (Walker and Solecki 1999; Bunnell et al. 2003). The benefits of maintaining high water quality are recognized outside the reserve through the delivery of relatively high-quality fresh water to an estimated 9 million people in New York City for less than if a water filtration plant were built. In addition, water discharged into Delaware Bay helps to support populations of anadromous fish and spawning horseshoe crabs, which in turn support large numbers of migrating shorebirds and local industries.

7.2.5 Water Quality

Summarizing patterns and trends in water quality, particularly at a global scale, encompasses an array of challenges that include basic definitional problems, a lack of worldwide monitoring capacity, and an inherent complexity in the chemistry of both natural and anthropogenic pollutants. From a management perspective, water quality is defined by its desired end use. Water for recreation, fishing, drinking, and habitat for aquatic organisms thus require higher levels of purity, whereas for hydropower, quality standards are much less important. For this reason, water quality takes on a broad definition as the "physical, chemical, and biological characteristics of water necessary to sustain desired water uses" (UN/ECE 1995).

Natural water chemistry is inherently highly variable over space and time (Meybeck and Helmer 1989; Meybeck 2003), and aquatic biota are adapted to this variability. With added pressure from human activities, the biogeophysical state of inland waters plus their variability is altered, often to the detriment of aquatic species (see Chapter 20), thereby compromising the sustainability of aquatic ecosystems. Many chemical, physical, biological, and societal factors affect water quality: organic loading (such as sewage); pathogens, including viruses in waste streams from humans and domesticated animals; agricultural runoff and human wastes laden with nutrients (such as nitrates and phosphates) that give rise to eutrophication and oxygen stress in waterways; salinization from irrigation and water diversions; heavy metals; oil pollution; literally thousands of synthetic and persistent engineered chemicals, such as plastics and pesticides, medical drug residues, and hormone mimetics and their by-products; radioactive pollution; and even thermal pollution from industrial cooling and reservoir operations.

Furthermore, despite important improvements in analytical methodologies (UN/ECE 1995; Meybeck 2002), the capacity to operationally monitor contemporary trends in water quality is even more limited than monitoring the physical quantity of water. In terms of the spatial coverage, frequency, and duration of monitoring, data currently available for global and regional-scale assessments are patchy at best, leading to oversimplified and sometimes misleading information. (See Table 7.6.)

Data abundance is generally associated with level of economic development: industrial countries show a higher level of data availability, while water quality in developing countries is less well monitored. Even when data from monitoring stations are available, they only provide a fragmented view of water quality issues for very local sections of rivers, necessitating potentially unreliable extrapolation to the rest of the basin (Meybeck 2002). For this reason, water quality assessments or trajectories are usually river- or station-specific. Even for the best-represented regions of the globe, a coherent time series of data is available for only the last 30 years or less, constraining the ability to clearly quantify trends in water quality.

Data comparability problems are yet another constraint on the utility of water quality data. Standardized protocols, in terms of sampling frequency, spatial distribution of sampling networks, and chemical analyses, are still not in place to ensure the production of comparable data sets collected in disparate parts of the world. The monitoring of groundwater supplies is even more problematic (Meybeck 2003; Foster and Chilton 2003); because ground-

Table 7.6. Data Assessment of Existing Monitoring Programs Worldwide. The entries relate to the quantity of available data, indicated by the number of + symbols. For the purposes of this assessment, data quantity is an aggregate measure of station network density, spatial coverage, frequency of data collection, and duration of monitoring programs. (Updated from Vörösmarty et al. 1997b)

water is hidden from view, many pollution and contamination problems that affect supplies have been more difficult to detect and have only recently been discovered.

These many factors make it difficult to estimate the impact of changing water quality on global water supply. The following sections provide an overview assessment of trends in water quality that have bearing on the capacity of the contemporary water cycle to provide provisioning services for fresh water and on the sustainability of inland water systems. Other assessments specifically target water quality issues over selected regional-to-continental domains (e.g., AMAP 2002; Hamilton et al. 2004).

7.2.5.1 General Trends in Water Quality

The state of inland water quality illustrates the long-term and complex nature of human interactions with their environment. The earliest changes attributable to humans likely occurred in tandem with land use change in small to medium-sized catchments some 5,000 or 6,000 years ago in the Middle East and Asia, where water and sediment budgets were substantially altered (Wasson 1996; Vörösmarty et al. 1998b; Alverson et al. 2003; Meybeck et al. 2004). Water also has been considered since ancient times to be the preferred medium for cleaning, transporting, and disposing of wastes—establishing a tradition that today has substantially transformed the physical, biological, and chemical properties of global runoff.

A set of syndromes depicting riverine changes arising from anthropogenic pressures has been proposed (GACGC 2000; Meybeck 2003) through which society transforms inland fresh waters from a pristine state fully controlled by the natural Earth system to a modern condition in which humans provide many of the predominant controls. In most of the densely populated areas of the world, river engineering, waste production, and other human impacts have significantly changed the water and material transfers through river systems (Vörösmarty and Meybeck 1999, 2004) to the extent that this now likely exceeds the influence of natural drivers. This is true today in many parts of the Americas, Africa, Australasia, and Europe (Vörösmarty and Meybeck 1999, 2004).

The contrast between pristine and contemporary states can be dramatic and potentially global in scope. Changes to the global nitrogen cycle are emblematic of those in water quality more generally, through which high concentrations of people or major landscape disturbances (such as industrial agriculture) translate into a disruption of the basic character of natural water systems. In addition, modern changes often ''reverberate'' far downstream of the original point of origin. Compared with the preindustrial condition, loading of reactive nitrogen to the landmass has doubled from 111 million to 223 million tons per year (Green et al. 2004) or possibly 268 million tons (Galloway et al. 2004). (See also Chapter 12.) Model results show these accelerated loadings transformed into elevated freshwater transports through inland waterways to the coastal zone, doubling pre-disturbance rates from 21 million to 40 million tons per year (Green et al. 2004; Seitzinger et al. 2002). North America, continental Europe, and South, East and Southeast Asia show the greatest change. (See Figure 7.5 in Appendix A.)

Riverine transport of dissolved inorganic nitrogen (immediate precursors to nutrient pollution, algal blooms, and eutrophication) have increased substantially from about 2–3 million tons per year from the preindustrial level to 15 million tons today, with order-of-magnitude increases in drainage basins that are heavily populated or supporting extensive industrial agriculture. Rivers with high concentrations of inorganic nitrogen constitute a major global source for inorganic nitrogen, despite relatively modest contributions to aggregate water runoff. (See Figure 7.6.) While it is noteworthy that aquatic ecosystems ''cleanse'' on average 80% of their global incident nitrogen loading (Green et al. 2004; Howarth et al. 1996; Seitzinger et al. 2002; Galloway et al. 2004), the intrinsic self-purification capacity of aquatic ecosystems varies widely and is not unlimited (Alexander et al. 2000; Wollheim et al. 2001). As a result, sustained increases in loading from land-based activities are already reflected in the deterioration of water quality over much of the inhabited portions of the globe, they extend their impacts to major coastal receiving waters (e.g., Rabalais et al. 2002), and they are likely to continue well into the future (Seitzinger and Kroeze 1998).

While the stark contrast between pristine and contemporary states demonstrates the overall impact of anthropogenic influences on water quality, much of the contamination of fresh water has occurred over the last century. The main contamination problems 100 years ago were fecal and organic pollution from untreated human wastewater. Even though this type of pollution has decreased in the surface waters of many industrial countries over the last 20 years, it is still a problem in much of the developing world, especially in rapidly expanding cities (WMO 1997; UN/WWAP 2003). (See also Chapter 27.)

In developing countries, sewage treatment is still not commonplace, with 85–95% of sewage discharged directly into rivers, lakes, and coastal areas (UNFPA 2001; Bouwman et al. 2005), some of which are also used for water supply. Consequently, water-related diseases, such as cholera and amoebic dysentery, among others, claim millions of lives annually (WHO/UNICEF 2000). In Europe, organic pollution and contamination by toxic metals are probably now less than the levels observed between the 1950s and1980s, due to improved environmental regulation (Meybeck 2003). In the developing world, the riverine evolution is likely to be similar to that found in Europe, with a major lag corresponding to their different stages of industrialization, urbanization, and intensification of agriculture (Meybeck 2003).

New pollution problems from agricultural and industrial sources have emerged in industrial and developing countries and have become one of the biggest challenges facing water resources in many parts of the world (WMO 1997). In Western Europe and North America, on the one hand phosphorus contamination in waterways has been reduced considerably with the introduction

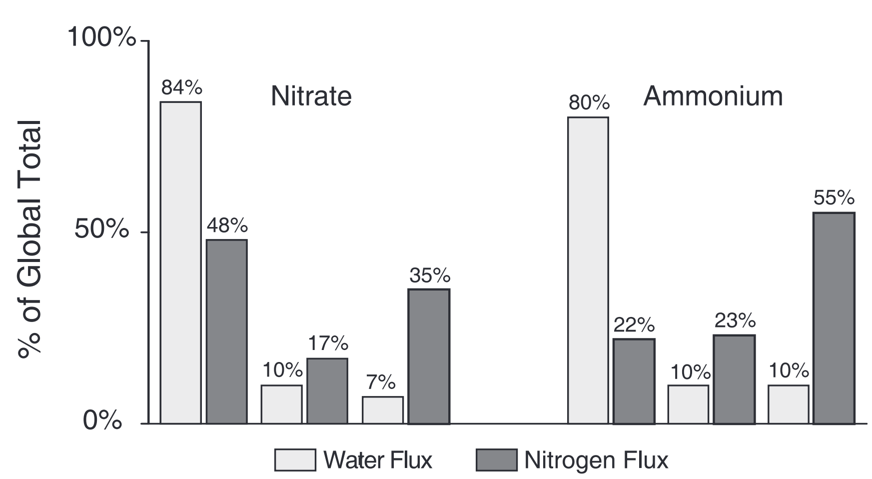

Figure 7.6. Global Summary of Inorganic Nitrogen Transport by Contemporary Rivers. Modern patterns of pollution from anthropogenic sources have created characteristically high-impact regions or ''hotspots'' that represent highly polluted river systems that today carry much greater quantities of nitrogen than their collective discharge would indicate. (Meybeck and Ragu 1997; Vörösmarty and Meybeck 2004)

of phosphate-free household detergents, investments in wastewater treatment plants, and to some degree modified agroecosystem management. On the other hand, residues of synthetic pharmaceuticals for humans and livestock are increasingly being discovered at low doses in rivers and lakes (Schiermeier 2003). There are indications that these residues can disturb the physiology of invertebrates, and it is still a matter of debate whether and, if so, to what degree these newly discovered pollutants may affect human physiology (Daughton and Ternes 1999; Jones et al. 2003).

Water contamination by pesticides has grown rapidly since the 1970s. In a medium-sized river basin like the Seine, over 100 different types of active molecules from pesticides can be found (Chevreuil et al 1998). Even if the use of xenobiotic substances is increasingly being regulated in Western Europe and North America, bans—when they exist—occur generally two to three decades after the first commercial use of the products. For example, DDT, atrazine (a common pesticide), and PCBs were in use for a long time before they were banned in parts of the industrial world. In general these bans take longer to implement in the developing world, so these products are still commercialized and used in some countries.

In the United States, PCB and DDT records in estuarine sedimentary archives peaked in the 1970s and are now markedly decreasing (Valette-Silver 1993). At the same time, persistent xenobiotics are widespread, with a recent study (Kolpin et al. 2002) finding traces of at least one drug, endocrine-disrupting compound, insecticide, or other synthetic chemical in 80% of samples from 139 streams in 30 states of the United States. The persistence of these products in continental aquatic systems can be high, and their degradation products can be more toxic than the parent molecules (Daughton and Ternes 1999). Because of the poor monitoring of the long-term effects of xenobiotics, the global and long-term implications of their use cannot be fully assessed.

7.2.5.2 Global Ranking of Water Quality Issues Based on Regional Assessment

A global water quality assessment, originally as part of the Dublin International Conference on Water and the Environment and in preparation for the Rio Summit (Meybeck et al. 1991) is summarized here. The original report determined a global ranking of key water quality issues based on U.N. Global Environmental Monitoring System data, the perceptions of local/regional scientists and managers, published reports and papers, and expert knowledge. Lakes, groundwater, and reservoir issues were considered, although as Siberia and northern Canada were not expressly covered in the 1991 report, these have been considered separately using the same approach (Meybeck 2003). Eleven variables were considered and ranked, the scoring of which ultimately reflects the aggregate impact of human pressures, natural rates of self-purification, and pollution control measures.

The results show that pathogens and organic matter pollution (from sewage outfalls, for example) are the two most pressing global issues (see Figure 7.7), reflecting the widespread lack of waste treatment. As water is often used and reused in a drainage basin context, a suite of attendant public health problems arises, thus directly affecting human well-being. At the other extreme, acidification is ranked #10 and fluoride pollution #11. The importance of the various issues varies between regions, however, and some of these globally low-ranked issues are particularly important in certain areas, such as acidification in Northern Europe, salinization in the Arabic peninsula, and fluoride in the Sahel and African Great Lakes (see maximum scores on Figure 7.7). Fluoride and salinization issues are mostly due to natural conditions (rock types and climate), but mining-related salinization can also be found (for instance, in Western Europe). All other concerns directly arise through human influences. An annotated continental summary is given in Table 7.7.

Although these updated results correspond well to the state of water quality in the 1980–90s (Meybeck 2003), since the 1990s the situation in most developing countries and countries in transition is likely worse in terms of overall water quality. In Eastern Europe, Central and South populated Americas, China, India, and populated Africa, it is probably worse for metals, pathogens, acidification, and organic matter, while for the same issues Western Europe, Japan, Australia, New Zealand, and North America have shown slight improvements. Nitrate is still generally increasing everywhere, as it has since the 1950s. In the former Soviet Union there has been a slight improvement in water quality due to the economic decline and associated decrease in industrial activities. Eastern Europe has also seen some improvements, such as those in the Danube and the Elbe basins. A few rivers, such as the Rhine, have seen a stabilization of nitrate loads after 1995.

7.3 Drivers of Change in the Provision of Fresh Water

The drivers of change in the global water cycle and the system's capacity to generate freshwater provisioning services act on a variety of spatial and time scales. Throughout history, humans have pursued a very direct and growing role in shaping the character of inland water systems, often applied at local scales, but sometimes reflecting provincial or national policies on water. The collective significance of human influences on the hydrologic cycle may today be of global significance, but this has only recently begun to be articulated (Vörösmarty and Meybeck 2004).

Humans today control and use a significant proportion of the runoff—from 40% to 50% (Postel et al. 1996)—to which the vast majority has access. Given high numbers of people dependent on water provisioning services derived from ecosystems and the growing degree of water crowding, urbanization, and industrialization, the global water cycle is and will continue to be affected strongly by humans.

Water engineering to facilitate use by humans has fragmented aquatic habitats, interfered with migration patterns of economically important fisheries, polluted receiving waters, and compromised the capacity of inland water ecosystems to provide reliable, high-quality sources of water. Land cover changes have also altered the patterns of runoff and created sources of pollution, negatively affecting human health, aquatic ecosystems, and biodiversity. (See Chapter 20.) Due to a growing reliance on irrigated agriculture for domestic food production and international trade, freshwater services—in decline in many parts of the world through non-sustainable resource use practices—are directly linked to the global food security issue. (See Chapters 8 and 26.) Finally, natural climate variability and anticipated changes associated with greenhouse warming convey additional, major constraints on the provision of renewable freshwater services.

7.3.1 Population Growth and Development

Population growth is a major indirect driver of change in the provision of fresh water. Although freshwater supplies are renewed through a more or less stable global water cycle that produces precipitation in excess of evapotranspiration over the continents, the mean quantity of water supply available per capita is ever-decreasing due to population growth and expanding con-

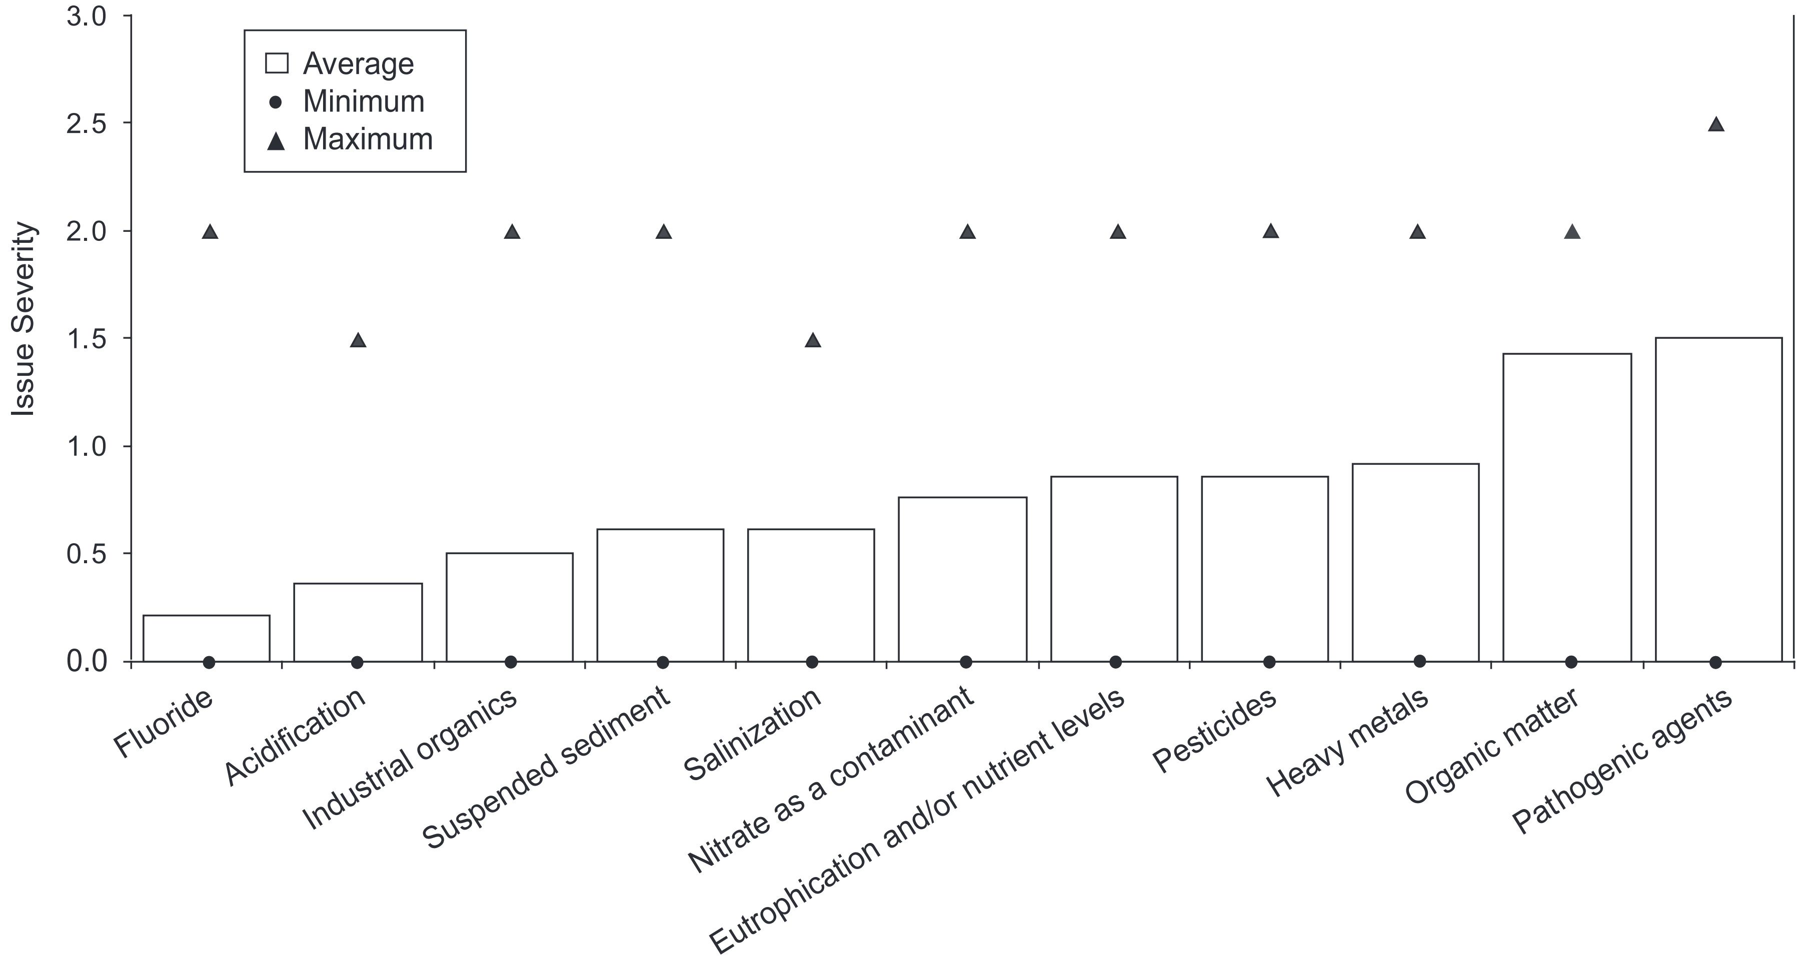

Figure 7.7. Ranking of Globally Significant Water Quality Issues Affecting the Provision of Freshwater Services for Water Resource End Uses. Averages show the general tendencies for specific pollutants, but a wide range is noted, with minima in all cases ranked zero and maxima often several times more severe than the mean condition. Although this ranking shows organic matter pollution and pathogens to be relatively more important at the global scale, information to quantify the degree to which water supplies are compromised by pollution is currently insufficient. Scores are as follows: 0: No problem or irrelevant; 1: Some pollution, water can be used if appropriate measures are taken; 2: Major pollution with impacts on human health and/or economic use, or aquatic biota; 3: Severe pollution—impacts are very high, losses involve human health and/or economy and/or biological integrity. (Based on expert opinion; Meybeck et al. 1991, updated by Meybeck 2003)

sumptive use (Shiklomanov and Rodda 2003). Human population doubled from 1960 until the present (Cohen 2003), and nearly 20 contemporary cities are home to 10 million people or more (Cohen 2003). Substantial flow stabilization and increased withdrawals have occurred across all regions, supporting an increase in the number of people sustained by the accessible, renewable water supply.

Continued growth in population will fuel increases in food production, which in the context of a stable cropland base (Bruinsma 2003) will require greater diversions of fresh water for irrigation or considerably more efficient use of water supplies. The same applies to industry and municipalities, amplifying current pressures on the global water supply. Economic development, technology, and lifestyle changes (such as increasing meat consumption) further define the functional availability of water in the context of declining per capita supplies. Over the twentieth century, water withdrawals increased by a factor greater than six—more than twice the rate of population growth (WMO 1997).

In addition to increased water demands, as mentioned in section 7.2.5, pollution from industry, urban centers, and agricultural runoff limits the amount of surface and groundwater available for domestic use and food production. Threats of water quality degradation are most severe in areas where water is scarce because the dilution effect is inversely related to the amount of water in circulation.

7.3.2 Managed Water Supplies

A broad array of water engineering schemes has enabled variability in the hydrologic cycle to be controlled and increasing amounts of water to be stored and withdrawn for human use. This technology refers to any sort of engineering used in the storage, management, and distribution of water, such as dams, canals, water transfers, irrigation ditches, levees, and so on. It also includes both traditional water harvesting techniques as well as modern production and treatment facilities like desalinization plants.

Global patterns of water management are not driven solely by investments in technology and large-scale engineering. Water is also managed through international trade, by way of the embodied or ''virtual'' water content of commodities exchanged. The agricultural sector, in particular, requires huge amounts of rainfall or irrigation water, much of which is lost to evapotranspiration, and in the case of irrigation there are also transit losses. Water input-to-crop output ratios, expressed on a weight-to-weight basis, vary from the hundreds to the thousands. Given enormous contrasts in local availability of fresh water, there is a potentially enormous comparative advantage in virtual water trade strategies that transport products from water-rich to water-poor areas.

This section first assesses the role of major engineering works in the provision of water and then considers the significance of virtual water trade of agricultural products in the global economy.

Table 7.7. Continental-scale Assessment of Major Water Quality Issues. The purpose of this table is to present a general overview. It does not capture fully large sub-regional differences that are known to occur. (Updated from Meybeck et al. 1991)

Continental Domain	Summary of Key Findings
Africa	Major sources of pollution in Africa, according to the 1992 assessment, are fecal contamination; toxic pollution downstream of major cities, industrial centers, and/or mining; and vector-borne diseases. The Nile Basin and Northern Africa show more contamination problems than other regions, but this also may be because of more information and monitoring stations in these regions, or more altered water flows that affect dilution potential in rivers.
Americas	In the United States and Canada, the major pollution problem is eutrophication from agricultural runoff and acidification from atmospheric deposition. Major problems also include persistent toxic water pollution from point and non-point sources. In South and Central America the major contaminant problems, except in the Amazon and Orinoco basins, where ecosystems are more intact and high flows foster dilution, are pathogens and organic matter, as well as industrial and mining discharges of heavy metals and pesticide and nutrient runoff.
Asia and the Pacific	Arid and semiarid regions tend to have different pollution problems than areas in the monsoon belt. In the Indian subcontinent the major problems are pathogens and contamination from organic matter. While these are prevalent in Southeast Asia as well, heavy metals, eutrophication, and sediment loads from deforestation are also critical in this sub-region. The Pacific Islands have higher levels of salinization than other regions in Asia, while still having problems with pathogens and organic matter, like much of the developing world. China has a combination of all pollution problems in its major watersheds. In the dry north, eutrophication, organic matter, and pathogens are major problems, while in the south in addition there is a large sedimentation problem. Finally, Japan, New Zealand, and Australia present similar pollution problems as other industrial nations, like the United States and Europe. Australia has particular problems with salinization due to agricultural practices, especially in the Murray-Darling Basin.
Europe	In the Nordic countries the major problem is acidification, while other contaminant levels are relatively low. In Western Europe eutrophication and nitrates pose the greatest challenge, while in Southern and Eastern Europe the major contaminants are organic matter and pathogens, nitrates, increasingly pesticides, and eutrophication.
Eastern Mediterranean and Middle East	Characterized by its arid climate, this area shows great demands and pressure on its scarce water resources. Industrial pollution and toxics are a problem in some locales, but overall salinization from overabstraction is the key concern in this region.

7.3.2.1 The Role of Engineering on Water Supply

7.3.2.1.1 Dams and reservoirs

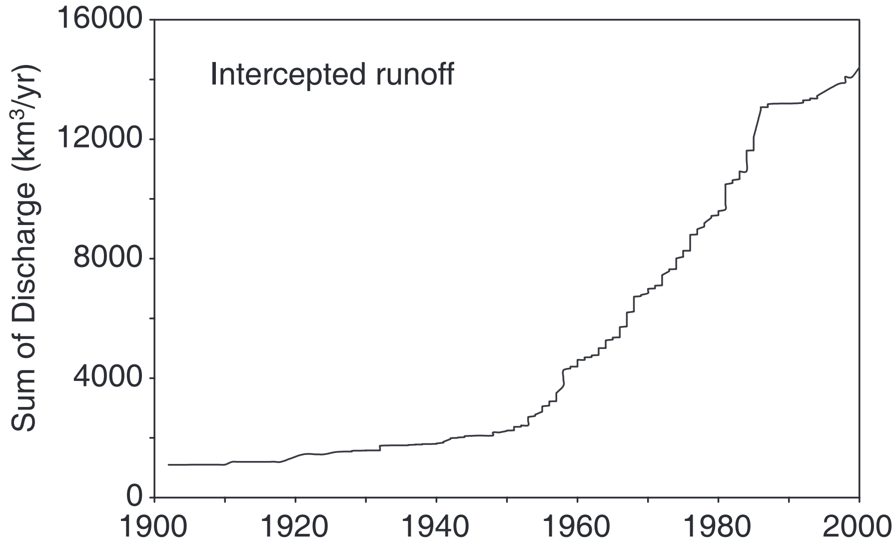
Humans have altered waterways around the world since historical times to harness more water for irrigation, industry, and domestic and recreational use. Dams have been a particularly significant driver of change, buffering against both spatial and temporal scarcity of water supplies and increasing the security of water and food supply over the past half-century. However, large engineering works that impound and divert fresh water have caused damage to key habitats and migratory routes of important commercial and subsistence fisheries (Revenga et al. 2000), as well as serious societal disruptions, including public health problems (as described later; see also Chapter 14) and forced displacements (WCD 2000).

Large dams are today the fundamental feature of water management across the globe (FC/GWSP 2004). Approximately 45,000 large dams (>15 meters in height) (WCD 2000) and possibly 800,000 smaller dams (McCully 1996; Hoeg 2000) are in place and an estimated $2 trillion has been invested in them over the last century. These facilities have served as important instruments for development, with 80% of the global expenditure of $32–46 billion per year focused on the developing world (WCD 2000).

Major stabilization of global river runoff from major engineering works expanded greatly between 1950 and 1990. (See Figure 7.8.) Currently the largest reservoirs—those with more than 0.5 cubic kilometers of storage capacity—intercept locally 40% of the water that flows off the continents and into oceans or inland seas (Vörösmarty et al. 2003). The volumetric storage behind all large dams represents from three to six times the standing stock of water held by natural river channels (Vörösmarty et al. 1997a, 2003; Shiklomanov and Rodda 2003). In addition, large reservoir construction has doubled or tripled the residence time of river water—that is, the average time that a drop of water takes to reach the sea, with the mouths of several large rivers showing delays on the order of many months to years (Vörösmarty et al. 1997a).

Such regulation has enormous impacts on the water cycle and hence aquatic habitats, suspended sediment, carbon fluxes, and waste processing (Dynesius and Nilsson 1994; Vörösmarty et al. 2003; Stallard 1998; Syvitski et al. 2005). Large dams, in particular, have been a controversial component of the freshwater debate. While contributing to economic development and food security, they also produce environmental, social, and human health impacts. A World Bank review (1996a) of the impacts and economic benefits of 50 large dams concluded that these projects showed proven economic and development benefits but had a mixed record in terms of their treatment of displaced people and environmental impacts. A further review by the World Commission on Dams on the performance of large dams showed considerable shortfalls in their technical, financial, and economic performance relative to proposed expectations, particularly irrigation dams, which often have not met physical targets, failed to recover cost, and have been less profitable than expected (WCD 2000).

In Pakistan, for example, the direct benefits from irrigation made possible by the Tarbela and Mangla dams are estimated at about $260 million annually, with the farmers who own irrigated land clearly benefiting from increased incomes (World Bank 1996a). However, the increased use of irrigation water has led to waterlogging and increased soil salinity in the Punjab area, with a



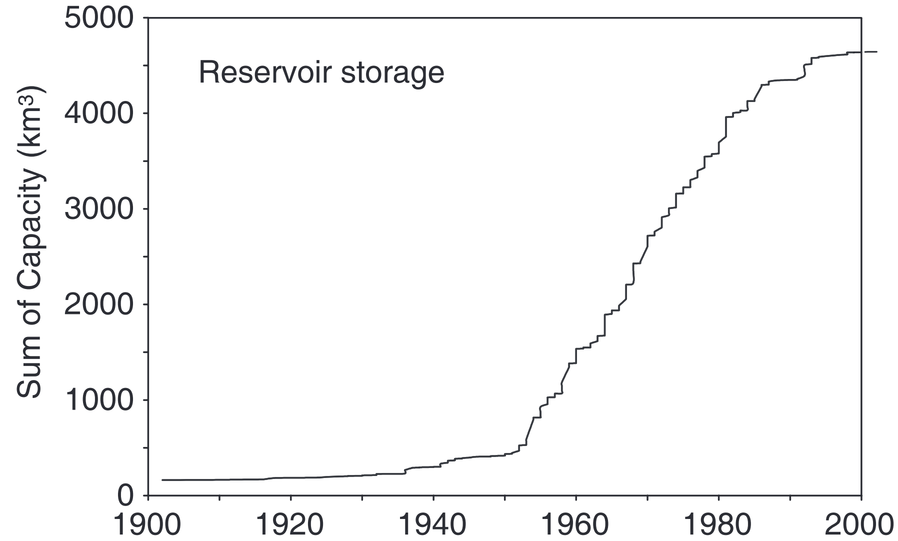


Figure 7.8. Time Series of Intercepted Continental Runoff and Large Reservoir Storage, 1900–2000. The series is taken from a subset of large reservoirs (>0.5 km³ maximum storage each), geographically referenced to global river networks and discharge. The years 1960–2000 have shown a rapid move toward flow stabilization, which has slowed recently in some parts of the world, due to the changing social, economic, and environmental concerns surrounding large hydraulic engineering works. (Vörösmarty and Sahagian 2000)

direct link to a decline in crop productivity, and an increase in malaria transmission (World Bank 1996b).

Hydroelectricity is another important benefit from dams. Total production of hydropower reached 2,740 terawatt-hours in 2001 or 19% of global electrical production, and many industrial (such as Norway and Iceland) and developing countries (Democratic Republic of Congo, Mozambique, Brazil, Honduras, Tajikistan, and Laos) rely on dams for more than 90% of their power production (UN/WWAP 2003). As with irrigation dams, in many circumstances the effectiveness of large dams for hydroelectricity generation has not been sufficient to meet the predicted benefits (WCD 2000), and they have caused loss of habitats and species as well as the displacement of millions of people (WCD 2000).

Flood control continues to be another major objective for building large dams. In Japan, for example, 50% of the population lives in flood-prone areas, and in the last 10 years floods have affected 80% of municipalities in the country. Japan is one of the top five dam-building countries in the world. Matsubara and Shimouke Dams on the Chikugo River in the Kyushu District in southern Japan, for instance, were built for flood control after a flood in 1953 inundated one fifth of the entire catchment, killing 147 people and destroying 74,000 households. These two dams successfully reduced peak flows in the river years later during a 1982 flood, saving lives and property (Green et al. 2000).

However, the effectiveness of large dams to replace the role of natural wetlands for flood mitigation is not well supported by scientific evidence. Wetlands and floodplains act as natural sponges; they expand by absorbing excess water in time of heavy rain and they contract as they release water slowly throughout the dry season to maintain streamflow. (See Chapter 20.) The large-scale conversion of floodplains and wetlands (some of it through dams) has resulted in declines in the natural mechanism for flood regulation. And while a handful of dams are being decommissioned in some countries (268 out of 80,000 in the United States, for example), an estimated 1,500 dams are under construction worldwide and many more are planned, particularly in the developing world (WWF and WRI 2004). River basins with the largest number of dams over 60 meters high planned or under construction include the Yangtze Basin in China with 46 large dams, the La Plata Basin in South America with 27, and the Tigris and Euphrates River Basin in the Middle East with 26 (WWF and WRI 2004).

The debate on cost, benefits, and performance of large dams continues, but given recent reviews (see WCD 2000), the traditional reliance on constructing such large operations for water supply is being called into question on environmental, political, and socioeconomic grounds (Gleick 1998; WCD 2000).

7.3.2.1.2 Interbasin transfers

Interbasin water transfers represent yet another form of securing water supplies that can greatly alleviate water scarcity. They include any canals, ditches, tunnels or pipelines that divert water from one river or groundwater system to another, typically from dammed reservoirs, and often represent massive engineering works involving both ground and surface waters. Changes to natural surface water hydrographs can be enormous and virtually instantaneous. The Great Man-Made River Project in Libya, for example, transports over 2 cubic kilometers of fossil groundwater a year through 3,500 kilometers of desert to huge coastal storage reservoirs that support 135,000 hectares of irrigable cropland, one third of the country's total (UN/WWAP 2003).

Two of the world's largest interbasin transfers are the 93% loss of flow (27 cubic kilometers per year) from the Eastmain River and a 97% gain of flow (53 cubic kilometers per year) in the La Grande River (Dynesius and Nilsson 1994), both in Canada. In total, the flow being diverted without return to its stream of origin in Canada alone totaled 140 cubic kilometers a year in the 1980s (Day and Quinn 1987), more than the mean annual discharge of the Nile River and twice the mean annual flow of Europe's Rhine River. The Farraka Barrage alone diverts over 9% of the Ganges River's historical mean annual flow and over 5% of the flow for the entire Ganges-Brahmaputra basin (Nilsson et al. 2005).

A gigantic diversion project is also under way in China, which proposes to move 40 cubic kilometers per year (MWR 2004) of water from southern China to the parched parts of northern China, thus connecting the Yangtze River with the Hai, Huai and Yellow Rivers. Three channels, two of which are over 1,000 kilometers long, will be needed for this transfer, which corresponds to 4% of the average flow of the Yangtze River (U.S. Embassy in China 2003). Developers plan to bring enough water to replenish groundwater aquifers in the north. This withdrawal from the Yangtze, even though it represents only a small fraction of the river's annual flow, will likely still have some effect on downstream ecosystems: sediment loads needed to maintain riparian and coastal wetlands will be reduced, and pollutants will be marginally less diluted, raising their concentration in the Yangtze River's lower reaches (U.S. Embassy in China 2003). In addition, as water flows north from one basin to another, the introduction of non-native species and the transfer of contaminants could affect native fauna in the receiving basins (Snaddon and Davies 1998; Snaddon et al. 1998; U.S. Embassy in China 2003).

Social effects of interbasin water transfers are complex. Populations in the recipient basin of water transfers gain water for irrigation, industry, and human consumption, all leading to indisputable economic and social benefits. However, those living in the basin of origin (and particularly those downstream of the diversion point) often lose precisely those same benefits (Boyer 2001), and many times they are displaced to other parts of the country, losing their homes and cultural heritage. While sometimes economic compensation is offered to people displaced by dams, the amounts usually do not cover the potential losses in terms of livelihoods, economic productivity, and cultural and historical heritage (WCD 2000).

Resettlement is an issue for water transfers as well as for dams, with many resettled communities suffering from a marginalized status, and cultural and economic conflicts with the population into which they are resettled. The central route of the Yangtze-to-Yellow water transfer in China, for example, will require the resettlement of 320,000 people, each of whom is supposed to receive the equivalent of $5,000 in compensation (U.S. Embassy in China 2003).

The trade-offs involved in interbasin transfer schemes include both direct societal costs and benefits, as well as those involving ecosystems services and biodiversity. Yet given increasing demands for water in the future, such transfers are likely to remain an important mechanism for alleviating regional water shortages (Nilsson et al. 2005).

7.3.2.2 Virtual Water in Trade

Virtual water, or VW, refers to the amount of fresh water used during the production process and thus "embodied" in a good or service (Allan 1993). While tabulations could be made for any product, VW has been explored mainly from the perspective of crop and livestock production and trade, given the predominance of agriculture in water use globally.

Operationally, VW in agriculture can be defined as the quantity of water used to support evapotranspiration in crops, which are then consumed domestically (as human food or animal feeds) or traded internationally. Additional water to process food products and to care for livestock can also be tabulated (Oki et al. 2003a), but VW estimates are fundamentally determined by irretrievable water losses through crops. There is a vast mismatch between the weight of agricultural commodities produced and the VW embodied in their production. For example, 1 kilogram of grain requires 1,000–2,000 kilograms (liters) of water, even under the most favorable of climatic conditions (Hoekstra and Hung 2002), producing 1 kilogram of cheese requires >5,000 kilograms of water, and 1 kilogram of beef requires an average of 16,000 kilograms of water (Hoekstra 2003).

Water has been transported in internationally traded products for hundreds of years, but the concept of trading VW has only recently begun to be considered as a mechanism to alleviate regional or global water security by exploiting the comparative advantage of water-rich or water-efficient countries (Allan 1996; Jaeger 2001). However, VW does not take into account the nature of food production systems and other factors, such as soil erosion, biodiversity impacts, or pollution. Moreover, for political and social reasons, countries may elect to be self-sufficient and independent in food production. For example, India, which is food self-sufficient in aggregate, serves as a net exporter of food and virtual water despite being water-stressed.

A substantial volume of VW trade in food commodities has nonetheless been taking place. (See Figure 7.9.) Worldwide, international VW trade in crops has been estimated at between 500 and 900 cubic kilometers per year, depending on tabulations made from the exporting or importing country perspective and the number of commodities considered (Oki et al. 2003a; Hoekstra and Hung 2002; Hoekstra 2003). (See Table 7.8.) An additional 130–150 cubic kilometers per year is traded in livestock and livestock products. For comparison, current rates of water consumption for irrigation total 1,200 cubic kilometers per year, and taking into account the use of precipitation in rain-fed agriculture as well, the total water use by crops has been estimated to range from 3,200 to 7,500 cubic kilometers per year, depending on whether allied agroecosystem evapotranspiration is included (Postel 1998; Rockström and Gordon 2001). The most important exporters of crop-related VW are the OECD and Latin America, though individual sub-regions, such as Western Europe, are net importers of VW. Asia (Central and South) is the largest importer of VW.

Of the top 10 virtual water exporters, 7 countries are in water-rich regions, while of the 10 largest importers of VW, 7 are highly water-short, indicating a general redistribution of VW from relatively wet to dry regions. However, the notable absence of clear-cut relationships linking the degree of domestic water scarcity to dependence on external VW supplies (Hoekstra and Hung 2002) suggests that an optimal redistribution of water through crop production and trade is yet to emerge. The consequences of food self-sufficiency thus entrench present-day patterns of water scarcity, as can decisions to pursue an aggressive export marketing strategy in the face of unsustainable water use. Future increases in water stress over the coming decades (Vörösmarty et al. 2000; Alcamo et al. 2000) and further integration of a global economy are likely to be powerful forces in adopting the notion of VW into food production and trade policies. An analysis of international trade in VW for Africa is provided in Box 7.4.

7.3.3 Land Use and Land Cover Change

Among the major processes influencing water quantity and quality at the river basin scale are changes in land use intensity and land cover change. (See Table 7.9.) Land use changes affect evapotranspiration, infiltration rates, and runoff quantity and timing. Particularly important for human well-being are contrasting reductions in the overall quantity of available runoff with some types of land cover change versus concentrated peaks of runoff associated with flooding under other land cover changes that can often be translocated far downstream through river networks (Douglas et al. 2005).

For example, expanding impervious areas due to urban expansion greatly increases the volume and rate of stormflow into receiving streams. Such changes also affect the water quality and biodiversity of freshwater ecosystems (Jones et al. 1997). Land use changes that compact soils and reduce infiltration are associated with deficiencies in groundwater recharge and dry period baseflow, the long-term global consequences of which are yet to be documented. Reduced infiltration can also lead to longer lifespans of pools with stagnant water, thus providing increased breeding opportunities for mosquitoes and other vectors of human disease.

The impact on local water budgets of changes from forest cover to pasture, agricultural, or urban land cover are well docu-

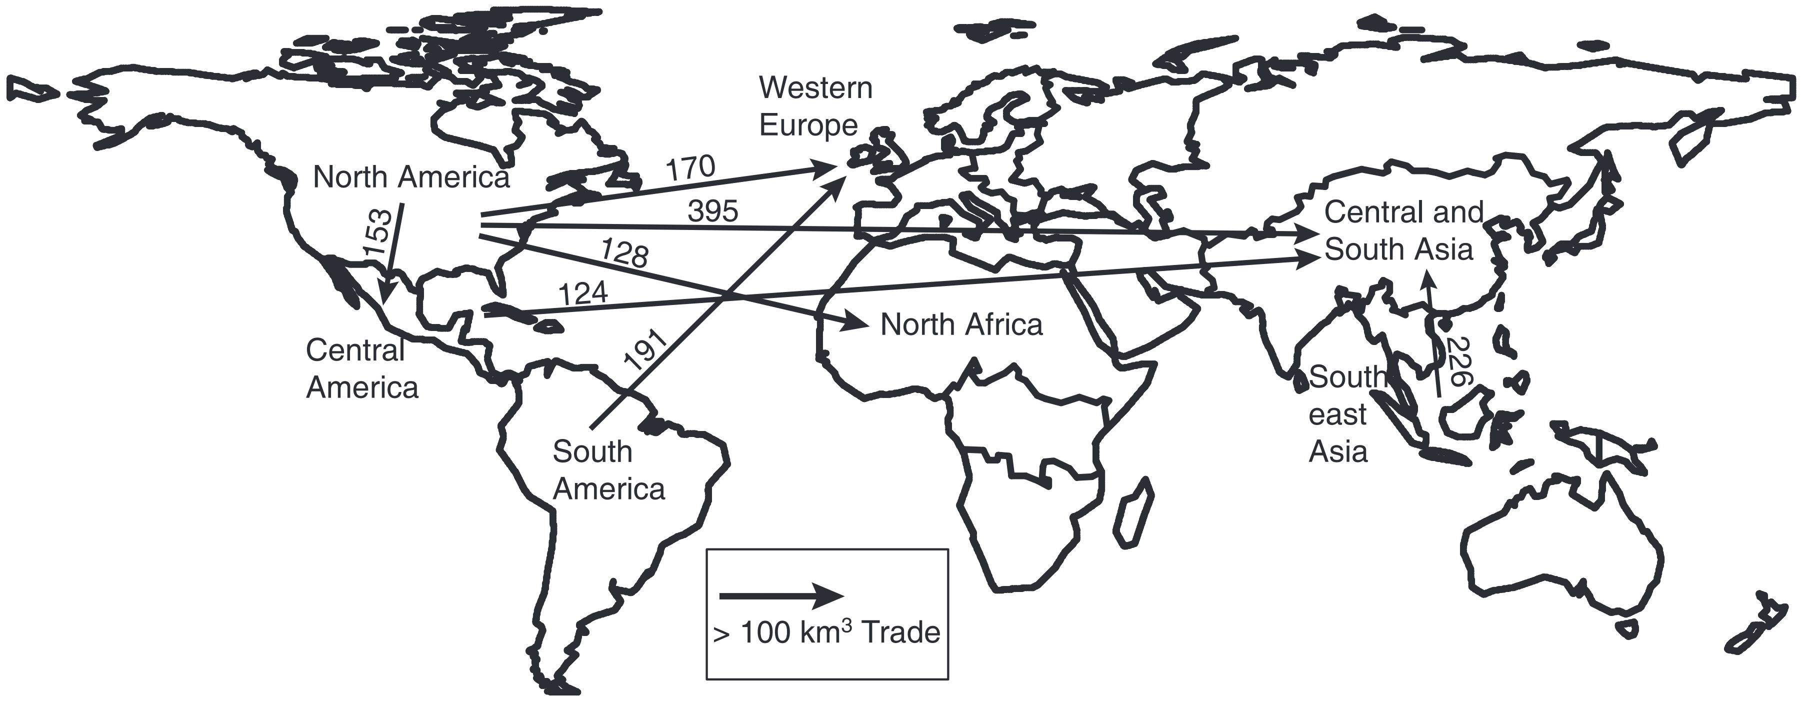

Figure 7.9. Net Inter-regional Trade in Major Crops Expressed as Embodied or "Virtual" Water Expended in Production of These Agricultural Commodities, 1995–99. The regions used differ from those used in the MA. Virtual water flows <100 km^3 for the full period are not shown. Rain-fed and irrigated agriculture are considered, although estimates do not include transfer and drainage losses during irrigation. (Hoekstra and Hung 2003)

Table 7.8. Annual Transfer of Virtual and Real Water through Global Trade of Cereal and Meat Commodities, 2000. "Virtual" water in this table is estimated as the fresh water required by the importing country to produce the commodity, while "real" water is the fresh water expended by the exporter to produce the same commodity. Water equivalents are vastly greater than the actual weights traded, from 1000:1 to 3000:1 for cereals and >20,000:1 for beef. Through such trade there is a water-saving equivalent to approximately 20% of agricultural water withdrawals. (Oki et al. 2003a)

Commodity	Virtual Water Trade	Real Water Trade	Water "Saved"
	(cubic kilometers per year)		
Maize	130	50	80
Wheat	460	270	190
Rice	190	110	80
Barley	92	38	54
Cereal total	870	470	400
Beef	86	82	4
Pork	28	20	8
Chicken	37	25	12
Meat total	150	130	24

mented in the hydrological and ecological literature. While historically a large portion of the available information was generated for temperate and boreal areas of North America and Europe (Swank and Crossley 1988; Buttle et al. 2000), information is becoming available for selected sites in Amazonia, South Africa, and Australia, among others (Bruijnzeel 1990; Le Maitre et al. 1999). The global impact of 110,000 square kilometers per year net deforestation (FAO 1999) on runoff, however, has yet to be fully quantified.

Impacts of land use change patterns of weather and climate at different scales are only starting to be understood. (See Chapter 13.) Fragmenting a landscape alone can generate changes in local weather patterns (Avissar and Liu 1996; Pielke et al. 1997). At the continental level, land use changes can reduce recycling rates of water leading to reduced precipitation and distortions in the atmospheric circulation patterns that link otherwise widely separated regions of the globe (Chase et al. 1996; Costa and Foley 2000; Pitman and Zhao 2000). There has also been continental-to-global-scale acceleration in the loading of pollutants, including nutrients, onto the land mass associated with industrial agriculture, urbanization, and grazing. (See Chapters 12 and 15.) These inputs are translated into greatly elevated fluxes to and transport through inland water systems (Chapter 20), the effects of which pass in many cases fully to the coastal zone (Chapter 19).

Intensive agricultural and urbanized areas have expanded rapidly in the last 50 years. The current extent of cultivated systems provides an indication of the location of freshwater ecosystems that are likely to experience water quality degradation from pesticide and nutrient runoff as well as increased sediment loading (Revenga et al. 2000). (See Figure 7.10 in Appendix A.) Figure 7.11 (in Appendix A) shows, from a drainage basin perspective, the distribution and pattern of urban areas, as judged by satellite images of nighttime lights for 1994–95 (NOAA-NGDC 1998). Because more urbanized river basins tend to have greater impervious area as well as higher quantities of sewage and industrial pollution, this figure suggests the contemporary geography of pressures on freshwater systems arising from these classes of contaminants (Revenga et al. 2000).

The two Figures show contrasting patterns of modified land use across the world. Intensively cropped lands are concentrated in five areas: Europe, India, eastern China, Southeast Asia, and the midwestern United States, with smaller concentrations in Argentina, Australia, and Central America. Africa is striking for its lack of intensively cropped land, with the exception of small patches along the Nile, on the Mediterranean coast, and in South Africa. This reflects the minimal use of chemical inputs and the low level of agricultural productivity in most African countries. Figure 7.11 shows that highly urbanized watersheds are concentrated along the east coast of the United States, Western Europe, and Japan, with smaller concentrations in coastal China, India,

BOX 7.4

Virtual Water Content Associated with African Food Supply

The interplay between water availability and irrigation is critical in defining whether a country (or regions within a country) can be self-sufficient in food production and do so in a sustainable manner. This is especially true in Africa, where the climate and hydrology are highly unpredictable and as much as 40% of irrigation withdrawals in the driest regions are estimated to be non-sustainable (Vörösmarty et al. 2005). Africa also represents a flashpoint for future water scarcity and food security, with a large and rapidly growing population, enormous expanses of dry landscapes, extensive poverty, lack of investment in water infrastructure, and a lingering human health crisis.

Virtual water is the fresh water needed to produce crops embodying all evapotranspiration on rain-fed or irrigated cropland, plus any transit losses for irrigation (Raskin et al. 1995; Allan 1996). There are enormous throughputs of water within agroecosystems to satisfy the evaporative demands of crops, with ratios of $>$1,000-to-1 by weight for cereal products and $>$15,000-to-1 for beef (Hoekstra 2003). Thus, while food trade can be highly beneficial in simply economic terms, it could also help compensate for local water scarcity by exploiting the comparative advantage of water-rich countries to produce food (Allan 1996; Jaeger 2000).

The map of Africa (see Box 7.4 Figure A in Appendix A) shows the spatial distribution of annual virtual water production on rain-fed and irrigated croplands, computed from long-term average (1950–95) water balance terms. VW embodied in meat (beef, pork, and chicken) production was also estimated as the sum of VW in feed and fodder plus a portion of evapotranspiration that occurs over grazing lands, where it is assumed that 30% of net primary production and hence evapotranspiration could be used sustainably.

In Africa, much of the sustainable (rain-fed) agriculture occurs within the more humid regions of the continent, while most irrigated agriculture occurs in the semiarid and arid regions in northern and southern Africa and along the Sahel. At the continental scale, about 18% of total African VW is used for meat production, although this number is probably much higher because it is doubtful that all grazing land is used sustainably. Food imports (both crops and meat) represent over 20% of Africa's total VW consumption, illustrating a reliance on external sources for meeting the food needs of today's population. This reliance will likely continue to increase in the future, though some unknown fraction is intra-continental.

Globally, VW from crop production is computed to co-opt 14,600 cubic kilometers (20%) of the 66,400 cubic kilometers annual evapotranspiration. For Africa, crop production co-opts only 9% of annual evapotranspiration, a reflection of the fact that three quarters of Africa's cropland is located in arid and semiarid climates characterized by highly limited soil moisture stocks (Vörösmarty et al. 2005). The bar chart (see Box 7.4 Figure B in Appendix A) illustrates that while sub-Saharan Africa relies heavily on rain-fed agriculture (60–75% for South, East, West) and very little on irrigated agriculture (3–7%) for food production, North Africa has very little rain-fed crop production and obtains more than 60% of its within-region VW from irrigated agriculture. Much of this irrigation water is withdrawn from highly exploited river corridors, such as the Nile, as well as groundwater. To satisfy overall food demand, North Africa nearly doubles its available VW through food trade.

Table 7.9. Brief Overview of Hydrologic Consequences Associated with Major Classes of Land Cover and Use Change (Bosch and Hewlett 1982; Swank et al. 1988; Bruijnzeel 1990; Hornbeck and Smith 1997; Jipp et al. 1998; Swanson 1998; Bonnell 1999; Le Maitre et al. 1999; Buttle et al. 2000; Le Maitre et al. 2000; Zavaleta 2000; Zhang et al. 2001; Paul and Meyer 2001; Sun et al. 2001; Zoppou 2001; Tollan 2002)

Type of Land Use Change	Consequences on Freshwater Provisioning Service	Confidence Level
Natural forest to managed forest	slight decrease in available freshwater flow and a decrease in temporal reliability (lower long-term groundwater recharge)	likely in most temperate and warm humid climates, but highly dependent on dominant tree species adequate management practices may reduce impacts to a minimum
Forest to pasture/agriculture	strong increase in amount of superficial runoff with associated increase in sediment and nutrient flux decrease in temporal reliability (floods, lower long-term groundwater recharge)	very likely at the global level; impact will depend on percentage of catchment area covered consequences are less severe if conversion is to pasture instead of agriculture most critical for areas with high precipitation during concentrated periods of time (e.g., monsoons)
Forest to urban	very strong increase in runoff with the associated increase in pollution loads strong decrease in temporal reliability (floods, lower long-term groundwater recharge)	very likely at the global level with impact dependent on percent of catchment area converted stronger effects when lower part of catchment is transformed most critical for areas with recurrent strong precipitation events
Invasion by species with higher evapotranspiration rates	strong decrease in runoff strong decrease in temporal reliability (low long-term groundwater recharge)	very likely, although highly dependent on the characteristics of dominant tree species scarcely documented except for South Africa, Australia, and the Colorado River in the United States

Central America, most of the United States, Western Europe, and the Persian Gulf (Revenga et al. 2000). While Figures 7.10 and 7.11 show the average composition of each large river basin in terms of intensively cultivated land or urban and industrial areas, they nonetheless hide within-basin differences that arise from highly localized patterns of crop production and urban point sources of pollution (Revenga et al. 2000).

The implications of these changes and the incomplete understanding of their consequences affect the manner in which humans interact with the water cycle. Integrated watershed management is the current paradigm for sustainable water use and conservation (Poff et al. 1997). It can yield important environmental and social benefits, as shown by a survey of 27 U.S. water suppliers that found the cost of water treatment in watersheds forested 60% or more was only half that of systems with 30% forest cover (Ernst 2004).

In practice, the integrated management approach is complex and difficult to implement because of limits to the understanding of interactions linking the physical and biotic processes that control water quantity and quality (Schulze 2004). Integrated management research typically has focused on local and short time scales and been limited to a very small portion of the world's watersheds. Most of the understanding of watershed dynamics and management principles comes from hydrological research on small watersheds and from studies at the local scale (Vörösmarty 2002). At present, the longest hydrological studies encompass only the last 20–40 years, but the recent application of GIS techniques facilitates reconstruction of past events to place the impact of contemporary land management into a longer-term perspective (Bhaduri et al. 2000).

One significant challenge to both scientific understanding and sound management is that multiple processes control water quantity, quality, and flow regime. The pattern and extent of cities, roads, agricultural land, and natural areas within a watershed influences infiltration properties, evapotranspiration rates, and runoff patterns, which in turn affect water quantity and quality. Additional challenges surround the fact that river basins extend across contrasting political, cultural, and economic domains (the Mekong River, for instance, flows through China, Laos, Thailand, Cambodia, and Viet Nam). Thus, there remains substantial uncertainty about the effects of management on different components of the hydrological cycle arising from the unique combinations of climatic, social, and ecological characteristics of the world's watersheds (Bruijnzeel 1990; Tollan 2002).

It is widely recognized that while much more information is needed to evaluate the impact of land use and cover change on freshwater provisioning services, integrated watershed management—despite its present degree of uncertainty—is both possible and would contribute significantly to improved management of water resources (Swanson 1998; Tollan 2002).

7.3.4 Climate Change and Variability

A major and natural characteristic of the land-based water cycle, and hence of water supply, is its variability over space and time. The large-scale patterns of atmospheric circulation dictate the world's climate zones and regional water availability. One particular concern arises from climate change, which in the past has shaped major shifts in the water cycle, such as changes in the Sahara from a much wetter region with abundant vegetation about 10,000 years ago to the desert of today (Sircoulon et al. 1999). A changing climate can modify all elements of the water cycle, including precipitation, evapotranspiration, soil moisture, groundwater recharge, and runoff. It can also change both the timing and intensity of precipitation, snowmelt, and runoff.

Two issues are critical for water supply: changes in the average runoff supply and changes in the frequency and severity of extreme events, including both flooding and drought. Both of these changes have been difficult to articulate due to complexities in the processes at work as well as a non-uniform and, in many parts of the world, deteriorating monitoring network, as discussed in section 7.1.2.

Shiklomanov and Rodda (2003) present a study of continental-scale variations in water supply as represented in the observational record spanning 1921–88. They used data from a total of approximately 2,500 stations, maximizing, to the degree possible, length of record, suitably large river basins, and hydrographs reflecting near-natural conditions. The stations represented <10% of all available records and reflect great disparities in maximum length of record (from 5 to 178 years). (Statistically, the optimal record length for trend analysis is on the order of 30 years (Lanfear and Hirsh 1999; Shiklomanov et al. 2002), but detectability of a trend also depends on the relative lengths of the "base" (pre-change) and changed periods of record (Radziejewski and Kundzewicz 2004).)

Year-to-year variations over five continents were 10% or less (see Figure 7.12) but rose to as high as 35% when examining 27 climate-based subdivisions. Relatively dry periods occurred in the 1940s, 1960s, and late 1970s, with global runoff declining by up to 3,000 cubic kilometers a year. This is in contrast to relatively wet conditions in the 1920s, late-1940s to early 1950s, and mid-1970s. Though there are limitations to making such global statements, the overall conclusion with respect to renewable supplies of runoff is that despite some recent continental-scale trends (an increase in South America and decrease in Africa), there was no substantial global trend in renewable supplies of runoff over the 67 years tested. Labat et al. (2004) did, however, compute an increasing global trend in runoff. This was correlated to increasing global surface air temperature, amounting to 4% per degree Celsius over the last century, though with regional increases (Asia, North and South America) and decreases (Africa) or stability (Europe) over the last few decades.

Care must be exercised in interpreting such long-term trends, which are anticipated to be associated with climate change. Maps of trends presented by the IPCC (Houghton et al. 2001) show large-scale and spatially coherent increases as well as decreases in precipitation over multi-decadal periods that start in 1910, although these patterns shift depending on the time frame observed. A similar time dependency is evident in interpreting changes in rain-to-snow ratios across Canada, with a time frame of 1948–96 indicating completely opposite results than with a time series starting at 1960 and ending in 1990 (Mekis and Hogg 1999; Lammers et al. 2001).

The clearest signatures require long time periods and sufficient spatial integration units (that is, large drainage basins). Peterson et al. (2002), for example, found it impossible to detect a coherent trend in runoff without first aggregating the flow records from six large Eurasian rivers and over 65 years. Insofar as northern Eurasia is among the regions historically to show the clearest trends in climate warming and the general absence of other confounding effects such as land cover change and water engineering, these results point to the difficulty in assessing recent runoff trends.

Nonetheless, there is evidence that climate change may already be causing long-term shifts in seasonal weather patterns and the runoff production that defines renewable freshwater supply. Shifts toward less severe winters and earlier thaw periods in cold temperate climates that depend on snowfall and snowmelt result

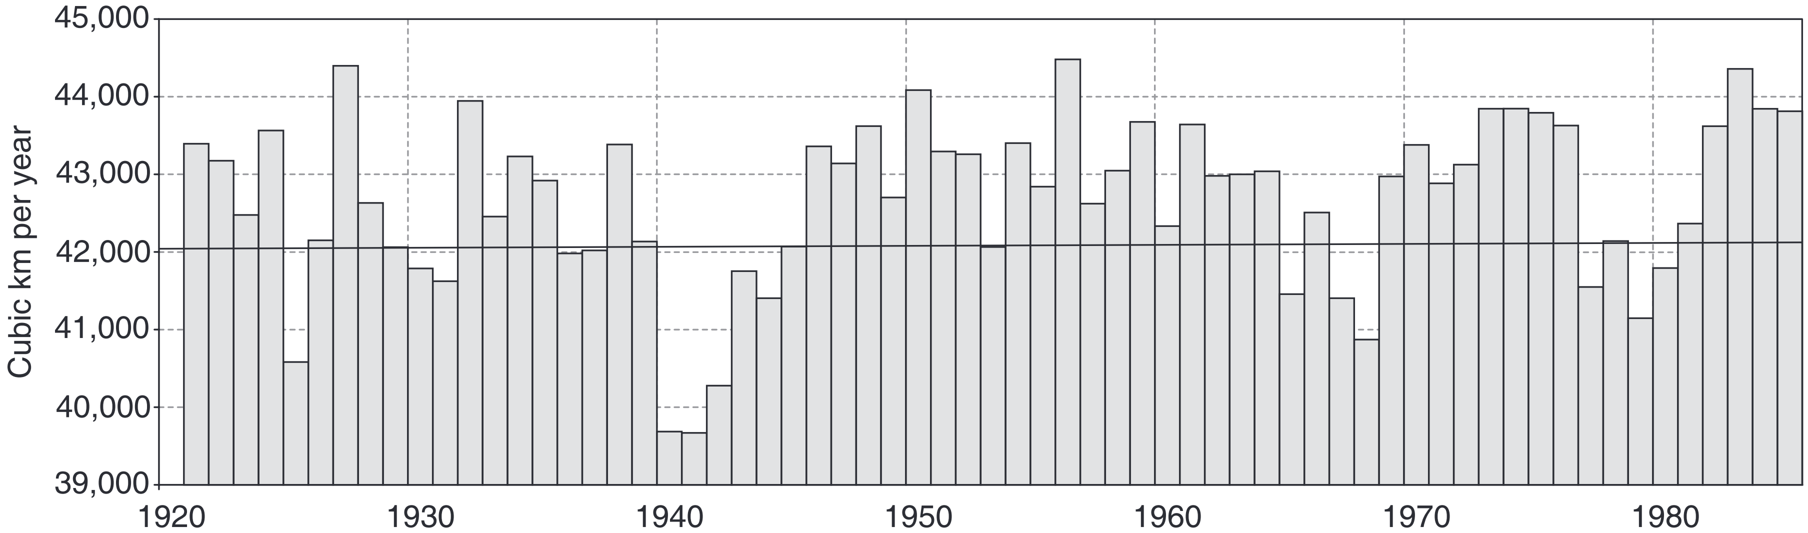

Figure 7.12. Time Series of Renewable Water Supply across the Global Landmass since 1920. The series is based on a subset of available discharge station records. (Shiklomanov and Rodda 2003)

in important changes in water availability (Dettinger and Cayan 1995; Hamlet and Lettenmaier 1999; WSAT 2000; Hodgkins et al. 2003). Multi-decade hydrological anomalies are apparent for Africa, with decreases on the order of 20% between 1951 and 1990 for both humid and arid zone basins that discharge into the Atlantic (Mahé 1993).

In the Sahel, persistent rainfall deficits could entrench desertification through a critical loss of water recycling between land and atmosphere, exacerbated by reduced soil infiltration when so-called hydrophobic soils are created in arid environments, and by soil compaction over poorly managed lands (Sircoulon et al. 1999). Such rainfall deficits also reduce replenishment of the groundwater resource, exacerbated by the decreased permeability of soils that favor storm runoff and flooding, even in the context of lower overall precipitation. In the transition zones between wet and dry regions across Africa, there is a highly uneven and erratic distribution of rainfall and river corridor flow (Vörösmarty et al. 2005). While this climate already produces chronic water stress, episodic droughts greatly increase the number of people at risk. Once each generation, the major sub-regions of the western Sahel, Horn of Africa, and SADCC region see a tripling in the number of people at risk from severe water stress (Vörösmarty et al. 2005).

An intensification of the water cycle, through more extreme precipitation in the United States (Karl et al. 1996; Karl and Knight 1998) and other parts of the world (Easterling et al. 2000; Houghton et al. 2001; Frich et al. 2002) has also been recorded. However, the effect of these increases on the rest of the hydrological cycle is only now being articulated.

In the United States, where sufficient records are available, Lins and Slack (1999) and Douglas et al. (2000) used stream gauging stations with 50 years of continuous records (from unregulated systems) to conclude that annual minimum and mean flows have increased. This was later confirmed by McCabe and Wollock (2002), who found statistically significant increases in annual moisture surplus (moisture that eventually becomes runoff) over the contiguous United States as a whole, but especially in the East. And while Yue et al. (2003) found similar increases in minimum and mean daily flows in northern Canada, they found the opposite to be true (significant decreases in minimum, mean, and maximum daily flows) in the southern part of the country.

Groisman et al. (2004) reported that warming in the northern half of the coterminous United States was related to a reduction in the extent of springtime snow cover and to the earlier onset of spring-like weather conditions and snow retreat. This has resulted in the increased frequency of cumulonimbus clouds and in a nationwide increase in very heavy precipitation. Warming in the southwest and northeast part of the country has led to greater summer dryness and increased fire danger. An interseasonal shift of precipitation from summer to fall in the Southeast was also noted.

The effect of increased precipitation extremes on floods is still debated (Douglas et al. 2000; Groisman et al. 2001; McCabe and Wolock 2002; Robson 2002; Milly et al. 2002) because flood response is influenced by many interacting factors, such as basin geology, terrain, and land cover as well as basin size and rainfall patterns. Also, the natural variability of flood flows can mask small changes in precipitation inputs.

Trends are also apparent in soil moisture distributed around the globe. Historical time series from more than 600 sites indicate a modest increase in growing period wetness for the majority of stations examined (Robock et al. 2000), contrary to the expectation (by general circulation models) of drier conditions in mid-continental areas due to climate change (e.g., Cubasch and Meehl 2000).

Taken together, these results indicate a high natural degree of variability and difficult-to-interpret shifts in runoff generation associated with historical climate change. The detection of such changes is complicated by the interactions among existing physical climate variations (that is, decadal and ENSO-type oscillations), land cover change, and water engineering, which for many parts of the world dominate the character of renewable water supplies.

7.3.5 Urbanization

During the twentieth century, the world's urban population increased almost fifteenfold, rising from less than 15% to close to half the total population (see Chapter 27), and by 2015 nearly 55% of the world will live in urban areas (UNPD 2003). In developing countries alone, the proportion of the population living in urban centers will rise from less than 20% in 1950 to 48% in 2015 (UNPD 1999, 2003). In fact, 60% of the fastest-growing cities with more than 750,000 people are located in the developing world, mostly in Asia (World Bank 2001). While 70% of the world's water use is for agriculture, the remaining withdrawals are for domestic household and other urban uses, including industry, and in many places these water resources are heavily polluted and limited by local shortages and distribution problems (UN-HABITAT 2003).

Urban residents bring with them a set of new challenges for water supply delivery, management, and waste treatment (WHO/UNICEF 2004; UN-HABITAT 2003). Because of the rapid rate of increase in cities around the world, water infrastructure is practically unable to keep apace, especially in the megacities with more than 10 million people. Large parts of these megacities lack the basic infrastructure for drinking water and sanitation, and most large cities in the developing world, and many in the industrial world, lack basic waste and storm water treatment plants (UN-HABITAT 2003).

The geographic location of many of these large and growing cities, such as close to coastal areas, and their rapid pace of growth has encouraged the overtapping of water resources that are not necessarily renewable, such as coastal aquifers. In Europe, for instance, nearly 60% of the cities with more than 100,000 people are located in areas where there is groundwater overabstraction (EEA 1995). Groundwater overexploitation is also evident in many Asian cities. Bangkok, Manila, Tianjin, Beijing, Chennai (formerly Madras), Shanghai, and Xian all have registered a decline in water table levels of 10–50 meters (Foster et al. 1998). These high levels of abstraction in many cases are accompanied by water quality degradation and land subsidence. For instance, the aquifer that supplies much of Mexico City had fallen by 10 meters as of 1992, with a consequent land subsidence of up to 9 meters (Foster et al. 1998).

Overabstraction is also an increasing problem with tourism-associated development, particularly in coastal areas. Groundwater overabstraction in such areas can reverse the natural flow of groundwater into the ocean, causing saltwater to intrude into inland aquifers. Because of the high marine salt content, even low concentrations of seawater in an aquifer are enough to make groundwater supplies unfit for human consumption (Scheidleder et al. 1999). Of 126 groundwater areas in Europe for which status was reported, 53 showed saltwater intrusion, mostly of aquifers used for public and industrial water supply (Scheidleder et al. 1999).

Unfortunately, the poor, mostly migrant workers from rural areas suffer most from reduced quality or quantity of water supply when they resettle to large cities. Poor residents of cities tend to concentrate in the outskirts, where safe drinking water and sanitation are less available, and they often depend on contaminated sources of water or intermediate water vendors who charge exorbitant prices.

In the context of these many problems, an emerging trend toward protecting water supplies for urban areas is noteworthy. A study of more than 100 of the world's largest cities, for example, found that more than 40% rely on runoff-producing areas that are fully or partially protected (Dudley and Stolton 2003). This reflects a growing recognition of the value of ecosystem services linked to sound watershed management approaches, as well as of the limits placed on urban water supply from polluted upstream source areas (UN-HABITAT 2003). The geography of downstream populations supported by upstream runoff-producing areas suggests the potential global importance of this management strategy. This is further demonstrated by Table 7.2, with data showing billions of people living downstream of particular MA ecosystems and their renewable freshwater flows.

7.3.6 Industrial Development

Industrial processes, which include withdrawals for manufacturing and thermoelectric cooling, today use about 20% of the total freshwater withdrawals, which has more than doubled between 1960 and 2000 (Shiklomanov and Rodda 2003). Even though this global use remains small in comparison to water used for agriculture, the current trend in shifting the manufacturing base from industrial to developing countries, due to globalization and international trade, is of concern for future water security. Much of the technology developed for industry is adapted to industrial nations, which are generally considerably more water-rich. When industrial plants are relocated to developing countries, many of which are water-poor or have limited water delivery services, these operations add pressure to the water resource base and increase conflict among water users. In addition, the environmental safeguards for effluent treatment are less well established or enforced in developing nations, adding to the scarcity problems by increasing pollution.

The most polluting industries, in terms of organic water pollutants, are those whose products are based on organic raw materials, such as food and beverage, paper and pulp, and textile plants (UN/WWAP 2003). Power station electric generation is the largest source of thermal water pollution. Estimates correlating water withdrawals for industrial use with population density by river basin show that many already water-stressed river basins are also centers for industrial production, such as in eastern China, India, and parts of Europe (UN/WWAP 2003).

Industrial emissions are released not only as thermal and chemical effluents into rivers and streams but also as gases and aerosols into the atmosphere. These can be transported for large distances and may end up deposited in other water bodies far from the emission source. Large areas of the continents show atmospheric deposition as the single most important source of nitrogen loading, with concomitant increases in pollutant transport through inland waterways (Green et al. 2004).

7.4 Consequences for Human Well-being of Changes in the Provision of Fresh Water

Water is essential for human well-being, but not all parts of the world receive the same amount or timing of available water supplies. Some areas contain abundant water throughout the year, others have seasonal floods and droughts, and still others have hardly any water at all. In river basins with high water demand relative to the available supply, water scarcity is a growing problem, as is water pollution. Water availability is already one of the major challenges facing human society, and the lack of water will be one of the key factors limiting development (WMO 1997; UN/WWAP 2003). The socioeconomic implications of delivering, using, managing, or buying water also have impacts on human well-being. This section begins with a brief overview of the benefits and required investments for water resource systems; examines the implications of freshwater scarcity, including treatment of pricing and equity issues; and concludes with descriptions of the consequences of too much water (flooding) and the connections between freshwater services and human health.

7.4.1 Freshwater Provision: Benefits and Investment Requirements

Over the long term, water use has generally increased geometrically, in line with population growth, increased food production, and economic development (L'vovich and White 1990), and during the last 40 years, there has been a doubling in the water used by society—from 1,800 to 3,600 cubic kilometers a year. In an aggregate sense, water is a required input generating value-added in all sectors of the economy, and trends in its use can be assessed from its ability to yield economic productivity. In the United States, for example, water productivity measured as GDP per cubic meter of freshwater use rose dramatically between 1960 and 2000 by about 25% per decade, to $18 per cubic meter (Postel and Vickers 2004), in response to shifts in regulation, technology, and restructuring of the economy.

Water provided for irrigation has a particularly important role, being responsible for 40% of global crop production (UN/WWAP 2003). And despite major challenges in conveying adequate drinking water and sanitation, more than 5 billion people are routinely provided with clean water and more than 3.5 billion have access to sanitation (WHO/UNICEF 2004). Further, with continued investments in water infrastructure, much of the world's population has benefited from allied improvements in public health, flood control, electrification, food security through irrigation, and associated economic development. From this standpoint, well-managed water resources have helped promote economic development, which is tied closely to improvements in many aspects of human well-being.

A good example is provided by a recent analysis (Hutton and Haller 2004) of the cost-effectiveness of different options to achieve MDG 7 (on access to safe water and basic sanitation). Of five scenarios tested, two considered Target 10—halving the proportion of people without sustainable access to safe water by 2015 and halving the proportion of people without sustainable access to improved sanitation. It was shown that for each dollar invested in both improved water supply and sanitation, a return of $3–34 can be expected. Among the health benefits of achieving the MDG drinking water target was a global reduction in diarrheal episodes of 10%. The economic benefits of simultaneously meeting the drinking water and sanitation MDG targets on households and the health sector amount to $84 billion per year, representing reduced health care costs, value of days gained from reduced illness, averted deaths, and time savings from proximity to drinking water and sanitation facilities for productive endeavor.

Because of the variability of the water cycle, economic benefits often accrue only after substantial investments in infrastructure and operations that stabilize and improve the reliability of water resources. Capital investments in water infrastructure totaled $400 billion in the United States over the last century (Rogers 1993). When the annual investment in water storage for irrigation globally during the 1990s of about $15 billion (WCD 2000) is tabulated, an important source of required capital can be seen, which can constitute a major fraction of agricultural investment for many developing countries (UN/WWAP 2003).

Worldwide, investments in dams have totaled $2 trillion (WCD 2000). World Bank lending for irrigation and drainage averaged about $1.5 billion per year from 1960 to 2000, although this continues to decrease from a peak of $2.5 billion in 1975 to its current rate of $500 million (Thompson 2001). Global costs for expanding irrigation facilities are estimated at $5 billion annually, but rehabilitation and modernization costs on existing irrigation works are estimated at an additional $10 billion or more per year (UN/WWAP 2003). Although projected funding for economic development and meeting the MDGs for the entire water sector is estimated to reach $111–180 billion a year, current investments in sanitation and water supply total from $10 billion to $30 billion annually (UN/WWAP 2003). Securing water resources is thus deeply embedded within development investment and planning but incompletely resolved. The private sector, with global revenues today standing at $300 billion annually (Gleick et al. 2002a), is a major player in providing potential investments, as described later.

7.4.2 Consequences of Water Scarcity

With population growth and the overexploitation and contamination of water resources, the gap between available water supply and water demand is increasing in many parts of the world. In areas where water supply is already limited, water scarcity is likely to be the most serious constraint on development, particularly in drought-prone areas. Earlier in this chapter we provided a quantification of water scarcity in physical terms. Here scarcity is mapped to issues relating directly to human well-being.

While decreased or variable water supply has sometimes presented itself as an opportunity to develop efficiency-enhancing responses (Wolff and Gleick 2002) and cooperation (Wolf et al. 1999; UN/WWAP 2003), more often it has spawned numerous development challenges, including increased levels of competition for water among people and between people and ecosystems; the use of non-sustainable supplies or development of costly alternatives; limits to economic growth, including curtailment of activities and required importation of food and other water-intensive commodities; pollution and public health problems; potential political and civil instability (Furlong and Gleditsch 2003; Miguel et al. 2004); and international disputes in transboundary river basins (Gleick 1998). These situations arise in part because society has typically managed ecosystems for one dominant service such as timber or hydropower without fully realizing the trade-offs being made in such management. This approach has led to the documented decline in freshwater ecosystem condition, with accompanying consequences for human well-being. The poor, whose livelihoods often depend most directly on ecosystem services, suffer most when ecosystems are degraded. (See Chapter 6.)

One of the problems thus far has been the difficulty of relating ecosystem condition to human well-being, particularly from the socioeconomic perspective. An emphasis on water supply, by developing more dams and reservoirs, coupled with weak enforcement of regulations, thus has limited the effectiveness of water resource management, particularly in developing regions of the world (Revenga and Cassar 2002).

As a consequence, policy-makers are now shifting from entirely supply-based solutions to demand management, highlighting the importance of using a combination of measures to ensure adequate supplies of water for different sectors, and slowly moving toward an integrated approach to water resources management (Schulze 2004) that is now linked directly to development initiatives (GWP 2000; UN-HABITAT 2003; Kakabadse-Navarro et al. 2004). Measures include improving water use efficiency, pricing policies, preservation of environmental flows, market incentives, privatization of water delivery, and public-private partnerships among others. (See MA *Policy Responses,* Chapter 7, for more on response measures in integrated water resource management.)

Human society has relied for decades on economic and social indicators for planning, but in virtually complete isolation of measures depicting the state and trends of ecosystem services. This section presents some of the latest findings relating water as an ecosystem service through social and economic indicators.

The need for integrated indicators or indices at the national or regional scale to help donors and decision-makers establish priorities in water resource management is widely acknowledged. Such metrics can also assist in monitoring progress toward sustainable development goals in a systematic manner. Many such tools have been proposed over the last several decades. For example, the Water Stress Index was developed in the 1970s to link population to water resources (Falkenmark 1997), and various other indices have been proposed, such as the Stockholm Environment Institute's Water Resources Vulnerability Index (Gleick et al. 2002b). New water scarcity indices capitalizing on geospatial data sets and high-resolution digital representations of river networks can define the climatic and hydrological sources of water-related stress (Vörösmarty et al. 2005).

One important indicator that combines physical, environmental, economic, and social information related to water availability and use is the Water Poverty Index. The WPI is similar to the Human Development Index but applicable to a more local scale, where the impacts of water scarcity are fundamentally expressed. It measures water stress at the household and community level and was designed to "aid national decision makers, at community and central government level, as well as donor agencies, to determine priority needs for intervention in the water sector" (Sullivan et al. 2003).

The WPI reflects an attempt to quantify inequities in water allocation and the inability of the poor to govern access to water. It has five key components, each based on a series of input variables that are weighed and aggregated into the overall index. When an element cannot be measured, proxy indicators are used in its place. The WPI relies in part on standardized data collected for other purposes, and thus can be used in comparative analysis of water stress across countries. For instance, to provide inputs on water management capacity the index uses Log GDP per capita, under-5 mortality rates, and a UNDP education index, all used previously in constructing the HDI. The five components of the WPI and some of its key variables are:

- *Water resources*: The physical characteristics of water availability and water quality. This component includes total water availability, its variability across time (seasonality), and its quality.
- *Access to water*: This includes not only the distance to water from dwellings but, more important, the time spent in collecting water, conflicts over water use, and access to sanitation.
- *Water use*: This represents withdrawals for domestic, agricultural, and industrial purposes. In many parts of the world, small-scale irrigation and livestock are key components of livelihood strategies and thus are tabulated as inputs.
- *Capacity to manage water*: This component is measured in terms of income, education level, membership in water users associations, and the burden of illness due to contaminated water.
- *Environmental integrity*: If the ecosystems that support water delivery are degraded, then provision of water per se plus the many services derived from freshwater systems will be jeopardized. This component evaluates the integrity of freshwater ecosystems based on the use of natural resources, crop losses reported in the previous five years, and household reports of land erosion. Overall, no variables of the actual condition of aquatic ecosystems are included, suggesting a component of the index that could benefit from revision.

The WPI has been tested internationally in 140 countries as well as at the local scale in South Africa, Tanzania, and Sri Lanka. Finland and Iceland were found to score the best, while Haiti and Ethiopia fared worst (Lawrence et al. 2003). The results of the local pilot analysis look promising, but the WPI would benefit from a better incorporation of ecosystem condition and capacity measures. Nevertheless, the WPI is a vehicle for understanding the complex relationship between water services and human well-being. Moreover, as the authors state, it constitutes "a systematic approach that is open and transparent to all" (Sullivan et al. 2003), allowing incremental improvements to the index to be made through community consensus.

There are also important gender-related issues associated with water poverty. Women and men usually have different roles in water and sanitation activities, and these differences are pronounced in rural areas across the developing world (Brismar 1997; UN/WWAP 2003). Women are most often the users, providers, and managers of water in rural households and the guardians of household hygiene. In many parts of the world, women and girls can spend several hours a day carrying heavy water containers, suffering acute physical problems as a result (WEDO 2004). The inordinate burden of acquiring water also inhibits women's and girls' opportunities to secure an education and contribute to family income (WEDO 2004).

7.4.3 The Cost and Pricing of Water Delivery

Water users in most countries are generally charged but a small fraction of the actual cost of water abstraction, delivery, disposal, and treatment (Briscoe 1999; WHO/UNICEF 2000; Walker et al. 2000), and in some countries implicit and explicit water subsidies can reach up to 93% (Pagiola et al. 2002). Moreover, externalities associated with freshwater use, such as salinization of soils, degradation of ecosystems, and pollution of waterways, have been almost universally ignored, promoting current inefficiencies in use and threats to freshwater ecosystems. In general, those with access to abundant or underpriced water use it in a wasteful manner, while many, usually the poor, still lack sufficient access to water resources.

When water is in short supply or when it is polluted or unsafe to drink, the expense of delivering water services can rise dramatically or force curtailment in use. As scarcity increases, the cost of developing new freshwater resources also reflects the need to secure water from sources sometimes at great distances from the eventual user, often involving complex hydrological engineering (Hirji 1998; Rosegrant et al. 2002). Until recently there were few incentives in most countries to use water efficiently. However, increasing costs of water supply, dwindling supplies, and losses of aquatic habitat and biodiversity are increasingly providing incentives to value water as an economic good. In most countries, governments bear the burden of water delivery to users, but maintaining necessary infrastructure and expanding it to reach unserved users or improve the efficiency of water delivery is the exception rather than the norm (Pagiola et al. 2002). Inadequate funding results in a lack of new connections and unreliable service, with serious consequences for the poor, who usually incur higher costs when forced to obtain water from alternative sources (Pagiola et al. 2002).

Water can be priced in a number of different ways, and the past decade has shown the increasing application of several common methods, including flat fees, fixed fees plus volumetric charges, decreasing block rates, and increasing block rates. Some of these measures discourage waste, while others lead to overuse. (See MA *Policy Responses,* Chapter 7). This section surveys recent trends in the price and cost of water, reviews cost-recovery strategies, and assesses the impact on human well-being of privatization and public-private partnerships that deliver freshwater services.

7.4.3.1 The Price of Water and Recent Trends

There are enormous disparities in the price of fresh water supplied to end-users, reflecting a complex interplay among several factors, including proximity to natural sources of sufficient quantity and quality, level of economic development, investments—both public and private—in water infrastructure, and governance. A survey of urban households across the developing world showed water costs from both public and private sources varying by a factor of 10,000, from \$0.00001 per liter (for piped supply in Calcutta) to as high as \$0.1 per liter (through private water vendors) (UN-HABITAT 2003). Even municipal supplies can constitute a substantial fraction of monthly family expenditure—for example, up to 20% in informal settlements in Namibia (UN-HABITAT 2003). An analysis of urban areas in Asia showed that prices charged by informal water vendors are more than 100 times that from domestic connections (ADB 2001). In Benin, Burkina Faso, Kenya, Mauritania, and Uganda, household connection fees to piped water supplies exceeded per capita GDP by factors of up to 5:1, rendering these unaffordable (Collignon and Vezina 2000).

Cities also have seen a marked increase in the cost of financing new water supplies. In Amman, Jordan, during the 1980s groundwater sources were used to meet water needs at an incremental cost of $0.41 per cubic meter. As groundwater supplies declined, the city began to rely on surface water pumped from a site 40 kilometers away at an average incremental cost of $1.33 per cubic meter (Rosegrant et al. 2002). In another example, the real cost of water supply for irrigation in Pakistan more than doubled between 1980 and 1990 (Dinar and Subramanian 1997).

In Algeria, drought during 2000–02 forced cuts in the provision of water supply from municipal networks (access restricted to several hours every two to four days), despite large investments in water supply networks by the Algerian government since 1962 (UN-HABITAT 2003). The situation was further exacerbated by lack of maintenance of the network, with water losses through leaking pipes and underpricing of the resource use. Today, price increases and a major facilities upgrade are under way. Many African cities have exhausted and polluted local groundwater supplies, necessitating expensive transport of fresh water from distant suppliers (200 kilometers in the case of Dakar, Senegal) (UN-HABITAT 2003) or the need to invest in desalination, which is among the costliest methods of supplying fresh water (Gleick 2000; UN/WWAP 2003).

In addition to direct prices paid, additional costs are incurred by the poor provision of water services. Time spent in traveling to supplies, queuing, and transporting water can be a significant burden on household incomes for the poor. Compared with the late 1960s, households without piped water supply in Kenya, Uganda, and Tanzania today spend triple the time each day securing water, an average of over 90 minutes (UN-HABITAT 2003). Public taps are often in short supply, as in many Asian cities, where several hundred people are served by a single source (McIntosh and Yñinguez 1997). Further, the true costs associated with water delivery services are amplified by significant health burdens incurred when supplies are insufficient to meet basic needs. In the case of Lima, Peru, a major portion of household income (27%) is represented by medical costs and lost wages from water-related disease (Alcazar et al. 2000), while in Khulna, Bangladesh, an average of 10 labor days per month are lost due illness from poor water provision (Pryer 1993).

7.4.3.2 Cost Recovery

The fourth guiding principle of the Dublin Statement on Development Issues for the 21st Century (ICWE 1992) articulated that "water has an economic value" and "should be recognized as an economic good." At the same time, the statement argued that water should be available to all people at affordable prices. After much discussion and controversy, which continues to this day, the Ministerial Declaration from the 2nd World Water Forum (2002) established that "the economic value of water should be recognized and fully reflected in national policies and strategies by 2005" and that "mechanisms should be established by 2015 to facilitate the full cost pricing for water services, while the needs of the poor are guaranteed."

Supporters of full-cost water pricing argue that to improve efficiency, the set price of water needs to reflect the cost of supplying, distributing, and treating it. There is some evidence that this principle works. For instance, price increases for water in Bogor, Indonesia, reduced domestic consumption by 30% (Rosegrant et al. 1995). Proponents of full-cost water pricing also point out that most of the poor are not meeting their basic water needs today under current public management, usually because of lack of government capacity and resources. Consequently, poor communities are already paying higher prices through intermediate water vendors than if they were connected to a water delivery system.

But while pricing water to reflect its true cost is relatively simple in theory, the political and social obstacles are formidable. Opponents to the idea of full-cost water pricing claim that access to water is a fundamental human right. Water, like air, should therefore not be treated as an exchangeable, marketable commodity, because if market conditions rule, access to water becomes dependent on the ability to pay and not an inherent entitlement. In the eyes of many, establishing a price for water or privatizing its delivery puts many of the poorest, most marginalized people at risk of not getting enough water to meet basic needs.

The majority of OECD countries have adopted or are adopting, as an operating principle, the full-cost recovery concept in water management, although what should be covered under this "full cost" is still a matter of debate. Infrastructure costs, however, are not usually included (UN/WWAP 2003). As pricing was restructured and subsidies reduced during the 1990s and in the current decade in industrial countries to capture the full-cost recovery of water, the real price of water was increasing in 18 out of 19 countries surveyed (Australia being the only exception). In two thirds of OECD countries, over 90% of single-family homes are currently metered (OECD 1999).

The concept of full-cost water pricing in the developing world has been introduced with the support of local communities in situations where a more reliable service is assured. In Haiti, for example, shantytown residents with no connection to the water utility pay 10 times more for water from water vendors (water trucks) than those who are connected to the private water utility grid in nearby villages (Constance 1999). Residents connected to the grid have their water use metered and pay the corresponding fees.

7.4.3.3 Water Privatization

One of the most controversial trends in today's globalized economy is the increasing privatization of some water management and delivery services. In many countries, due to increasing costs of maintaining and expanding water networks and overstretched government budgets, private companies have been invited to take over some of the management and operations of public water systems. Private-sector investment in theory results in more financing for infrastructure as well as more-efficient operations and cost recovery, and the hope is that the public will benefit from a more stable and reliable water delivery system at a reasonable price.

Opponents to privatizing water services argue that putting private companies in charge of water will drive prices to the point that marginalized groups have no capacity to secure sufficient water even for their most basic of needs. In addition, because the profit motive fails to recognize environmental externalities, they argue that privatization will increase risk to the very ecosystems that help supply fresh water. The debate on public-private partnerships for water management was prominent on the agenda of the World Water Forum gatherings (in particular, at the 2nd Forum in The Hague and the 3rd Forum in Kyoto), as well as at the World Summit on Sustainable Development.

Despite trends toward privatization, at present over 80% of the world's investments in water, sanitation, and hydropower systems are by publicly owned bodies or international donors (Winpenny 2003). Therefore, the responsibility for providing water, over the short to medium term, will remain largely a public enterprise. Among industrial countries, there is much variation in the degree of privatization. In the United States in 2000, private companies provided only 15% of municipal water supply, although in the nineteenth century they provided nearly 95% (Gleick et al. 2002a). France, in contrast, shows more than half of all residents currently served by private companies (Gleick et al. 2002a).

In Latin America, Chile has been successful at delivering water through privatization, and nearly all houses in Santiago have access to clean water and sanitation. Despite exchange-rate fluctuations, a foreign company, Suez, has remained the water provider for Santiago and its region, investing over $1 billion in water infrastructure. Water in Chile has been priced at rates affordable by the middle classes, and stamps are given to poor people to guarantee near-universal access. Conversely, in Argentina, what looked like a positive trend did not withstand economic troubles. In 1993 privatization in Buenos Aires increased the share of residents served with water from 70% to 85%—an increase of 1.6 million people, with a concurrent drop in prices (Peet 2003). Exchange-rate fluctuations in many developing countries, such as the currency devaluation in Argentina in 2002, add challenges to successful implementation of privatization schemes. If the currency of a country devalues, the price paid for water will be worth much less, and the foreign firm could pull out of the market, leaving users without reliable service (Peet 2003).

South Africa is using a different pricing scheme to improve poor people's access to water and has made good progress in providing water to nearly two thirds of those who lacked access in 1994, when apartheid officially ended. Despite the relatively low cost of water, however, some rural residents opted to consume free—but contaminated—water from other sources. In February 2000, to improve public health for the poor, the government introduced a scheme to provide households with 6,000 free liters of water per month, enough to provide 25 liters per person per day, with charges for additional use.

Privatization can be executed in many ways, depending on the level of transfer from public to private hands. Full transfer of ownership and operations of water resource systems so far has been rare. The majority of cases embody the transfer of certain operational aspects, such as water delivery, but the ownership of the water resources usually remains with the state, thereby forming a public-private partnership.

These partnerships have been demonstrated over the last few years to capture the benefits of privatization without all of the risk (Blokland et al. 1999). They do not privatize all of the water assets, but they do give private actors control over some elements of the water rights, infrastructure, and distribution systems. Yet public entities typically maintain ownership over some or all of these systems. Public-private partnerships work best when strong regulatory controls exist. A typical arrangement in France, for example, delegates the operation, maintenance, and development of public potable water and sanitation to private companies, though public bodies retain ownership of the system (Barraque et al. 1994; Gleick et al. 2002c).

Experience has shown that a clear legal framework, where risks are decreased and the cost of capital decreases, would be necessary to enlist private-sector involvement (Winpenny 2003). More detailed analysis of privatization as a response option for the sustainable management of water resources and freshwater ecosystems is presented in Chapter 7 of the MA *Policy Responses* volume.

7.4.4 Consequences of Too Much Water: Floods

In addition to water scarcity, the accumulation of too much water in too little time in a specific area can be devastating to populations and national economies. (See Chapter 16.) According to the latest *World Disasters Report* (IFRC/RCS 2003), on average 140 million people are affected by floods each year, more than all other natural or technological disasters put together. Between 1990 and 1999, there were over 100,000 people reportedly killed by floods. The majority of these deaths were in Asia (56,000), followed by the Americas (35,000), Africa (9,000), and Europe (3,000) (IFRC/RCS 2000).

In addition to human lives, floods are a costly natural hazard in monetary terms, with more than $244 billion damage from 1990 to 1999, the most of any single class of natural hazard (IFRC/RCS 2000). Although this arises from potential changes in climate variability and extreme weather, humans also play an important role, settling and expanding into vulnerable areas (Kunkel et al. 1999; van der Wink et al. 1998).

While catastrophic flooding has negatively affected society for thousands of years, naturally occurring floods also provide benefits to humans through maintenance of ecosystem functioning such as sediment and nutrient inputs to renew soil fertility in floodplains, providing floodwaters to fish spawning and breeding sites and helping to define the dynamics to which coastal ecosystems are adapted. Although floods are primarily natural events, human activity influences their frequency and severity. By converting natural landscapes to urban centers, deforesting hillsides, and draining wetlands, humans reduce the capacity of ecosystems and soils to absorb excess water and to evaporate or transpire water back into the atmosphere, creating conditions that promote increased runoff and flooding.

There are, then, potentially costly consequences of upstream anthropogenic activities on hydrological function that place downstream populations at risk, sometimes affecting other nations, as in the case of more than 250 international river basins (Wolf et al. 1999). Douglas et al. (2005) reported on a simulation study suggesting that, in aggregate, a 32% conversion of forests to agriculture across the pan-tropics has led to a mean increase in annual basin yields of approximately 10%, with a concomitant rise in seasonal high flows. More than 800 million people live along floodplains in river basins containing some amount of tropical forest, and if the most threatened of the existing forests are converted to agriculture in the future, approximately 80 million of them could be at risk from the hydrologic impacts associated with these land conversions. Costa et al. (2003) present empirical evidence that large-scale savanna clearance in the Tocantins basin in Brazil (175,000 square kilometers) has been associated with increases of 24% in mean annual and 28% in wet season flows, independent of climate variations.

Nevertheless, there is some agreement that the most catastrophic floods in large basins result from storms so large and persistent that peak flows are unaffected by land cover (Calder 1999; Bruijnzeel 2004). Further, the proclivities of particular regions to landslides, soil erosion, and debris flows, as in the Himalayas, constitute the dominant source of risk (Gilmour et al. 1987; Hamilton 1987; Gardner 2002). Thus the costs and benefits of designing interventions to mitigate floods have their limits, and there may be little opportunity to escape potential vulnerabilities to flooding, given current patterns of human settlement in high-risk areas.

These findings should not suggest abandonment of good land stewardship, which yields fundamental benefits in sustaining ecosystem services. But they do argue for clearly identifying the source areas of hazard and designing response strategies to protect life and property. Even when specific and well-established policy goals for watershed protection are formulated, stakeholder interests and sustainable funding issues add to the challenge of designing effective upstream-downstream management strategies (Pagiola 2002).

Further information on the impact of natural hazards, including floods, on human well-being can be found in Chapter 16.

7.4.5 Consequences of Poor Water Quality on Human Health

Water is an essential resource for sustaining human health, and there is a basic per capita daily water requirement of 20 to 40 liters of water free from harmful contaminants and pathogens for the purposes of drinking and sanitation, which rises to 50 liters when bathing and kitchen needs are considered (Gleick 1996, 1998, 1999). Yet billions of people lack the services to meet this need, as documented earlier. Water-related diseases include four major classes: waterborne, water-washed, water-based, and water-related vector-borne infections (Bradley 1977). Threats to health also arise from chemical pollution.

7.4.5.1 Water-Related Diseases

As a whole, water-related diseases are a leading cause of morbidity and mortality in many parts of the developing world, with estimates ranging from 2 million to 12 million deaths per year (Gleick 2002), although monitoring and reporting remain poor in many countries. (See Table 7.10.) UN/WWAP (2003) reports 3.2 million deaths each year from water-related infectious disease, or about 6% of all deaths. The lack of access to safe water and to basic sanitary conditions also translates into the annual loss of 1.7 million lives and at least 50 million disability-adjusted life years. (The DALY is a summary measure of population health, calculated as the sum of years lost due to premature mortality and the healthy years lost due to disability for incident cases of the ill health condition. The DALY is not only an effectiveness indicator in the economic evaluation of different intervention options but also a reflection of the impact of ill health on the income-generating capacity of the poor.)

The first three categories of water-related diseases are most clearly associated with lack of access to improved sources of drinking water, and in turn to ecosystem condition. Improved sanitation through the safe disposal of human waste is a major development objective that improves the health of those served directly by separating drinking water from wastewater. In developing countries, however, 90–95% of all sewage and 70% of industrial wastes are dumped untreated into surface waters (UNFPA 2001), placing both downstream populations as well as ecosystem functions at risk. (See Chapter 15.) The fourth category of water-related disease is associated with ecological conditions that favor disease vector breeding. These may be natural (such as those supporting malaria transmission by *Anopheles gambiae* mosquito across large parts of Africa south of the Sahara) or anthropogenic, through improperly planned irrigation systems, dams, and urban water systems. (See Chapter 14.)

Waterborne diseases are caused by consumption of water contaminated by human or animal waste and containing pathogenic parasites, bacteria, or viruses. They include the diverse group of diarrheal diseases as well as cholera, typhoid, and amoebic dysentery. These diseases occur where there is a lack of access to safe drinking water for basic hygiene, and most could be prevented by treating water before use. The World Health Organization estimates that there are 4 billion cases of diarrhea each year in addition to millions of other cases of illness associated with lack of access to safe water (WHO/UNICEF 2000). This translates into 1.7 million deaths per year, mostly among children under the age of five (WHO 2004). Morbidity and mortality from microbial contamination are orders of magnitude greater in developing countries than in the industrial world.

Water-washed diseases are caused by poor personal hygiene and skin or eye contact with contaminated water; their incidence is associated with the lack of access to basic sanitation and suffi-

Table 7.10. Selected Water-Related Diseases. Approximate yearly number of cases, mortality, and disability-adjusted life years. The DALY is a summary measure of population health, calculated as the sum of years lost due to premature mortality and the healthy years lost due to disability for incident cases of the ill-health condition. (WHO 2001, 2004)

Disease	Number of Cases	Disability- Adjusted Life Years *(thousand DALYs)*	Estimated Mortality *(thousand)*	Relationship to Freshwater Services
Diarrhea	4 billion	55,000[a]	1,700[a]	water contaminated by human feces
Malaria	300–500 million	46,500	1,300	transmitted by *Anopheles* mosquitoes
Schistosomiasis	200 million	1,700	15	transmitted by aquatic mollusks
Dengue and dengue hemorrhagic fever	50–100 million dengue; 500,000 DHF	616	19	transmitted by *Aedes* mosquitoes
Onchocerciasis (river blindness)	18 million	484	0	transmitted by black fly
Typhoid and paratyphoid fevers	17 million			contaminated water, food; flooding
Trachoma	150 million, 6 million blind	2,300	0	lack of basic hygiene
Cholera	140,000–184,000[b]		5–28[b]	water and food contaminated by human feces
Dracunculiasis (Guinea worm disease)	96,000			contaminated water

[a] Specifically attributable to unsafe water, sanitation, and hygiene from WHO (2002).

[b] The upper part of the range refers specifically to 2001 as reported in UN/WWAP 2003.

cient water for effective hygiene (Bradley 1977; Gleick 2002; Jensen et al. 2004). These include scabies, trachoma, and flea, lice, and tick-borne diseases. Trachoma alone is estimated to cause blindness in 6 million people (WHO/UNICEF 2000). In addition, the transmission of intestinal helminths (*Ascaris, Trichuris,* and hookworm) is linked to a lack of sanitation facilities and is estimated to account for a global annual loss of over 2 million DALYs.

Water-based diseases are those caused by aquatic organisms that spend part of their life cycle in the water and another part as parasites of animals. As parasites, they usually take the form of worms, using intermediate animal vectors such as snails to thrive, and then directly infecting humans either by boring through the skin or by being swallowed. They include Guinea worm infection, schistosomiasis (bilharzia), and a few other helminths (certain liver flukes of local importance in Southeast Asia, for instance, such as *Opisthorchis viverrini*) that infect humans through either direct contact with contaminated water or the consumption of uncooked aquatic organisms.

Although these diseases are not usually fatal, they prevent people from living normal lives and impair their ability to work. For instance, 200 million people worldwide are infected with schistosomiasis, of which 20 million suffer severe consequences, with an estimated global annual burden of 1.7 million DALYs (WHO 2004). The prevalence of water-based diseases often increases where dams are constructed, because stagnant water is the preferred habitat for aquatic snails, their most important intermediary hosts. For instance, the Akosombo Dam in Ghana, the Aswan High Dam on the Nile in Egypt, and the Diamma Dam at the mouth of the Senegal river have resulted in huge increases of local schistosomiasis prevalence. (See also Chapter 14.)

Water-related vector-borne diseases are caused by parasites that require a vector (such as insects) to develop and transmit the disease to humans. For example, *Anopheles* mosquitoes are the vectors for a protozoan parasite (*Plasmodium*) that causes malaria. These diseases are strongly ecosystem-linked, in contrast to the other three categories of water-related diseases, where water quality (and to some extent quantity) is the key determinant. Their distribution reflects the distribution of ecosystems suited to the propagation of the vectors.

Vector species, moreover, are highly diverse, so that detailed ecological requirements differ over wide ranges. Anopheline mosquitoes—vectors of malaria (1.3 million deaths a year and an annual burden of over 46 million DALYs), for example—breed in different types of freshwater ecosystems and brackish water coastal lagoons. *Aedes,* vectors of dengue and yellow fever, originally breeding in leaf axils of bromeliads, are cosmopolitan in human settlement areas, where they breed in small water pools. Urban filariasis vectors (*Culex* ssp.) breed in organically polluted water. And the blackfly vectors of onchocerciasis breed in oxygenated waters of rapids.

These vector-borne diseases are not typically associated with lack of access to safe drinking water but rather with water management practices in tropical and sub-tropical regions of the world. Several parasitic diseases endemic of tropical regions, such as Rift Valley Fever and Japanese encephalitis, spread easily with the presence of reservoirs, irrigation ditches and canals, and rice fields (WCD 2000). (See Chapter 14.) In all, more than 30 diseases have been linked to irrigation and paddy agriculture (WRI et al. 1998). Consequently, improved water management, drainage, and storage practices can help reduce the transmission risk, particularly in areas where anthropogenic conditions have led to the introduction of these diseases.

7.4.5.2 Chemical Pollution

Another set of diseases affecting industrial and developing nations alike arises in response to chemical pollution of water by heavy metals, toxic substances, and long-lived synthetic compounds. While evidence of the long-term impacts of chemical pollution can be detected even in the remote Arctic (AMAP 2002), the impacts on poor populations in developing countries are difficult to identify, given the lack of reliable and comprehensive records. However, exposure to chemical agents in water has been related to a range of chronic diseases, including cancer, lung damage, and birth defects. Many such diseases develop over several years, making the links between cause and effect difficult to establish. On a global scale, the burden of disease from chemical pollution is much lower than from microbial contamination and parasitic diseases, but in some highly polluted regions these risks can be substantial (WRI et al. 1998). Exposure to chemical pollutants can also compromise the immune system, rendering people more susceptible to microbial and viral infections. The cumulative and synergetic effects of long-term exposure to a variety of chemicals, especially at low concentrations, cannot be well quantified at present.

Naturally occurring inorganic pollutants constitute a class of chemical pollution with serious long-term health effects. Arsenic, which occurs naturally in some soils, for example, can become toxic when exposed to the atmosphere, as seen in areas with high water abstraction from underground aquifers (WRI et al. 1998). Arsenicosis is the result of arsenic poisoning from drinking arsenic-rich water over long periods of time and is a great concern in many countries, including Argentina, Bangladesh, China, India, Mexico, Thailand, and the United States (Bonvallot 2003). WHO estimated in 2001 that in Bangladesh alone, 35–77 million people—close to half the population—were exposed to drinking water from deep wells contaminated with high levels of arsenic (5–50 times the limit of 0.01 milligrams per liter recommended by WHO) (Bonvallot 2003). Arsenic is a carcinogen linked to skin, lung, and kidney cancer, although these diseases can go undetected for decades (WRI et al. 1998). In other parts of the world, high fluoride concentrations in drinking water have resulted in long-term effects that weaken the skeleton.

Chronic effects also arise from anthropogenic pollutants such as discharge from mining operations, pesticide runoff, and industrial sources. Long-term lead poisoning from old water pipes, for example, can cause significant neurological impairment (WRI et al. 1998). Mercury contamination can also originate from industrial discharge and runoff from mining activities, accumulating in animal tissue, particularly fish (WCD 2000).

Nutrient runoff is another concern from the standpoint of human health, especially in light of pandemic increase in loadings to inland water ecosystems, for example, of nitrogen (described earlier; see also Chapters 12 and 20). Although there is no global assessment of how many water bodies exceed the WHO guidelines on nitrate levels, most countries report that nitrates are one of the most common contaminants found in drinking water (WRI et al. 1998). Coastal and inland waters in regions with high levels of eutrophication have been observed to often propagate toxic algal blooms (toxic cyanobacteria) that can cause chronic disease. (See Chapter 19.) In China, for instance, the presence of cyanobacterial toxins in drinking water has been associated with elevated levels of liver cancer (WCD 2000). Excess nitrate in drinking water has also been linked to methaemoglobin anemia in infants, the ''blue baby'' syndrome (WRI et al. 1998).

Discharge from aquaculture facilities can also be loaded with pollutants, including high levels of nutrients from uneaten fish feed and fish waste, antibiotic drugs, and other chemicals, including disinfectants such as chlorine and formaline, antifoulants such as tributyltin, and inorganic fertilizers such as ammonium phosphate and urea (GESAMP 1997). These chemicals can significantly degrade the surrounding environment, particularly local waterways (GLFC 1999). The use of antibiotics and other synthetic drugs in aquaculture can also have serious health effects on people and ecosystems more broadly. The antibiotic chloramphenicol, for example, can cause human aplastic anaemia, a serious blood disorder that is usually fatal. While many countries have banned the use of chloramphenicol in food production, the level of enforcement varies considerably (GESAMP 1997; Health Canada 2004). A further risk from antibiotic use is the spread of antibiotic resistance in both human and fish pathogens. The U.S. Center for Disease Control and Prevention reported that certain antibiotic resistance genes in *Salmonella* might have emerged following antibiotic use in Asian aquaculture (Angulo 1999 as cited in Goldburg et al. 2001).

There is also evidence from studies on wildlife that humans may be at risk from persistent organic pollutants and residual material that has the ability to mimic or block the natural functioning of hormones, interfering with natural physiological processes, including normal sexual development (WRI et al. 1998). Certain chemicals such as PCBs, DDT, dioxins, and at least 80 pesticides are regarded as ''endocrine disrupters,'' chemicals that may interfere with normal human physiology, undermining disease resistance and affecting reproductive health (WRI et al. 1998).

Finally, pharmaceutical products excreted by livestock or humans comprise a set of ''emerging contaminants,'' whose impacts on human well-being, ecosystems, and species are not yet understood. These contaminants are hard to detect with current technologies, but their impact on wildlife are already observed in some parts of the world. In the United States, the first nationwide survey conducted in 1999 and 2000 found hormones in 37% of the streams surveyed and caffeine in more than half (Kolpin et al. 2002). Just recently, 42% of the sampled male bass in a relatively pristine stretch of the Potomac River in the United States were found to be producing eggs. The exact cause is still unknown, but it is hypothesized that it could be caused by chicken estrogen left over in poultry manure or perhaps human hormones discharged into the river with processed sewage.

7.4.5.3 Sanitation and Provision of Clean Water: Challenges for the Twenty-first Century

Providing ''improved'' clean water supply and sanitation to large parts of the human population remains a challenge (WHO/UNICEF 2004; United Nations Statistics Division 2004). (See Box 7.5 for definitions of improvement.) The most recently completed and comprehensive assessment of improved water and sanitation (WHO/UNICEF 2004) concluded that 1.1 billion people around the world still lack access to improved water supply and more than 2.6 billion lack access to improved sanitation, with strong geographic variations. (See Table 7.11 and Figures 7.13 and 7.14 in Appendix A.) Asia contains two thirds of all people who lack access to improved drinking water and three quarters of those who lack access to improved sanitation. Africa is next most prominent in terms of numbers still awaiting improvements in supply and sanitation. Other continents show much smaller numbers but may have relatively low rates of service, as in Oceania, with less than 50% served for both supply and sanitation.

There has been progressive improvement in the provision of sanitation since 1990 (see Table 7.12), recently prompted by the ambitious target for sanitation of the MDG environmental sustainability goal—namely, to halve by 2015 the proportion of people lacking such service in 1990. Worldwide, the goal was set to move coverage from 49% to 75%, and progress is nearly on track with the interim target for 2002 of 62% nearly attained. Of the nine regions analyzed, however, only four are on track or nearly, while five are behind schedule. The greatest challenge remains sub-Saharan Africa, which met only 4% of a targeted 17% improvement by 2002. Western Asia and Eurasia are less off their targets but have not moved forward. Overall, improvements in sanitation in rural areas have been significantly less than in urban areas, and there has even been a decline in the provision of sanitation in rural areas of Oceania and the former Soviet Union (WHO/UNICEF 2004).

BOX 7.5

Defining Improved Water Supply and Sanitation

''Improved'' water supply includes household connections, public standpipes, boreholes, protected dug wells, protected springs, and rainwater harvesting systems, but it does not include protected rivers or ponds, unprotected wells or springs, and unmonitored vendor-provided water (bottled water is not considered improved due to quantity limits arising from its high expense).

''Improved'' sanitation technologies include connections to a public sewer, connections to a septic system, pour-flush latrines, simple pit latrines, and ventilated improved pit latrines. Excreta disposal systems are considered adequate if they are private or shared (but not public) and if they hygienically separate human excreta from human contact. ''Not improved'' sanitation systems are service or bucket latrines (where excreta are manually removed), public latrines, or open pit latrines.

The rapid and disorganized growth in cities and peri-urban areas in developing countries is likely to hinder progress toward improved water delivery and sanitation systems. In 2000 alone, 16 cities around the world became megacities, with more than 10 million inhabitants each, housing 4% of the world's population (United Nations 2002). Most of these megacities fall within regions already suffering from water stress (UN/WWAP 2003). In Africa, Asia, and Latin America, 25–50% of the population live in informal or illegal settlements around urban centers where no public services and no effective regulation of pollution and ecosystem degradation are available (UN-HABITAT 2003). Half of the urban population in Africa, Asia, and Latin America and the Caribbean suffers from one or more diseases associated with inadequate water and sanitation (UN/WWAP 2003).

Even if government or municipal authorities were inclined to expand water and sanitation services to informal urban settlements, the lack of formal land ownership, plot designation, and infrastructure make this very difficult and unlikely. In many countries, water and sanitation authorities are only allowed to provide services and connect households to the water grid if proof of landownership is provided (UN-HABITAT 2003). These problems are in addition to the basic inability of slum dwellers to pay for connection charges and monthly fees without subsidies. With urban populations expected to encompass 80% of the world's population by 2030 (UNPD 1999), the supply of water and sanitation to city dwellers is set to become one of the greatest challenges to development.

7.5 Trade-offs in the Contemporary Use of Freshwater Resources

This chapter has provided an assessment of the recent history and contemporary state of global freshwater provisioning services. It

has documented a growing dependence of human well-being on fresh water, which in turn has promoted a variety of engineering strategies aimed at delivering reliable freshwater supplies. So effective has been the ability of water management to influence the state of this resource that anthropogenic impacts are now evident across the global water cycle. Much of the human influence is negative due to overuse and poor management, which has resulted in human-induced water scarcity, widespread pollution, and habitat and biodiversity loss. The capacity of ecosystems to sustain freshwater provisioning services thus has been greatly compromised throughout much of the world and may continue to remain so if historic patterns of managed use persist.

Sector-specific decisions often drive the nature of human interactions with water, with often unintended or purposefully ignored externalities on ecosystems. There is no shortage of examples. Flow stabilization optimizing hydroelectricity can severely fragment and degrade aquatic habitats and lead to losses of economically important fisheries. Industrial development with poor effluent management can result in severe pollution, leading to the loss of aquatic ecosystem function and biodiversity. Connecting urban dwellers to water supply and sewerage systems without due attention to water treatment, as has been commonplace, results in the release of toxic compounds and waterborne diseases that affect downstream water users. In arid and semiarid regions, decisions to promote national food self-sufficiency can translate into great risk to downstream populations and costly infrastructure, as rivers that normally carry water and sediments nourishing coastal lands and floodplains are diverted onto croplands or stabilized behind dams.

Trade-offs are thus an unavoidable component of human-freshwater interactions. Trade-offs are also inevitable in meeting Millennium Development Goals and other international commitments. To demonstrate this, a heuristic analysis is presented here to explore how emphasis on a particular objective could influence the capacity to attain others. The analysis uses the contemporary setting as its starting point, which is then tracked with respect to the impact of five specific interventions. These correspond directly to major objectives embodied in the Kyoto Protocol (carbon mitigation), the MDGs (poverty alleviation, hunger reduction, improved water services), and the Conventions on Biological Diversity and Wetlands (pragmatic ecosystem maintenance applied to inland and coastal ecosystems).

A non-intervention case (current trends) is also considered, analyzing the implications of allowing contemporary trends to continue. A time frame of approximately 10–15 years is considered, allowing sufficient time for general patterns to emerge. This time frame also is associated with the first targets of the MDGs.

The interventions and their impacts are specifically viewed through the lens of freshwater services and ecosystem maintenance. Thus, for carbon mitigation the positive impacts of expanding hydropower to reduce carbon emissions are considered, together with the negative impacts of flow fragmentation that compromises the normal functions of inland freshwater and coastal ecosystems. To maximize relevancy to the international development agenda, the findings refer to poor countries alone. The interventions and key results are summarized in Table 7.13 and Figure 7.15. In each case the contemporary baseline is the starting point, given by the intermediate of three circles. Improvement is depicted by movement outward to the larger circle. Declining condition is represented by a move inward, and no appreciable change settles on the middle curve.

It is important to note that these experiments are not predictions but instead are thematic devices to demonstrate broad-scale effects that can be supported by findings in this chapter. Although the details could be argued legitimately one way or another, it is the basic character of the response that is sought. Furthermore, as will become apparent, it is the behavior of the full set of experiments rather than individual cases that becomes most instructive.

Current Trends in Figure 7.15 is the first case, representing no meaningful change in the pace at which human development is attained or interventions are made to reverse ongoing threats to ecosystem services. This scenario shows direct beneficiary effects on human well-being but also sustained and substantial declines in the condition of aquatic ecosystems. On the positive side, there is some alleviation of hunger through increased food production that relies on expanded irrigation and use of agrochemicals; continued improvement to health by way of drinking water and sanitation access; some progress toward reducing poverty; and an expansion of hydropower, which in some parts of the developing world (such as South America) is already an important source of energy, with some beneficiary effects on carbon mitigation.

At the same time, aquatic ecosystems and their biodiversity will be increasingly degraded in this scenario due to the combined forces of industrial, agricultural, and domestic sources of pollution, hydropower with associated flow fragmentation, and habitat destruction. Lack of environmental regulation and enforcement exacerbates the trend. Reduced and highly regulated water flows in rivers continue to decrease the transport of water and sediment to estuaries and coastal wetlands. Food provisioning services, in terms of natural inland and coastal fisheries, are in decline, and freshwater provisioning will continue to be placed in jeopardy by the dual threats of overuse and pollution.

Major supporting and regulating services also continue their decline due to loss of ecosystem function across both inland aquatic systems and their linked terrestrial ecosystems. Particularly relevant to fresh water are losses in flood control (from poor land management, erosion, loss of wetlands), in self-purification potential of waterways (from chronic and acute land-based sources of pollution), and in protection of human health (from inappropriate waste disposal). The links between ecosystem services and human well-being mean that these losses of natural services could ultimately compromise the attainment of important development goals.

While the value of controlling greenhouse gases or instituting the MDGs is almost universally accepted, results in Table 7.13 and Figure 7.15 suggest that pursuing each objective in isolation of other development goals or environmentally sound management principles will be counterproductive. Interventions in accordance with strategies being promoted through the Conventions on Biological Diversity and Wetlands, which stress protection and wise use of ecosystems and their services for sustainable development, yield several positive effects on human well-being. These improvements arise from a purposeful strategy of integrated environmental management, which links environmental stewardship directly to poverty alleviation, food security, and clean water targets (CBD 2004; Ramsar Convention 2004).

There is a growing recognition that maintaining biodiversity and ecosystem integrity will require compromise and trade-offs. A good example is the critical choice between providing water for crop production or for healthy rivers and wetlands. In areas where irrigation and storage reservoirs are upstream of sensitive ecosystems, both livelihoods and environmental integrity can be at stake. One possible strategy to accommodate potential losses in food production and income is by managing basin-wide improvements in water productivity for agriculture through new crop breeding, innovative technologies, and water reuse strategies (Molden 2003), all saving water and reducing the need for irrigation and flow stabilization.

While only qualitative in nature, these findings clearly demonstrate the consequences of optimizing one development goal or conservation objective over others. This assessment indicates that there would be substantial inconsistencies in the major development and sustainability strategies should they not become better integrated. The impacts of these conflicts on freshwater provisioning services and ecosystem functioning are likely to compromise the sought-after progress inherent in these same international commitments. The conjunction of several incongruous objectives will further exacerbate the deterioration of inland and coastal systems documented in Chapters 19 and 20.

It is very certain that the condition of inland waters and coastal ecosystems has been compromised by the conventional sectoral approach to water management, which, if continued, will constrain progress to enhance human well-being. In contrast, the ecosystem approach, as adopted by CBD, Ramsar, FAO, and others, shows promise for improving the future condition of water provisioning services, specifically by balancing the objectives of economic development, ecosystem needs, and human well-being.

Table 7.13. Major Objectives Optimized in Experiments to Discern the Compatibility of Development Goals and International Conventions. These objectives are considered in the context of freshwater provisioning services and protection of inland and coastal waters. General categories of responses are given, as depicted in Figure 7.13. Positive, intermediate, and negative effects are relative to contemporary condition. A time horizon of 10–15 years is considered.

Sectoral Intervention	Relevant International Commitment	Positive Effects	Intermediate or Small Effects	Negative Effects
Current trends (non-intervention)			some progress toward carbon mitigation, poverty reduction, hunger alleviation, and access to water services	persistent decline in health of inland and coastal ecosystems and their services (provisioning, regulating, supporting)
Carbon mitigation	Kyoto Protocol	reduced CO_2 emissions through increased reliance on hydropower assumed to override reservoir respiration and methane emission; progress on hunger reduction, water services, poverty reduction as under current trends	water storage for irrigation yields some reservoir fisheries for food; urban benefits of hydroelectricity; rural poverty alleviation effects small in relation to current trends	waterborne disease increases in tropical regions; dams fragment habitat and modify fluxes of constituents and water through inland waterways; loss of inland fisheries; erosion, nutrient imbalance in coastal systems due to upstream reservoir trapping
Hunger reduction	MDG 1, Target 2	major beneficial effects on nutrition	well-fed populations show increased health benefits and poverty reduction; consumptive losses from expanded irrigation mean less water for hydroelectricity; little effect on improved water/sanitation	expanded irrigation and impoundment storage means less available water for inland and coastal ecosystems
Improved water services (access to clean water and sanitation)	MDG 7, Target 10	improved health; increased productivity of labor reduces poverty	similar water quality as under current trends if waste treatment assumed (not the norm); no impact on carbon mitigation or hunger alleviation assumed	inland and coastal pollution from sewage, assuming no treatment
Poverty alleviation	MDG 1, Target 1	rising standards of living; increased availability of hydropower with benefits for carbon mitigation; increased food demands and availability	increased access to water services leads to improved health for those served; effect mitigated by increased pollution and water-related diseases for remaining poor	strong impacts on natural ecosystems from agricultural pollution; water diversions for crops and industrial production; river fragmentation from dams
Pragmatic ecosystem maintenance (inland and coastal wetlands)	Convention on Biological Diversity, Convention on Wetlands (Ramsar)	integrated management leads to protection of inland/coastal ecosystems with improved freshwater provision (quantity and quality)	land management improves carbon mitigation and crop productivity; food sources from aquatic systems; stable water supplies allow for some high-productivity irrigation and well-managed reservoirs (for C mitigation as well); improved water quality leads to better health; aggregate benefit from all factors reduces poverty	no single objective met fully; compromises among stakeholders inherent in such a multiobjective framework

Figure 7.15. Trade-off Analysis, Depicting Major Interventions and Consequences on Condition of Ecosystems and Development Goals. Note that in the absence of integrated sustainable development and environmental protection plans, current trends and development-related interventions may compromise ecosystem functioning. Better balanced effects are noted by instituting strategies guiding the Convention on Biological Diversity and Convention on Wetlands (Ramsar). An approach balancing ecosystem protection and economic development could yield an aggregate net benefit to the entire suite of objectives. The contemporary starting point is the middle circle. Movement toward the outside circle indicates improvement while movement inward depicts negative trends. See text and Table 7.13 for further interpretation.

Main Messages

Biodiversity, including the number, abundance, and composition of genotypes, populations, species, functional types, communities, and landscape units, strongly influences the provision of ecosystem services and therefore human well-being (*high certainty*). Processes frequently affected by changes in biodiversity include pollination, seed dispersal, climate regulation, carbon sequestration, agricultural pest and disease control, and human health regulation. Also, by affecting ecosystem processes such as primary production, nutrient and water cycling, and soil formation and retention, biodiversity indirectly supports the production of food, fiber, potable water, shelter, and medicines.

Species composition is often more important than the number of species in affecting ecosystem processes (*high certainty*). Thus, conserving or restoring the composition of communities, rather than simply maximizing species numbers, is critical to maintaining ecosystem services. Changes in species composition can occur directly by species introductions or removals, or indirectly by altered resource supply due to abiotic drivers (such as climate) or human drivers (such as irrigation, eutrophication, or pesticides).

Although a reduction in the number of species may initially have small effects, even minor losses may reduce the capacity of ecosystems for adjustment to changing environments (*medium certainty*). Therefore, a large number of resident species, including those that are rare, may act as "insurance" that buffers ecosystem processes in the face of changes in the physical and biological environment (such as changes in precipitation, temperature, or pathogens).

Productivity, nutrient retention, and resistance to invasions and diseases tend to increase with increasing species number in experimental ecosystems that have been reduced to a small number of species (10 or fewer). This is known with *high certainty* for experimental herbaceous ecosystems and with *low certainty* for natural ecosystems, especially those dominated by long-lived species. In natural ecosystems these direct effects of biodiversity loss may often be masked by other environmental changes that are caused by the factors that resulted in the loss of biodiversity (such as eutrophication or climate change). Nevertheless, human activities that cause severe reductions in species number can directly impair these ecosystem services.

Preserving interactions among species is critical for maintaining long-term production of food and fiber on land and in the sea (*high certainty*). The production of food and fiber depends on the ability of the organisms involved to successfully complete their life cycles. For most plant species, this requires interactions with pollinators, seed disseminators, herbivores, or symbionts. Therefore, land use practices that disrupt these interactions will have a negative impact on these ecosystem services.

Intended or accidental changes in the composition of ecological communities can lead to disproportionately large, irreversible, and often negative alterations of ecosystem processes, causing large monetary and cultural losses (*high certainty*). In addition to direct interactions, the maintenance of ecosystem processes depends on indirect interactions, whose disruption can lead to unexpected consequences. These consequences can occur very quickly; for example, in a wide range of terrestrial, marine, and freshwater ecosystems, the introduction of exotic species by humans has altered local community interactions. Alternatively, these consequences may be manifest only after a long time. For example, the intraspecific genetic diversity of certain plant species decreases when the populations of their animal pollinators or dispersers are reduced.

Invasion by exotic species, facilitated by global trade, is a major threat to the biotic integrity of communities and the functioning of ecosystems. Empirical evidence suggests that areas of high species richness (such as hot spots) are more susceptible to invasion than species-poor areas. On the other hand, within a given habitat the preservation of its natural species pool appears to decrease its susceptibility to invasions. On the basis of our present theoretical knowledge, however, we still cannot predict with accuracy whether a certain organism will become a serious invader in a given ecosystem.

The extinction of local populations, or their reduction to the point that they become functionally extinct, can have dramatic consequences in terms of regulating and supporting ecosystem services. Local extinctions have received little attention compared with global extinctions, despite the fact that the former may have more dramatic ecosystem consequences than the latter. Before becoming extinct, species become rare and their ranges contract. Therefore their influence on ecosystem processes decreases, even if local populations persist for a long time, well before the species becomes globally extinct. We do not have sufficient knowledge to predict all the consequences of these local extinctions. However, because they tend to be biased toward particular organisms that depend on prevailing land uses and types, rather than occurring at random, we can anticipate some of the most obvious impacts.

The properties of species are more important than species number in influencing climate regulation (*medium certainty*). Climate regulation is influenced by species properties via effects on sequestration of carbon, fire regime, and water and energy exchange. The traits of dominant plant species, such as size and leaf area, and the spatial arrangement of landscape units are particularly important in climate regulation. The functional characteristics of dominant species are thus a key element determining the success of mitigation practices such as afforestation, reforestation, slowed-down deforestation, and biofuel plantations.

The diversity of landscape units also influences ecosystem services (*high certainty*). The spatial arrangement of habitat loss, in addition to its amount, determines the effects of habitat loss on ecosystem services. This is because the effects of habitat loss on remaining habitat fragments are greater on the edges than in their cores. Thus, fragmentation of habitat has disproportionately large effects on ecosystem services. These effects are best documented in the case of carbon sequestration and pollination in the tropics.

Maintenance of genetic and species diversity and of spatial heterogeneity in low-input agricultural systems reduces the risk of crop failure in a variable environment and reduces the potential impacts of pests and pathogens (*high to medium certainty*). Agroforestry systems, crop rotations, intercropping, and conservation tillage provide opportunities to protect crops and animals from pests and diseases while maintaining yields without heavy investment in artificial chemicals.

Global change drivers that affect biodiversity indirectly also affect biodiversity-dependent ecosystem processes and services. Among these global change drivers, a major threat to biodiversity-dependent human well-being is large-scale land use change, especially the intensification and extensification associated with large-scale industrial agriculture *(high certainty).* This threat is most obvious for those human groups that are already vulnerable because their livelihoods rely strongly on the use of natural and seminatural ecosystems. These include subsistence farmers, the rural poor, and traditional societies.

A considerable amount of new research is needed to understand the role of different components of biodiversity in the provision of ecosystem

services. Although the available evidence clearly points to the key importance of the maintenance of the genetic, species, and landscape diversity of ecosystems in order to preserve the ecosystem services they provide, important knowledge gaps remain to be filled. These are particularly obvious in the case of high-diversity ecosystems, ecosystems dominated by long-lived plants, and trophic levels other than plants.

11.1 Introduction

Biodiversity refers to the number, abundance, and composition of the genotypes, populations, species, functional types, communities, and landscape units in a given system. Biodiversity is both a response variable that is affected by changes in climate, resource availability, and disturbance (see Chapter 4) and a factor with the potential to influence the rate, magnitude, and direction of ecosystem processes. This chapter focuses on this second aspect—the effects of biodiversity on ecosystem processes and the ecosystem services that humans obtain from them.

Ecosystem services are broadly defined as the benefits provided by ecosystems to humans; they contribute to making human life both possible and worth living (Daily 1997; MA 2003). Biodiversity affects numerous ecosystem services, both indirectly and directly. Some ecosystem processes confer direct benefits on humanity, but many of them confer benefits primarily via indirect interactions.

This chapter focuses on regulating and supporting ecosystem services (see Chapter 1) that result from interactions between two or more species or genotypes. The regulating ecosystem services addressed in this chapter include pollination, seed dispersal, climate regulation, carbon sequestration, and pest and disease control. (See Figure 11.1.) Biodiversity also provides supporting ecosystem services, which are necessary for the production of all other—more direct—ecosystem services. For example, by influencing primary production and nutrient and water cycling, biodiversity indirectly supports the production of food, fiber, and shelter. The enormous value of biodiversity per se and its importance in the provision of cultural ecosystem services are described in detail in Chapters 4, 10, and 17. Here the focus is on how biodiversity affects the quantity and temporal stability of the supply of those services.

Consideration of all components of biodiversity—genotypes, species, functional traits and types, communities, and landscape units—is essential in order to understand its role in ecosystem processes and thus in the provision of ecosystem services. Although traditionally the focus has been mainly on species number, there is now broad consensus that functional diversity—the value, range, and relative abundance of organismal traits present in a community—is the most important component of biodiversity influencing ecosystem functioning (Díaz and Cabido 2001; Loreau et al. 2001; Hooper et al. 2005). Recent scientific literature on the functional role of biodiversity has generated conflicting results that are sometimes difficult to interpret. However, some basic points of agreement have emerged that are relevant to land use and conservation policies.

Most of the current evidence and theory described early in this chapter deal with direct interactions among terrestrial plants. Although a growing number of studies incorporate other ecosystem processes, most of what we know about biodiversity effects on ecosystem functioning refers specifically to the production of plant biomass (the tissues formed using the solar energy captured by photosynthetic plants). However, there is growing empirical evidence suggesting that the influence of interactions between plants and microorganisms and between plants and animals as well as the influence of indirect interactions on ecosystem properties are both important and widespread. Because these intertrophic and indirect interactions have received much less attention in the literature, they are emphasized in this chapter. The effects of terrestrial biodiversity on ecosystem services is discussed first, followed by a similar discussion of the effects of marine biodiversity on ecosystem processes provided by oceans and coastal areas, a topic whose importance has been recognized only recently.

Two major aspects of ecosystem functioning form the focus of this analysis: resource dynamics at given point in time (which includes processes such as primary and secondary production, nutrient cycling, and water dynamics) and long-term stability of such processes in the face of environmental variability or directional change.

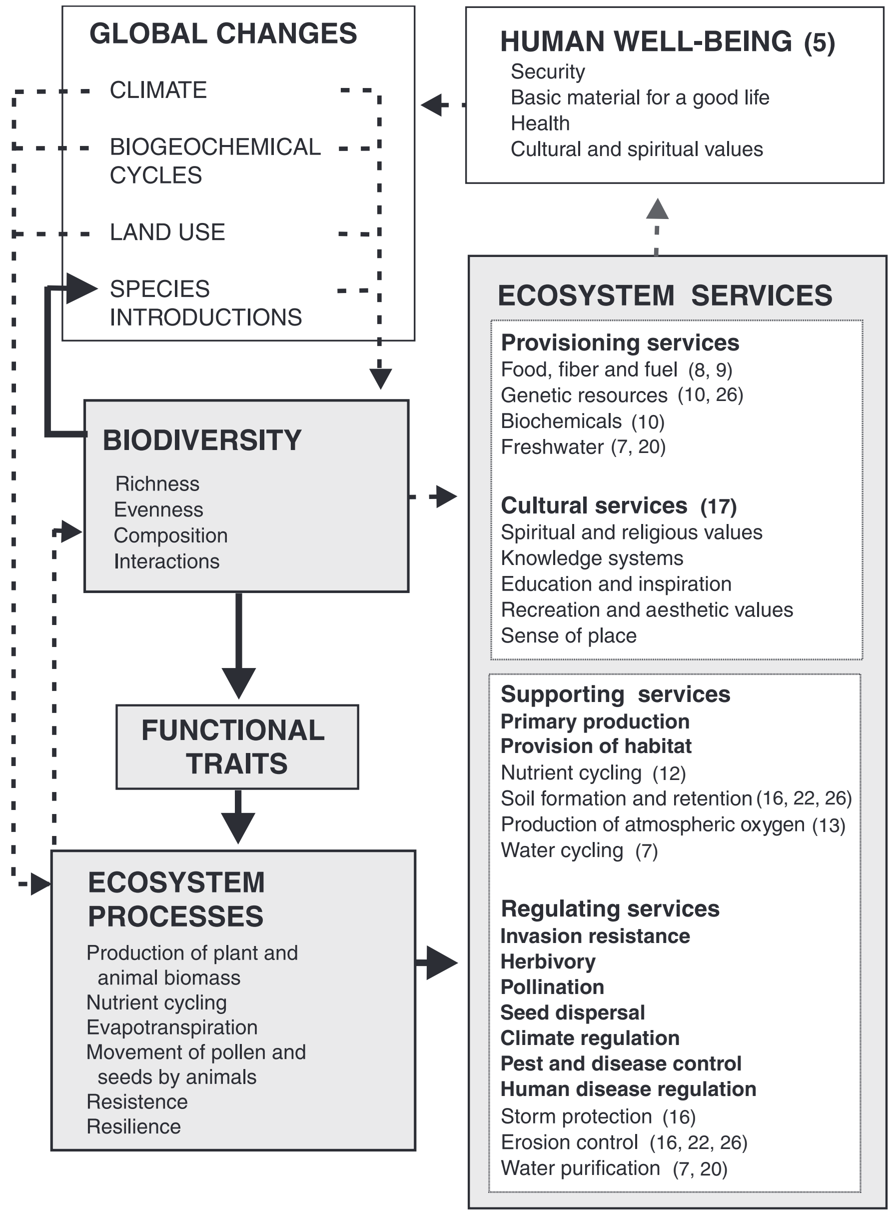

Figure 11.1. Biodiversity as Response Variable Affected by Global Change Drivers and as Factor Modifying Ecosystem Processes and Services and Human Well-being (modified from Chapin et al. 2000). Solid arrows indicate the links that are the focus of this chapter. Regulating services are the benefits obtained from the regulation of ecosystem processes. Supporting services are those that are necessary for the production of all other services. Ecosystem services in bold are developed in detail in this chapter. Other services are not addressed here because the role of biodiversity in regulating them in ecosystem processes is minor or uncertain, or because they are developed in detail elsewhere in this volume (relevant chapter number is indicated in parentheses).

11.2 Terrestrial Biodiversity Effects on Supporting Services

Region-to-region differences in ecosystem processes are driven mostly by climate, resource availability, and disturbance—not by differences in species richness. In most ecosystems, changes in the number of species are the consequence of changes in major abiotic and disturbance factors, so that the ecosystem effect of species richness (number of species) per se is expected to be both comparatively small and very difficult to isolate. For example, variation in primary productivity depends strongly on temperature and precipitation at the global scale and on soil resources and disturbance regime at the region-to-landscape-to-local scales. Factors that increase productivity, such as nutrient addition, often lead to lower species richness because more productive species outcompete less productive ones. In nature, therefore, high species diversity and high productivity are often not positively correlated (Grime 1979, 2001; Gough et al. 1994; Waide et al. 1999).

When elaborating management recommendations, it is extremely important to bear these considerations in mind and to interpret the conclusions of experiments within the right context. Here again, if taken uncritically, results from synthetic assemblages may lead to misleading recommendations to land managers (see also Fridley 2001; Schmid 2002; Hodgson et al. 2005).

Similarly, artificial increases of species richness in naturally species-poor areas (such as moorlands, boreal forests, or desert shrublands) may not result in any substantial ''improvement'' in ecosystem services. In natural ecosystems, low species richness does not necessarily imply impaired ecosystem properties and services. In most synthetic-community experiments, the assemblage of experimental communities occurs by random draws of species from a species pool decided by the experimenter, and the abundances of different species are artificially even, at least at the initial stages. This strongly differs from the process of community assembly that occurs in nature, in which the local assemblage is the product of a ''filtering'' process exerted by the environment on the regional species pool (Zobel 1997; Díaz et al. 1998).

Extinction in natural ecosystems similarly tends to be biased to certain organisms (Vitousek et al. 1997; Grime 2002; see also Chapter 4) rather than being a random process. In most natural assemblages, any unused resources are likely to be quickly used by members of the species pool, even in communities with low species richness (Zobel 1997; Hodgson et al. 1998). Some low-species-richness combinations in synthetic communities, on the other hand, are artificially maintained and could not persist in nature (Hodgson et al. 1998; Lepš 2005). This does not necessarily invalidate the results of experiments based on artificial assemblages; however, it is crucial to understand that low species richness in these experiments and in real ecosystems stem from different causes. Low diversity in nature tends to occur at either very high or very low productivity and to result from different processes in each situation. Most often, it results from strong abiotic constraints at low productivity and high biotic constraints at high productivity (see, e.g., Huston 1999; Pärtel et al. 2000).

Nevertheless, biodiversity can directly affect supporting services such as primary productivity, soil formation, and nutrient cycling, which in turn influence provisioning services such as genetic resources and production of food, timber, fuel, and fiber. The mechanisms by which that happens, and the empirical evidence accumulated to date are discussed in the remainder of this section.

In general, the most important component of plant biodiversity influencing ecosystem services is functional composition. And, other things being equal, a greater number of resident species should result in greater production, higher nutrient retention, and enhanced resistance to invasion, at least in experimental studies using a low number of resident species. There is also some indication that a high number of species within each functional type (a group of organisms that responds to the environment or affects ecosystem processes in a similar way) should lead to more stability in the face of perturbations than a low number of species, although direct experimental evidence of this is limited.

Productivity of agroecosystems may not increase if individual agricultural fields are planted with higher species richness, because under intensive modern agriculture a single strain of a single crop species is likely to give the highest yield or the highest profit in a given field (Swift and Anderson 1993). The situation may be different, however, in agroecosystems managed using approaches that incorporate biodiversity (such as the ''agricultural diversification'' or ''integrated pest management'' paradigms described later), where species composition and resource levels are under much looser control by the land managers, and thus recruitment from the natural species pool plays a more relevant role (Swift and Anderson 1993; Fridley 2001).

In high-biodiversity agriculture, a larger number of species may provide ''ecological insurance'' against crop failures, which is especially important to poor farmers disconnected from market insurance systems. (See Chapters 6 and 26.) Changes in species numbers may have only subtle short-term effects in some ecosystems but may directly influence their capacity for long-term adjustment in the face of a changing environment.

Major changes in species composition due to direct introduction or removal of species, or caused indirectly by changing relative abundances via altered resource supply (such as irrigation or eutrophication), can shift the functional trait composition of ecosystems and therefore deeply modify their derived services. Therefore, the preservation of the integrity, in terms of size and composition, of the regional species pool is a key factor in maintaining the rate, magnitude, and long-term persistence of those ecosystem processes that support ecosystem services. The regional species pool is defined as the set of species occurring in a certain region that is capable of coexisting in the target community.

11.2.1 Ecosystem Resource Dynamics, with Emphasis on Primary Production

The relationship between plant species richness and ecosystem production (including both total biomass achieved and the rate at which that biomass is achieved—that is, productivity) and the efficiency of resource use is probably the single most tested—and most debated—aspect of the relationship between biodiversity and ecosystem functioning. One important source of controversy among authors stems from the different results that emerge from studies at different spatial scales, where the controlling processes may differ (Fridley 2001; Loreau et al. 2001; Hooper et al. 2005). Specifically, some studies have focused on the relationship between species richness within a single habitat, whereas others have compared patterns among different habitats. For example, when ecosystems developed in different habitats are compared, soil fertility is a strong determinant of primary production and plant species diversity.

Two synthesis articles published in the last few years provide a good overview of the state of the art in this topic (Loreau et al. 2001; Hooper et al. 2005). Some of the main empirical findings and underlying theoretical issues related to the role of biodiversity in regulation ecosystem resource dynamics in general, and to primary production in particular, are summarized here.

Experimental manipulation of species richness in greenhouse (Naeem et al. 1995; Symstad et al. 1998) and large-scale field experiments (Tilman et al. 1996, 1997a, 2001; Hector et al. 1999, 2001) has shown a positive relationship between plant species richness and primary production, especially at low number of species (see Schläpfer and Schmid 1999; Schwartz et al. 2000; Hector 2002; Schmid et al. 2002; Tilman et al. 2002b). (See Table 11.1.)

In some experimental studies, total plant biomass has experimentally been shown to be greater, on average, and levels of soil nitrate—the limiting resource—lower (less leaching) at higher levels of plant species richness (Tilman et al. 1996, 1997a). Tilman et al. (2001) found that both species richness and functional type composition were significant controllers of productivity, and that no low-richness plot was as productive as many higher-richness combinations of species were. However, other experimental studies have found that ecosystem processes are more strongly linked to plant species and functional type composition than to species richness (Hooper and Vitousek 1997; Tilman et al. 1997a; Wardle et al. 1997a, 1999; Crawley et al. 1999; Lavorel et al. 1999; Kenkel et al. 2000; Paine 2002; Hooper and Dukes 2004). The influence of plant species richness or composition on soil processes such as decomposition and microbial activity is less well understood (Wardle et al. 2004).

For forest ecosystems, most data come from observational field surveys that compare natural, managed, or old forest plantations with different tree species richness. Single-species tree stands and adjacent two-species stands have been the most studied (reviewed by Cannell et al. 1992; Kelty et al. 1992). In general, two-species forests are more productive than stands dominated by a single species, but they are not necessarily more productive than the best monoculture.

Inhibitory and enhancing effects are also common. In the United Kingdom, for example, studies of two-species combinations of a pool of four species have shown that mixtures that con-

Table 11.1. Main Components of Biodiversity Involved in Supporting and Regulating Ecosystem Services Addressed in This Chapter. Bullets indicate importance and/or degree or certainty (•••> ••> •). The mechanisms and shape of the relation between the provision of ecosystem services and diversity remain highly speculative in many cases. In the cases of most saturating curves, the level at which diversity effects saturate for different ecosystem services is poorly known. Biodiversity also contributes to provisioning and cultural ecosystem services in important ways.

Ecosystem Services	Main Components of Biodiversity Involved	Mechanisms That Produce the Effect	How the Provisioning of Service Scales to Diversity
Supporting services			
Amount of primary production	••• functional composition of plant assemblage	faster-growing, bigger, more efficient, more locally adapted plants will produce more biomass	complex relationship; processes depend on identity of dominant species, not species richness
		in low-diversity systems, coexisting plants with very different (complementary) resource use strategies will take up more resources	saturating curve
	•• species richness of plant assemblage	a larger species pool is more likely to contain groups of complementary species and individual species that are highly productive, both of which should lead to higher productivity of the community	saturating curve
Stability of primary production	••• genetic diversity	large genetic variability within a crop species buffers production against losses due to diseases and environmental change	saturating curve
	••• species richness	polycultures (more than one species cultivated together) maintain production over a broader range of conditions	saturating curve
	••• functional composition of plant assemblage	life history, resource use strategy, and regeneration strategy of dominant plants determine resistance and resilience of ecosystem functioning against perturbations	complex relationship; stability depends on identity of dominant species, not species richness saturating curve; subordinate species can totally or partially compensate for functions of dominants
Provision of habitat	••• habitat diversity, including spatial distribution, size and shape of landscape units	connectivity, landscape heterogeneity, and large landscape units are necessary for migrating species and species that need large foraging areas	complex relationship, likely to be different for different kinds of organisms
	••• functional composition of vegetation	some vertebrates need a complex vegetation structure for breeding and roosting	complex relationship; stability depends on identity of dominant species, not species richness
	•• species richness	the more species at each trophic level, the more species herbivores, predators, and/or pathogens are provided a resource base	saturating curve
Regulating services			
Invasion resistance	••• species composition	some key native species are very competitive or can act as biological controls to the establishment and naturalization of aliens	complex relationship; processes depend on identity of dominant species, not species richness
	••• arrangement of landscape units	landscape corridors (e.g., roads, rivers, extensive crops) can facilitate the spread of aliens	complex relationship; size and nature of suitable corridors likely to be different for different organisms
	•• species richness and diversity	all else being equal, species-rich communities are more likely to contain highly competitive species and fewer vacant niches, and therefore to be more resistant to invasions	decreasing curve, often exponential decay to zero in experimental studies

Table 11.1. ***continued***

Ecosystem Services	Main Components of Biodiversity Involved	Mechanisms That Produce the Effect	How the Provisioning of Service Scales to Diversity
Pollination	••• functional composition of pollinator assemblage	loss of specialized pollinators leads to a reduction of number and quality of fruits produced and plant genetic impoverishment	complex relationship; processes depend on identity of dominant species, not species richness
	•• species richness of pollinator assemblage	lower pollinator species richness leads to a reduction of number and quality of fruits produced and plant genetic impoverishment	linear relationship for co-evolved pollination systems; saturating curve or linear relationship for generalist pollination systems
	•• arrangement and size of landscape units	large landscape units and/or connectivity among them maintain plant genetic pool and number and quality of fruits	saturating curve
Climate regulation	••• arrangement and size of landscape units	size and spatial arrangement of landscape units over large areas influence local-to-regional climate, by lateral movement of air masses of different temperature and moisture	threshold for effect is patch size (landscape diversity) of about 10 km diameter, depending on wind speed and topography
	•• functional composition of vegetation	height, structural diversity, architecture, and leaf seasonal patterns modify albedo, heat absorption, and mechanical turbulence, thus changing local atmospheric temperature and air circulation patterns	linear relationship between albedo and heating; albedo depends on structural diversity and on the plant functional types that dominate the canopy
Carbon sequestration	••• arrangement and size of landscape units	carbon loss is higher at forest edges; as forest fragments decline in size, a larger proportion of the total landscape is losing carbon	nonlinear relationship; as patches get larger, changes in carbon sequestration should saturate (the edges become a smaller proportion of total area); conversely, as patches get smaller, carbon loss increases exponentially with degree of fragmentation
	•• functional composition of vegetation	fast-growing, fast-decomposing, short-leaved, small-sized plants retain less carbon in their biomass than slow-growing, slow-decomposing, long-leaved, large-statured plants	saturating relationship with plant size; linear relationship with surface area of landscape units; note that the diversity has to do with the column to the left; in some cases the shape of this relationship is not related to diversity
	• species richness of vegetation	high species richness can slow down the spread of pests and pathogens, which are important agents of disturbance and carbon loss from ecosystems	saturating curve
Pest and disease control in agricultural systems	••• genetic diversity of crops	reduces density of hosts for specialist pests, and thus their ability to spread	saturating curve, but substantial effects are achieved with only a few species
	•• high richness of crop, weed, and invertebrate species	similar to genetic diversity, but also increases habitat for natural enemies of pest species	saturating curve in general, but some weed or invertebrate species may lead to a complex relationship
	•• spatial distribution of landscape units	natural vegetation patches intermingled with crops are the habitat of many natural enemies against insect pests	saturating curve as the size and number of natural vegetation patches increase; saturation point likely to be different for different groups of natural enemies

tain the pine *Pinus sylvestris* are always more productive than any monospecific stand due to the nursing effect of pines on other species with no detriment to itself, whereas mixtures of Norway spruce (*Picea abies*) and alder (*Alnus glutinosa*) have lower productivity than monospecific stands of either species (Brown 1992). These results suggest that, for temperate forests, species identity and combination might be more important than tree species richness per se. Forest productivity seems to be improved in two-species stands when there is complementarity in resource use (for instance, early and late successional species, shade-tolerant and shade-intolerant species, or different duration of the growing season).

Few studies have compared primary production of forests over a wide range of species richness. The Forest Inventory and Analysis database in the United States shows a positive correlation between tree species richness and stand productivity (Caspersen and Pacala 2001). However, the lack of environmental description hinders the interpretation of this association, especially because for two-species mixtures it is known that whether mixtures are more productive than pure stands depends on site conditions. In the western Mediterranean basin, productivity has also been compared across a range of forests with different tree species richness (Vilà et al. 2003). Here, monospecific pine forests have lower wood production than mixed (two- to five-species) forests. However, the species-rich forests are associated with humid climates, certain bedrock types, and early successional stages, which may be the cause of higher productivity.

The production of leaf litter may be greater in forests with two or more tree species than in monospecific forests, but whether there was a positive effect beyond two-species mixtures depended on the species and functional identity of the dominant tree species (Vilà et al. 2004). Similarly, the effect of tree species interactions on decomposition, a key process in nutrient cycling, seems to be species- and mixture-specific (Fyles and Fyles 1993), depending on the leaf litter quality of the trees and the associated microbial detritivore community (Blair et al. 1990; Wardle et al. 1997). Species-specific effects do not necessarily contradict the possibility of diversity effects. However, the lack of long-term monitoring with a reasonable number of species limits the ability to assess the relative importance of composition versus number of tree species. Therefore, general conclusions about the causal links between species richness and ecosystem processes in forests cannot yet be made.

On the other hand, an increasing number of reports indicate that the functional components of biodiversity (value, range, and relative abundance of plant traits) play an important role in ecosystem resource dynamics. Significant associations of ecosystem processes with plant functional composition and richness have been found more consistently than associations with species richness (Díaz and Cabido 2001). Considerable evidence, both from experiments and from nonmanipulative field studies of plant communities, shows that not all species are equally important to ecosystem functioning. Some are particularly crucial due to their traits or relative abundance.

In particular, the relative distribution of plant biomass among species is highly inequitable in most communities, with a minority of species (dominants) contributing most of the total biomass. The traits of the dominant plant species are usually the key drivers of an ecosystem's processing of matter and energy (see Hobbie 1992; Aerts 1995; Chapin et al. 1996; Aerts and Chapin 2000; Lavorel and Garnier 2002 for reviews). Therefore, at any given time the relative roles of species and functional type richness in ecosystem functioning tend to be small compared with the effect of the most dominant species. In these situations, the loss or introduction of dominant plant species may lead to much more important shifts in ecosystem functioning than those of other plant species, irrespective of changes in species richness (Lepš et al. 1982; Hooper and Vitousek 1997; McGrady-Steed et al. 1997; Wardle et al. 1997a; Mikola 1998; Symstad et al. 1998; Grime et al. 2000).

Even in situations where the average effect of the loss of randomly chosen plant species is a decrease in ecosystem productivity and nutrient use, large variations in ecosystem processes exist depending on which species or functional types are lost. The literature on invasive species provides dramatic examples of major ecosystem changes brought about by very small changes in species richness, usually the addition of a single species. (See Table 11.2.)

Biodiversity can influence ecosystem processes via at least two qualitatively different but not mutually exclusive mechanisms. One is the ''niche complementarity effect'' or ''niche differentiation effect.'' Because the range of functional types is likely correlated with species number, species-rich communities may achieve more efficient resource use in a spatially or temporally variable environment than in species-poor communities (Tilman 1999; Loreau 2000). Complementary interactions, which are caused by differences among species in their resource and environmental needs, allow combinations of species to obtain more resources and produce more biomass than could any single species. Typical examples of resource-use complementarity are plant species with shallow and deep roots, warm-season and cool-season grasses, and diurnal and nocturnal pollinators or predators. In species-poor situations, increasing species richness would add novel traits, which will allow a more complete use of available resources. Positive interactions between species, such as facilitation and mutualism (increased availability of nitrogen to grasses as a consequence of the presence of nitrogen-fixing legumes, for example), may also enhance biomass production.

The second mechanism that can explain the positive effects of species diversity on ecosystem processes is the ''sampling effect'' (Aarssen 1997; Huston 1997; Tilman et al. 1997b), also called the ''selection probability effect'' (Loreau 1998): the greater the number of species initially present in an ecosystem, the higher the probability of including a species that performs particularly well under these conditions. Because any given species has a greater chance of being present at higher species richness, communities with higher number of species would be more likely to contain ''better-performing'' species (bigger, faster-growing, more tolerant to the prevailing conditions, more likely to have facilitative effects on other species, and so on) and thus to function ''better'' than species-poor communities. The sampling effect emphasizes the effects of a single dominant species and its greater chance of being present (''sampled'') in communities with more species.

The niche complementarity effect and the sampling effect are not mutually exclusive, and their relative importance varies among ecosystems, depending on the environmental conditions. For example, the niche complementarity effect should be most relevant in areas of high spatial heterogeneity of environmental conditions and resource availability, whereas the sampling effect should be most relevant in small habitat patches, in early successional communities, and in areas with high resource availability (Fridley 2001). Differences among species are central to both mechanisms (Díaz and Cabido 2001). This is because the traits of the dominant plants have a strong influence on local ecosystem functioning (sampling effect) and because the greater the differences among coexisting species in terms of traits, the more likely they are to be complementary (rather than overlapping) in their resource use (niche complementarity effect).

Most biodiversity studies have focused on plant biomass, in part because of its importance in the production of food and fiber. However, much less is known about biodiversity effects on other important ecosystem processes, such as nutrient cycling, secondary production, or water dynamics. Another difficulty in generalizing from past biodiversity studies is that most empirical findings and theoretical developments are derived from a focus on herbaceous plant communities, where results are expressed rapidly. Further progress in the understanding of the role of biodiversity on ecosystem processes and services will depend on widening the scope of investigation toward other ecosystem processes, vegetation types, and trophic levels.

11.2.2 Ecosystem Stability, with Emphasis on Primary Production

For continued delivery of ecosystem services, both rate and magnitude of ecosystem processes and their stability over long periods of time, especially in the face of environmental variability, matter. Stability of an ecosystem is defined as its capacity to persist in the same state. Ecosystem stability is often divided into two components: resistance and resilience. Resistance is the capacity of a system to remain in the same state in the face of perturbation. Resilience is the rate at which a system returns to its former state after being displaced from it by a perturbation (Lepš et al. 1982). Temporal variability in community composition, including that associated with the invasion by non-native species, is an inverse measure of resistance.

Ecological theory predicts a positive relationship between species richness and the stability of ecosystems. Species-rich communities should have greater interspecific variation in responses to perturbation or environmental variation, and therefore variation in ecosystem services should be less than in species-poor communities (Tilman 1996; Doak et al. 1998; Yachi and Loreau 1999; Lehman and Tilman 2000). In addition, when species compete, the number of feedback loops in a competitive community in-

Table 11.2. Ecological Surprises Caused by Complex Interactions. Voluntary or involuntary introductions of species often trigger unexpected alterations in the normal provision of ecosystem services by terrestrial, freshwater, and marine ecosystems. Thus the introductions or deletions can have consequences opposite the intended management goals and can affect ecosystem services negatively. In all cases, the community and ecosystem alterations have been the consequence of indirect interactions among three or more species.

Study Case	Nature of the Interaction Involved	Ecosystem-service Consequences	Source
Introductions			
Top predators			
Introduction of brown trout (*Salmo trutta*) in New Zealand for angling	trophic cascade, predator increases primary producers by decreasing herbivores	negative — increased eutrophication	Flecker and Townsend 1994
Introduction of bass (*Cichla ocellaris*) in Gatun Lake, Panama	trophic cascade, top predator decreases control by predators of mosquito larvae	negative — decreased control of malaria vector	Zaret and Paine 1973
Introduction of pine marten (*Martes martes*) in the Balearic Islands, Spain	predator of frugivorous lizards (main seed dispersers)	negative — decreased diversity of frugivorous lizards due to extinction of native lizards on some islands; changes in dominant shrub (*Cneorum tricoccon*) distribution because marten replaced the frugivorous-dispersing role	Riera et al. 2002
Introduction of Artic fox (*Alopex lagopus*) in the Aleutian archipelago	predator of seabirds that transport large quantities of nutrient-rich guano from productive ocean waters to land	negative — reduced transport of nutrient from ocean to land; reduced soil fertility, nutrient status of plants, primary productivity and induced compositional shifts from productive grass-sedge to less productive shrub-forb communities	Croll et al. 2005
Intraguild predators			
Potential egg parasitoid (*Anastatus kashmirensis*) to control gypsy moth (*Lymantria dispar*)	hyperparasitism (parasitoids that may use parasitoids as hosts)	negative — disruption of biological control of pests; introduced parasitoid poses risk of hyperparasitism to other pest-regulating native parasitoids	Weseloh et al. 1979; see other examples in Rosenheim et al. 1995
Gambusia and *Lepomis* fish in rice fields to combat mosquitoes	intraguild predator (adult fish feed on juveniles as well as on mosquito larvae)	opposed to goal — decreased control of disease vector (mosquito)	Blaustein 1992
Intraguild preys			
Opposum shrimp (*Mysis relicta*) in Canadian lakes to increase fish production	intraguild prey depletes shared zooplankton preys	opposed to goal — decreased salmonid fish production	Lasenby et al. 1986
Apparent competitors			
Rats (*Rattus* spp) and cats (*Felis catus*) in Steward Island, New Zealand	rats induce high cat densities and increase predation on endangered flightless parrot (*Strigops habroptilus*)	negative — reduced diversity	Karl and Best 1982 see Müller and Bordeur (2002) for more examples
Herbivores			
Zebra mussel (*Dreissena polymorpha*) in Great Lakes, United States	zebra mussel reduces phytoplankton and outcompetes native bivalves	negative — reduced diversity positive — increased water quality	Benson and Boydstun 1995 Lodge 2001
Mutualists			
Myna bird (*Acridotheres tristis*) for worm pest control in Hawaiian sugarcane plantations	myna engages in the dispersal of the exotic woody weed *Lantana camara*	negative — increased invasion by *Lantana* produced impenetrable thorny thickets, reduced agricultural crops and pasture carrying capacity, and sometimes increased fire risk; displaces habitat of native birds	Pimentel et al. 2000
Ecosystem engineers			
Earthworm (*Pontoscolex corethrurus*) in Amazonian tropical forests converted to pasture	dramatically reduces soil macroporosity and gas exchange capacity	negative — reduced soil macrofaunal diversity and increased soil methane emissions	Chauvel et al. 1999
C4 perennial grasses *Schizachyrium condesatum, Melinis minutiflora* in Hawaii for pasture improvement	increases fuel loads, fuel distribution, and flammability	negative — increased fire frequency affecting fire-sensitive plants; reduced plant diversity; positive feedback for further invasion of flammable exotic species on burned areas	D'Antonio and Vitousek 1992
N-fixing firetree (*Myrica faya*) in Hawaii	increases soil N levels in newly formed N-poor volcanic soils	negative — increased fertility, increased invasion by other exotics, reduced regeneration of native *Metrosideros* tree, alteration of successional patterns	Vitousek et al. 1987

(continues over)

creases with species richness. Community biomass is stabilized because a decline in abundance of one species allows its competitors to increase, partially compensating for the initial decrease. In total, theoretical analyses suggest that increased species richness should slightly destabilize the production by individual species but more greatly stabilize production by the entire community (May 1973; Doak et al. 1998; Lehman and Tilman 2000).

Experimental manipulations provide weak evidence to support these theoretical predictions. In well-controlled laboratory experiments, species-rich communities were more resistant to perturbation (Naeem and Li 1997; McGrady-Steed et al. 1997). Also, African comparative field data suggested that greater species richness led to greater ecosystem stability (McNaughton 1993). Year-to-year variation in total community biomass (an inverse

Table 11.2. *continued*

Study Case	Nature of the Interaction Involved	Ecosystem-service Consequences	Source
Deletions/harvesting			
Top predators			
Sea otter (*Enhydra lutris*) harvesting near extinction in southern California	cascading effects produce reductions of kelp forests and the kelp-dependent community	negative — loss of biodiversity of kelp habitat users	Dayton et al. 1998
Pollution-induced reductions in predators of nematodes in forest soils	heavy metal bioaccumulation produces reductions in nematophagous predators and increases herbivorous nematodes	negative — disruption of forest soil food webs and increases in belowground herbivory; decrease in forest productivity	Parmelee 1995
Intraguild predators			
Declining populations of coyote (*Canis latrans*) in southern California	releases in raccoons (*Procyon lotor*) and feral house cats	negative — threat to native bird populations	Crooks and Soulé 1999
Overhavesting of seals and sea lions in Alaska	diet shifts of killer whales increased predation on sea otters	negative — conflict with other restoration programs; failure of reintroduction of sea otters to restore kelp forest ecosystems	Estes et al. 1998
Keystone predators			
Harvesting of triggerfish (*Balistaphus*) in Kenyan coral reefs	triggerfish declines release sea urchins, which outcompete herbivorous fish	negative — increased bioerosion of coral substrates; reduced calcium carbonate deposition	McClannahan and Shafir 1990
Herbivores			
Voluntary removal of sheep and cattle in Santa Cruz Is., United States, for restoration	release of the exotic plant component from top-down control	opposite to goal — explosive increases in exotic herbs and forbs and little recovery of native plant species	Zavaleta et al. 2000
Overfishing in the Caribbean, reducing herbivorous and predatory fish and reducing fish biomass	lack of fish grazers allowed macroalgae to outcompete coral following disturbances	negative — coral cover was reduced from 52% to 3%, and macroalgae increased from 4% to 92%	Hughes 1994
Ecosystem engineers			
Voluntary removal of exotic tamarisk (*Tamariscus* sp.) for restoration of riparian habitats in Mediterranean deserts	long-established tamarisk has replaced riparian vegetation and serves as habitat to endangered birds	opposite to goal — reduction in biodiversity; structural changes in riparian habitats	Zavaleta et al. 2000

measure of resistance) in a Minnesota grassland in the United States was greater in plots with lower species richness (Tilman 1996). However, these grassland plots differed in species richness mainly because of different rates of nitrogen addition, not because of direct experimental control of species richness (e.g., Givnish 1994; Huston 1997); therefore, additional field experiments are required to confirm these findings.

The evidence for a positive effect of biodiversity on stability is stronger in the case of resistance and weaker in the case of resilience (Schmid et al. 2002). Both components of ecosystem stability are strongly influenced by key traits of the dominant species, which explains why the effect of species life history on the stability characteristics of an ecosystem usually outweighs the effects of species richness (Lepš et al. 1982; Sankaran and McNaughton 1999; Osbornová et al. 1990; Grime et al. 2000).

In addition, there can be trade-offs between the traits that favor resistance and those that favor resilience (Lepš et al. 1982; McGillivray et al. 1995). For example, the dominance of short-lived, fast-growing, nutrient-demanding plants, with high output of persistent seeds, leads to high resilience and low resistance. These systems, such as annual grasslands, change very easily in the face of a perturbation but return to their initial condition relatively quickly. On the other hand, communities dominated by long-lived, slow-growing, stress-tolerant plants that allocate much energy to storage and defense tend to be more resistant and less resilient. These systems, such as mature forests in relatively dry climates, are resistant to environmental perturbations, but when they are finally displaced away from their initial condition, they recover very slowly. Management alternatives that simultaneously try to maximize both resistance and resilience are therefore not likely to succeed.

Although the resistance/resilience characteristics of an ecosystem can be explained to a large extent by the functional traits of the most abundant species, less abundant species also contribute to the long-term preservation of ecosystem functioning. For example, subordinate and rare plants, despite their often negligible role in resource dynamics, can be crucially important in maintaining species richness of higher trophic levels (species further up the food chain) (Lepš et al. 1998; Lepš 2005). Subordinate and rare species can increase in abundance under changing environmental conditions, providing a source of colonizers or acting as positive or negative "filters" to the establishment of other species (Grime 1998; Fukami and Morin 2003; Magurran and Henderson 2003). The key role of some less abundant species, often mediated by complex and indirect interactions, is addressed in more detail later in the chapter.

The presence of multiple species, abundant or rare, within each functional type increases functional redundancy and may have important implications for ecosystem stability (Walker 1995; Grime 1998; Walker et al. 1999; Hooper et al. 2005). Functional redundancy occurs when several species in a community carry out the same process, such as nitrogen fixation. It is important because the larger the number of functionally similar species in a community, the greater the probability that at least some species will survive changes in the environment and maintain the functional properties of the ecosystem (Walker 1992; Chapin et al. 1996; Naeem and Li 1997). If there is no functional redundancy (that is, species richness is low in any given functional type), the loss of a single species could result in the elimination of an entire functional type (for instance, all the nitrogen-fixers, all the woody deciduous species, all the scavengers, or all the nocturnal pollinators), which would have a larger impact on ecosystem functioning than randomly deleting the same number of species from a variety of functional types.

Direct empirical support for this idea is still scarce, but species assigned to the same functional type have been reported to differ in their tolerances to frost (Gurvich et al. 2002), warming (Chapin et al. 1996), drought (Buckland et al. 1997), disturbance (Cowling et al. 1994; Walker et al. 1999), and changes in soil and atmosphere composition (Dormann and Woodin 2002). This suggests that the effect of species loss should depend on the number and composition of the species remaining, with the largest changes occurring when the last member of a functional type is lost. Thus the effect of species loss on stability cannot always be easily predicted (Díaz et al. 2003).

11.3 Terrestrial Biodiversity Effects on Regulating Services

11.3.1 Invasion Resistance

Invasions of species beyond their native range constitute a global driver of change of major concern for the conservation of natural and managed areas. Invasive species threaten biodiversity (Wilcove et al. 1998), change ecosystem functioning (Levine et al. 2003), and have economic costs (OTA 1993; Pimentel et al. 2000). For example, the economic costs of invasive exotic (alien) species in the United States are estimated in the tens of billions of dollars, the majority of which is due to crop losses and the application of herbicides and pesticides to reduce exotic weeds and pests. In addition, millions of dollars are spent annually in the United States to control numerous invasive species, including purple loosestrife (*Lythrum salicaria,* $45 million), Australian Melaleuca tree (*Melaleuca quenquenervia,* $3–6 million), feral pigs (*Sus scrofa,* $500,000), brown tree snake (*Boiga irregularis,* $4.6 million), fire ant (*Solenopsis invicta,* $200 million), gypsy moth (*Lymantria dispar,* $11 million), Dutch elm disease (*Ophiostoma ulmi,* $100 million), and aquatic weeds (several species, $100 million) (Pimentel et al. 2000).

Invasive species can have important negative impacts on ecosystem services and human well-being (OTA 1993; Pimentel et al. 2000): weeds and pests reduce agricultural yields; invasive eels reduce freshwater fisheries; invasive termites damage homes and other infrastructure; aquatic weeds clog waterways used for transportation and recreation; invasive mussels clog water pipes, threatening the flow of water used in such tasks as cooling power plants; invasive grasses increase fire frequency and intensity, threatening homes and other infrastructure. Conversion of native communities to invasive-dominated communities also has aesthetic and cultural impacts.

Trends in species introductions (Levine and D'Antonio 2003; Padilla and Williams 2004; Ruiz et al. 2000; Ribera Siguan 2003) and modeling predictions (Sala et al. 2000) strongly suggest that biological invasions will continue to increase in number and impact. In addition, human impacts on environmental characteristics required by native species (via eutrophication, pollution, nonsustainable harvesting, and so on) suggest that biotic resistance to invasions may decrease and that the number of communities dominated by invasive species will increase.

Invasibility—the overall susceptibility to invasion—depends on a region's climate and environmental properties and on the interaction between the invader and the recipient community (Lonsdale 1999; Hooper et al. 2005). The presence and abundance of invaders in an ecosystem are functions of both invasibility of the system and of the supply of invading species or propagules. Here we focus on the resistance to invasions that may be afforded by species already present in a community—biotic resistance (Elton 1958). Biotic resistance is defined as the ability of resident species to inhibit the establishment, growth, survival, and reproduction of invasive species. Biotic resistance may vary from habitat to habitat and over time due to changes in the identity, composition, and diversity of the species in the community.

In general, the available evidence and theoretical predictions suggest that higher species richness and functional type richness can increase the resistance of a community against invasion by exotic species. In addition, some individual species may be particularly important in conferring invasion resistance to a community. Therefore, all else being equal, maintaining native species assemblages should diminish the ability of exotic species to become invasive, and it is most likely that the loss of biodiversity from a particular habitat will decrease the invasion resistance of this habitat.

The location on the landscape where exotic species are most likely to invade can also be predicted. Numerous studies have found a positive correlation between native and exotic species richness across habitats (Rejmánek 1996; Levine et al. 2002; Stadler et al. 2000; Lonsdale 1999; Stohlgren 2003 and references therein), where high native species richness is not the cause of high richness of exotic species. Rather, these studies suggest that the factors that promote the richness and coexistence of native species, such as benign climate, intermediate levels of disturbance, and habitat heterogeneity, also promote the richness and coexistence of exotic species (Levine and D'Antonio 1999; Byers and Noonburg 2003). These results have major conservation implications, because they suggest that hot spots for diversity are particularly at risk of invasion by introduced species, and that the loss of native species (from communities of low or high native species richness) is expected to increase invasibility.

A number of mutually compatible mechanisms have been proposed to explain the effect of biodiversity on invasion resistance (Mack et al. 2000). For all hypothesized mechanisms, it is the traits of the resident species, not merely the species richness, that determine the invasibility of a system (Foster et al. 2002; Prieur-Richard et al. 2002; Dunstan and Johnson 2004).

One proposed mechanism for high species richness inhibiting invasibility is the "niche hypothesis," which suggests that communities that are relatively impoverished in numbers of native species cannot provide biological resistance to exotic species because there are unused resources in the system (sometimes referred to as a vacant niche). Diverse communities will resist invaders because they reduce resource availability and increase competition. Consistent with the niche hypothesis, the loss of biodiversity has been shown to reduce invasion resistance in experiments in which biodiversity and community composition have been manipulated while holding the habitat conditions constant (e.g. Stachowicz et al. 1999; Dukes 2002; Naeem et al. 2000; Hector et al. 2001; Kennedy et al. 2002; Fargione et al. 2003; van Ruijven et al. 2003).

Several types of biodiversity loss decrease invasion resistance, including losses of species richness, of functional richness, and of particular species. Loss of biodiversity may reduce competition and provide increased space and resources for invading species. For example, reduced species richness in a grassland experiment led to increases in resource availability (both light and soil nitrogen) and caused higher levels of invasion (Knops et al. 1999). Invasion resistance in diverse stands has been associated with the closeness of neighbors (Kennedy et al. 2002) and with increasing temporal stability (reducing fluctuations of open space, for example) (Stachowicz et al. 1999). At this local scale, species invasion seems limited not only by species richness, but also the richness of functional types (grasses, herbs, and shrubs) (Symstad 2000). Overall, these studies suggest invading species can be most successful when they make use of resources that are incompletely used by the resident community (for example, brown trout) (Fargione et al. 2003).

The loss of biodiversity is most likely to result in unused resources in habitats that already have low functional redundancy, and for communities, such as oceanic or habitat islands, in which functional redundancy is also limited at the regional species pool level (that is, few species can disperse there naturally) (Rejmánek 1996). Thus, certain communities are susceptible to invasion because of a lack of competition from endemic species occupying one or more niches—a lack of biotic resistance. For example, the higher success of invasion by vertebrates in oceanic islands compared with corresponding continental areas is partially explained by the lack of native vertebrates that could act as predators or competitors (Brown 1989). Some stressful environments may have low species richness and in some cases low functional redundancy, but invasion is constrained by environmental conditions.

Natural enemies (pathogens, parasites, and herbivores) are important agents of biotic resistance to invasion. Invaders benefit from escaping their specialized natural enemies left behind in their region of origin, but they may be inhibited by the accumulation of natural enemies in the invaded range (Maron and Vilà 2001). Naturalized plant species that have accumulated more pathogen species native to their new habitat are less frequently listed as noxious weeds, whereas naturalized plant species that escape a greater proportion of their native pathogen species are more frequently listed as this, implying that associations with these pathogens help keep them from becoming pests in their native range (Mitchell and Power 2003).

It has also been shown that invasive animal species have fewer parasites in invaded than in native ranges (Torchin et al. 2003). Many invasive animal species have become pests only after losing their native parasites, which suggests a possible role for parasite species richness in controlling invasive species.

Similarly, invasive species may be successful because they accumulate fewer root pathogens than rare species (Klironomos 2002). In the Netherlands, weeds invading across an experimental gradient of plant species richness were found to be significantly reduced by the presence of a plant species, *Leucanthemum vulgare,* that acted as a host to parasitic nematodes, which then acted to control invading weeds (van Ruijven et al. 2003). Generalist native herbivores can also reduce the growth, seed set, and survival of introduced plants, but the evidence that they hinder the spread of invasive exotic plants is scarce (Maron and Vilà 2001). The natural enemies hypothesis is an integral part of the conceptual basis for biological control, in that specialized enemies are identified and introduced to control pests. Numerous examples of successful biological control demonstrate the importance of natural enemies in controlling invasive species (Hajek 2004; see also Chapter 10).

There is a general consensus that invasions flourish in areas disturbed by human activities (Hobbs and Huenneke 1992). Disturbances can be defined as events that create available space for the germination of propagules, increase the availability of resources, and reduce competition with colonizing species, such as changes in land use resulting in soil erosion or changes in water courses. Temporary increases in the availability of resources can reduce competition and increase the establishment and expansion of plant populations (Davis et al. 2000; Davis and Pelsor 2001). The ability of a biotic community to resist invaders may thus depend on its susceptibility to disturbances that create resource pulses.

Disturbance-induced invasions are more common when the disturbance in question does not have a long evolutionary history in an area. For example, livestock tends to favor invasion by exotic plants in areas where large herbivores have only recently been introduced (Milchunas et al. 1988; Díaz et al. 1999). There is some theoretical and empirical evidence suggesting that increased species and functional type richness can increase invasion resistance by decreasing both average resource availability and resource fluctuations (Prieur-Richard and Lavorel 2000). In addition, disturbances may interact with each other, with the highest rates of invasion occurring after multiple disturbances (such as biomass removal, fire, or soil disturbance) (Petryna et al. 2002).

Impacts of invasive species include altering the local environment in directions that are more favorable for them but less favorable to native species. Specifically, invading species may alter geomorphic processes (soil erosion rates, for instance, or sediment accretion), biogeochemical cycling, hydrological cycles, or fire or light regimes (Macdonald et al. 1996; Levine et al. 2003). For example, invading trees in the fynbos of upland South Africa reduce stream flow from mountain catchment areas, altering the hydrological regime of the whole area. In the fynbos biome, there are over 1500 threatened plant species and over 50% are threatened by the spread of introduced trees and shrubs, which prevent germination and growth of native species (Le Maitre 1996). Similarly, in Great Britain (Usher 1987), in the mixed oak (*Quercus petraea*) and holly (*Ilex aquifolium*) woodlands, the introduced species *Rhododendron ponticum* is thought to inhibit woodland regeneration both by casting a dense shade and by forming an impenetrable leaf litter layer on the ground.

Many invasive species also enhance the frequency and intensity of fires, to which many native species are not adapted. For example, numerous invasive grasses produce a great deal of flammable standing dead material and many resprout quickly after fires, giving them a competitive advantage over native species (D'Antonio and Vitousek 1992). However, some invasive species may have positive effects on native species. For example, some native species may benefit from preying upon invasive species, such as the endangered Hawaiian hawk (*Buteo solitarius*), which benefits from preying on the now-established invasive rat (*Rattus norvegicus*) (Klavitter et al. 2003).

Another hypothesis is that invasive species may exhibit positive feedbacks on subsequent invaders, either through mutualistic interactions or by modifying ecosystem properties (Simberloff and Von Holle 1999; D'Antonio and Vitousek 1992). For example, although it is thought that native species benefit more from the presence of mycorrhizal fungi than exotic plants do and that plant invaders will often be non-mycorrhizal (Klironomos 2002; Bever 2003), the intentional introduction of "improved" ectomycorrhizal fungi to increase crop or forest plantation production has altered the invasibility of many systems. These fungi may form mutualisms with invasive species and replace indigenous flora and fungi (Richardson et al. 2000). Another example of an established invader promoting subsequent invasions via mutualistic interactions is introduced honeybees that provide reliable pollination to invading plants.

Although we have focused on the inhibitory effects of native species on invaders, it is also possible that some native species may benefit invaders. For example, generalist herbivores disperse the seeds of the exotic plants they consume over long distances, having more of a facilitating than an inhibiting effect on exotic plant invasion (Maron and Vilà 2001), especially in regions with a short evolutionary history of grazing by ungulates.

11.3.2 Direct and Indirect Interactions between Species

Many ecosystem processes and the services they provide depend on obligate or facultative interactions among species. Direct interactions between plants and fungi, plants and animals, and indirect interactions involving more than two species are essential for ecosystem processes such as transfer of pollen and many seeds, transfer of plant biomass production to decomposers or herbivores, construction of habitat complexity, or the spread or suppression of plant, animal and human pathogens. Because of this, interactions between different trophic levels are among the most important processes by which biodiversity regulates the provision of ecosystem services, as illustrated in Figure 11.1 (see also Chapin et al. 2000a). Although experimental evidence is growing (e.g. van der Putten et al. 2001; Haddad et al. 2001), most of the examples come from the dramatic community and ecosystem effects of the introduction or removal of only one or a small number of species. There is clearly still insufficient information to determine whether there are general principles that describe how biotic linkages between different trophic levels and indirect interactions affect various ecosystem processes. Nevertheless, the available studies suggest that the integrity of these interactions is important for maintaining ecosystem processes and that threats to them via habitat destruction and fragmentation (see Box 11.1) are likely to result in losses of ecosystem service.

11.3.2.1 Interactions between Plants and Symbiotic Microorganisms

The interactions between plants and symbiotic microorganisms, such as mycorrhizal fungi, endophytic fungi, and nitrogen-fixing microorganisms, can greatly influence ecosystem processes and have considerable impacts in the provision of ecosystem services by natural and agricultural ecosystems. These interactions are complex and can tip the balance between different plant-community members, with various consequences for the provision of plant-related ecosystem services.

The effects of mycorrhizal fungi on plant communities are both profound and widespread. Arbuscular mycorrhizal fungi form symbiotic relationships with approximately 80% of the land plants on Earth (Smith and Read 1997), in which the mycorrhizal fungus receives benefits from the plant in the form of carbon and provides various benefits to the plant, such as phosphorus absorption (Jakobsen et al. 2002) and resistance to pathogens (Klironomos 2000).

The abundance, species composition, and richness of AMF communities influence the productivity, composition, and species richness of plant communities. This is because AMF have different effects on different plant species, ranging from mutualism to parasitism (Sanders 1993; van der Heijden et al. 1998a; Moora et al. 2004; Rillig 2004), and therefore benefit some species more than others (Grime et al. 1987; Gange et al. 1993; Hartnett et al. 1993; Moora and Zobel 1996; Wilson et al. 2001; van der Heijden et al. 2003). It is likely that AMF enhances plant species diversity when they favor less abundant species, but decreases in plant diversity are likely when AMF favor dominant plant species (Urcelay and Díaz 2003).

The presence and species composition of the AMF community can even alter the relationship between plant species richness and productivity. In the absence of AMF, the relationship between plant species richness and productivity is positive and linear, whereas in the presence of AMF, the relationship is positive but asymptotic (Klironomos et al. 2000). The effects of different AMF species can also differ considerably.

Increasing AMF species richness can result in more-efficient exploitation of soil phosphorus and an increase in the size of the plant nutrient pool. Van der Heijden et al. (1998b) found that increased AMF species richness led to a significant increase in the amount of soil phosphorus captured by the plant community.

Much less is known about the effects of the richness and composition of ectomycorrhizal fungi communities on ecosystem processes (Dahlberg 2001). EMF are common in nutrient-limited forest ecosystems and can play a critical role in tree nutrition and carbon balance, supplying soil resources to their plant host in exchange for sugars (Smith and Read 1997). The effects of EMF on plants appear to be species-specific, such that the loss of EMF species richness could, in theory, reduce plant species richness and productivity (e.g., Timonen et al. 1997; Baxter and Dighton 2001). However, no relationship has been found between ecosystem productivity and EMF species richness (Gehring et al. 1998), although more research is clearly needed before general conclusions can be drawn.

Based on the limited available evidence, it is likely that other fungal groups also play important functional roles. For example, systemic fungal endophytes (fungi that live inside aboveground plant tissues and receive nutrition and protection from the host) change the performance, herbivore resistance, biomass allocation, and final biomass of plant individuals and may thus also have a considerable effect on competitive interactions among plants (Clay and Holah 1999; Matthews and Clay 2001; Pan and Clay 2002). The presence of fungal endophytes may also inhibit the activity of other microbial organisms like AMF (Chu-Chou et al. 1992; Guo et al. 1992) or soil invertebrates (Bernard et al. 1997), with possible indirect effects on plant community diversity or productivity. Toxic alkaloids in the leaf litter of endophyte-infected plants could inhibit decomposition, slowing rates of nutrient cycling (Bush et al. 1997). Pathogenic fungi in the root zone may influence plant distribution and competition by favoring certain species (de Rooij-van der Goes et al. 1998; Packer and Clay 2000). There are currently no results from biodiversity-ecosystem functioning experiments explicitly considering endophytes and soil fungal pathogens, but the complex relationships described above suggest that fungal diversity may play an important role in the structure and functioning of ecosystems.

Ecosystem productivity and carbon accumulation may be enhanced by nitrogen-fixing microorganisms. These include both nitrogen-fixing bacteria in symbiotic relationships with plants (especially, but not exclusively, legumes), and free-living microorganisms. As in the case of AMF, not only the presence but also the identity of the symbiotic nitrogen-fixing bacteria is important, since different genotypes may have different effects on host plant species (Thrall et al. 2000).

The input of nitrogen to soils from nitrogen-fixing plants is crucial in the productivity and successional dynamics of many natural ecosystems and can have important positive and negative impacts on ecosystem services (Walker and Vitousek 1991; Doyle 1994; Fridley 2001). Some of the positive effects of biodiversity on plant biomass production have been attributed, at least in part,

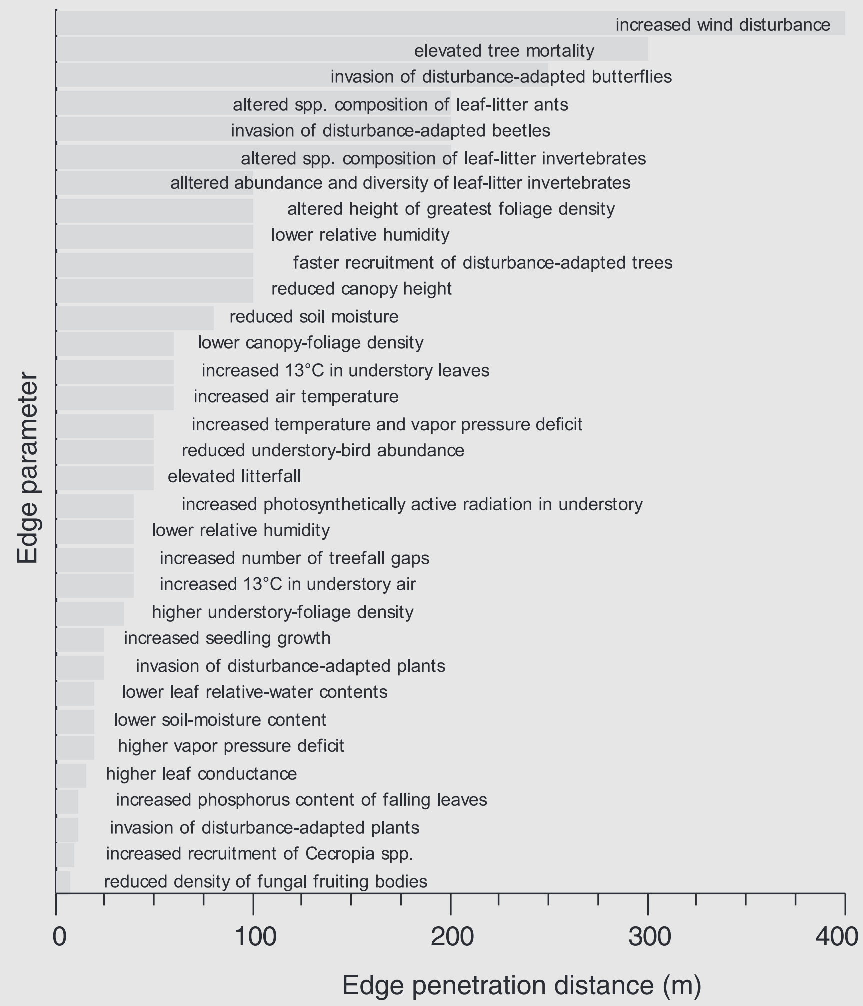
BOX 11.1

Impacts of Habitat Fragmentation on the Links between Biodiversity and Ecosystem Processes

Throughout the world, habitat fragmentation is one of the most critical threats to biodiversity and ecosystem services, such as pollination, seed dispersal, herbivory, and carbon sequestration (Dirzo 2001a; Laurance et al. 2002; Dirzo and Raven 2003). In the tropics, for example, millions of hectares of forest are destroyed each year (Whitmore 1997; Achard et al. 2002), typically leaving small islands of forest surrounded by a sea of pastures, crops, and scrubby regrowth. In other areas, such as the eastern United States and much of Europe, forests have been fragmented for centuries. Hence, the fragmented landscape is rapidly becoming one of the most ubiquitous features of our planet.

Habitat fragments are ecologically different from intact habitat, and they are often biologically depauperate. This occurs for several reasons. First, habitat destruction is often nonrandom. Humans tend to clear areas overlaying productive, well-drained soils and to avoid areas with steep or strongly dissected topography. Consequently, habitat remnants are often confined to areas with poor soils, rugged topography, and low species richness. Second, because they are limited in area, habitat fragments contain only a fraction of the habitat diversity found in a particular area (Wilcox 1980). Third, small fragments usually have higher local extinction rates than large fragments because they contain smaller, more vulnerable populations (MacArthur and Wilson 1967; Stratford and Stouffer 1999). Fourth, habitat fragments are influenced by edge effects, which are ecological changes associated with the artificial, abrupt margins of habitat fragments (Janzen 1986; Laurance et al. 2002; Hobbs and Yates 2003). Edge effects can be remarkably varied, altering physical gradients, species distributions, and many ecological and ecosystem processes. (See Figure.) Fifth, fragments that are isolated tend to support fewer species than do those that are near other habitat areas (MacArthur and Wilson 1967; Lomolino 1984).

By altering species richness, relative abundance, and composition, habitat fragmentation also indirectly affects many ecosystem processes. Smaller fragments often become hyper-disturbed, leading to progressive changes in floristic composition (Laurance 1997; Hobbs and Yates 2003).



Distances to Which Various Edge Effects Penetrate the Interiors of Fragmented Rainforests in Central Amazonia. Some edge effects, such as microclimatic alterations like higher vapor pressure deficits and lower soil-moisture content, penetrate only limited distances (<50 m) into forest fragments. Other edge effects, however, such as elevated wind disturbance, can penetrate hundreds of meters into fragments. As a result, even large fragments can be substantially altered by wind disturbance.

to the presence of nitrogen-fixing legumes in the assemblages (e.g. Hector et al. 1999). Nitrogen-fixing symbiotic relationship is at the very basis of intercropping (Vandermeer 1989) and renders high economic profit in many semi-natural pasture and agroforesty ecosystems. However, the invasion by trees with nitrogen-fixing symbiotic microorganisms has had dramatic consequences in some naturally nutrient-poor ecosystems (such as the firetree, *Myrica faya,* in Hawaii, where a nitrogen-fixing tree was previously absent).

11.3.2.2 Interactions between Plants and Animals

The provision of ecosystem services by plants and animals is inextricably linked. This is because animals interact with plants directly by eating them or by moving their pollen and seeds across the landscape. This has short-term consequences on ecosystem processes and also long-term evolutionary consequences (such as evolution of plant chemical defenses and floral and fruit structures). Major ecosystem services are supported by the direct interactions between plants and animals, such as herbivory, pollination, and seed dispersal. Animals and plants can also influence each other indirectly by changing each other's habitat and resource availability (such as the provision of nesting sites by plants to animals or the increased availability of soil nutrients to plants due to physical disturbance caused by animals).

11.3.2.2.1 Herbivory

Herbivory—the consumption of plant tissues or fluids by animals—is ubiquitous in ecosystems and often has a dramatic impact on ecosystem processes. This section describes the ecosystem effects of the interactions between wild herbivores and plants. The ecosystem effects of domestic herbivores are addressed in Chapters 8 and 22.

The consequences of herbivory for ecosystem services and human well-being go far beyond its widely recognized role in terms of impact on the production of plant biomass (such as food, wood, and fiber). This is because herbivores consume an important portion of the world's primary production, and in many cases they stimulate plant biomass production and nutrient cycling and favor stability (by decreasing the amount of standing dead biomass, for instance, and thus the probability of high-temperature fires). Herbivory has also played a key role in the development of plant functional biodiversity over evolutionary time (Dirzo 2001b).

Herbivory tends to be an antagonistic interaction in which plant performance (yield, reproduction, and survival) is often negatively affected. However, we now know that the impacts of herbivory move along a gradient from negative, neutral (compensation), and even positive (overcompensation) effects on plants (Strauss and Agrawal 1999). For example, mammals may speed

New trees regenerating near forest edges tend to be disturbance-loving pioneer and secondary species rather than old-growth, forest-interior species (Viana et al. 1997; Laurance et al. 1998b). Large canopy and emergent trees, which contain a high proportion of forest biomass, are particularly vulnerable to fragmentation (Laurance et al. 2000). As the biomass from the dead trees decomposes, it is converted into greenhouse gases such as carbon dioxide and methane. This loss of living biomass is not offset by increased numbers of lianas and small successional trees in fragments (Laurance et al. 2001), which have lower wood densities and therefore store less carbon than the old-growth species they replace (Nascimento and Laurance 2004). In fragmented forests worldwide, millions of tons of atmospheric carbon emissions may be released each year by this process. Edge-related losses of biomass increase sharply once fragments fall below 100–400 hectares in area, depending on fragment shape (Laurance et al. 1998b).

In addition to reduced carbon storage, the rate of carbon cycling is also altered in fragmented habitats. In undisturbed forests, carbon can be stored for very long periods in large trees, some of which can live for more than 1,000 years (Chambers et al. 1998). In forest fragments, however, the residence times for carbon will decrease as smaller, short-lived plants replace large old-growth trees (Nascimento and Laurance 2004). The dynamics of this cycle can have major effects on carbon storage in vegetation and soils and on the rate of input of organic material into tropical rivers and streams (Wissmar et al. 1981).

There is limited understanding of the ecosystem consequences of the effects of fragmentation on complex interspecific interactions. Many species can be negatively affected by secondary or "ripple effects" in fragmented habitats (Terborgh et al. 1997). For example, plants that rely on specialized pollinators can experience reduced fecundity in fragments if their key pollinators disappear (Aizen and Feinsinger 1994), although exotic pollinator species can sometimes compensate for the loss of native pollinators (Hobbs and Yates 2003). Moreover, the loss of seed dispersers has dramatically affected the life cycle of plants worldwide (Chapman and Chapman 1996; Terborgh and Wright 1994; Wright and Duber 2001), and scientists have shown that in areas affected by fragmentation or with heavy poaching, the number of seeds dispersed decreases (e.g., Wright and Duber 2001; Wright et al. 2000). Reduced dispersal may in turn decrease the genetic diversity of plant populations, since seeds are one of the main vectors of gene flow between populations (Pacheco and Simonetti 2000). Small, fragmented plant populations may show increased inbreeding, reduced genetic fitness, and increased susceptibility to environmental stress (Heschel and Paige 1995).

In addition, the rapid loss of large predators (wolves, bears, and tigers, for example) in many fragmented landscapes can lead to a phenomenon known as mesopredator release (Soulé et al. 1988), in which medium-sized omnivores (coyotes, raccoons, coatis, and opossums, for instance) that were formerly controlled by the large predators undergo population explosions. These omnivores may then decimate vulnerable species, such as nesting birds (Crooks and Soulé 1999) and large-seeded trees (Asquith et al. 1997).

In summary, from the point of view of biodiversity-mediated ecosystem services, habitat fragments are not simply reduced versions of nonfragmented habitats. Rather, they are often fundamentally altered in terms of their species composition and ecosystem functioning. By reducing biodiversity, habitat fragmentation affects a number of regulating processes, such as herbivory, pollination, seed dispersal, and carbon storage. When fragmented, forests may have a diminished capacity to provide natural products such as certain fruits, fibers, game, and pharmaceuticals; they may experience drastically altered fire regimes that can affect local communities, livestock, and croplands; and they may have a reduced capacity for capturing and storing atmospheric carbon in its living vegetation.

up biomass production by plants by removing dead parts or by eliminating apical dominance leading to the proliferation of secondary branches. This gradient of herbivore impacts and plant responses, together with the lack of information for most ecosystems, makes it difficult to understand the role of herbivores in ecosystem processes or the effect of their biodiversity on that role (e.g., van der Putten et al. 2001; Wardle et al. 2003). However, as this section illustrates, although negative impacts on plants are common, ecosystem services and even biodiversity maintenance depend on this biotic interaction.

Approximately 50% of the total species richness is accounted for by phytophagous insects and their food plants (Strong et al. 1984; Heywood and Watson 1995). Most of this biodiversity is concentrated in the tropics (Dirzo and Raven 2003), where herbivory rates, largely by insects, are also higher (Coley and Barone 1996).

The loss of herbivores can affect species throughout the community in ways that can be difficult to predict. In both tropical and nontropical ecosystems, herbivory by mammalian vertebrates can be high, and it appears that, regardless of species richness, removal of large herbivores can have profound effects on ecosystem diversity and functioning, including terrestrial, marine, and freshwater ecosystems (Pimm 1980). In the tropics, for instance, loss of mammalian herbivores resulting from hunting and habitat deterioration may reduce herbivory and seed dispersal, resulting in patches with high density and low species richness of seedlings. The high density and low species richness of these patches increases the abundance of insect herbivores and their parasites (Chapman and Chapman 1996; Dirzo 2001b; Wright 2003). The consequences of species loss depend on both the magnitude and type of animals that are removed and also on the potential for the remaining animals to ecologically compensate in the absence of those lost. In most systems, current knowledge is insufficient to predict the effect of herbivore loss reliably.

In grasslands and rangelands where native or domestic ungulates have been present over evolutionary time, these herbivores assist with nutrient cycling and buffer against disturbances. Herbivores open up the vegetation by eating and trampling it. Also, their feces and urine decompose faster than plant litter. As a consequence, nutrients, especially nitrogen, are recycled faster. In areas where ungulates have been present over evolutionary time, the loss or voluntary suppression of grazing leads to considerable accumulation of standing and dead biomass. In some areas, this increases fire frequency and intensity, with negative consequences for plant and soil communities (Collins et al. 1998; Perevolovsky and Seligman 1998). Biomass accumulation has also been reported to favor rodent outbreaks, because the tall, dense canopy provides a refuge from predators (Noy-Meir 1988).

In addition, herbivores can change the characteristics of their host plants over ecological and evolutionary time. Herbivory has selected for adaptive responses by plants, including physical and chemical traits, such as the omnipresent plant secondary metabolites (tannins, alkaloids, cardiac glycosides, non-protein amino acids, and so on). These traits have in turn selected for adaptive responses by animals, including detoxification mechanisms. Such adaptive and counter-adaptive responses lead to coevolutionary changes that, beyond their academic importance, have important practical ramifications in terms of, for example, biological control and pharmacology (see Chapter 10).

The role of herbivores in supporting ecosystem services related to the maintenance of genetic resources and food production has been underestimated. The high economic losses of crops caused by insect pests would suggest, at first glance, that herbivory reduces ecosystem services, particularly if considering only the economic value. This interaction can have direct ecological and economic benefits, however, when herbivores operate as effective control agents of potential weeds (reviewed later in this section).

In addition, the impacts of herbivores on wild plants have led to the evolution of defensive mechanisms, particularly secondary plant metabolites, which are of great actual or potential importance for humans. For instance, about 25% of the currently prescribed drugs have their origin in defensive plant secondary compounds (Dirzo and Raven 2003), which in turn are believed to have arisen as a result of the interactions between plants and herbivores over evolutionary time.

The potential benefit of many other metabolites, still poorly investigated, is considerable. For example, the metabolite dihydromethyldihydroxypyrrolydine (DMDP) is produced in the foliage of the tropical liana *Omphalea diandra.* This and other related species in the genus are strongly protected against phytophagous insects, except the highly specialized caterpillars of the moth *Urania fulgens,* which, in turn, sequester the metabolite in their bodies. Remarkably, this metabolite plays some role in blocking the activity of HIV, has negative effects on bruchid beetles that attack stored grains in the tropics, and has shown some activity against cancer and diabetes (Dirzo and Smith 1995).

11.3.2.2.2 Pollination

Pollination, the transfer of pollen between flowers, without which many plants cannot achieve sexual reproduction, is an interaction between animals and plants that is essential for the provision of plant-derived ecosystem services. Worldwide, there is increasing realization of the extent to which both wild plant communities and agricultural systems depend on pollination services (Buchmann and Nabhan 1996; Allen-Wardell et al. 1998). (See Box 11.2.)

Because many fruits and vegetables require pollinators, pollination services are critical to the production of a considerable portion of the vitamins and minerals in the human diet. When agroecosystems are managed in a way that reduces a diverse assemblage of native pollinators, crops are at risk of suffering yield losses (Kremen et al. 2002).

Estimates of the annual monetary value of pollination vary widely, from $120 billion per year for all pollination ecosystem services (Costanza et al. 1997), to $200 billion per year for the role of pollination in global agriculture alone (Richards 1993). The range of these numbers reflects the lack of common methods for valuing the services provided by nature in general (see Chapter 2) and pollinators in particular. Recent research in coffee ecosystems in Costa Rica (Ricketts et al. 2004) however have shown that for stingless bee pollinators, which nest only in the forest, the services provided by adjacent forest patches contribute to 20% greater coffee yields within one kilometer of the forest, and 7% overall to the income of the coffee farms.

Existing evidence indicates that species richness and composition of pollinators are linked with plant reproduction and establishment and thus with all the supporting, regulating, and provisioning services that stem from terrestrial vegetation. The direct impact of losing effective pollinators is primarily on plant reproductive success and fruit production. Most pollination systems are ''somewhat generalized'' (Waser et al. 1996), in that most flowers attract and can be pollinated by a range of pollinators that often vary under different climatic conditions. Therefore flowers usually will continue to be visited even if the most effective pollinators have been eliminated. Because some pollinators are much more effective than others, however, less pollen may be deposited, or it may be deposited at the wrong place on the plant, or the visits may occur at times when the flower is less receptive to receiving pollen. Rarely will plants completely fail to produce seed when their most effective pollinator is removed; they are more likely to produce less seeds or fruit of reduced viability or quantity.

Previously, low fruit production in plants was widely attributed to nutrient limitation, but increasingly studies have pointed to pollen limitation as a cause of fruiting failure (Burd 1994; Johnson and Bond 1994). The contribution of pollination to crop yields is beginning to garner attention on the scientific agenda and to be considered an essential agricultural input for optimal production. Pollination is now increasingly recognized as a key component of biodiversity and sustainable livelihoods, and an International Pollinators Initiative has been formed to address pollinator conservation.

Adequate richness and density of pollinators also influence plant genetic diversity and thus indirectly affect supporting ecosystem services related to it. Threats to pollination services may lead to genetic impoverishment of species. Pollination is the means by which genes are exchanged in a population. Where the number of individuals of a given species is low (as a result of habitat fragmentation, for instance, or selective harvesting) pollinators may carry fewer pollen grains to each flower visited (Kearns et al. 1998; Kunin 1992). In self-compatible species (where individuals may fertilize themselves), this ''pollination deficit'' leads directly to increased inbreeding, reduced genetic fitness, and increased susceptibility to environmental stress (Heschel and Paige 1995), as seen often in small fragmented plant populations.

Although most pollination systems tend to be generalized, the greatest risks of reproductive failure or genetic impoverishment occur in highly specialized pollination systems, where the suite of effective pollinators is the smallest. Specialized pollination systems occur most commonly in desert ecosystems (Ollerton and Kamner 2002; Waser et al. 1996). The greatest richness of bee species, for example, occurs in arid and semiarid environments such as Israel and the American Southwest (O'Toole 1993). Closely related *Acacia* tree species in Tanzania drylands flower at different times of the day, thereby reducing the opportunities for sharing pollinators (Stone et al. 1998).

Nevertheless, at a local level, whether in moist tropical systems or desert systems, there is a strong linkage between effective pollination systems and biodiversity. Larger individual fruit of more uniform shape and better seed production generally correlate with a greater number of visits from pollinators (Alderz 1966). Since changing weather conditions may favor some pollinators over others, having the largest suite of potential pollinators is the best

BOX 11.2

Global Status of Pollinators

Approximately 80% of Angiosperms, including many important agricultural species, are pollinated by animals (the rest are wind- or water-pollinated or are self-compatible). Worldwide, the number of flower-visiting species is estimated to be about 300,000 (Nabhan and Buchmann 1997). Bees (Hymenoptera: Apidae) account for 25,000–30,000 species (O'Toole and Raw 1991) and together with flies, butterflies and moths, wasps, beetles, and some other insect orders encompass the majority of pollinating species (Buchmann and Nabhan 1996). Vertebrate pollinators include bats, non-flying mammals (monkeys, rodents, lemurs, and so on), and birds.

The challenges of identifying declines in pollinators are considerable given the rarity of many species, the lack of baseline data, and high spatial and temporal variation in pollinator populations (Williams et al. 2001). Evidence is generally either direct, from isolated case studies showing declines of specific taxa in a particular place or time, or indirect, from studies of pollinator abundance across gradients of human disturbance. If, as seems to be the case, pollinator populations are reduced in areas with human disturbance, and the area affected by that disturbance is increasing, we can expect pollinator populations to decline over time.

Direct evidence of pollinator declines has been reported in at least one region or country on every continent except Antarctica, which has no pollinators. However, no consistent assessment is available at the continental level, though efforts are currently under way on at least two continents.

Marked declines of bumblebees (*Bombus* spp.) have been reported for the United Kingdom (Williams 1986), Belgium (Rasmont 1988), and eastern Germany (Peters 1972) and for native solitary bee species in Germany (Westrich 1989) and in the United Kingdom (Falk 1991). Changes have been attributed to habitat loss resulting from agricultural intensification. Day (1991) compiled information on the status of bees from several national *Red Data Lists,* identifying more than 400 listed species from north of the Alps but virtually none from the Mediterranean. Although several case studies from Poland, Lithuania, Turkey, Russia, and Ukraine are available, data are insufficient to draw conclusions about general trends in these countries (Banaszak 1995). Similarly, a widespread pollinator decline may be occurring in North America (Buchmann and Nabham 1996; Allen-Wardell et al. 1998), but conclusive data are not yet available (see special section in *Conservation Ecology* 5:1 (2001)).

Honeybee (*Apis mellifera*) colonies, both managed and wild, have undergone marked declines in both the United States and some European countries. The number of managed honeybee colonies in the United States has dropped from 5.9 million in the 1940s to 1.9 million in 1996 (Ingram et al. 1996; USDA National Agricultural Statistics Service 1997), and most feral colonies have also been lost (Kearns et al. 1998). In the European Union, honeybee colonies are reported to have declined by 16% between 1985 and 1991, with losses expected to increase (Williams et al. 1991). A major cause of honeybee declines is parasitic mites (*Varroa jacobsoni* and *Acarapsis woodi*). The range expansion of Africanized honeybees in the United States is also predicted to decrease managed honeybee colonies, largely because beekeepers fear liability lawsuits (Allen-Wardell et al. 1998).

The related Himalayan cliff bee (*Apis laboriosa*) has declined significantly. In a regional study, all but one censused cliff showed declines in number of colonies or total loss across a 15-year period (Ahmad et al. 2003). Bee population characteristics may show changes before population declines can be detected. For example, the most abundant orchid bee in lowland forest in Panama, *Euglossa imperialis,* frequently has high levels of sterile males resulting in low effective population sizes (Zayed et al. 2003). Recent research points to reduced genetic diversity in specialist bees compared with generalists (Packer et al. 2005).

Butterfly (Lepidoptera) populations have decreased in Europe, based on local and national studies in the United Kingdom, the Netherlands, and Germany. Comparison with historical records (1970–82) showed that half of British resident butterflies have disappeared from over 20% of their range and that a quarter have declined by more than 50% (Asher et al. 2001). Swaay and Warren (1999) report in the *Red Data Book of European Butterflies* that many European butterflies are under serious threat because of changing land use and agricultural intensification.

Mammalian and bird pollinators also show strong declines. Nabhan (1996) notes that 45 species of bats, 36 species on non-flying mammals, 26 species of hummingbirds, 7 species of sunbirds, and 70 species of passerine birds are of global conservation concern. The black and white ruffed lemur of Madagascar, an important pollinator of the island's celebrated Traveler's Palm, is highly threatened (Buchmann and Nabhan 1996). Lower visitation rates by bats and reduced fruit set occurred on a dry forest tree, *Ceiba grandiflora,* in disturbed habitats (Quesada et al. 2003).

Pollinator biodiversity is sensitive to a number of factors, many of them related to land use. Given that these drivers are widespread and often increasing, the indirect evidence indicates that declines in pollinators may also be increasing. In order to persist in agroecosystems, pollinators need local floral diversity and nesting sites. Large monocultures fail to provide these. For example, cultivated orchards surrounded by other orchards have significantly fewer bees than orchards surrounded by uncultivated land (Scott-Dupree and Winston 1987). On melon farms in the western United States, wild bee communities become less diverse and abundant as the proportion of natural habitat surrounding farms declines (Kremen et al. 2004). The most important species for crop pollination became locally extinct throughout large parts of the landscape. In addition, all species declined along this gradient, so more resistant species could not compensate for the loss of more sensitive species (Kremen 2004).

The implications for pollinator services are evident: only farms near natural habitats sustained communities of pollinators sufficiently large to provide needed levels of pollination (Kremen et al. 2002). Distance from natural habitat affected pollinator communities and services in a similar way on coffee farms in Costa Rica (Ricketts et al. 2004; Ricketts 2004). The sizes, shapes, and interdigitation patterns of natural habitat in an agricultural landscape may profoundly affect the persistence of pollinators.

Globally important threats to plant-pollinator systems, while based on land use practices, are driven by a number of forces of varying scales and points of origin. These include forces driving agricultural intensification and consequent habitat loss and fragmentation of wild ecosystems, climate change, use of environmental chemicals, diseases and parasites of pollinator populations, changing fire regimes, introduction of alien plants, and competition with introduced pollinators. Each of these forces may introduce what appear to be only marginal impacts, but effects can cascade through the ecosystem in ways that may have serious repercussions for pollinator populations.

For example, the introduction of domesticated livestock to grassland ecosystems may depress pollinators if the livestock pressure exceeds the levels of grazing to which the resident pollinator populations are adapted. Intensively managed livestock tend to trample pathways and water edges that otherwise serve as nesting sites and water access points for wasp and bee pollinators (Gess and Gess 1993). Changes in the herbaceous layer of vegetation, due to grazing and the introduction of tall, fire-tolerant grasses, may lead to hotter fires, which destroy the dead wood that several groups of bees use as nesting sites (Vinson et al. 1993).

insurance policy for reproductive success and consistent gene flow between plant individuals (Kremen et al. 2002).

Poor reproduction observed in several rare plants has been linked to the loss of specialized pollinators. Examples are populations of members of the Scrophularaceae plant family in South Africa (Steiner 1993) and bird-pollinated vines in Hawaii (Lord 1991). The high degree of mutualism seen in some pollination interactions is illustrated by plants such as figs, yuccas, and food plants that are both pollinated by and serve as brood sites for the larval stage of many lepidopteran pollinators. Highly specialized relationships occur between fig tree species (considered keystone species for the maintenance of several vertebrate populations in the forest) (Terborgh 1986) and their pollinators, fig wasps, making them particularly dependent on the pollinators (Wiebes 1979). Some geographical regions of the world may have a higher occurrence of specialized pollination systems than others. South Africa, for example, has hundreds of plant species that rely on long-tongued flies for pollination. Many of these plant species rely on a single long-tongued fly species (Johnson 2004).

Key pollinators for one plant species may also provide pollination services to other plants at other times of the year. For example, Sampson (1952) noted that grazing livestock may destroy or alter riparian vegetation that serves as a key resource to pollinators at certain times of the year, thus reducing the ability of those pollinators to carry out pollination services not only on the riparian vegetation but on other plants flowering at different seasons. There is a concern that pollinator declines could, through such interconnectedness, ultimately affect multiple trophic levels (Allen-Wardell et al. 1998), yet understanding of these complex and diffuse relationships is still very incomplete. A growing body of research, however, is investigating the interactions among members of ''pollination webs,'' similar to the complex interactions that define food webs (Memmott 1999).

Human well-being and plant reproductive success are bound together by the need for a large and diverse suite of pollinators to assure continued and reliable delivery of effective pollination services. Pollination services generally cannot be reduced to a focus on a single ''service provider.'' The world's agricultural community is presently largely relying on the domesticated honeybee, *Apis mellifera,* to provide a complex and variable service, and that specific provider is faced with a number of disease and parasite challenges. A matrix of healthy natural ecosystems, interspersed and adjacent to human settlements and agricultural fields, can provide significant insurance that pollination services remain intact.

11.3.2.2.3 Seed dispersal

The movement of seeds away from the parent plant is an essential process in plant population and community dynamics. This is achieved in various ways, including wind, water, or explosion of fruit capsules. Most plants, however, including those directly used and managed by humans, depend on seed dispersal by animals. The seeds of a large proportion of woody plants are dispersed by animals (about 80–95% in the tropics and about 30–60% in temperate forests) (Jordano 1992). Many herbaceous plants also rely on animals for their seed dispersal, but the literature on these links and on their ecosystem-service importance is much sparser than that for woody species.

Seeds can be dispersed by animals that eat the fruit and discard the seeds (frugivores) or by seed eaters. In the latter case, most seeds do not survive consumption, but the survival of a small proportion of them is enough to ensure the perpetuation of plant populations. Fruit-eating animals include insects and vertebrates, ranging from ants to elephants, although in tropical forests a variety of frugivorous birds and mammals are the main vertebrate dispersal agents (e.g., Leighton and Leighton 1984). Species that are important for forest regeneration include those of birds, bats, monkeys (Julliot 1996), opossums (Medellin 1994), fish (Goulding 1980), and ants (Horvitz and Beattie 1980; van der Pijl 1982). Flying seed dispersers (bats and birds) are the main vectors that promote forest regeneration in human-disturbed forests by carrying seeds from adjacent habitats to disturbed areas (Gorchov et al. 1993; Silva et al. 2002).

The removal of a frugivore species may have severe effects on several plant species. Most seed dispersal systems can be characterized as generalized (many animals disperse several species of fruits) (Jordano 1987). However, even in generalized seed dispersal systems each animal species deposits seeds in a distinct pattern that affects plant distribution (Jordano and Schupp 2000). One single species of animal may operate as the disperser of several plant species. For instance, agoutis (medium-size rodents; *Dasyprocta* spp.), are the main seed dispersal agent of several large-seeded plants in tropical ecosystems and thus influence the floristic diversity of the understory (Asquith et al. 1999).

In a similar manner to pollination, reduced dispersal also may decrease the genetic diversity of plant populations, since seeds are one of the main vectors of gene flow between populations (Pacheco and Simonetti 2000). The reduction of frugivore populations may have disproportionately large effects. For example, when an animal population is reduced, its resource use shifts to the most preferred items, such that the least preferred resources are used little if at all. Not eating the fruits may have negative impacts on the populations of plants with animal-dispersed fruits. Thus reductions of animal populations (rather than extinction) may be sufficient to dramatically change the ecosystem services provided by frugivores (Redford and Feinsinger 2001).

The value of seed dispersal is hard to estimate, but many tree crops of high economic importance depend on the seed dispersal services of animals. Conversely, the persistence of large enough populations of wild vertebrates strongly depends on the availability of fruits of such crops. Several trees whose crops have an important role in local and export economies depend on seed dispersal by wild vertebrates. Examples include the Brazil nut (*Bertholletia excelsa*), which represents a multimillion-dollar business, and the açai palm (*Euterpe oleracea*) (Baider 2000). Also, several cosmetics are based on nuts or seeds from tropical forests.

Several tree species, such as figs and palms, are also some of the most important keystone species in the tropics (Terborgh 1986; Galetti and Aleixo 1998), because they serve as food sources during periods of fruit scarcity. Monkeys, tapirs, peccaries, and several bird species rely on keystone fruit species in Neotropical forests, and empirical evidence suggests that the structure of vertebrate communities could collapse if these keystone plant species are removed from the forest (Terborgh 1986). The overharvesting of Brazil nuts, açai palm, and Araucaria pine seeds (*Araucaria angustifolia*) in many areas—including inside protected areas—is threatening not only the plant populations but also the animals that depend on their seeds, such as peccaries, toucans, and other large-bodied frugivores (Galetti and Aleixo 1998; Solórzono-Filho 2001; Baider 2000; Moegenburg 2002).

11.3.2.3 Predation and Food Web Interactions

Indirect interactions among species are widespread in nature and refer to the effects of one species on a second species mediated by a third species. For example, a predator may increase abundances of some plant species by reducing the abundance of herbivores. It is difficult to predict the effects of changes to these interactions because the indirect links are often poorly understood. Even if such interactions are known to exist, their strength, and hence their effects, typically vary with environmental conditions (Berlow et al. 1999). However, if these interactions are disrupted, disproportionately large, and often unexpected, alterations in ecosystem properties and services may occur.

Because indirect interactions are often not immediately obvious, and because the loss or addition of organisms with certain traits can trigger positive feedback (self-accelerating) processes in ecosystems, the introductions or removal of species can cause ''ecological surprises.'' Human alterations of the species composition of natural ecosystems can be unintended—such as mortality due to pollution, accidental species introductions, and extinctions caused by habitat losses—or deliberate, as when actions are taken in pursuit of some management goals—such as sustained exploitation, increased production, improved provision of ecosystem services, conservation, restoration, or increased attraction of tourists. Both types of interventions can disrupt ecosystem functioning and alter the provision of ecosystem services. Although some accidental changes have improved the provision of some services, highly undesirable effects are by far more common, or at least more commonly reported. These often involve very important monetary, environmental, and cultural costs.

Not all ecosystems are equally likely to yield unexpected or unwanted results. Rich, complex food webs have higher functional redundancy and more indirect interactions, many of which are weak. A system with many weak interactions may be more resistant to environmental change or loss of individual species. In highly interconnected food webs, however, the effect of changes in richness of one functional group are less predictable and may affect the abundance of other species or the richness of other functional groups through a complex set of direct and indirect interactions (e.g., Buckland and Grime 2000). Trophically simple systems such as temperate freshwater communities have responded particularly strongly to the deletion of high trophic level species. For example, high-latitude lakes have simple food structures and low functional redundancy and therefore are highly vulnerable to food-chain disruption (Schindler 1990). Strong interactors can also cause destabilization (Luckinbill 1979). Modeling approaches also suggest that increasing diversity can increase food-web stability under the condition that most of the interactions within the food web are weak (McCann and Hastings 1997). Stability increases with dietary breadth and number of alternative prey (Fagan 1997; Morin 1999).

The traits of introduced or removed species strongly affect whether these changes will result in unexpected or unwanted disruptions. The structure and organization of communities are often dependent on a few interactions, changes in which have disproportionately large effects relative to their abundance. Therefore, preserving functional diversity and interactions may be more important than maintaining species richness per se. Introduction or removal of species for which there are few functional analogues are likely to produce the strongest effects. Specifically, introduction of species with traits not found in species already present can produce large-scale alterations of ecosystem processes and structure (such as the introduction of exotic N-fixing trees and C_4 grasses in Hawaii).

The removal of a top predator often induces increases in herbivores and thus reductions in plants, altering community structure and ecosystem properties. Predators, by preferentially eating a competitively dominant prey, may facilitate increases in abundance of other species (Paine 1969). Removal of such keystone predators can greatly reduce prey diversity, because the dominant competitor may seriously reduce populations of species. Such effects of predator removals have been extensively documented in numerous terrestrial and aquatic ecosystems (Pace et al. 1999). Ecosystems in which such effects, known as ''trophic cascades,'' are particularly likely include physically homogeneous habitats with few consumers, food-limited predators and herbivores, systems in which predators strongly suppress herbivores, and nutrient-enriched systems. For example, in whole-lake experiments, nutrient enrichment strongly promotes trophic cascading (Carpenter et al. 1995). Trophic cascades may be smaller when mid-level omnivorous consumers compensate for the activities of the suppressed herbivores. For example, the exclusion of fish in Venezuelan rivers did not produce cascading effects, as these fish eat both insects and algae (Flecker 1996).

As mentioned earlier, interactions among species can vary spatially and temporally and may range from strongly positive to strongly negative. For example, in dry woodlands, shrubs may facilitate the establishment of tree seedlings during dry years, but they also provide habitat for beetles (*Tenebrionidae*) that eat the seedlings (Kitzberger et al. 2000). Therefore, the effects of shrubs on the trees vary in space and time. In wetter years, direct facilitation becomes less important, and net effects may become dominated by indirect negative effects caused by the herbivores.

11.3.2.4 Ecosystem Engineers

Ecosystem engineers are organisms that directly or indirectly modulate the availability of resources other than themselves to other species by causing physical changes in the biotic or abiotic materials of the environment. They may dramatically modify the composition and functioning of an ecological community (Jones et al. 1994). On land, woody plants dominate the physical structure of the habitat. Deforestation causes massive changes in habitat structure and leads to loss of species at several trophic levels (Holling 1992). Some species modify an ecosystem's disturbance regimes because they have traits that affect probabilities of disturbance. For instance, highly flammable grasses induce high fire frequency, which in turn alters community composition and ecosystem functioning (D'Antonio and Vitousek 1992; Levine et al. 2003). In hurricane-prone tropical forests, deeper-rooted trees may be less likely to fall during high winds, thereby altering understory communities (Lawton and Jones 1995). Examples of animal ecosystem engineers are numerous. Beavers damming streams, termites building mounds, and elephants killing trees are all examples of animals that modify the structure of their habitat. These modifications can strongly affect the hydrology, productivity, and the provisioning of ecosystem products (such as fish in beaver ponds).

11.3.3 Biodiversity Effects on Climate Regulation

Certain components of biodiversity, such the characteristics of the dominant species and the distribution of landscape units, influence the capacity of terrestrial ecosystems to sequester carbon and regulate climate at the local, regional, and global scales. (See also Chapter 13.) Indirect feedback to global climate may accrue because plants sequester carbon in biomass (decreasing carbon release to the atmosphere). Climate may also be altered by plants through changes in albedo, evapotranspiration, temperature, and fire regime. Changes in land use, over large land surface areas, will change how biodiversity affects climate. Equally important are the functional traits of dominant plant species and the spatial arrangement of landscape units. Thus biodiversity needs to be explicitly considered in climate change mitigation practices such as afforestation, reforestation, slowed-down deforestation, and biofuel plantations.

11.3.3.1 Biophysical Feedbacks

The functional traits and structural complexity of plant canopies influence water and energy exchange through their effects on albedo (Chapter 13). Albedo is the proportion of incoming radiation that is reflected by the land surface back to space. Complex canopies trap more reflected radiation, thereby reducing albedo. In dense vegetation, albedo is determined by the properties of the dominant plant functional types, with albedo decreasing from grasses to deciduous shrubs and trees to conifers (Chapin et al. 2002). In open-canopied ecosystems, which account for 70% of the ice-free terrestrial surface (Graetz 1991), all individuals contribute to albedo, and more biologically diverse—and hence more structurally complex—communities have lower albedo (Thompson et al. 2004). For example, the increase in shrub density in Arctic tundra in response to regional warming (Sturm et al. 2001) has reduced regional albedo and increased regional heating (Chapin et al. 2000b). (See Chapter 25.)

Greater structural diversity of the canopy increases the efficiency of water and energy exchange, which influences water use efficiency of vegetation and runoff to streams. Complex canopies generate mechanical turbulence that mixes within-canopy air with the bulk atmosphere and therefore increases the efficiency with which water, heat, and CO_2 are exchanged between the ecosystem and the atmosphere. (See Chapter 13.) Mechanical turbulence depends on the structural diversity of the vegetation—the number, size, and arrangement of roughness elements such as trees or shrubs. Changes in structural diversity are particularly important when they add individuals that are taller or more wind-resistant than the surrounding vegetation. Even a low density of trees (less than 100 trees per hectare, for example) in a savanna or woodland substantially increases turbulent exchange with the atmosphere (Thompson et al. 2004).

The functional composition of vegetation (for instance, the structural complexity, phenology, or height) influences not only the total quantity of energy absorbed and exchanged with the atmosphere but also the partitioning of this energy flux among three pathways: latent heat flux (evapotranspiration) as a result of evaporation of water at the surface and its condensation in the atmosphere, sensible heat flux (heat associated with a temperature increase of the air), and ground heat flux (the heat conducted into the ground) (Oke 1987).

Forests transmit a larger proportion of their energy to the atmosphere as latent heat (evapotranspiration) than grasslands do because of their deeper roots and greater leaf area (Chapin et al. 2002). They therefore have a net moistening effect on the atmosphere (Shukla et al. 1990), which becomes a moisture source for downwind ecosystems. In the Amazon, for example, 60% of precipitation comes from water transpired by upwind ecosystems. Species with traits that enhance stand-level evapotranspiration, such as high stomatal conductance, therefore enhance the regional precipitation derived from a given moisture source. Since water is the resource that most strongly limits global plant production (Chapin et al. 2002; Gower 2002), these properties also contribute substantially to global productivity. In the boreal forest, post-fire deciduous stands have higher albedo and stomatal conductance than pre-fire conifer stands (Baldocchi et al. 2000) and therefore have a net cooling effect on climate. Because increasing temperatures will increase fire frequency, this may act as a one of the few potential negative feedbacks to high-latitude warming (Chapin et al. 2000c).

Large-scale changes in landscape patterns have effects on regional climate. The diversity of patches on a landscape exerts an additional impact on biophysical coupling between land and atmosphere and therefore on local-to-regional climate. Large patches (more than 10 kilometers in diameter) that have lower albedo and higher surface temperature than neighboring patches create cells of rising warm air above the patch (convection); this air is replaced by cooler moister air that flows laterally from adjacent patches (advection). Climate models suggest that these landscape effects substantially modify local-to-regional climate. In Western Australia, the replacement of native heath vegetation by wheatlands increased regional albedo. As a result, air tended to rise over the dark heathland, drawing moist air from the wheatlands to the heathlands. The net effect was a 10% increase in precipitation over heathlands and a 30% decrease in precipitation over croplands (Chambers 1998). Most vegetation changes generate a climate that favors the new vegetation, making it difficult to return the vegetation to its original state.

11.3.3.2 Carbon Sequestration

Biodiversity affects carbon sequestration primarily through its effects on species traits, particularly traits related to growth (which governs carbon inputs) and woodiness, a key determinant of carbon turnover rate within the plant. As described earlier, species diversity can enhance productivity through temporal and spatial niche diversification and through increasing the probability of including productive species in the community. Species differences in productivity result from a wide range of plant traits, including growth rate, allocation patterns, phenology, nutrient use efficiency, resource requirements, traits that influence access to resource pools (such as root depth or symbioses with mycorrhizae or N-fixing microorganisms), and traits that influence conditions that limit growth (such as temperature or moisture) (Lambers and Poorter 1992). Woodiness is particularly important in enhancing carbon sequestration because woody plants tend to contain more carbon, live longer, and decompose more slowly than smaller herbaceous plants.

Plant species also strongly influence carbon loss via decomposition and their effects on disturbance. Decomposition is influenced by traits linked to leaf litter quality (carbon quality and nutrient concentrations, for example), effects on soil environment (temperature, moisture, oxygen, and so on), carbon exudation rate from roots, and interactions with other species (Eviner and Chapin 2004). For example, wood decomposes more slowly than herbaceous material, and slow-growing plants characteristic of low-resource environments produce leaves that decompose more slowly than those of more rapidly growing plants (Cornelissen 1996; Pérez-Harguindeguy et al. 2000), enhancing carbon sequestration.

In general, the suite of traits that promotes rapid growth and high productivity also leads to rapid decomposition. Thus there is a tradeoff among traits that promote short-term carbon accumulation versus long-term carbon storage. Plant traits also influence the probability of disturbances such as fire, wind-throw, and human harvest, which temporarily change forests from accumulating carbon to releasing it (Valentini et al. 2000; Schulze et al. 2000). In addition to the effects of plant traits on carbon gain and loss from ecosystems, other forms of diversity can be important by influencing the spread of pests and pathogens, which are important agents of disturbance and carbon loss from ecosystems (see next section).

Landscape diversity and spatial pattern also influence carbon loss from ecosystems. In particular, the edges of forest fragments are often places of high plant mortality because the radically altered environment at forest edges kills trees via wind throw and desiccation (e.g., Hobbs 1993 for Australia; Chen et al. 1992 for western North America; Laurance et al. 1998a for Amazonia). Elevated tree mortality leads to a decline of living biomass near forest edges (Laurance et al. 1997) and an increase in decomposition (Laurance et al. 2000). The net effect is a decline in carbon storage at the edges of forest fragments. As forest fragments decline in size, a larger proportion of the total landscape loses carbon. Another potential effect of habitat fragmentation is the alteration of natural fire regimes, either by reducing the frequency and extent of fires (for example, when fires are suppressed in the surrounding matrix) (Baker 1994) or by increased burning in ecosystems that are highly vulnerable to fire (as in tropical rainforests) (Gascon et al. 2000; Cochrane and Laurance 2002; see also Chapter 16).

11.3.4 Pest and Disease Control in Agricultural Systems

Both the diversity of natural enemies and the landscape diversity may influence pest and disease control in agricultural systems. Yields of desired products from agroecosystems may be reduced by attacks of herbivores above and below ground, fungal and microbial pathogens, and competition with weeds. Modern agriculture has focused on reducing biodiversity in order to generate monocultures of the most profitable species or genetic variety. Landscape diversity (such as the intermixing of crop and noncrop patches) and crop rotation can also reduce the need to breed for new pest and disease resistance and to discover new pesticides.

However, biodiversity may enhance pest resistance in agricultural systems through both ecological and evolutionary processes. Because of the high population densities and short life cycles of many weeds and pests, resistance to synthetic biocides typically evolves rapidly, necessitating continuing costly investments to develop and employ new synthetic biocides. Most improvements in crop resistance to herbivores, pathogens, and weeds are transitory. Use of biodiversity can reduce the frequency with which biocides need to be applied and, hence, the selective pressure and rate at which resistance evolves (Palumbi 2001).

Biodiversity-based techniques that reduce or eliminate the need for biocides can be based on the species richness of crop plants or natural enemies (pathogens or parasites). Techniques that use crop plant biodiversity to reduce or eliminate application of biocides include intercropping of genetically different strains of a single crop species, intercropping of crop plants of different species, and crop rotation. Techniques that encourage populations of predators, parasites, and pathogens of the species that attack crop plants include no-till or low-till soil management and planting of other plant species that either repel crop predators or attract them away from the crop.

11.3.4.1 Techniques Based on Crop Plant Biodiversity

The productivity of agricultural systems with high crop genetic diversity or species richness tends to be more stable over time than that of low-diversity systems, in part due to improved pest and disease control (Power and Flecker 1996; Power 1999) (see also the earlier section on ecosystem stability). Traditional agricultural systems often include substantial planned genetic and species diversity (Pretty 2002). In contrast, the low diversity of most commercial monoculture systems often results in large crop losses from a pest complex that is less diverse but more abundant than that in more diverse systems. Indeed, a low-diversity global strategy of food production could potentially be destabilized by pests and disease (Tilman et al. 2002a).

A large proportion of global food production is accounted for by just three crops: wheat, rice and maize. The relative scarcity of outbreaks of diseases on these three crops is a testament to the success of plant breeding, cultivation practices, and the use of agrochemicals. Because of the rapid evolution of biocide-resistant organisms, however, these successes may not be sustainable in the long term. For example, within about one or two decades of the introduction of each of seven major herbicides, herbicide-resistant weeds were observed. Insects also frequently evolve resistance to insecticides within a decade. Resistant strains of bacterial pathogens appear within one to three years of the release of many antibiotics for livestock (Palumbi 2001).

By the beginning of the twenty-first century, some 2,645 cases of resistance of species to biocides had been recorded in insects and spiders, involving more than 310 pesticide compounds and 540 different insect species (www.cips.msu.edu/resistance/; www.cips.msu.edu/resistance/rmdb/background.html). During the 1990s, there was a 38% increase in compounds to which one or more arthropod species were resistant, and a 7% increase in arthropod species that are resistant to one or more pesticides.

Increased genetic diversity of crops nearly always decreases pathogen-related yield losses. Recently rice blast, a major and costly fungal pathogen of rice, was controlled in a large region of China by planting alternating rows of two rice varieties (Zhu et al. 2000). This tactic increased profitability and reduced the use of a potent pesticide. The use of mixtures of different crop varieties has been shown to effectively retard the spread or evolution of fungal pathogens of grains (Ngugi et al. 2001; Mundt 2002). There is some evidence that these approaches may also be useful for the control of plant viruses (Power 1991; Matson et al. 1997; Hariri et al. 2001).

High crop species richness enhances the ecosystem services derived from agriculture and often improves the stability of production over time by reducing the incidence of herbivores, pathogens, and weeds. In monoculture plantations of rubber trees, sugarcane, or cacao, the larger and more isolated the plantation, the greater the impact of herbivores on the plants of the agroecosystem (Harper 1977; Strong 1974). Plantations of cacao and rubber tend to have considerably lower levels of herbivory when adjacent to natural, diverse forests. In a review of reported tests of herbivore density in polycultures compared with monocultures, 52% of 287 herbivore species occurred at lower densities in polycultures compared with only 15% that occurred at higher density (Andow 1991). Sometimes even growing a mixture of two crops is enough for broad pest control; for example, in the Philippines, intercropping maize and peanuts helps to control the maize stemborer (Conway 1997). Numerous studies indicate that increasing crop species richness commonly decreases the severity of weed infestations (Liebman and Staver 2001). This is because greater crop species richness often increases the overall usage of available resources by the crops, leaving fewer leftover resources on which weeds can subsist.

Plant species richness also tends to suppress the spread of viral infection in crops: 89% of plant viruses with a known transmission mechanism are transmitted by plant-feeding insects (Brunt et al. 1996). Greater plant species richness reduces the abundance of their insect vectors, and so the majority of viruses that are transmitted by insects tend to be found at lower densities in polycultures than monocultures (Power and Flecker 1996). The richness of crop species in an agroecosystem has a much less predictable effect on the prevalence of microbial pathogens that do not rely on insect vectors, such as most fungi (Matson et al. 1997).

Fungal diseases are usually but not always less severe in polycultures than monocultures (Boudreau and Mundt 1997). Variations occur because the effects of intercropping on disease dynamics depend on a variety of factors, including microclimate effects and the spatial scale of pathogen dispersal (Boudreau and Mundt 1994; Boudreau and Mundt 1997). Crop diversification can alter microclimate in ways that either encourage or inhibit pathogen growth, depending on the characteristics of the pathogen, plants, and local environment (Boudreau and Mundt 1997). Long-distance aerial dispersal is an important survival strategy for fungal and fungus-like pathogens that cause crop diseases, such as rusts (*Uredinales*), powdery mildews (*Erysiphales*), and downy mildews (members of the protist family *Peronosporaceae*) (Brown and Hovmøller 2002). Therefore, deployment of increased crop species richness at larger spatial scales may be necessary to reduce their spread. This idea is supported by studies of increased crop genetic diversity (Zhu et al. 2000; Wolfe 2000), but untested with species diversity.

11.3.4.2 Techniques Based on the Biodiversity of Natural Enemies of Crop Predators, Parasites, and Pathogens

The species richness of natural enemies of pests increases with that of crops (Andow 1991). Compared with monocultures, species-rich agroecosystems are likely to have higher predation and parasitism rates and higher ratios of natural enemies of herbivores, all of which may contribute to lower pest densities. The spraying of biocides is much more likely to wipe out the organisms that control the pests than the pests themselves or to so reduce their predator populations that the resurgence of pests can cause considerable damage before control is reestablished (Naylor and Ehrlich 1997). Traditional subsistence systems that rely on diverse agroecosystems, such as the Javanese home garden or the milpa farming system in Mexico, typically support natural enemies of pests, such as spiders, ants, and assassin bugs (see the Javanese rice paddy case study in Chapter 26). However, the positive impacts of increased species richness on natural pest control are not universal (Altieri and Schmidt 1986).

Natural pest control services are likely to be detrimentally affected by loss of species richness (Schläpfer et al. 1999). However, in only a few cases has the role of natural enemy species richness in controlling pests been tested explicitly. Species richness of parasitoids increases parasitism rates in the armyworm caterpillars in some but not all locations in the United States (Menalled et al. 1999). Perhaps the most comprehensive understanding of the importance of predator species richness comes from spiders. There are indications of complementarity of function among spider species—that is, they catch prey using different methods, occupy different microhabitats, or are active at different times or seasons. Because of this, increasing spider species richness leads to higher and less variable predation rates and increased food web stability (Marc and Canard 1997; Riechert et al. 1999; Sunderland and Samu 2000; and see section 11.2.1 for general discussion of diversity and functional complementarity).

Recent theoretical evidence suggests that the species richness of predators and parasites of herbivorous insects may be important for the control of some types of insect pests, whereas composition, the presence of a particular predator or parasite species, may be more important than species richness for other types of pest (Wilby and Thomas 2002b), though this is yet to be rigorously tested in the field. Understanding whether and when natural enemy species richness will increase pest control is an important goal of contemporary agroecological science.

Mixtures of two or more plant species have also been developed to manipulate the density of pests and their natural enemies. For example, two kinds of plants are sometimes cultivated together with maize to control stem-borers: a plant that repels the insects and another that attracts them. This strategy has also been shown to be helpful in suppressing the parasitic weed *Striga* (Khan et al. 2000). Natural plant compounds that have been used in traditional farming systems can be useful in controlling pests in many agricultural settings. Examples include the neem tree (*Azadirachta indica*)—a natural insecticide source that has been used against rice pests in India for decades—and a variety of other plants such as the custard apple (*Annona* sp.), turmeric (*Curcuma domestica*), Simson weed (*Datura stranonium*), and chili peppers (*Capsicum frutescens*) (Pretty 1995).

11.3.4.3 Integrated Pest Management and Low-till Cultivation Systems

Integrated pest management, an approach that combines traditional agricultural systems with modern techniques, includes the promotion of natural pest controls through enhanced biodiversity of crops and natural enemies of crop pests, parasites, and pathogens (as just described), the development of host-plant resistance, and the use of pesticides when absolutely necessary. IPM can be highly successful in mitigating pest pressure in regions where farmer training programs and information services are adequate (Conway 1997; Naylor and Ehrlich 1997). However, despite cases of notable success with IPM, such as the control of the brown planthopper in Indonesian rice systems (Kenmore 1984), relatively few crops are managed widely with IPM techniques on a global scale. Because of favorable pricing policies for pesticides in many locations and the knowledge-intensive nature of IPM, this practice has yet to significantly reduce the amount of pesticides applied in agriculture worldwide.

A central component of IPM is a low-till cultivation system, which maintains a permanent or semi-permanent organic cover on the soil, consisting of either a growing crop or dead organic matter in the form of a mulch or green manure. Low-till cultivation provides habitat for natural enemies to control insect pests and increases local genetic, species, and landscape diversity, as well as enhancing soil stability, organic matter content, and carbon sequestration (Sánchez 1994; Swift 1999; Pretty and Ball 2001; Lal 2004). However, this practice often relies on the heavy use of herbicides to control weeds that might otherwise be controlled by tillage and thus can have strong negative impacts on plant biodiversity (Pretty 2002). No-till with no or minimum use of herbicides is also a viable option, at least for small farms (Petersen et al. 2000; Ekboir 2002).

11.3.4.4 Summary on Biodiversity and Natural Pest Control

To summarize, the maintenance of natural pest control services is strongly dependent on biodiversity. This service benefits food security, rural household incomes, and national incomes of many countries. (See also Boxes 11.3 and 11.4.) In many cases, perhaps the majority of them, increased crop genetic diversity and species richness at different trophic levels lead to more efficient natural control of pests and diseases in agricultural systems. However, further research is required to elucidate the ecological mechanisms of pest and disease control in order to understand both the successes and failures of reduced-input agricultural systems.

Nonetheless, the available evidence suggests that conserving the genetic diversity of crops and crop relatives at a global scale and deploying that diversity locally will protect and enhance natu-

BOX 11.3

Biodiversity and the Multifunctionality of Agricultural Systems

Modern agricultural methods brought spectacular increases in productivity (Conway 1997; Pretty 2002; Tilman et al. 2002a). Large-scale agriculture, however, brings simplification and a loss of biological diversity and thus reduces the potential of agriculture to provide ecosystem services other than food production. Worldwide, a third of the 6,500 breeds of domesticated mammals and birds are under immediate threat of extinction owing to their very small population size. Over the past century, it is believed that 5,000 animal breeds have already been lost. The situation is most serious in the already industrialized farming systems, with half of breeds at risk in Europe and a third at risk in North America. Asia, Africa, and Latin America have approximately 20% of their breeds at risk (FAO/UNEP 2000; Blench 2001). There is strong evidence that more genetic diversity keeps options open for both breeders and farmers in the face of a changing environment.

Unlike many other economic sectors, agriculture is inherently multifunctional. It jointly produces much more than just food, fiber, or oil, having a profound impact on many elements of local, national, and global economies and ecosystems (FAO 1999; see also Chapters 10 and 17). These impacts can be negative or positive. For example, an agricultural system that depletes organic matter or erodes soil while producing food imposes costs that others must bear; but one that sequesters carbon in soils and keeps both planned and unplanned species richness high enhances ecosystem services other than food and fiber production. For centuries, traditional agricultural systems have contributed to ecosystem services such as regulation of water supply, soil fertility, and plant and animal pathogens and pests; storm protection and flood control; and carbon sequestration. In contrast, industrialized agriculture has become progressively more expensive in terms of energy (inorganic fertilizers, pumped irrigation, and mechanical power) (Pretty 1995), human and environmental health (toxic contamination, soil erosion and salinization, eutrophication of land and water) (Conway and Pretty 1991; Pretty 1995; Altieri 1995; EEA 1998), and social impact (rural uprooting, poverty, and economic inequity) (Pretty 2002; see also Chapter 6).

Sustainable agricultural systems that substitute goods and services derived from nature for externally derived fertilizers, pesticides, and fossil fuels enhance the provision of ecosystem services and human well-being in several ways. First, they increase the energy-efficiency of food production (Pretty 1995; Pretty and Ball 2001) (see also Chapters 8 and 26), thus decreasing the externals costs to society as a whole. Second, they enhance the provision of human health (see also Chapter 14). Third, by protecting genetic, species, and landscape diversity, they enhance the provision of biodiversity-linked regulating and supporting ecosystem services derived from it.

ral pest control services that provide economic and food production benefits. Moreover, high-biodiversity agriculture has cultural and esthetic value and can reduce many of the externalized costs of irrigation, fertilizer, pesticide, and herbicide inputs associated with monoculture agriculture (Pretty et al. 2000 2001).

11.3.5 Biodiversity Effects on Human Disease Regulation

Human health, particularly risk of exposure to many infectious diseases, may depend on the maintenance of biodiversity in natural ecosystems. (See Chapter 14.) Over 60% of human pathogens are naturally transmitted from animals to humans (Taylor et al. 2001). Many of these are transmitted by arthropod vectors from wildlife species, creating the potential for ecological processes to affect human disease risk. A greater richness of wildlife species might be expected to sustain a greater number of pathogen species that can infect humans. However, evidence is accumulating that greater wildlife species richness may decrease the spread of wildlife pathogens to humans. The effect of biodiversity on disease risk is also expected to depend on the details of interactions between the wildlife host and arthropod vector species. Unfortunately, such data are lacking for most such diseases.

Spread of one disease for which there is data, Lyme disease, seems to be decreased by the maintenance of the biotic integrity of natural ecosystems. Lyme disease is the most common vector-transmitted disease of humans in North America, and thousands of cases occur annually in Europe and Asia as well (Ostfeld and Keesing 2000a). Where it has been studied in eastern North America, the ticks that transmit the disease primarily acquire the pathogen from the white-footed mouse, *Peromyscus leucopus* (Barbour and Fish 1993). Therefore, ecological processes that reduce the number of ticks feeding on mice have the potential to reduce disease transmission to humans.

A greater number of small mammal species could reduce the number of ticks feeding on mice either by reducing mouse abundance through competition or by attracting ticks that would otherwise have fed on mice. Modeling analyses of data collected in southeastern New York State suggests that the current level of mammal biodiversity decreases disease risk to humans by up to 50% relative to realistic scenarios of decreased biodiversity (Schmidt and Ostfeld 2001; LoGiudice et al. 2003; Ostfeld and LoGiudice 2003). In a complementary analysis of large-scale geographic gradients in mammal biodiversity, states in the eastern U.S. inhabited by more species of small mammals reported fewer cases of Lyme disease per capita (Ostfeld and Keesing 2000a).

In another survey, Lyme disease risk was over four times greater in forest fragments less than 2 hectares in area than in larger fragments that typically harbor a greater number of mammal species (Allan et al. 2003). In these latter two studies, Lyme disease risk also appeared to be a function of other variables correlated with mammal species richness, such as climate, geographic location, and the presence and abundance of specific mammal species. Together, these results strongly suggest that current biodiversity of small mammals supports public health by reducing peoples' risk of contracting Lyme disease, but that this ecosystem service is being eroded by habitat fragmentation.

Risks of other infectious diseases might also depend on biodiversity, although data to fully understand such links are sparse and inconsistent. Lyme disease is epidemiologically representative of emerging diseases in general. Vector-transmitted diseases are over twice as likely as other diseases to be emerging diseases, and 75% of emerging human diseases are naturally transmitted from animals to humans (Taylor et al. 2001). Therefore, biodiversity might be important in controlling many emergent diseases. Whether the same biological processes that appear to control Lyme disease risk also control risk of other vector-borne pathogens remains largely untested, however. Whether biodiversity can also decrease the risk of wildlife pathogens that do not require arthropod vectors for transmission to humans is even less well understood. Thus, the available data indicate that human health is supported as an ecosystem service by biodiversity in some cases, but the generality of this service is poorly known. (See also Chapter 14.)

BOX 11.4

Putting a Monetary Value on High-biodiversity Agricultural Landscapes

How much are traditional high-diversity agricultural landscapes worth? It is relatively easy to assess the negative costs of unsustainable agriculture in terms of abatement and treatment costs following pollution, increased sediment deposition into dams, the socioeconomic costs of rural uprooting, and so on. It is much more difficult to calculate the value of both the positive direct contributions of agricultural systems containing highly planned and unplanned biodiversity and the indirect effects on supporting and regulating ecosystem services. Environmental economists have developed methods for assessing people's stated preferences for environmental goods through hypothetical markets (see Chapter 2), which permits an assessment of their willingness to pay for nature's goods and services or to accept compensation for losses (Stewart et al. 1997; Hanley et al. 1998, Brouwer et al. 1999).

A variety of these assessment methods suggests that traditional agricultural landscapes are highly valued. Although it is impossible to precisely quantify this, several proxies can be used, including how much governments are willing to pay farmers to produce certain habitats or landscapes, how often the public visits the countryside, and how much they spend when they get there (Willis et al. 1993; Foster et al. 1997; Stewart et al. 1997; Hanley et al. 1998).

U.K. government programs have attempted to preserve and restore some of the habitat and other positive countryside attributes that were lost during intensification. The annual per household benefit of these areas, using a variety of valuation methods (including contingent valuation, choice experiments, and contingent ranking), varies from £2–30 to £380. If we take the range of annual benefits per household to be £10–30 and assume that this is representative of the average households' preferences for all landscapes produced by agriculture, then this suggests national benefits of the order of £200–600 million per year. Expressed on a per hectare basis, annual benefits are £20–60 per hectare of arable and pasture land.

Another study compared paired organic and nonorganic farms, and concluded that organic agriculture produces £75–125 per hectare of positive externalities each year, with particular benefits for soil health and wildlife (Cobb et al. 1998).

Another proxy measure of how much we value landscapes can be made based on actual visits made to the countryside. Each year in the United Kingdom, day and overnight visitors make some 433 million visit-days to the countryside and another 118 million to the seaside (Pretty et al. 2003). The average spent per day or night varies from nearly £17 for U.K. day visitors to £58 for overseas overnight visitors. This indicates that the 551 million visit-days to the countryside and seaside result in expenditure of £14 billion per year. This is three and a half times greater than the annual public subsidy of farming. While none of these estimates are definitive, in total they clearly indicate that the landscape is highly valued by society.

Should farmers receive public support for the ecosystem services they produce in addition to food? Should those that pollute or otherwise decrease the provision of ecosystem services to the public have to pay for restoring them? The external costs and benefits of agriculture raise important policy questions for both industrial and developing countries. Three categories of policy instruments are available: advisory and institutional measures, regulatory and legal measures, and economic instruments. In practice, effective pollution control and supply of desired public goods requires a mix of all three approaches, together with integration across sectors. Regulatory and legal measures can be used to internalize external costs: those who decrease the ecosystem-service potential of the environment below a set standard are subject to penalties. Economic instruments can also be used to make sure that those who damage the environment bear the costs of the damage and also as a reward for good behavior. A variety of economic instruments are available for achieving internalization, including environmental taxes and charges, tradable permits, and targeted use of public subsidies and incentives.

11.4 Biodiversity Effects on the Provision of Marine Ecosystem Services

The ocean covers approximately 70% of Earth's surface area and contains nearly 99% of its habitable volume, so ecosystem services disrupted in the ocean will have large global consequences. The services provided by ocean ecosystems include global materials cycling, transformation and detoxification of pollutants and wastes, support of coastal recreation and tourism, and support of world fisheries and aquatic ecosystems. (See Chapter 18.) All these services are affected by the diversity of life in the ocean, although quantification of many of the links between biodiversity and marine ecosystem services has only occurred recently (Peterson and Lubchenco 1997). Marine biodiversity provides many of the same types of services as those of terrestrial biodiversity just described, with the exceptions of pollination and seed dispersal.

11.4.1 Invasion Resistance

In several marine ecosystems, decreases in the richness of native taxa were correlated with increased survival and percentage cover of invading species. This suggests that, as in terrestrial plant ecosystems, invasion resistance is enhanced by the integrity of the native species pool. For example, diverse systems use resources such as available space more completely. In experimentally assembled benthic (sea floor) communities, decreasing the richness of native taxa was correlated with increased survival and percent cover of invading species. Open space was the limiting resource for invaders, and a higher species richness buffered communities against invasion through increasing temporal stability (such as reducing fluctuations of open space) (Stachowicz et al. 1999). High biodiversity is also expected to contribute to community resilience by creating insurance through functional redundancy (Stachowicz et al. 2002). Although there are few studies of the effects of biodiversity in marine ecosystems, the available evidence suggests that marine systems may possess similar mechanisms of invasion resistance as found in terrestrial systems.

11.4.2 Direct and Indirect Interactions between Marine Species

11.4.2.1 Interactions between Plants and Symbiotic Microorganisms

Coral reefs and the ecosystem services they provide are seriously threatened by a hierarchy of anthropogenic threats. (See Chapter 19.) As one of the most species-rich communities on Earth, coral reefs are responsible for maintaining a vast storehouse of genetic and biological diversity. Substantial ecosystem services are provided by coral reefs, such as habitat construction, nurseries and spawning grounds for fish, nutrient cycling and carbon and nitrogen fixing in nutrient-poor environments, wave buffering, sediment stabilization, and tourism. Reef-related fisheries constitute approximately 9–12% of the world's fisheries. Coral reefs support the pelagic food web by exporting nutritional material such as mucous, wax esters, and dissolved organic matter. The total economic value of reefs and associated services is estimated as $503 million in Australia and as $900 million in the Caribbean (Moberg and Folke 1999).

Corals require a symbiosis with zooxanthellan algae, which provide carbon, and ecosystem services can be maintained only if the interaction between corals and their obligate symbiotic algae is preserved. The interaction with zooxanthellae is strain-specific and changes with temperature and biogeographic region, light environment, and depth (Baker et al. 2004). High temperatures, such as experienced globally as a result of the 1998 El Niño events, disrupt the symbiosis, make corals less resilient to other stresses, and can lead to massive coral mortality (Hughes et al. 2003). Thus there is a direct causal link between climate warming and disruption of a critical biological interaction that can trigger collapse of an entire reef system, with consequent loss of ecosystem services that are provided. (See Chapter 19.)

11.4.2.2 Ecosystem Engineers and Herbivory

Macroalgae and corals modify wave action regimes and allow sediment stabilization, greatly affecting intertidal community diversity (Lawton and Jones 1995). Corals are threatened by a variety of human impacts, and many kelp macroalgae communities are threatened by overgrazing. The effects of overgrazing may be reversible. For example, recovery of sea otter (*Enhydra lutris*) populations after decades of overhunting on the coast of western North America has promoted the reestablishment of structure-forming kelp forests and its associated community as a result of the reestablishment of the predation of herbivorous sea urchins by otters (Dayton et al. 1998; Springer et al. 2003).

11.4.2.3 Predators and Food Webs

Overfishing reduces the capacity of the marine system to continue to provide ecosystem services by impoverishing and threatening marine biodiversity, particularly top predators (Myers and Worm 2003). The loss of a top predator is likely to have effects on their prey and other species throughout the food web. Removal of fish with key characteristics from the ecosystem may result in loss of resilience and a change in the ecosystem from one equilibrium state to another (e.g., Sutherland 1974; Hughes 1994). For example, recent declines in great whales, a preferred food of killer whales, caused the killer whales to shift to sea otters. Rapid decimation of otters by killer whales took predation pressure off a keystone herbivore, urchins, which then overgrazed kelp beds and transformed them into crustose algal–dominated communities called "urchin barrens" (Springer et al. 2003).

As in terrestrial and aquatic communities, there are many examples of how biodiversity, particularly the loss of populations of individual species, influences ecosystem processes and the provisioning of ecological services. In the rocky intertidal zone, for example, most primary productivity is contributed by a few strong interacting species (Paine 2002). A loss of biodiversity that includes those species has a large effect on primary productivity. Similarly, Duarte (2000) found a strong link between ecosystem functioning and biodiversity in seagrass beds worldwide, with the caveat that ecosystem processes depend on particular members of a community rather than on species numbers.

Some species may have a disproportionately large effect relative to their abundance (Power et al. 1996). For example, the main predators of large commercial fish species are not larger fish, but rather small jellyfish that feed on fish larvae (Purcell 1989). In addition, species loss in species-rich communities is more likely to be compensated for by increases of functionally similar species, as described early in the chapter in the section on ecosystem stability.

Many species interactions vary spatially and temporally from strongly positive to strongly negative. For example, predatory whelks (*Nucella emarginata* and *N. canaliculata*) in intertidal communities consume mussels (*Mytilus trossulus*), but also influence them indirectly through their effects on barnacles (*Balanus glandula*), habitat facilitators of mussels. These spatially and temporally fluctuating interactions have important consequences on community structure and ecosystem organization (Berlow 1999).

11.4.3 Biodiversity Effects on Climate Regulation

The major importance of marine biodiversity in climate regulation appears to be via its effect on biogeochemical cycling and carbon sequestration. The ocean, through its sheer volume and links to the terrestrial biosphere, plays a huge role in cycling of almost every material involved in biotic processes. (See Chapter 12.) Of these, the anthropogenic effects on carbon and nitrogen cycling are especially prominent.

Biodiversity influences the effectiveness of the biological pump that moves carbon from the surface ocean and sequesters it in deep waters and sediments (Berner et al.1983). Some of the carbon that is absorbed by marine photosynthesis and transferred through food webs to grazers sinks to the deep ocean as fecal pellets and dead cells. The efficiency of this trophic transfer and therefore the extent of carbon sequestration is sensitive to the species richness and composition of the plankton community (Ducklow et al. 2001). Some phytoplankton in the southern ocean, for example, are more palatable than others, so an increase in their abundance increases grazing, the formation of fecal pellets, and the export of carbon to depth. (See Chapter 25.)

The biodiversity of marine sediments can play a key role in ecosystem processes. Sedimentary habitats cover most of the ocean bottom and therefore constitute the largest single ecosystem on Earth in terms of spatial coverage. Although only a small fraction of benthic organisms that reside in and on sediments have been described and few estimates of total species numbers and biogeographic pattern have been attempted, there is sufficient information on a few species to suggest that sedimentary organisms have a significant impact on major ecological processes (Snelgrove et al. 1997). Benthic organisms contribute to the regulation of carbon, nitrogen, and sulfur cycling, to water column processes, to pollutant distribution and fate, to secondary production and transport, and to the stability of sediments. Linkages between groups of organisms and the level of functional redundancy of marine sediment biodiversity is poorly known, and there are very few empirical studies (e.g., Bellwood et al. 2004).

11.4.4 Biodiversity Effects on Pollution and Human Disease Regulation

The marine microbial community provides critical detoxification services—filtering water, reducing effects of eutrophication, and degrading toxic hydrocarbons. Very little is known about how many species are necessary to provide detoxification services, but these services may critically depend on one or a few species. For example, American oysters in Chesapeake Bay on the U.S. East Coast were once abundant but have sharply declined, and with them their filtering ecosystem services (Lenihan and Peterson 1996). Reintroduction of large populations of filtering oysters may significantly improve water clarity in the bay (Jackson et al.

2001). The process of degrading toxic hydrocarbons, such as those in an oil spill, into carbon and water requires oxygen. Nutrient pollution can generate oxygen deprivation and thereby significantly reduce the ability of marine microbes to detoxify hydrocarbons (Peterson and Lubchenco 1997).

11.5 Biodiversity, Ecosystem Services, and Human Well-being: Challenges and Opportunities

The message emerging from the evidence assessed in this chapter is clear: the loss of biodiversity can reduce the provision of ecosystem services essential for human well-being. Knowledge of the links between biodiversity and ecosystem processes is still incomplete, but existing evidence suggests that a precautionary approach may be prudent and that research should be targeted to assist with the development of appropriate management interventions.

The biggest challenges are posed by the limited understanding of the ways in which biodiversity regulates ecosystem functioning at local and regional scales and the intrinsic difficulty of predicting unexpected, accelerated, and some times irreversible changes triggered by alterations of local and regional biodiversity by human intervention. Global extinctions are serious and irreversible, but alteration of the functional composition of local communities, the extinction of local populations, or their reduction to levels that do not allow them to play strong ecosystem roles (functional extinctions) are of major concern.

The vast majority of supporting and regulating ecosystem services provided by biodiversity are delivered at the local to regional scale. Often, when the functioning of a local ecosystem has been pushed beyond a certain limit by direct or indirect biodiversity alterations, the ecosystem service losses may persist for a very long time. In this sense, modern industrial agricultural practices based on the reduction of local biodiversity to one or a very small group of desired species is a major threat to the maintenance of supporting and regulating ecosystem services.

The evidence presented in this assessment suggests than in many instances biodiversity conservation is an economically sound way of improving human well-being. Conserving and managing biodiversity sustainably can maintain a number of ecosystem services whose importance is only now starting to be recognized without necessarily compromising the delivery of economic products from ecosystems.

The idea that there is an unavoidable trade-off between biodiversity and the economic output of ecosystems ignores the external costs of intensive ecosystem exploitation. When these considerable costs are taken into account, including those of lost supporting and regulating services—in the case of agricultural intensification, for instance, external costs are related to pollution and related health hazards, erosion, and carbon emissions resulting from the burning of fossil fuel by machinery and the production of pesticides—the net benefits of intensive exploitation are substantially reduced.

Thus by minimizing external costs and maximizing nonprovisioning ecosystem services, management practices that incorporate biodiversity may represent a cost-effective option. This is particularly important for the less-favored sectors of society, such as local indigenous communities and subsistence farmers, who normally bear the largest burden of those external costs. The recognition of both the external costs and the value of supporting and regulating ecosystem services can provide a solid basis for developing appropriate schemes of biodiversity management.

*This appears in Appendix A at the end of this volume.

Main Messages

An adequate and balanced supply of elements necessary for life, provided through the ecological processes of nutrient cycling, underpins all other ecosystem services. The cycles of several key elements—phosphorus, nitrogen, sulfur, carbon, and possibly iron and silicon—have been substantially altered by human activities over the past two centuries, with important positive and negative consequences for a range of other ecosystem services and for human well-being.

In preindustrial times, the annual flux of nitrogen from the atmosphere to the land and aquatic ecosystems was 90–130 teragrams (million tons) per year. This was more or less balanced by a reverse "denitrification" flux. **Production and use of synthetic nitrogen fertilizer, expanded planting of nitrogen-fixing crops, and the deposition of nitrogen-containing air pollutants have together created an additional flux of about 200 teragrams a year, only part of which is denitrified.** The resultant N accumulation on land and in waters has permitted a large increase in food production, but at the cost of increased emissions of greenhouse gases and a frequent deterioration in freshwater and coastal ecosystem services, including water quality, fisheries, and amenity value.

Phosphorus is also accumulating in ecosystems at a rate of 10.5–15.5 teragrams per year, which compares with the preindustrial rate of 1–6 teragrams of phosphorus a year, mainly as a result of the use of mined P in agriculture. Most of this accumulation is occurring in soils, which may then be eroded into freshwater systems, causing deterioration of ecosystem services. This tendency is likely to spread and worsen over the next decades, since large amounts of P have accumulated on land and their transport to water systems is slow and difficult to prevent.

Sulfur emissions have been progressively reduced in Europe and North America but not yet in the emerging industrial areas of the world: China, India, South Africa, and the southern parts of South America. A global assessment of acid deposition threats suggests that tropical ecosystems are at high risk. Human-induced alteration of the iron and silicon cycles is less well understood, but it is believed, with *medium certainty,* to be a significant factor in altering the productivity of the ocean. This may be a significant benefit to the service of carbon sequestration.

Human actions, many associated with agriculture, have increased the "leakiness" of ecosystems with respect to nutrients. Tillage often damages soil structure, and pesticides may decrease useful nontarget organisms, increasing nutrient leaching. Simplification of the landscape and destruction of riparian forests, wetlands, and estuaries allow unbuffered flows of nutrients between terrestrial and aquatic ecosystems. Specific forms of biodiversity are critical to the performance of the buffering mechanisms that ensure the efficient use and cycling of nutrients in ecosystems.

In contrast to the issues associated with nutrient oversupply, there remain large parts of Earth, notably in Africa and Latin America, where harvesting without nutrient replacement has led to a depletion of soil fertility, with serious consequences for human nutrition and the environment.

12.1 Introduction

Nutrients comprise the 22 or so chemical elements known to be essential for the growth of living organisms. (See Table 12.1.) The list varies somewhat because some elements are only needed in very specific groups of organisms or specific circumstances. This chapter deals mainly with nitrogen, sulfur, phosphorus, and carbon—all elements needed in relatively large quantities (the so-called macronutrients), and with cycles that have been substantially altered by human activities. Emerging issues related to iron and silicon will also be addressed.

Broadly speaking, nutrients can occur in gaseous form (such as N_2, CO_2), mineral form (such as apatite, the main P-containing mineral), inorganic ionic form (NH_4^+, NO_3^-, SO_4^{2-}, H_2PO4^-), and organic form (bound into various C-based compounds in living or dead organisms or their products). Nutrients are mostly taken up by plants in the ionic form and by animals in organic forms through consumption of living or dead tissues; microorganisms in general may use nutrients in any mineral or organic form, with sometimes high degrees of specialization at the guild or species level. The interconversion between forms is mediated by the ecosystem.

Nutrient cycling describes the movement within and between the various biotic or abiotic entities in which nutrients occur in the global environment. These elements can be extracted from their mineral or atmospheric sources or recycled from their organic forms by converting them to the ionic form, enabling uptake to occur and ultimately returning them to the atmosphere or soil. Nutrient cycling is enabled by a great diversity of organisms and leads to creation of a number of physical structures and mechanisms that regulate the fluxes of nutrients among compartments. These structures and processes act as buffers to limit losses and transfers to other ecosystems, as described later. Nutrients are distributed among a large number of living or dead compartments, and their relative abundance among these compartments is typical of certain ecosystems. For example, this is the case in terrestrial ecosystems, where nutrients may be greatly concentrated in living biomass (such as tropical rainforests) or in humus and soil organic matter (such as tundra ecosystems) (Lavelle and Spain 2001).

Fertility is the potential of the soil, sediment, or water system to supply nutrient elements in the quantity, form, and proportion required to support optimum plant growth (implicitly, in the context of ecosystem services, for human benefit). The largest flux of nutrients is their release from organic materials, as a result of decomposition by microbial communities. This flux may not be measurable, as part of it may be immediately reincorporated in microbial biomass. Microbial activity depends primarily on the availability of a food source and on regional and local climatic, edaphic, or hydrological factors. Locally, biological parameters such as the chemical composition of the organic material (which depends in turn on the plant community that produced it) and the soil invertebrates present act as proximate determinants.

The maintenance of fertility is a supporting service for the production of food, timber, fiber, and fuel. It is also necessary for ecological processes such as succession and for the persistence and stability of ecosystems. In systems intensively managed by humans, such as cultivated systems, the inherent fertility of ecosystems is supplemented through fertilization and management practices, such as the use of N-fixing plants, the acceleration of microbial processes by tillage, the addition of suitable organic inputs to the soil, and, in many parts of the world, biomass burning.

Fertilization is the input of nutrients to a system by humans, deliberately or as an unintended consequence of other activities. It includes supplements of N, P, S, potassium, calcium, magnesium, and micronutrients for agriculture; atmospheric N and S deposition; and the effects of elevated CO_2 in the atmosphere. Iron fertilization in the ocean has been performed experimentally (Coale et al. 1996; Moore et al. 2001).

It is possible to have an excessive supply of nutrients. In aquatic systems, this condition is known as eutrophication. Eutrophication, usually resulting from leaching of nutrients from soils managed for agriculture, is a form of nonvoluntary fertilization of

inland and coastal waters. Increase in nutrients in sewage effluent is another form of cultural eutrophication related to increases in human population.

Fertility can also be decreased by human activities, through soil erosion, nutrient mining (harvesting of nutrients at a rate in excess of their rate of replenishment), alteration of the soil biota or structure, salinization through poorly managed irrigation, acidification through inappropriate fertilization, deposition of acidifying pollutants, or excessive use of N-fixing crops.

Life on Earth is closely regulated by the efficient cycling and availability of nutrients. Human manipulation of this service has greatly affected all ecosystems. Climate regulation is affected by decomposition and nutrient cycling at regional or continental scales through the release of greenhouse gases and carbon sequestration in ecosystems. When nutrient cycling is impaired, the aesthetic and recreational value of freshwater and marine ecosystems may decrease significantly.

Nutrient cycling requires a large number of different organisms from diverse functional groups. It is a prime example of ''functional biodiversity'' in action. Conversely, dysfunctions in nutrient cycling, leading, for example, to eutrophication, have severe negative effects on biodiversity.

Nutrient cycling occurs everywhere, being a necessary part of the function of all ecosystems, but at widely varying rates. The specific ecosystem service of fertility is unevenly distributed around the land and oceans of the world. The most fertile soils—for instance, the deep, dark, loamy soils of the Eurasian steppes, the North American prairies and the South American pampas—have mostly been converted from grasslands to intensive agroecosystems over the past two centuries. Agriculture is currently expanding into areas with soils of inherently lower fertility, such as the old, red soils of tropical Africa, South America, and Southeast Asia (Wood et al. 2000).

The world's oceans contain vast reservoirs of nutrients. However, these are found primarily at depths below about 200 meters, where there is insufficient light for (net) photosynthesis (Dugdale 1976). As a consequence, high levels of marine primary production require the uplifting of nutrients from deeper water into the euphotic zone (Summerhayes et al. 1995). Along the west coast of the continents, equator-ward trade winds drive surface water away from the coast to be replaced by water rich in nutrients from the sub-euphotic zone. These coastal upwelling systems constitute only about 1% of the ocean surface but contribute about 50% of the world's fisheries (Ryther 1969), due to not only high new production rates but also to a short food chain in which much of the phytoplankton production is eaten directly by fish. The central oceans and seas, especially in tropical regions, are generally low in nutrients and productivity.

Human activities have resulted in large-scale changes in nutrient cycles over the last two centuries, which have occurred at an accelerated rate since about 1950. Specifically, shifts in land use patterns, increased fertilization associated with high-yield crops, and lateral transfer of nutrients across ecosystem boundaries have dramatically changed the rate, pathways, and efficiency of nutrient cycling. Traditional small-scale, low-input cultivation practices generally lead to nutrient depletion when fallow periods are shortened. On the other hand, the sustainability of soil fertility under large-scale, high-input intensive agriculture is still in question, given that this form of agriculture is only a few decades old.

The increase in demand for food, fuel, and fiber during the last 50 years has led to supplementation of the natural nutrient supply in agroecosystems by artificial sources, and the global annual nitrogen and phosphorus input to ecosystems has more than doubled in this period (Vitousek et al. 1997; Smil 2000; Falkowski et al. 2000).

All over the world, the complex regulation mechanisms in natural systems and biological controls operated by plants and invertebrates across many scales have been severely impaired, wherever food production has increased through the input of additional nutrients and use of tillage. Large-scale additions of nutrients in agroecosystems can no longer be retained and recycled locally. Undesired transfers from terrestrial to aquatic ecosystems have become a serious and growing problem worldwide (Howarth et al. 2000). At the same time, deposition from the atmosphere of nutrients, originating from industry, agriculture, biomass fires, and wind erosion, is spreading unprecedented quantities of N, P, and possibly Fe and Si to downwind ecosystems over large regions (Brasseur et al. 2003).

In contrast, severe nutrient depletion is observed in soils in some regions, notably in sub-Saharan Africa (Sanchez 2002). In these areas, particularly where the inherent soil fertility is low for geological and ecological reasons and fertilizer inputs are limited by economic constraints, the nutrient stock in croplands is decreasing. (See Tables 12.2 and 12.3.) This is having a serious impact on human food security in the region.

Some of the important questions addressed in this chapter include: What will be the consequences for ecosystems and human well-being of the expected 30% increase in the human contribution to fixed N and other nutrients over the next 30 years? (See also Chapter 9 of the *Policy Responses* volume). Is the increasing frequency and extent of eutrophication observed in fresh and marine waters likely to be stopped or reversed? How will these changes in the natural nutrient cycling system affect other ecosystem services?

12.2 Important Issues Common to All Nutrient Cycles

12.2.1 Ecosystem Stoichiometry: The Balance between Nutrients

Living organisms tend to contain a relatively constant proportion of elements, especially carbon, nitrogen, and phosphorus. In

freshwater microalgae, the elemental contents expressed as molar stoichiometric ratios are C (125), N (19), and P (1) (Reynolds 1990), the same order of magnitude as the Redfield ratio (106:16:1) proposed for suspended particulate matter in oceans (Redfield 1958). The average proportions for land plants are about 200:13:1 (although these can be much wider for woody plants) because the need for structural tissue drives up the C content. Since the proportions of various functional groups of plants are also relatively fixed, ecosystems too have broad proportionality in their nutrient content. This has major implications: for instance, it means that the cycles are inextricably linked through shared organic molecules produced by living organisms. A perturbation to one cycle is a perturbation to all.

In response to an unbalanced composition of nutrients in their food, organisms tend to either eliminate excess nutrients or develop strategies to better capture nutrients that limit their growth. For example, in large water bodies, the efficiency of remineralization is higher for P than for N. This causes a shift in the N/P ratio of the available nutrients. This shift may be corrected by natural nutrient inputs, or further modified by inputs from human activities in the watershed. The result may be twofold: first, a new phytoplankton community may develop, with species more aligned to the new N/P nutrient ratio and concentration, and, second, the C/N/P composition of the phytoplankton may change, affecting its nutritional value for the primary consumers and energy transfer efficiency in the food chain.

Up to the 1980s, N was considered the nutrient that limits primary production of the world oceans. The "North Atlantic paradigm"—the view that oceanic primary production is under control of dissolved inorganic N—was established on the basis of studies mostly conducted in the North Atlantic Ocean, where most of the marine stations were situated. However, this view of the world oceans' biogeochemistry has proved to be incorrect. Multidisciplinary studies in a wider range of locations and situations have revealed the important role of other nutrients (Dugdale et al. 1995). (See Boxes 12.1 and 12.2.) For instance, silicon is essential for diatoms, the workhorses of the marine ecosystem, and may be quickly depleted as an excess of N and P becomes available. Phosphorus is required for all phytoplankton, including for N fixation (described later), and so does not have a fixed stoichiometric ratio. Interaction of the biota with the great nutrient cycles in the oceans makes it necessary to consider each situation with regard to potential nutrient limitation.

12.2.2 The Role of Organic Matter

Organic matter (that is, C-based compounds of biological origin) plays several pivotal roles in determining nutrient availability to plants. The largest labile stock of nutrients in soils, sediments, and waters is typically contained in organic compounds. Since uptake by plants is almost exclusively in the inorganic form, the biologically mediated process of organic matter decomposition is crucial to nutrient availability (Parton et al. 1988).

Soil and sediment organic matter is a heterogeneous mix of particles of partly decayed plant and animal tissues; the living biomass of microbes (principally fungi and bacteria); amorphous, decomposition-resistant high molecular weight C polymers known as humic substances; and a small quantity of simpler, less recalcitrant organic molecules, such as carbohydrates, amino acids, and lipids.

BOX 12.1

Iron as an Essential Fertilizer in Oceans

A number of trace metals are required for plant growth. Most appear to be present in sufficient quantities. However, iron is a special case for ocean organisms as it is required in many enzyme systems, including those in photosynthesis and in the processing of inorganic and gaseous nitrogen. A shortage of Fe has been shown to influence the uptake kinetics of $Si(OH)_4$—reducing, for example, the maximal uptake rate (Leynaert et al. 2001). Open ocean Fe enrichment experiments found Fe to affect the initial slope of the light versus carbon uptake curve in primary production (Barber et al. 1996).

The distribution of Fe in the oceans is poorly known due in part to the difficulty of obtaining uncontaminated samples, as the techniques for obtaining clean samples were developed only recently. However, the vertical profiles of Fe often follow the same pattern as NO_3 (Martin 1992). Since the NO_3 profiles are the result of biological production and regeneration, it appears that biological processes to a large extent control the distribution of Fe also. Input of Fe from the atmosphere is an important source of Fe, and some regions of the open ocean may experience enhanced productivity from the occurrence of remote dust events.

BOX 12.2

Silicon: A Key Element Linking Land to Ocean Ecosystems

Silicon, like iron, has its major sources on land but is a critical element in marine ecosystems. Dust atmospheric deposits allow transport from land to oceans and other continents, with significant effects on transfers of carbon to the deep ocean and neoformation of clay minerals that regulate nutrient cycling in terrestrial ecosystems.

Sustained C storage in the ocean requires a mechanism known as the "biological pump"—the export of particulate organic C to the deep ocean (Buesseler 1998). $Si(OH)_4$ is required for building the frustule of diatoms, the most productive and fastest growing of the phytoplankton (Smetacek 2000). Diatoms contribute as much as 75% of the annual primary production in coastal upwellings and Antarctic waters and about 40 % of the global marine annual primary production (Nelson et al. 1995) Where Si is in short supply, the plankton community is dominated by small-bodied algae, whose primary production simply cycles within the surface waters. To sink into the deep ocean waters, and thus be sequestered for useful periods of time, C must be in larger, heavier bodies, such as diatoms (Dugdale et al. 1995). Large areas on the fringe of the Southern Ocean are apparently Si-limited at certain times of the year. If we are to better understand and model the marine cycle of C, Si has to be taken into consideration by marine biogeochemists (Tréguer and Pondaven 2000; Ridgwell et al. 2002).

During the last decade, the Si budget of the world ocean and of key marine regions has been revised (Tréguer et al. 1995; Nelson et al. 1995; Tréguer and Pondaven 2000; De Master 2002). Our present best estimate for the annual production of the biogenic Si deposited in diatom frustules is 240 (40 Tmol per year for the world ocean (Nelson et al. 1995). The estimates of the net export of biogenic Si range between 120 and 129 teramoles (10^{12} moles) per year (Tréguer et al. 1995; Ridgwell et al. 2002).

In Amazonia, recycling of Si by plants allows neosynthesis of soil clay minerals that accumulate at the soil surface forming thick microporous horizons of microcrystalline kaolinite where aluminum oxide horizon should have normally formed (Lucas et al. 1993). A similar mechanism has been observed in Mexican paramo with a perennial grass cover (Dubroeucq et al. 2002). In that case, allophane is formed instead of imogolite, an aluminium-rich colloid that is toxic at high concentrations. Soil fauna then redistribute these minerals in the upper part of the soil profile.

Organic matter provides energy for all microbial and faunal activities and thus allows them to build the microaggregate structures that control soil hydraulic properties and serve to further conserve organic matter. For example, deposition of straw on the soil surface of degraded soils of the Sahelian region attracts termites that feed on this resource and significantly improve water infiltration and storage in the galleries and porous constructions (Mando et al. 1997). The amorphous polymers act as reserves of nutrients, which are sequestered in their chemical structures for periods of centuries to millennia. Since its surface bears a significant electrical charge, organic matter (along with clay) is the main location on which the cationic and anionic forms of plant nutrients are retained prior to uptake, without being leached out of the soil (Jenkinson and Rayner 1977; Schlesinger 1997; Lavelle and Spain 2001).

Agricultural practices and the policies that accompany their evolution may have a significant impact on the role and dynamics of organic matter in the provision of soil ecosystem services. For example, the prohibition against burning sugarcane crop residues in some tropical countries will probably have an impact on the storage of C in soils. Pasture rotation practiced in some areas aims to reconstitute organic stocks by the annual crops by inserting perennial grass lays that will increase organic matter stocks (Franzluebbers et al. 2000).

12.2.3 Nutrient Retention in Ecosystems: Buffers and Safety Nets at All Scales

In natural ecosystems, regulation of nutrient cycling operates at different scales of time and space, allowing the flow of nutrients released by microbial activities to adjust to plant demand, thus limiting losses to other parts of the ecosystems or to different ecosystems. In natural ecosystems, this "synchrony" between release of nutrients and their use by microorganisms and plants is determined by complex interactions among physical, chemical, and biological processes. It is rarely achieved to a comparable degree in agroecosystems, which as a result lose nutrients to aquatic ecosystems or to the atmosphere (Cadisch and Giller 1997).

Regulation of nutrient fluxes occurs in biological structures ("self-organizing systems," according to Perry 1995), which can be observed at seven different scales, ranging from microbial aggregates (Scales 1 and 2), through ecosystems (Scales 3 and 4) to landscapes (Scales 5 and 6) and the entire biosphere (Scale 7) (Lavelle and Spain 2001; Lavelle et al. 2004), as follows.

Scale 1, microbial communities in microbial aggregates and biofilms—At this scale, highly diverse microbial populations may control some transformations, whereas others that rely on a low number of species are vulnerable. For example, this is the case for microorganisms that control nitrification (the transformation of ammonia into nitrate, a form usable by plants), a critical step in N cycling. The functionality of these communities is rarely impaired by ecosystem degradations in spite of decreases in microbial diversity reported in some cases. The most sensitive function may be nitrification, since it is operated by a relatively small, diverse group of microbes. The risk to this function seems to be very limited, although it is speculated that threshold effects might be observed in some conditions.

Scale 2, microbial loops involving microbes and their micro-predators in soil and sediment aggregates, leaf packs, and freshwater systems or water columns—These are rarely severely impaired, although changes in soil nematode communities, and in microbial abundance and composition, have been observed in response to aggressive land use practices such as agricultural intensification (Bongers 1990; Yeates 1994). When larger-scale regulating systems are impaired, the diversity and abundance of the micropredator food web (protozoa, nematodes, and acari in soils; specific invertebrate microplancton in fresh water and seas) may affect parameters of nutrient cycling, such as C and N mineralization (DeRuiter et al. 1993), through changes in their regulation of microbial activities. An index of soil "maturity" has been proposed to evaluate the functionality of this compartment (Bongers 1990). Clear changes in its communities have been observed, although effects on nutrient cycling have been reported only in laboratory experiments.

Scale 3, physical structures of animals and roots that have an impact on sediments and soils by their bioturbation effects—Mutually beneficial interactions with microflora and indirect effects of organisms that create the soil architecture by producing solid bricks of associated soil particles (called aggregates) and pores of different sizes and shapes (such as galleries, burrows, and interaggregate voids) allow regulations of nutrient cycling at different nested scales of time and space (Lavelle and Spain 2001).

For example, digestion of soil organic matter in earthworm guts is largely performed by the microflora that was ingested with the soil and further stimulated during the gut transit. In the case of the tropical geophagous earthworm *Millsonia anomala,* 90% of the energy thus assimilated by the worm is further spent on mechanical activities—the transit of huge amounts of soil (up to 20 times the weight of the worm daily; 1,000 milligrams of dry soil per hectare per year for an earthworm community). Soil that has transited through the earthworm guts is deposited in the soil and at the surface in the form of globular casts that are the stable aggregates that constitute most of the soil in the upper horizon. These aggregates are microsites where C-sequestration and nutrient conservation are active. Porosity created by these biological activities participates in water infiltration and storage and in soil aeration (Lavelle and Spain 2001).

Diversity of plants and soil invertebrates may influence nutrient cycling and prevent nutrient losses at the ecosystem scale, although the generality of this process has not yet been demonstrated nor have underlying mechanisms been clearly identified (Chauvel et al. 1999; Tilman and Downing 1994). The functionality of the nutrient buffer provided by biodiversity can be evaluated through indicators of soil and sediment quality based on invertebrate communities (Velasquez 2004; Ruiz 2004). Direct and indirect effects of soil bioturbators on nutrient cycling are reasonably well understood, and their use as indicators of soil quality is now well established.

Scale 4, ecosystems as mosaics of physical domains of different species of plants and animals—Excess nutrients released in a patch may diffuse away and be absorbed in adjacent nutrient-depleted patches. This feature is deliberately manipulated in most agroforestry and agricultural systems with plants that are associated with high nutrient needs (such as an annual crop of cereals) planted in patches or bands to capture excess nutrients (such as legume shrubs). Secondary successions in forests may also rely on different timing and rates of accumulation of nutrients in adjacent patches (Bernier and Ponge 1994). Research has proved the value of having a mosaic of patches at different stages of the succession (that is, a combination of patches with young, mature, and senescent groups of trees), although models suggesting optimal combinations of these patches do not exist.

Scale 5, landscapes or seascapes—At this scale, nutrients released in excess from nutrient-rich ecosystem patches may be absorbed by adjacent nutrient-poor patches. For instance, riparian forests may absorb nutrients leaking from crop areas and thus prevent them from entering a river system. On the River Seine in France, 25–55% of the N coming from below the root zone of agricultural land or from aquifers is retained or eliminated by riparian forest or wetlands before reaching surface waters (Billen and Garnier 1999). More generally, it is estimated that wetlands on average intercept 80% of N flowing from terrestrial systems (although figures vary due to temperature and size of the area; see Chapter 7). Again, there is ample empirical evidence of the efficiency of these buffers, although predictive models do not exist (Krug 1993; Haycock et al. 1993).

Scale 6, river basins, oceanic biogeochemical provinces, terrestrial biomes—At this scale, climatic factors (such as ambient temperature or the level of water in terrestrial systems) regulate the overall rates of biological activities and chemical transformations. Organic matter produced in warm surface layers of aquatic bodies descends to cold, deep strata, where consumers are not active due the lack of light. Specific mechanisms of thermal convection and deep ocean currents driven by temperature-, salinity-, and density-induced gradients move nutrient-rich deep ocean water to the surface, where potential consumers are active.

Scale 7, the biosphere—Global atmospheric and oceanic circulation created by the redistribution of energy at the Earth's surface determines distribution of nutrients through various mechanisms, including deposition of atmospheric dust and nutrient conveyer belts associated with major currents in the oceans. The variation in nutrient concentrations in different basins of the world's oceans has its origin in the circulation of the water between the ocean basins, driven by changes in heat input at the ocean surface and changes in salinity from variations in river inputs to the different basins. The macro-circulation of the oceans has been described as a "conveyer belt" (Broecker and Peng 1982), wherein deep water formed in the north Atlantic sinks and makes its way through the Antarctic and then north into the Pacific and Indian Oceans. As it flows, it receives organic particles formed by primary production and fecal pellets formed by grazing by zooplankton that are traveling in the opposite direction. This counter-current exchange mechanism results in increasing nutrient concentrations in the deep water as it travels westward from the Atlantic Ocean.

The scale structure is hierarchical, with each scale comprising the sum of the elements present in smaller scales. Effects at small scales are accumulative, and their effects are additive at larger scales. Impairment of services at one scale is likely to be caused, at least in part, by changes at a smaller scale, and it is at these smaller scales that interventions are most effectively targeted in order to tackle the causes of large-scale trends. Interventions at larger scales generally are only able to mitigate the effects of change in the short term.

The existence of different levels of buffers at nested scales also has the potential to reduce the vulnerability of nutrient cycling services, since different options exist to support the services. Damage occurring at lower scales, such as accidental loss of soil fauna that aerate soil (earthworms, for instance), may not have immediate or lasting effects, since soil structures created by these invertebrates may last long enough to enable populations to be restored if the disturbance is not too severe.

However, sometimes disturbances have multiple effects that accumulate over time and space, causing the system to collapse. Highly intensive land management for crop production, for example, can have detrimental effects at Scales 2–5, reducing soil fauna and root diversity (Scales 2 and 3) through use of pesticides and tillage (Lavelle and Spain 2001), homogenizing the ecosystem at plot scale (Scale 4) through use of monocultures, and simplifying the landscape composition through the use of fewer crop varieties (Scale 5). Precise data on the degree and duration of impacts that will lead to irreversible effects, such as soil and sediment erosion or replacement of native by invasive species of invertebrates, and other severe consequences for biodiversity and the vulnerability of the system are currently lacking. At present, only indicators of soil quality allow us to compare different sites and states and to evaluate trends.

12.2.4 Soil Erosion

Soil erosion is one of the key processes underlying land degradation and desertification. Erosion affects nutrient cycling and reduces the fertility of the soil through a reduction in the pool of available nutrients. Soil erosion results in drastic modifications to the structure as well as the biological and chemical properties of the soil matrix. The resulting dust and sediments have off-site impacts that may be as large, or larger, than the loss of production sustained on the eroded site. Persistently high rates of erosion affect more than 1.1 billion hectares of land worldwide (Berc et al. 2003; Jacinthe and Lal 2001), redistributing 75 billion tons of soil (Pimente et al. 1995) with 1.5 to 5.0% C-content (Lal 2001).

When nutrient-rich topsoil is transported from one place to another, nutrients are redistributed over the landscape. In the process, some is lost to riverine systems and eventually to the ocean, with major off-site economic and human well-being consequences, such as silting of reservoirs and eutrophication of lakes. On the other hand, dust deposits transported in the high atmosphere from Africa to North America are likely to stimulate the formation of new clay minerals in highly weathered soils and contribute (in other regions) to fertilization of nutrient-deficient marine areas. (See Figure 12.1.)

Erosion reduces the potential to sequester atmospheric CO_2 in soils by reducing the primary productivity. Exposure of subsurface layers to near-surface environments results in acidification of carbon-containing layers in most soils (Lal 2003). Soil erosion is the main way in which stable, mineral-associated soil organic C is translocated in large quantities into aquatic systems (Starr et al. 2000). The organic matter can end up in anoxic environments, where it is better protected than on land, and the accompanying nutrient fluxes may increase aquatic primary productivity. Thus not all C in eroded soil is returned to the atmosphere immediately, but the net effect is likely to be carbon emissions.

12.2.5 Input and Output Processes

Ecosystem nutrient balance is the net result of inputs minus outputs. Negative and positive balances are ultimately unsustainable. The magnitude and duration of nutrient imbalance that can be tolerated is determined by an ecosystem's buffering capacity. This is roughly indexed to the size of the nutrient stocks, divided by the normal net flux, which gives the turnover time.

Input of nutrients to ecosystems occurs through five processes. First, weathering from geological sources generally produces relatively small quantities of nutrients over long periods of time but is nevertheless an important input mechanism that sustains the levels of P, potassium, iron, aluminum, sodium, and silicon in natural ecosystems. The nature and composition of bedrock, in interaction with the climate, largely determines the flux. In all cases, this flux decreases with the age of the weathering surface. The rate at which anions are liberated through weathering determines the long-term capacity of ecosystems to absorb acid deposition, an ecosystem service of major importance in regions downwind of anthropogenic sources of NO_x and SO_2.

Second, atmospheric input of nutrients can occur through wet or dry deposition of elements previously released to the atmosphere by fires (biomass or combustion of fossil fuels), intensive farming practices (such as pig farms or cattle feedlots), and wind erosion. Atmospheric inputs have been substantially increased by human activities.

Third, biological processes include the fixation of atmospheric C (CO_2) through photosynthesis, and atmospheric N (N_2) through biological N fixation.

Fourth, nutrients can be released from the biomass of mobile organisms that enter an ecosystem and suffer mortality. This also occurs through the lateral transfer of nutrients, primarily in water flows. The burgeoning human trade in agricultural and forest products is now a significant pathway of nutrient transfer glob-

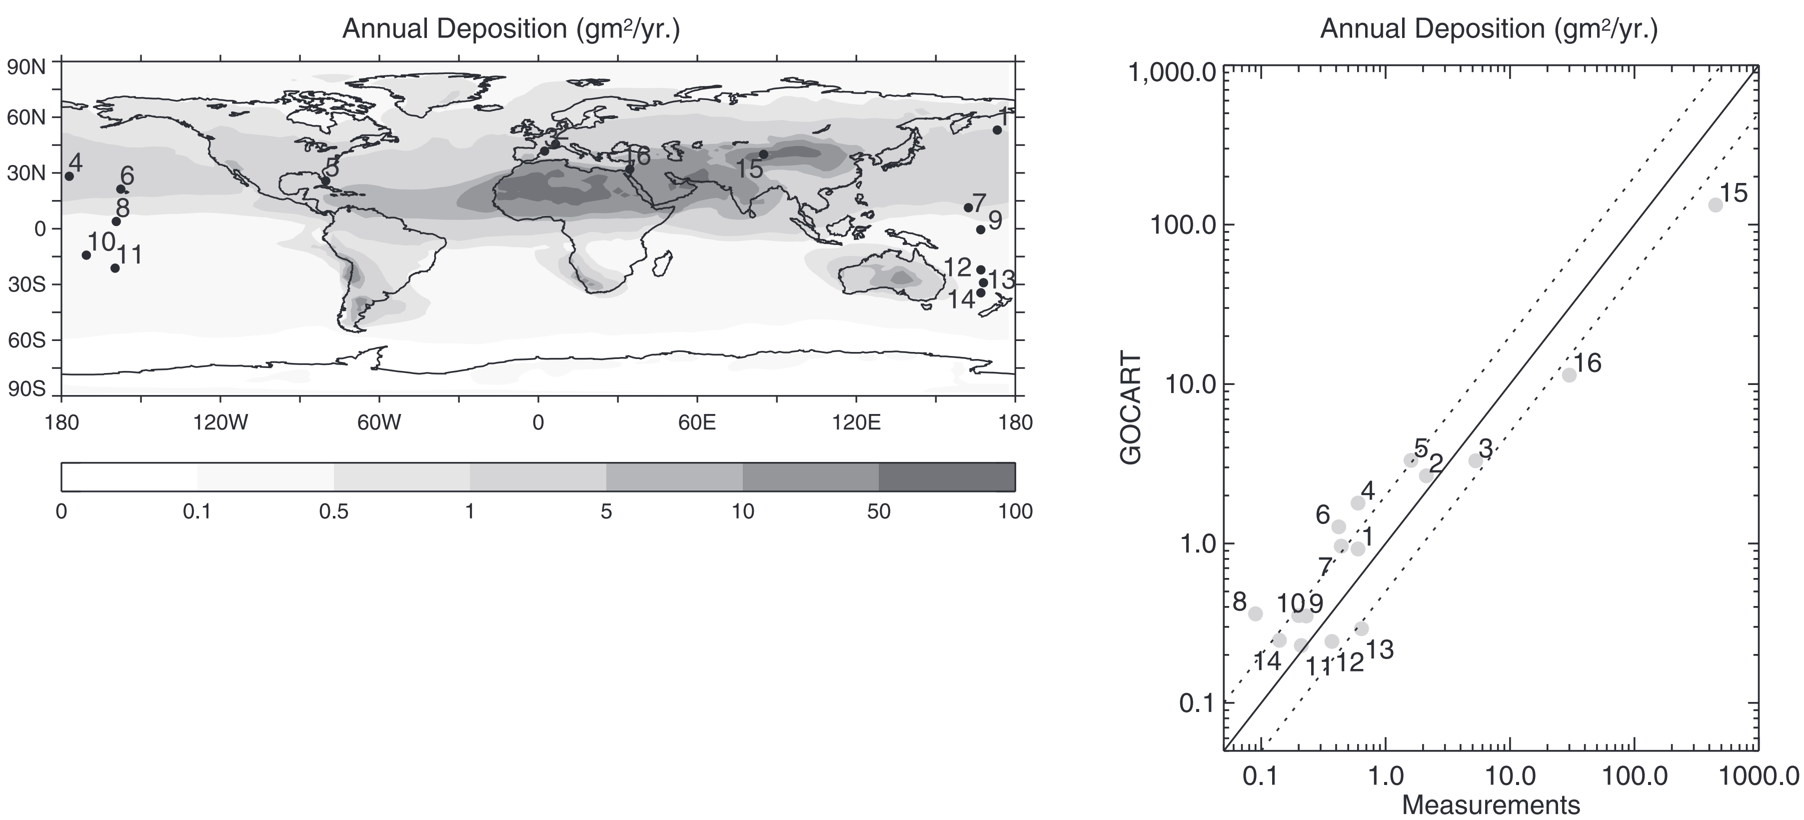

Figure 12.1. Global Dust Deposition. Estimates of global dust emissions can be derived from dust cycle models combine with remote sensing. The output of one such model, GOCART, is shown here, along with validation data for 16 locations. The estimates from a variety of models range from about 1,000 TG/yr (Tegen and Miller 1998) to 3,000 Tg/yr (Mahowald et al. 1999), for particles with radii of less than 10μm. The often-cited wider range of global dust emissions of 60–3,000 Tg/yr (Duce 1995) is partly based on such model estimates, and partly on extrapolations from very limited regional measurements. A central value of 2,000 Mt/yr global dust deposition appears reasonable. It excludes the small-scale transport of larger soil particles, which do not remain airborne for long. To obtain estimates of nutrient deposition from these, the dust deposition can be multiplied with the crustal abundance of the elements: O : 46.6%; Si : 27.7%; Al : 8.1%; Fe : 5.0%; Ca 3.6%; Na : 2.8%; K : 2.6%; and Mg 2.1%. These averages neglect regional variability, which is not well determined for dust aerosol. For the nutrients deposited with the dust, the bioavailability of the substances in the dust must also be considered, which in the case of iron is estimated to range between 1 and 10% (e.g., Fung et al. 2000). Thus the upper limit of biologically active Fe transport from land to the oceans as dust is $2{,}000 \times 0.05 \times 0.1 = 10$ TgFe/yr, and the lower limit is probably around 0.5 TgFe/yr. (Tg $= 10^{12}$g)

ally—some of it from the nutrient-depleted developing world to the nutrient-saturated industrial world and, on a smaller scale, between rural and urban ecosystems.

Fifth, direct anthropogenic inputs occur through fertilization practices used in intensive agriculture and through the release of human sewage and livestock wastes.

The output of nutrients from ecosystems also involves five processes. Soil erosion is the main mechanism whereby nutrients are transported in large quantities from terrestrial to aquatic ecosystems. Although a natural process of soil rejuvenation, erosion is typically accelerated to many times above the long-term ''natural'' rate in systems where cultivation, overgrazing, and vegetation clearance are practiced. The essential nutrients that are most affected by erosion are C, P, K, and N.

Second, leaching is the vertical flow of water in the soil profile that transports significant amounts of nutrients in solution from the soil system into groundwater and thence laterally to rivers, lakes, and oceans. Leaching losses of nutrients are highest in cultivated or disturbed systems.

Third, gaseous emissions of CO_2, CH_4, and CO (among other gases) to the atmosphere result from the decomposition of organic matter, including digestion by animals, and the vastly accelerated decomposition that occurs in fires. Processes related to the conversion between inorganic forms of N lead to emissions of N_2, N_2O, NO, and NH_3. Phosphorus has no significant gaseous forms in most ecosystems. Anthropogenic activities, such as ploughing, fertilization, fossil fuel burning, flooding, drainage, deforestation, and changes to fire regimes, have altered the amounts and proportions of emissions of nutrients to the atmosphere. This is the ultimate underlying cause of contemporary climate change and air quality deterioration.

The fourth output source is the emigration of fauna or the harvest of crop, forest, fish, or livestock. As noted earlier, export from one ecosystem generally means import to another.

Fifth, the effective permanent removal of nutrients from the biosphere only occurs at a slow rate and through a small number of processes. For instance, for the atmospheric concentration of CO_2 to stabilize at levels that will not cause dangerous climate changes, anthropogenic carbon emissions must drop, within the next few centuries, to a level determined by the long-term sequestration sinks to a few teragrams (million tons) of carbon per year (Prentice et al. 2001).

12.3 Global Nutrient Cycles

12.3.1 The Global Nitrogen Cycle

There have been extremely significant changes in the global nitrogen cycle in the last two centuries, and N inputs to the global cycle have approximately doubled in this time. (See Figures 12.2 here and 12.3 in Appendix A.) Although most aspects of this balance have been assessed with a high level of accuracy (fertilizer inputs, atmospheric deposition, inland N fixation), a large uncertainty remains regarding the extent of N fixation in oceans, as explained later. Three processes are primarily responsible for the increased flows of N in the global cycle.

First, industrial-era combustion, especially of fossil fuels, has increased the emission of reactive N gases (NO_y) to the atmosphere, where they participate in the production of tropospheric ozone (the main harmful component of air pollution) before depositing, as a gas, as nitric acid dissolved in precipitation, or as dry aerosols on land or sea. Because of the reactivity of the gases, the impact is restricted to a region of up to about 1,000 kilometers downwind of the source. Worldwide deposition of N as wet or dry deposits, in the form of NO_3^- or NH_4^+ ions, is especially concentrated in regions with farm cattle production. Highest deposition rates reach 50 kilograms per hectare per year, with local maximums of up to 100 kilograms in Europe, North America, China, and India, as well as Southwest America, Colombia, and a few regions in Africa (see Chapter 9). In other places, the recent rise in deposition (compared with the beginning of the twentieth century) has remained limited.

Initially, N deposition stimulates net primary productivity, since N is the most widely limiting nutrient in terrestrial ecosystems (largely because it is so readily lost by gaseous emission or leaching). Once the capacity of the recipient ecosystem for N inputs is reached (a point known as N saturation, indicated by a sudden increase in nitrates in water draining from the system), the excess is leached into adjacent rivers, lakes, and coastal zones, causing eutrophication. This can lead to biodiversity loss in both terrestrial and aquatic ecosystems, and, in severe cases, net primary production may decline (Schulze et al. 1989). However, given the moderate rise in N use predicted, the minor contribution to plant growth that Nadelhoffer et al. (1999) have calculated should remain limited. According to Frink et al. (2001), this should pose little hazard to biodiversity.

Second, the invention of the Haber-Bosch process for converting atmospheric N_2 to ammonia laid the foundation for the exponential growth in N fertilizer use in the second half of the twentieth century. It enabled the high-yielding crops of the Green Revolution, which brought about a large increase in the production of relatively cheap food and improved the well-being of millions of people. However, less than half of the applied N fertilizer finds its way into the crop plant. The remainder leaches into water bodies or returns to the atmosphere, most benignly as N_2, but some as the powerful and long-lived greenhouse gas N_2O, which is also involved in stratospheric ozone depletion. The atmospheric concentration of N_2O has been rising by roughly 0.8 parts per trillion per year (0.25%) during the industrial era, largely through this mechanism. In 1998, it averaged 314 ppt, up from a preindustrial level of 270 ppt (Prather et al. 2001). (See also *Policy Responses* volume, Chapter 9.) The present trend indicates a plateau may have been reached, although some models predict future increases. Whichever model is correct, no decrease is expected, since human population seems to have already exceeded the maximum number that can be supported without chemical fertilizers.

Third, the natural process of biological N fixation has been harnessed for agricultural purposes. Worldwide plantings of N-fixing crops, such as soybeans, now capture about 40 teragrams of nitrogen a year, an ecosystem service worth several billion dollars annually in avoided fertilizer costs and contributing substantially to human nutrition. The negative consequences are ultimately similar to those resulting from industrial N fixation: increased emissions of N_2O and leaching of N from the land into water bodies once organic N has been mineralized. In addition, severe acidification of soils following repeated harvests of N-fixing crops can occur, unless balancing quantities of cations are added (Pate 1968). Increase in N fixation is still considered important for sustained agricultural production, and is set to continue.

In marine ecosystems, estimates of N fixation by organisms vary by more than tenfold, ranging from less than 30 to more than 300 teragrams per year (Vitousek et al. 1997). There is speculation, supported by some evidence, that biological N fixation through the cyanobacterium *Trichodesmium* has increased during the modern era as a result of increased iron fertilization by windborne dust (Moore et al. 2001).

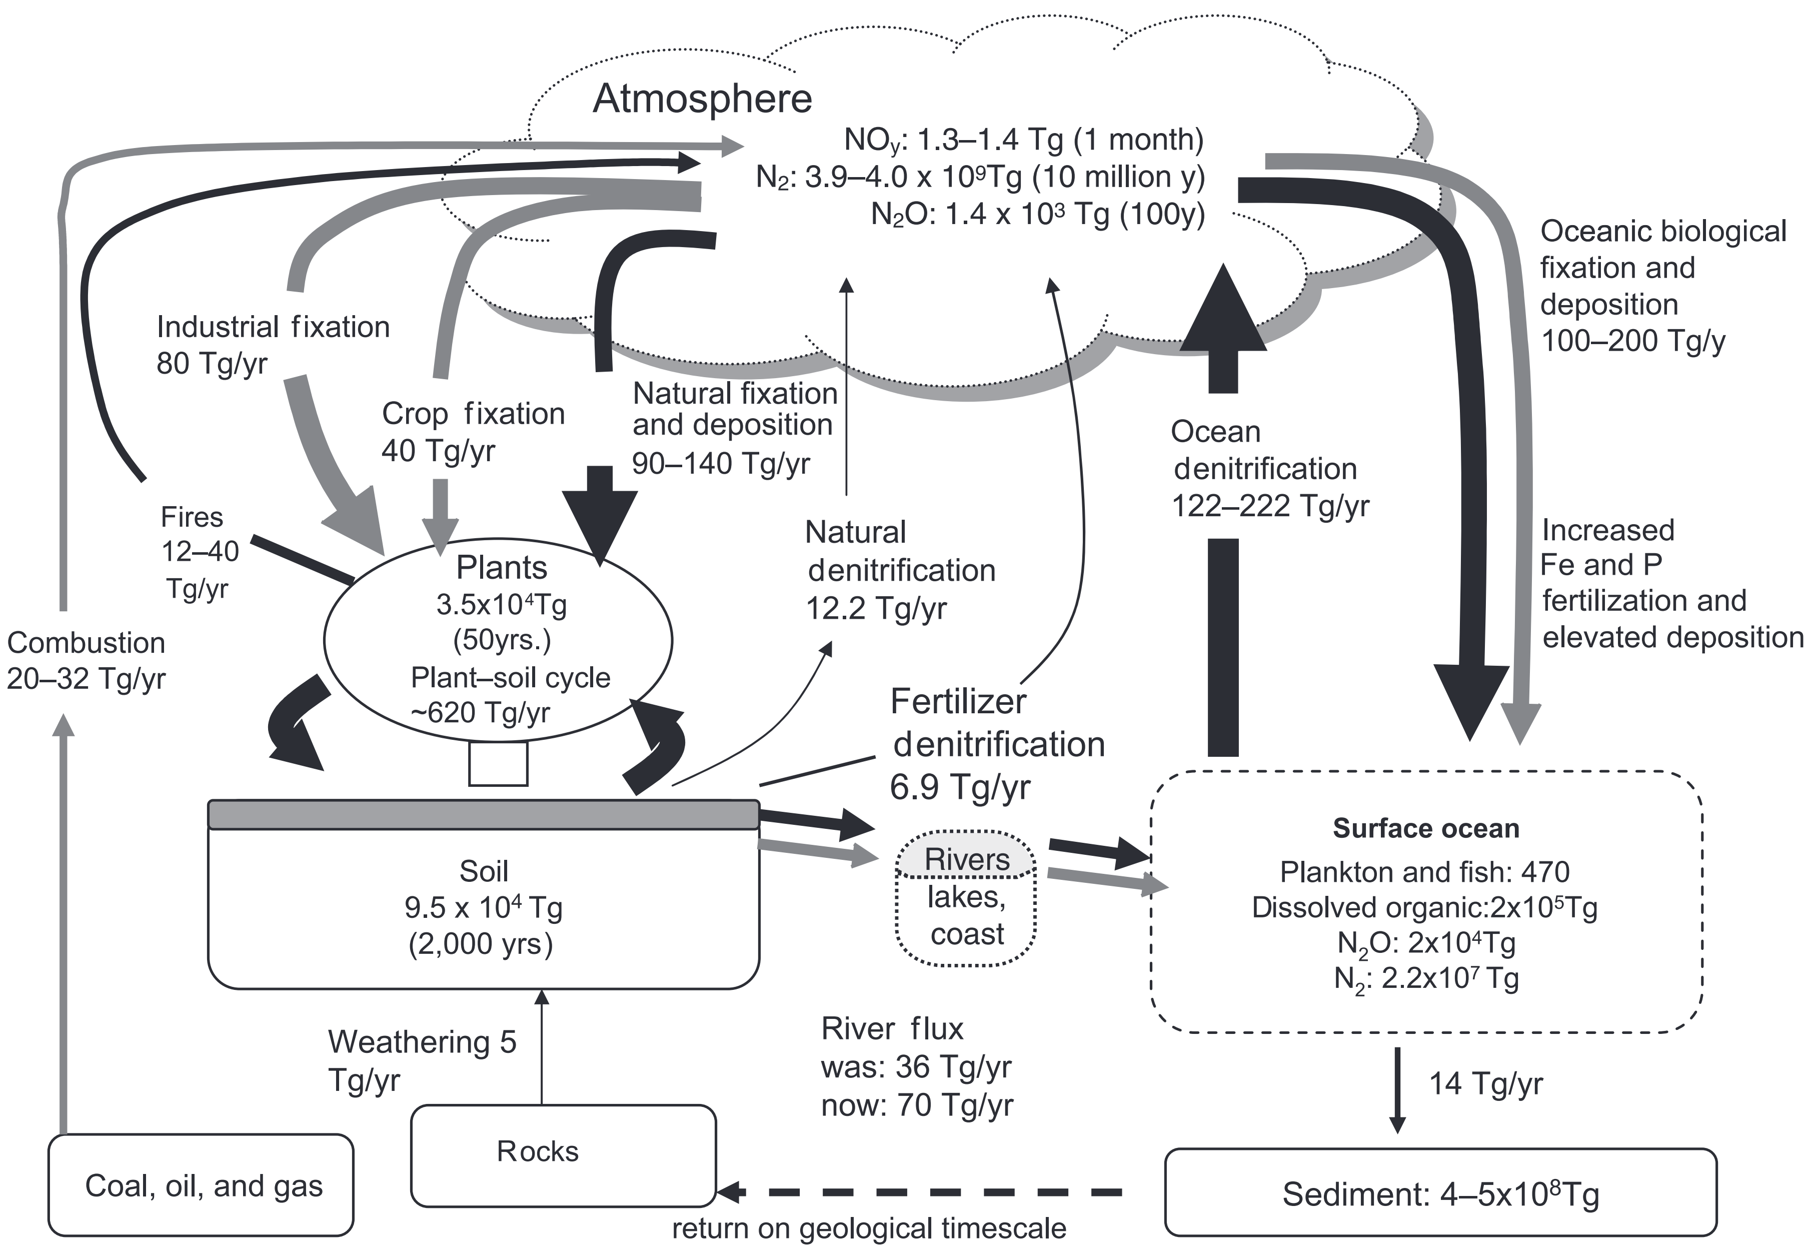

Figure 12.2. Key Pools, Fluxes, and Turnover Times in the Global Nitrogen Cycle as Modified by Human Activity. The turnover times are represented in parentheses. The size of the pools (i.e., the stocks in a particular form) are all expressed as TgN, which equals 10^{12}g of nitrogen in elemental form, or a million tons. The fluxes or flows between pools are in TgN/yr. Pools where the flows in and out are small relative to the size of the stock have a slow turnover time—in other words, they change slowly, but are also slow to mend once altered. The solid arrows represent the basic "natural" (i.e., preindustrial) cycle. The grey arrows and boxes represent the new or enhanced flows and accumulations caused by human activity. The width of the arrows is approximately proportional to the flux rates. It is clear that the addition of a major new flux from atmosphere to land, by way of industrial and crop nitrogen fixation, has created an imbalance leading to increased flow to the ocean, in the process contributing to eutrophication of rivers and lakes. Some of the nitrogen oversupply leads to increased emissions of N_2O and NO_y, which are increasing in the atmosphere, contributing to global warming, tropospheric pollution, and stratospheric ozone depletion. (Reeburgh 1997; Prather et al. 2001; Brasseur et al. 2003)

Part of the accumulated N is eliminated in gaseous forms through the denitrification process. Although it resembles a natural mitigation of eutrophication, nitrous oxides produced from fertilizer denitrification account for 6.9 teragrams of N per year, representing a flux of 56% increase in total denitrification from terrestrial ecosystems. Furthermore, 20–32 teragrams in gaseous forms are released to the air each year through combustion, creating atmospheric pollution. (See Chapter 13.)

The overall N budget on Earth has thus been significantly modified. In preindustrial times, the annual flux of nitrogen from the atmosphere to the land and aquatic ecosystems was estimated at 90–140 teragrams of N per year. This was more-or-less balanced by a reverse "denitrification" flux. Production and use of synthetic nitrogen fertilizer, expanded planting of nitrogen-fixing crops, and deposition of nitrogen-containing air pollutants together create an additional flux of about 210 teragrams a year, only part of which is denitrified (Vitousek et al. 1997). This 210-teragram increase can be attributed to chemical fertilizers (80), biomass burning (40), N-fixation in legume crops (40), fossil fuel combustion (20), land clearing (20), and wetland drainage (10).

12.3.2 The Global Phosphorus Cycle

The lithosphere is the ultimate source of all phosphorus in the biosphere. (See Figure 12.4.) Paradoxically, while apatite (the naturally occurring phosphate rock) is one of the most easily weathered primary minerals, P is amongst the least biologically available major nutrients. This is because the forms of phosphorus in the biosphere are poorly soluble, immobile, or otherwise inaccessible.

As a result, P occurs in sufficient supply in young, arid, and neutral soils, although with some exceptions, depending on the nature of the parent material. On the other hand, P often co-limits (with N) plant and animal production on old, highly weathered soils, such as those that dominate tropical Africa, South America, and Australia. Since NH_4^+ and NO_3^- are both more readily leached out of soils than phosphate, freshwater and some

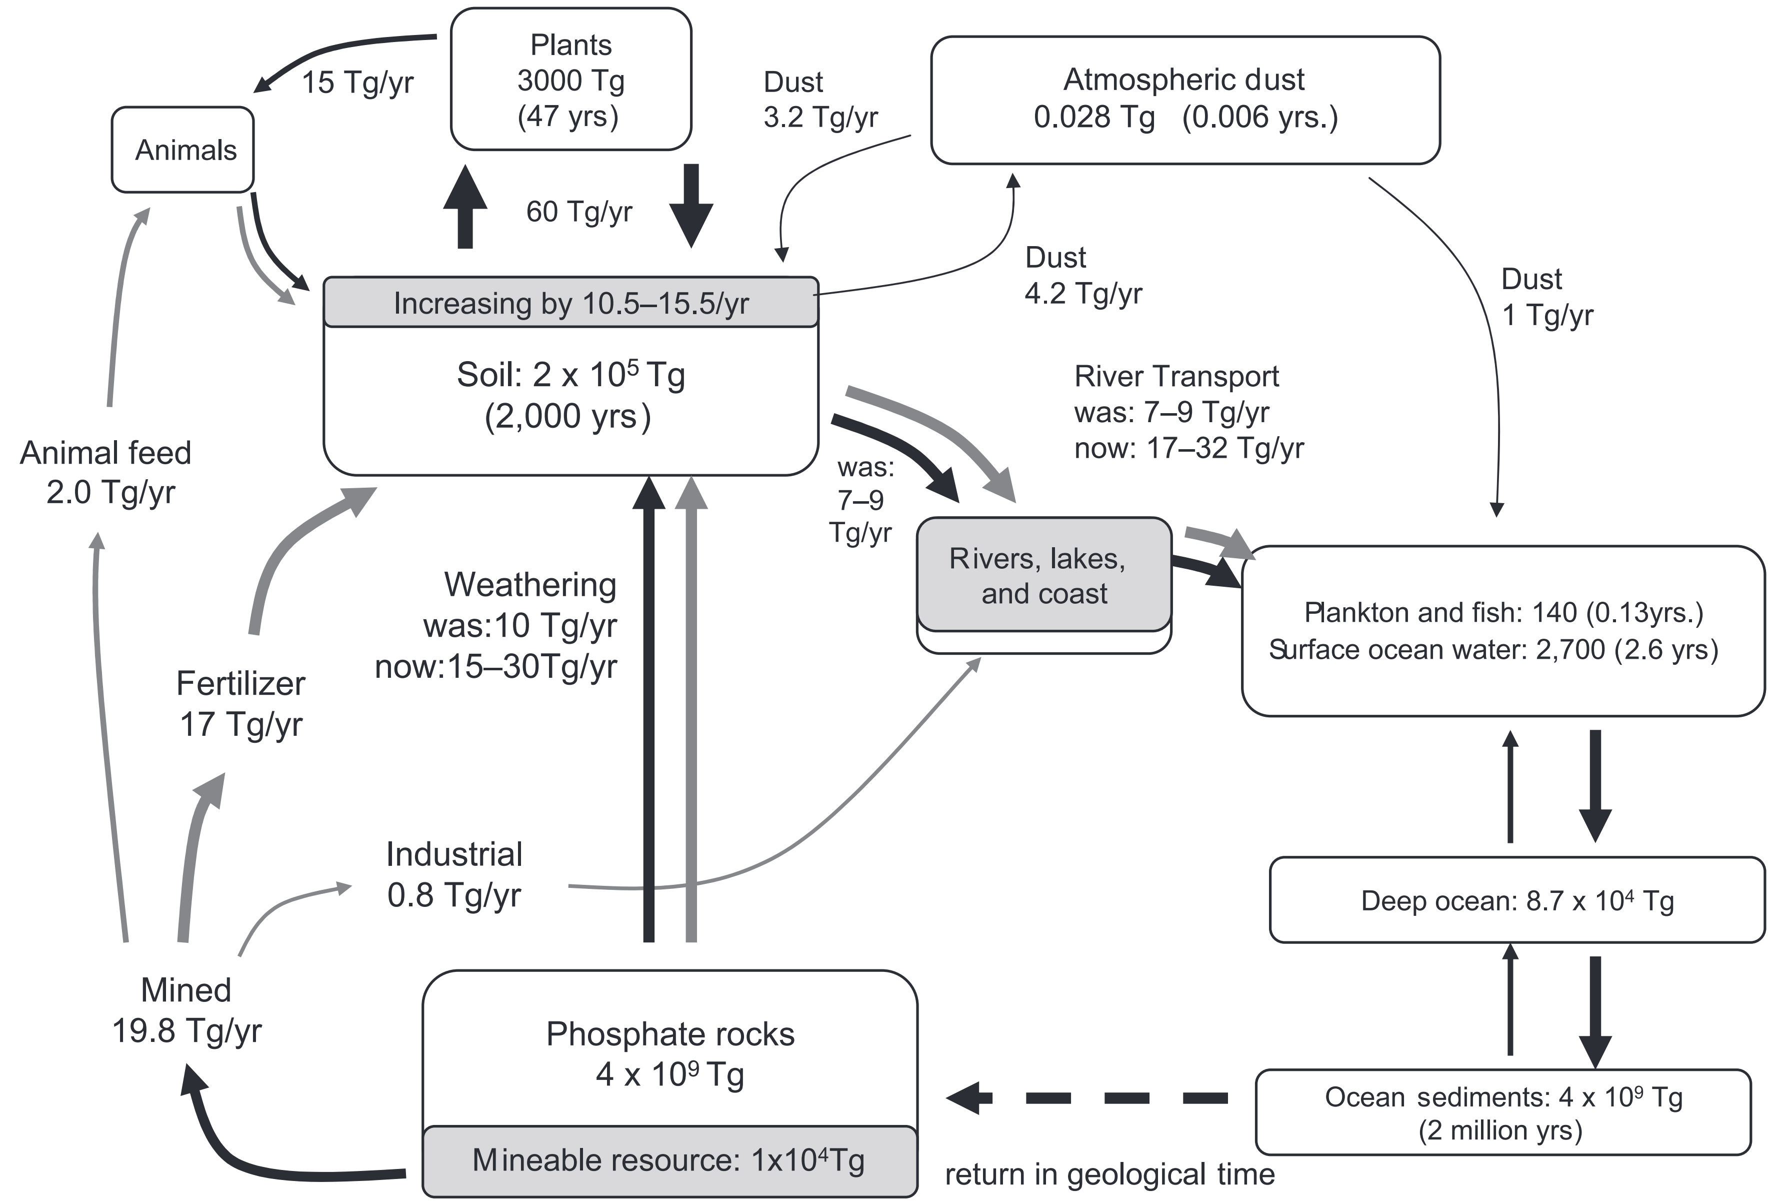

Figure 12.4. Schematic Diagram of Main Parts of Global Phosphorus Cycle. Pools are in TgP, fluxes in TgP/yr, and turnover times are in years. The grey arrows are the fluxes that are entirely or partly anthropogenic. P is building up in terrestrial soils as a result of P fertilizers, and is leaking into rivers, lakes, and coastal waters, where it is the main driver of eutrophication. (Reeburgh 1997; Carpenter et al. 1999)

coastal ecosystems are typically more responsive to increases of P than of N, making P the principal driver of eutrophication in lakes and estuaries. Phosphorus is transported principally adsorbed onto or absorbed into soil particles rather than in solution. In addition, where intensive animal husbandry is practiced, P can be lost in large quantities in surface runoff. As such, phosphorus in fact does not strictly cycle (other than in very long geological time frames) but follows a one-way path from terrestrial to aquatic systems. Return from marine systems to land in the form of bird guano, although sometimes locally important, is a very minor flux in total.

The availability of P in landscapes where it is scarce is greatly enhanced by biological processes. Specialized symbiotic fungi, known as mycorrhizae, transfer P from inaccessible forms to the plant and help to reduce leakage of P from the system. There is widespread empirical evidence that low P availability constrains biological N fixation (Smith 1992) contributing to the co-limitation just mentioned. However, the mechanism resulting in this constraint remains poorly understood (Vitousek et al. 2002).

Figure 12.4 shows the contemporary and preindustrial global P cycles. The contemporary cycle is not in balance. As a result of the large P inputs from the lithosphere, mainly through phosphate mining, and accelerated weathering as deep soil is exposed as a result of surface erosion, P is accumulating in terrestrial ecosystems in both the industrial and developing world (with some conspicuous exceptions, such as most of sub-Saharan Africa). The main mechanism by which the P leaves the land and enters freshwater ecosystems is soil erosion. Agricultural P is the principal driver of eutrophication. P concentrated in sewage effluents and animal and industrial wastes, including P-containing detergents, makes a relatively small global contribution (Bennett et al. 2001), although it may be important locally. For example in the United States 36% of sewage sludge is applied to the land, with the rest going to landfills, incineration, or other ''surface disposal'' methods.

Because the amount of P accumulated on land is large, and the processes of release are relatively slow but hard to prevent, this problem is highly likely to grow substantially in the coming decades. However, the rapid increase in no-till agricultural systems in several parts of the world and an increasing trend to incorporate buffer strips or hedgerows in agricultural landscapes may help to mitigate the problem significantly in some areas. For example, in the United States in 1989, 3% of cropland was no-till; in 1998 it was 16.3% (20 million hectares). In Brazil, 3% of cropland was no-till in 1990 and in 1998 it was 25% (10 million hectares). In Argentina, the figure was 2% in 1990 and 28% (6 million hectares) in 1998. And in Australia, the no-till area jumped from 0.1% in 1990 to 50% (10 million hectares) in 1998. (Eutrophication is dealt with extensively later in this chapter.)

12.3.3 The Global Sulfur Cycle

In many respects the sulfur cycle parallels the nitrogen cycle, except for a significant input from the lithosphere via volcanic activity and the absence of a biological process of S fixation from the atmosphere to the land or water. (See Figure 12.5.) The main human perturbation to the global S cycle is the release of SO_x (SO_2 plus a small amount of SO_3) to the atmosphere as a result of burning S-containing coal and oil and the smelting of sulfite ores.

SO_x gas impairs respiration in humans at high concentrations and is moderately toxic to plants. Other S gases, such as H_2S and mercaptans (sulfur-containing organic chemical substances), are not very toxic but are highly offensive to human olfaction even at low concentrations. Consequently, S-containing gases are usually vented from tall smokestacks in order to be widely diluted at ground level. Coupled with the simultaneous removal of ash particles from the smoke, this contributed greatly to the emergence of the ''acid rain'' deposition problem in the twentieth century (Smil 1997). Sulfuric acid is one of the major components of acid deposition, along with nitric acid, carbonic acid, and various organic acids. In preindustrial times it was largely neutralized by the simultaneous deposition of alkaline ash. High increase in S deposition (22–47 teragrams per year) has led to a situation where this compensation is no longer operating.

In the atmosphere SO_x forms SO_4^{2-}, a crystalline aerosol that acts as a powerful nucleus for cloud condensation and helps to retard climate change. The sulfate dissolves in rainwater, forming dilute sulfuric acid, and is deposited on Earth's surface in wet or dry form, the proportions of which depend on the prevailing climate.

Damage to ecosystems results not so much from the direct effects of acid, SO_x, or SO_4^{2-} on plants (S, in small doses, is a fertilizer), but from the direct effect of leaching of SO_4^{2-} from soil in drainage. To maintain electrical neutrality of drainage, cations, principally Ca^{2+}, are lost; the resulting acidification brings Al^{3+} and H^+ into solution (Galloway 2003). The Al^{3+} ion impairs nutrient absorption, especially phosphorus uptake, by the roots of all but a very specialized group of plants. It is also highly detrimental to aquatic organisms and ecosystems. Soil, river, and lake acidification is extremely difficult and expensive to remedy. The buffering capacity of the ecosystem, which is related to soil depth, soil chemistry, and weathering rate, provides an ecosystem service worth billions of dollars, both in avoided damage and mitigation actions. The capacity of this service is, however, finite and easily exceeded.

As a result of severe human health problems associated with SO_2 in urban smog and concerns regarding ecosystem health in areas exposed to high loadings of acid deposition, sulfur has been progressively reduced or eliminated from industrial, domestic, and transport sector emissions in Europe and North America. This has been achieved by switching from high-S coal and oil to lower-S fuels and by installing flue-gas desulfurization equipment. This has been so successful that S deposition has declined to such an extent that sulfur is now becoming a limiting nutrient in many parts of Europe. The result is that N deposition, resulting from vehicular, industrial, and agricultural emissions, has now become the major

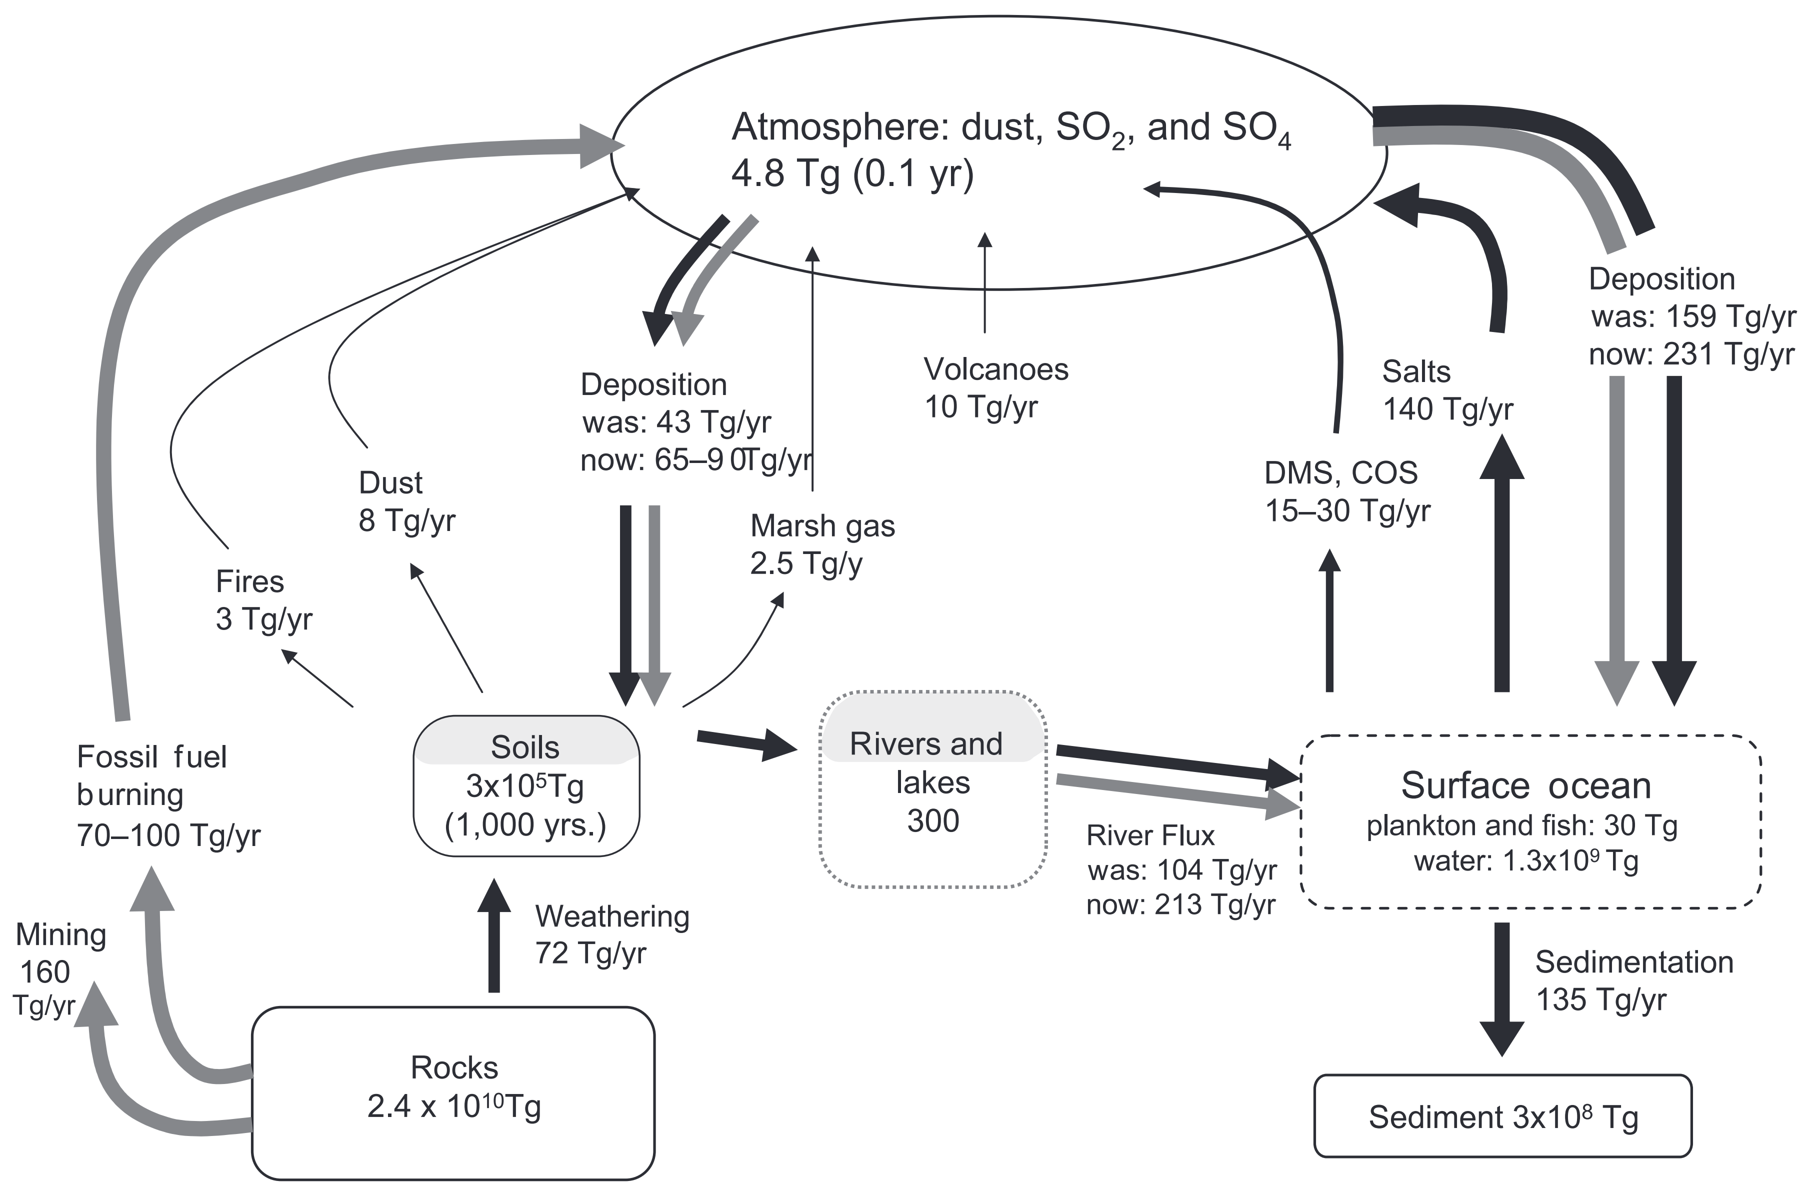

Figure 12.5. Main Pools and Fluxes in Global Sulfur Cycle. Pools are in TgS, fluxes in TgS/yr, and turnover times in years. The solid arrows represent the preindustrial cycle, while the grey arrows and boxes show the human additions, circa 2000. Emissions of S from burning fossil fuels and smelting ores are the main causes of increased S deposition, which accumulates in soils, leading to acidification of the soils and particularly of poorly buffered freshwater bodies draining from them. (Reeburgh 1997; Brasseur et al. 2003)

component of acid deposition in these regions. A perverse consequence of this is that global warming will increase by about 0.3 watts per square meter (about 10%) as the anti-greenhouse effects of sulfate aerosols diminish (Ramaswamy et al. 2001).

However, sulfur emission reduction is not widely practiced in the emerging industrial areas of the world: China, India, South Africa, and the southern parts of South America. A global assessment of acid deposition threats (Kuylenstierna et al. 2001), based on a combination of emission locations, wind transport patterns, and the buffering capacity of soils in the receiving regions, suggests that tropical ecosystems in the developing world are at high risk of acidification. (See Figure 12.6 in Appendix A.)

12.3.4 The Global Carbon Cycle

The global carbon cycle has been assessed recently and comprehensively by the Intergovernmental Panel on Climate Change (Prentice et al. 2001) because of its centrality to the issue of global climate change. This chapter will not repeat that work nor the discussion of C-climate interactions covered in Chapter 13 on air quality and climate. Suffice to say here that the global C cycle is currently out of balance (see Table 12.4), principally as a result of the burning of fossil fuels, but also due to the conversion of high C-density natural ecosystems, such as forests and grasslands, to lower C-density agroecosystems. It should be noted that the C cycle has been perturbed by about 13% relative to its preindustrial state, compared with figures of 100% or more for the N, P, and S cycles (Falkowski et al. 2000).

There is an important interconnectivity between the cycles of N, P, S, Fe, and Si and the C cycle (Mackenzie et al. 2002). Human actions have significantly perturbed those cycles, and this has knock-on effects on the C cycle due to considerations of stoichiometry and the co-limitation or regulation of key processes. Mechanisms such as N fertilization and the sequestration of C in deep oceans through the "biological pump" contribute an uncertain but large proportion of the ~ 4 billion tons per year carbon storage service that the biosphere currently provides (Prentice et al. 2001). Some key processes, such as N and CO_2 fertilization of terrestrial ecosystems, are highly likely to reach saturation, possibly during this century (Scholes et al. 2000).

The global fixation of carbon through photosynthesis has been suggested as a general index of the health of both terrestrial and aquatic ecosystems, all other conditions of temperature, moisture, and nutrient supply being equal (Schlesinger 1997). Global indices of this type (such as the Normalized Differential Vegetation Index) are now available and show an increase in biomass in the high northern hemisphere latitudes, consistent with climate change, and no overall trend (but high interannual variability) in the sub-tropical deserts. They also reveal large areas of algal blooms in coastal areas, especially those that are semi-enclosed, such as the China Sea, indicating eutrophication.

12.4 Consequences of Changes to Nutrient Cycles

Alterations of nutrient cycling include situations of nutrient excess, leading to eutrophication of soils and water bodies, and nutrient deficiency linked to soil exhaustion and some specific natural situations in oceans.

Table 12.4. Stocks of Carbon in Major Compartments of the Earth System and Their Residence Times. The Table indicates change in carbon stocks per year in the 1990s as a result of imbalances in the cycle caused by human emissions of 6.4 ± .6 PgC from the burning of fossil fuels, and 1.4–3.0 PgC from land use change. (Reeburgh 1997; Prentice et al. 2001)

	Components	Stock	Residence Time	Accumulation Rate
		(PgC)	*(years)*	*(Pg/year)*
Atmosphere	CO_2	750	3–5	3.2 ± 0.2
Land biota	plants	550–680	50	land net uptake 1.4 ± 0.7
Soil	peat	360	$>10^5$	
	inorganic carbonates	1220		
	microbial biomass	15–30	<10	
	POC	250–500	$<10^2$	
	amorphous polymers	600–800	10^2–10^5	
Lakes and rivers	sediments	150	10^{-1}–10^3	?
Lithosphere	kerogen	15×10^6	$>>10^6$	
	methane clathrates	11×10^3	–	
	limestone	60×10^6	–	
Ocean: surface	DOC	40	–	oceanic net uptake 1.7 ± 0.5
	POC	5	–	
	living biomass	2	10^{-1}–10^1	
Ocean: deep	DIC	38,000	$\sim 2 \times 10^3$	
	DOC	700	5×10^3	
	POC	20–30	10^1–10^2	
	sediments	150		

Notes: 1 Pg = 10^{15}g = 1 billion tons
Kerogen consists of coal, oil, gas, and other lower-grade fossil carbons such as lignite and oil shales.
Clathrates are a solid form of methane hydrates found at depth in ocean sediments.
DIC: dissolved inorganic C; DOC: dissolved organic C; POC: particulate organic C.

12.4.1 Nutrient Excess in Fresh and Marine Waters

As noted earlier, a major consequence of fertilizer inputs and atmospheric deposits, and of impairment of buffers and regulatory mechanisms at all scales, is eutrophication of aquatic systems—both fresh and saline waters. (See Chapters 19 and 20 for more on coastal and inland water systems.)

12.4.1.1 Eutrophication of Aquatic Ecosystems

Eutrophication is the fertilization of surface waters by nutrients that were previously scarce (Carpenter et al. 1999). In the 1960s it became obvious that a change was occurring in many lakes and reservoirs, especially in industrial countries, resulting from an increase in their nutrient load. This was a consequence of human activity, with increased inputs of urban and industrial wastewater and agricultural runoff containing mainly C, N, and P. The problem is now apparent in many coastal areas as well. Eutrophication is regarded as the most widespread water quality problem in many countries (OECD 1982; NRC 1992; Nixon 1995; Carpenter et al. 1998; Howarth et al. 2000). (See also Box 12.3.)

Eutrophication leads to many changes in the structure and function of aquatic ecosystems and thus the services they provide. The symptoms of eutrophication are well known: increase in phytoplankton, benthic, and epiphytic algae and bacterial biomass; shifts in composition to bloom-forming algae, which may be toxic or inedible; development of rooted macrophytes and macroalgae along the shores; anoxia (oxygen depletion) in deep waters; increased incidence of fish and shellfish mortality; decreases in water transparency; taste, odor, and water treatment problems; and in coastal areas, coral mortality. Such characteristics are detrimental to many water uses, including for drinking, fisheries, and recreation. Although possible, remediation measures are costly, and mostly consist of reducing the inputs of nutrients to tolerable levels.

Most attention has focused on P inputs rather that on N or C, because P is often the element limiting the growth of aquatic biota in temperate freshwater environments. Phosphorus is less abundant than N in fresh waters relative to plant needs, and its concentrations are reduced to very low levels by uptake during the growing season. It is therefore P that often regulates the extent of algal and other plant development in the aquatic environment.

BOX 12.3

Case Study of Eutrophication of Inland Waters: Lake Victoria, East Africa

Observations in 1990–91 in the center of Lake Victoria have been compared with data from 1960–61 (Hecky et al. 1994). The results indicated a stronger stratification, with less oxygen in a greater part of the deep zone of the lake. This eutrophication process results mainly from an increase of human activities in the watershed, with increased inputs of nutrients linked with urbanization, deforestation, and cultivation. Some shift in the phytoplankton population has also occurred. The increase in nutrients first led to an increase in diatoms. The resulting depletion in dissolved silicon promoted a shift in the diatom species and finally the establishment of blue-green alga (Cyanophycea) (Verschuren et al. 1998). Introduction of alien fish species such as *Lates niloticus* (Nile perch) and four species of *Oreochromis* (tilapia) also contributed to a strong modification of the trophic food web, with probable feedback on the phytoplankton community, as well as the fish community, with a strong decrease in the number of the endemic cichlids species (Lévêque and Paugy 1999).

A debate took place during the 1970s on the possible reduction or ban of P in detergents as a means of reducing the eutrophication of lakes. The pro-P argument relied on the small fraction of P load resulting from the detergents as compared with other urban or agricultural sources (Lee and Jones 1986). While phosphorus use has been totally banned in some countries (in Switzerland and some states of the United States), and partial restrictions occur in others, the use of high-P detergents is unrestricted in a number of other countries.

Agricultural production in some countries is not keeping pace with the increase in food demand. (See Chapter 8 for more on food production). Although in sub-Saharan Africa and Latin America a significant part of the required increase in cereal production could result from an increase in the cultivated area, the increase would transform land that is currently supplying other ecosystem services. Increase in food production is also possible from higher yields in existing agricultural areas (Pinstrup-Anderson 1999). This will require the development of more-sustainable practices making a better use of natural biological processes (Swift and Woomer 1994) and an increased use of fertilizers, which could be mitigated by an improvement in the efficiency of their use.

In Western Europe or North America, the quantity of fertilizer applied today is the same as it was in 1970, whereas the average yield of wheat, for example, has more than doubled. Assuming a slowdown in the growth of world population and crop production and an improvement in fertilizer use efficiency, it is forecast that total fertilizer use will have to increase from the present level of 140 million tons $N + P_2O_5 + K_2O$ to 167–199 million tons per year by 2030, meaning annual growth rates of 0.7–1.3%. This compares with an annual rate of increase over the past 30 years of 2.4% (FAO 2000). A significant part of the increase in P fertilizers may enter the aquatic reservoir if conservation practices and erosion control are not implemented on a very large scale.

12.4.1.2 Eutrophication and Carbon Sequestration

Elevated net primary production associated with eutrophication would seem to favor carbon sequestration. However, when recycling of C through decomposer chains prevails on sedimentation in rivers and lakes, these systems behave as sources of CO_2 since their CO_2 partial pressure (pCO_2) is higher than that of the atmosphere. In a survey of pCO_2 in the surface water of 1,835 lakes around the world, 87 % of the samples were supersaturated (mean pCO_2 : 1,034 (atm) (Cole et al. 1994). In highly polluted aquatic systems, the pCO_2 may reach higher values, such as 5,700 (atm in the upper estuary of the Scheldt River, which receives industrial and urban wastes from France, Belgium, and the Netherlands (Frankignoulle et al. 1996).

The net global C budget of inland waters has been approached from a different point of view. From their measurements on lakes, Cole et al. (1994) have estimated the potential release of CO_2 from lakes at about 0.14 billion tons of carbon per year, which is about half as large as riverine transport of organic and inorganic C to the ocean. This indicates that terrestrial systems, among which forests are usually considered as C sinks, export some organic matter that later contributes to CO_2 emission. From considerations of primary production, Dean and Gorham (1998) estimated that lakes are currently accumulating organic C at an annual rate of about 42 teragrams a year. Most of the C in all but the most oligotrophic of these lakes is primary production in the lakes themselves. The sediments of reservoirs accumulate an additional 160 teragrams annually, and peatlands contribute 96 teragrams annually. These three C pools collectively cover less than 2% of Earth's surface and constitute a C sink of about 300 teragrams a year.

12.4.1.3 Marine Dead Zones

Low oxygen conditions in coastal marine waters are primarily the result of enrichment in nitrogen with consequent enhanced growth of phytoplankton. These nitrogen-fed phytoplankton sink to the sea floor when they die, and the organic matter is regenerated by bacterial activity, consuming oxygen. At low oxygen concentrations, most marine life is unable to survive, leading to the designation of "marine dead zones." The size of these reaches up to 70,000 square kilometers (Brian et al. 2004), and they have been reported off South America, Japan, China, Australia, New Zealand, and the west coast of North America. The number of such areas has doubled every decade as more and more artificially produced nitrogen fertilizers are used in agriculture and as human population increases result in increased nitrogen containing sewage effluent.

The hypoxic conditions are seasonal in some regions, such as the Gulf of Mexico (fed by nutrients from the Mississippi River) and off the coast of Oregon, where low oxygen conditions have appeared in recent years. The Oregon events are related to upwelling conditions when north winds displace surface waters and deep waters rise as replacements. These deep waters have high nutrients, but in recent years have also had low oxygen content. Benthic populations, such as crabs, are quickly affected by such conditions and can provide useful indicators for early warning of low oxygen.

The occurrence of dead zones and their size appears to be a function of nitrogen inputs, which continue to grow in most parts of the world. Denitrification (which returns nitrate to the atmosphere as N_2 and N oxides) takes effect only when oxygen concentrations are already low and so becomes effective only after the dead zone phenomenon has occurred. In the future, this phenomenon may be as important as overfishing in the decline of fisheries. (See Chapter 18 for more on marine fisheries.)

12.4.2 Nutrient Deficiencies

A significant proportion of agricultural soils, mainly located in developing countries, are suffering nutrient deficiencies. Similar situations may occur in coastal and marine systems as a result of shortage of water flow from terrestrial systems, or naturally in the high nutrient, low chlorophyll zones, where deficiencies in Si and Fe limit primary production.

12.4.2.1 Agricultural Soils

The fertility of any soil will decline if the nutrient content of the harvest removed from the system (as grain, timber, livestock, and so on) exceeds the nutrient input from natural and anthropogenic sources. In general, the nutrient balances in the industrial world are positive, especially for N, as crops use less than half of the applied fertilizer, leading to the eutrophication problem just described. In large areas of South America (Wood et al. 2000) and Africa (Smaling et al. 1997; Sanchez 2002), on the other hand, the nutrient balance is negative, leading to declining soil fertility. In the case of South America, the magnitude of the imbalance appears to be decreasing as incomes rise and farmers can afford more fertilizer. In Africa, the cost of fertilizer to low-income farmers is usually prohibitive.

The situation is exacerbated by two factors: ecological features and farmers' perception of risk in many of the poorest developing regions. First, much of the agricultural population in nutrient-deficient areas lives on soils derived from basement rocks, on very old, stable land surfaces. The P and base cation content of these soils is inherently low; as a result, natural biological N fixation is also low. Because the soils are sandy and low in organic C, they lose N through leaching. Their low N status leads them to be burned frequently (since the grass that grows on them is too low in N for cattle to digest in the wintertime), causing further N loss. Nitrogen is the key component of protein, and it is precisely these areas that show a steady decline in per capita protein consumption, to levels well below the recommended daily intake. The same areas also show high levels of stunted growth associated with malnutrition (Scholes and Biggs, in press).

Where farmers perceive that there is a risk of not achieving an acceptable level of yield at harvest (perhaps because of drought) to cover their input costs, they are often unwilling to invest in fertilizers to replace nutrients like P and K removed in the harvested produce.

12.4.2.2 High Nutrient, Low Chlorophyll Regions of the Ocean

Large parts of the ocean are characterized by the presence of adequate N and P in the euphotic zone but low phytoplankton biomass and low primary and new production (Minas et al. 1986). The best known of these regions are between the coast of Ecuador out to the Galapagos Islands, the equatorial Pacific out to the dateline, the northeast Pacific, and portions of the Southern Ocean.

Open ocean fertilization experiments have shown the first of these to be limited by Fe (Coale et al. 1996). Responses to Fe additions have been observed in the Southern Ocean as well, but with limited effects on phytoplankton productivity and growth rates. The equatorial Pacific is chronically low in $Si(OH)_4$ with some secondary effects due to the relatively low Fe concentrations (Ku et al. 1995). The Southern Ocean north of the polar front has been identified as a low $Si(OH)_4$ region (Dugdale et al. 1995). The origin of this condition is now understood as the result of a seasonal drawdown of $Si(OH)_4$ by diatoms, which proceeds southward over the course of the austral summer. Drawdown of NO_3 is small compared to the uptake of $Si(OH)_4$, a condition that may be related to low Fe (Takeda 1998). However, unusually high $Si(OH)_4$ uptake by diatoms can result from other processes that slow their growth (Claquin et al. 2002).

The interest in high nutrient, low chlorophyll regions has been sparked by the possibility of increasing their productivity through fertilization, with relatively small quantities of Fe and/or Si. This has been suggested as an option for slowing the increase in atmospheric CO_2. However, the scientific understanding of the consequences of full-scale implementation of such an action remains insufficient for adequate assessment.

12.4.3 Threats to the Global Marine Nutrient Cycling System

Global marine nutrient cycling is beginning to be understood in spite of the complex interactions among physical, chemical, and biological processes that occur across the moving boundaries of water masses. Several processes require examination, as each may be a significant source of increased or decreased services in the future.

First, N fixation seems to be enhanced when Fe and P are added (Beherenfeld and Kolber 1999; Bidigare and Ondrusek 1996; Sanudo Wilhelmy et al. 2001; Karl et al. 1997, 2002). Since the expansion of the Sahara in the early 1970s, the dust load has increased nearly fourfold (Prospero and Nees 1986). Furthermore, Tegen and Fung (1995) have shown that about half the dust reaching the Equatorial Atlantic is due to disturbed soil conditions, and this dust contains more Fe than undisturbed desert dust. Increased N availability is likely to increase C fixation and its further sequestration in sediments and would therefore constitute a positive contribution to mitigation of climate change.

Second, denitrification is considered a useful process in the elimination of part of the N burden in estuaries and coastal areas, whereas it may limit production in N-limited areas, as N fixation is severely limited by Fe and Si availability (Naqvi et al. 2000; Codispoti and Christensen 1985). This is thought to be the current state of the world's oceans. If so, this would imply that oceanic biological processes (as distinguished from the physical dissolution of CO_2 into water due to increased partial pressures of CO_2 in the atmosphere) are actually adding C to the atmosphere instead of removing it (e.g., Falkowski 1997).

Third, increased NH_4^+ from terrestrial effluents inhibits the ability of diatoms to use NO_3^-. In San Francisco Bay, a long-term decline in productivity has been ascribed to increased NH_4 concentrations of anthropogenic origin (Karl et al. 2001). However, the Anamnox process (oxidization of NH_4 into free N by reaction with nitrite) is likely to mitigate the problem in anoxic areas (Devol 2003).

Fourth, decreased productivity is linked to reduced inputs of Si and Fe from terrestrial sources. Changes in the input of $Si(OH)_4$ from rivers as a result of damming and changes in farm practices may also have an impact on the productivity of marine diatoms (Leynaert et al. 2001). When $Si(OH)_4$ concentrations fall below about 2 μM, other algal groups are able to outcompete diatoms, potentially leading to the dominance of less desirable or even toxic bloom species.

12.5 Monitoring and Assessment

Given the large diversity of mechanisms, pools, and fluxes involved in nutrient cycling, decision-makers face a large number of different, although closely related issues. (See Table 12.5.) For example, eutrophication of fresh water, which is mainly a consequence of excessive nutrient inputs and mismanagement of wastes at the landscape scale, is aggravated by atmospheric N deposits and by the reduction of plant cover and biodiversity at the plot and landscape scales. Once the pools, fluxes, or mechanisms relevant to the particular issue have been identified, adequate indicators or descriptors of their sizes or intensity can be identified and monitored. (See Table 12.6.)

Although alterations in nutrient cycling are generally observed at scales from plot to landscape and region, the mechanisms involved are generally operating at much smaller scales. Efforts to improve the general quality of nutrient cycling could improve from fine-tuning the inputs to the needs of cultivated plants as much as possible, in order to limit the risk of leakage from terrestrial ecosystems to groundwater and to freshwater and marine systems, and through greater attention to the state of the various buffering systems described earlier.

In practice, the best indicators of nutrient cycling efficiency will be measured at the plot level (diversity and cover of plants and indicators of quality based on soil fauna communities) and at the landscape level (density and distribution of buffering zones such as riparian forests, diversity of land use types in mosaics). Links between diversity at these two scales and adequate nutrient cycling have been observed in a number of studies (Wardle et al. 1999; Niklaus et al. 2001; Reich et al. 2001; Tilman et al. 2001). Cover crops, diversification of land use types in time (rotations) and space, no-tillage practices at the plot scale, and the use of hedgerows, riparian forests, and wetlands have all been shown to improve the tight cycling of nutrients (Nair 1993; Palm 1995; Entry and Emmingham 1996; Inamdar et al. 1999; Fassbender et al. 2000).

However, with a few exceptions, the mechanisms that link measurements of landscape features and plant and invertebrate diversities and so on to nutrient cycles have not been established satisfactorily, nor have thresholds for degradation of their diversity been established. This is in part due to a lack of extensive datasets that would allow statistical relationships to be established. However, the apparently large time lag between the loss of biological diversity and the impairment of soil functions might obscure significant statistical relationships (Lavelle et al. 2004).

12.6 Implications of Altered Nutrient Cycles for Human Well-being

Nutrient cycling and soil or water fertility play key roles in terrestrial and aquatic systems, and these roles benefit many segments of society. Substantial human benefits are derived directly and indirectly from nutrient cycling and fertility services.

Principally, millions of people earn their living from the production of commodities, such as food and other products, yielded by terrestrial and aquatic systems. The livelihoods of many rural households in developing countries in particular are highly dependent on direct harvesting of wild foods and non-food products. (See Chapters 18 and 26 for more on livelihoods based on food production.) More generally, benefits are derived directly from the use of noncommercialized ecosystem products generated by the fertility service of terrestrial and aquatic systems, such as biodiversity and its services. Thus nutrient cycling and fertility are essential for supporting the supply of farmed and wild products and the benefits people derive from their consumption and use.

Various approaches and methods have been developed to value nutrient cycling and fertility services. These methods can be grouped into two broad categories: benefit-based and cost-based approaches. (See Chapter 2.) The most commonly used benefit-based method is the production function approach that measures the marginal contribution of fertility to the total value of generated products after accounting for the marginal contribution of all other inputs and factors used in the production process. Examples of studies that have used such an approach to quantify relationships include yield reduction (productivity loss) versus land degradation (Aune and Lal 1995; Lal 1995). The most researched land degradation factors are soil erosion and nutrient mining in the United States (Hertzler et al. 1985; Burt 1981; Pierce et al. 1984), Mali (Bishop and Allen 1989), Zimbabwe (Grohs 1994), and Ethiopia (Sutcliffe 1993).

In principle, this method is applicable to both commercialized and noncommercial products of terrestrial and aquatic systems. However, it is relatively easier to apply to situations where products are commercially exploited and marketed and where the value of products directly harvested from the wild for noncommercial use is usually calculated using prices and values of similar products exchanged in the market. But the accuracy and realism of figures derived from the production function approach is questionable. A fundamental assumption of this method is that the market prices of agricultural outputs reflect their marginal costs of production; in most economies, market distortions (such as U.S. and European farming subsidies) ensure that market prices are not equal to marginal costs.

Among the most commonly used cost-based approaches is the replacement cost method. This uses the value of commercial fer-

Table 12.5. Problems in Ecosystem Functioning Linked to Nutrient Cycling Dysfunctions and Indicators to Assist Diagnostic. Numbers of scales in the first column relate to classification of scales made in section 12.2.3.

Scales	Dysfunction Observed	Possible Diagnostic	Indicators
Terrestrial			
1–2: Micro	plant growth limited by unexpected nutrient deficiencies	microbial diversity modified	diversity in microfoodwebs communities (micro- and meso-fauna)
		beneficial or key microorganisms (N-fixers; mycorrhizae; white rot fungi) absent	nodulation in legumes
	fungal or bacterial diseases	impairment of soil structure preventing optimal function of foodweb controls	Maturity Index (Bongers 1990)
3–4 Ecosystem	soil compaction and erosion deficient water infiltration C losses	abundance and functional diversity of plants and soil natural tillers (earthworms, termites, ants) insufficient to allow adequate regulation of microbial communities and soil structure	synthetic indices of soil quality (Vélasquez 2004; Ruiz-Camacho 2004)
5: Landscape	groundwater and adjacent freshwater systems loaded with nitrates and phosphates	leakage due to dysfunction of regulations at scales 1—4 not mitigated by the presence of suitable buffer zones for nutrient absorption and refugia for useful soil fauna	landscape metrics given by analysis of composition and structure of landscape
	erosion	insufficient C supply for faunal activities	
6: Global	soil nutrient depletion at large scales	unbalanced nutrient budgets for terrestrial biomes inadequate management options	erosion, indices of soil quality crop production
		lack of formation and financial support	indicators of human development
Fresh Water			
1–2: Micro	algal blooms	eutrophication (nutrient excess loading)	OECD trophic levels (based on total P, chlorophyll, transparency in lake water)
3–4: Ecosystem	changes in fish communities	aquatic habitat destruction; increased input of suspended solids from land erosion	in rivers, changes in water regime; natural habitat diversity; invertebrates and fish communities structure
	fish kills	eutrophication; excess nutrient and organic matter load, pollution by pesticides or other humanmade substances	low oxygen in rivers and anoxia in deep layers of lakes
			in lakes, changes in hydrological seasonality
5: Landscape	decrease in inland fisheries	decrease in water quality and in self-epuration capacity; increased control on river flows (dam construction, canals, regulated river, etc.)	decrease in aquatic biodiversity and in habitat diversity changes in riparian vegetation
		pollution (nutrients and chemicals)	total N and P in water
6: Global	decrease in availability of fresh water (drinking water)	alteration of the self-epuration capacity	total N and P in water
Marine and Coastal			
1–2: Micro	algal blooms fish kills	changes in N-cycling microbial communities due to sewage effluents (nutrients and heavy metals)	changes in microbial communities
3–4: Ecosystem	algal blooms fish kills	organic matter loading producing hypoxia	low oxygen concentration
	decreases in productivity; decreased fish catches	reduced water and nutrient flows from terrestrial ecosystems (damming, irrigation, industrial use of water)	low chlorophyll concentration
5: Landscape	eutrophication (algal blooms fish kills)	habitat disturbance (landfill, mangrove/seagrasses clearing/disruption of estuaries)	habitat structure in coastal environments
		impaired regulation of populations of primary producers by fishes due to overfishing	decreasing trend in fish catches
6: Global	eutrophication in non-directly affected areas	nutrient overloading of major current systems	nutrient load in water

Table 12.6. Biophysical Structures That Allow Regulation of Nutrient Cycling at Different Scales, Processes Involved, and Indicators of Their Functionality

Scale	Biophysical Structures (self-organizing systems)	Process	Indicators of Service	Human Alterations	Indicator of Alteration
Micro	soil + sediments: microaggregates waters: water column	micro-foodweb effects	soils: maturity index (Bongers 1990) all: diversity in microfoodwebs communities (micro- and meso fauna)	organic and chemical contamination	fertilizer and pesticide application
Ecosystem	biogenic structures created by roots and bioturbators	habitat creation modified access to resources regulation of hydraulic properties and organic matter dynamics	physical structure of soils and sediments bioindicators of soil quality (Ruiz-Camacho 2004, Vélasquez 2004) bioindicators of fresh water quality (AFNOR 1992)	organic and chemical contamination physical disruption (tillage)	fertilizer and pesticide application description of tillage and other practices
	herbivory, foodweb effects	acceleration of nutrient release from living plant biomass CH_4 production in cattle guts	nutrient balances at plot level monitoring at plot level	conversion of natural and crop systems to pastures	grazing pressure
	saprophagy, comminution incorporation in stable aggregates	changes in decomposition rates organic matter sequestered	monitoring decomposition rates invertebrate communities (bioindicators of soil quality) distribution of organic matter in particle size fractions	organic and chemical contamination	land use practices
	quality of organic matter produced by primary producers	influence rates and pathways of nutrient cycling and release	chemical analysis of plant material: C: nutrient ratios, phenolic compounds	change in plant cover	N--fixing primary producers; ligneous vs. herbaceous
	texture and structure of soils and sediments; variations in ecosystem and landscape	regulation of nutrient storage and release	texture, nature of clay minerals, effective calcium carbonate porosity, aggregation	fertilization sedimentation and dust deposits physical disruption, compaction of soils and sediments	external inputs (fertilizers, deposits, importation) texture, formation of dunes (desert ecosystems) tillage, grazing pressure

(continues over)

tilizers needed to maintain stable levels of productivity (or natural fertility) as a proxy for the value of this ecosystem service. However, the replacement cost method generally underestimates the marginal contribution of natural fertility to production, as it assumes perfect substitutability between natural and manufactured fertility. It is known that this is not the case, although economic theory struggles to suggest the replacement value of natural processes for which no human-made process is a full substitute (see Freeman 1993 for a further discussion of this issue).

As an illustrative approximation, the nitrogen made available through cycling and nonagricultural biological nitrogen fixation on land totals around 5,000 teragrams a year. Hence, at a global average price of nitrogen fertilizer ($1,100 per ton of nitrogen), its annual replacement value is $5.5 trillion. Even if only the cycling on agricultural fields is considered, the total annual replacement value is around $1.1 trillion. Similarly, the estimate for phosphorus is 60 teragrams a year on land, with a annual replacement value of $240 billion, and of $48 billion for agricultural lands only. As marine systems are not deliberately fertilized, such an approach does not apply, but nutrient cycling is essential in support of coastal and ocean fisheries.

More-recent approaches to the valuation of the nutrient cycling service, such as the Habitat Equivalent Analysis, although they have not yet been applied in a comprehensive manner, would certainly provide much lower figures (Huguenin et al. in press). Other measures of the value of soil nutrients stocks include user cost or resource rent estimated as the dynamic price or production value lost to future generations from a unit of the nutri-

Table 12.6. *continued*

Scale	Biophysical Structures (self-organizing systems)	Process	Indicators of Service	Human Alterations	Indicator of Alteration
Landscape	vertical distribution in soils and water columns	transfers and losses	monitoring concentrations along soil profiles and water columns and sediments	intensification of agriculture and forestry	changes in landscape composition and structure (remote sensing)
				urbanization	
	mosaic of ecosystems (patches, ecotones, and buffering zones)	buffering zones regulating transfer of nutrient between domains (terrestrial to aquatic)	composition of landscape/seascape as assessed by remote sensing techniques (fragmentation, homogeneity, shape etc. indices)	pollution	fertilizer application detergent use N–-fixation in agriculture and forestry
		transfer from continent to rivers and oceans	eutrophication erosion rates, stream discharge		population density socioeconomic indicators (education, wealth)

ents' stock depleted today (Hertzler et al. 1985; Brekke et al. 1999; Nakhumwa 2004).

Nutrient cycling and fertility also generate noncommercial but nevertheless important benefits for various groups in society. They increase the risk-buffering capacity of agroecosystems—that is, the capacity of these systems to respond to environmental, climatic, and economic risks by adapting to these stresses without decreasing their productive capacities. The specific ecological mechanisms through which this occurs have not been fully documented, but it appears that belowground biodiversity plays an important role in this regard (Lavelle et al. 2004). Small-scale farmers in developing countries are particularly exposed and vulnerable to these forms of risk (Izac 2003). It is particularly difficult, both conceptually and empirically, to calculate the economic value of this enhanced capacity to manage risks. This enhanced capacity can also be thought of as a contribution to the long-term maintenance of the productive capacity of a system or to its sustainable use, so future generations will also benefit from this.

There are other issues related to the negative effects of service impairment that occur outside the immediate area where fertility is declining. For instance, soil erosion is particularly important and creates on-site and off-site (externality) effects, and economic evaluation of soil erosion is therefore not complete without the inclusion of costs and benefits for both on- and off-site effects. These may include the cost of dredging silted dams and of restoring impaired inland and coastal aquatic systems, in addition to the direct cost of fertilizer applications. Generally only anecdotal evidence is available concerning the costs of impaired aquatic systems, although estimates of the benefits and costs of nutrient loading for specific fisheries have been provided (UNEP 2002)

The historical changes in nutrient cycling and fertility analyzed in this chapter affect human well-being in two different ways. The first is directly, through changes in the perceived benefits or values of these ecosystem services from an anthropogenic perspective. Some of these changes in well-being are relatively easy to quantify in monetary terms; others are much more difficult to assess in this way, but nevertheless affect extremely important dimensions of human livelihoods. The second way in which human well-being is affected by these changes is through specific benefits that are currently not explicitly valued by society but that may have significant future ecological and welfare implications, such as the capacity of organisms involved in the marine nitrogen cycle to respond to global environmental changes.

In the case of terrestrial systems, negative trends in fertility and nutrient cycling have historically been remedied by greater and greater applications of fertilizers (inorganic and organic). However, such remedies can mask the effects of these trends only to a degree and can also result in increased costs of production. World fertilizer consumption increased rapidly in the 1970s and 1980s but slowed down in the 1990s, partly due to environmental legislation in industrial countries. (See Chapter 26.)

In the case of coastal and marine systems, high anthropogenic nutrient loads have resulted in anoxia and loss of fisheries, changes in the composition of inorganic nitrogen, declining productivity in some estuaries, and changes in species composition of the phytoplankton. (See Chapter 19.) These undesirable effects are directly related to agricultural fertilization and animal husbandry practices and to human population increases. Although many industrial countries are able to mitigate some of these effects through sewage treatment practices and in some cases control of agricultural practices, such mitigation is not universal.

Many countries have coped with the decreasing profitability of agriculture, caused in part by the necessity to supplement the natural nutrient cycle with fertilizers, by providing direct public subsidies to primary producers. Although low crop productivity across sub-Saharan Africa cannot be attributed entirely to increased costs of production, it is clear that deterioration in ecosystem services related to fertility has had a direct impact on productivity and subsequent rural livelihoods. Claims that fertility depletion is the single most important cause of poverty in sub-

Saharan Africa have not been supported by empirical evidence and failed to consider the myriad of other factors that also contribute to the highest rural poverty in the world. It is, however, undeniable that a net loss in nutrient cycling services that are essential for primary production has a negative effect on the financial situation of the rural poor.

One consequence of the changes documented in this chapter is the loss of sustainability, or resilience, in production systems. This is mainly, but not uniquely, through a loss of nutrient stocks, sequestered carbon, and biodiversity. This consequence is particularly important for future generations of farmers and particularly so in cases where threshold levels of irreversibility seem to have been reached. In these cases, this generation's running down of natural capital is either increasing costs of production for future generations of farmers or, in some cases, is closing off future production options altogether.

Main Messages

Ecosystems, both natural and managed, exert a strong influence on climate and air quality. Ecosystems are both sources and sinks of greenhouse gases, aerosol precursors, and pollutants. Their physical properties affect heat and water fluxes, influencing temperature and precipitation—altering, for example, the reflection of solar radiation (albedo) and the flow of water through plants to the atmosphere (evapotranspiration), where it becomes available for rainfall. Thus ecosystems provide the following atmospheric "services":

- warming (for example, sources of greenhouse gases and reduction of albedo by boreal forests compared with bare soil and snow);
- cooling (for example, sinks of greenhouse gases, sources of aerosols that reflect solar radiation, and evapotranspiration);
- water recycling and regional rainfall patterns (for example, evapotranspiration and sources of cloud condensation nuclei);
- atmospheric cleansing (for example, sinks for pollutants such as tropospheric ozone, ammonia, NO_x, sulfur dioxide, and methane);
- pollution sources (for example, particulates from biomass burning, NO_x, carbon monoxide, and precursors of tropospheric ozone); and
- nutrient redistribution (for example, source of nitrogen deposited elsewhere and reduction of erosion and nutrient-rich airborne dust compared with bare soil).

Changes in ecosystems have made a large contribution to the changes in radiative forcing (the cause of global warming) between 1750 and the present. The main drivers are deforestation, fertilizer use, and agricultural practices. Ecosystem changes account for about 10–30% of the radiative forcing of carbon dioxide from 1750 to present and a large proportion of the radiative forcing due to methane and nitrous oxide. Ecosystems are currently a net sink for carbon dioxide and tropospheric ozone, while they remain a net source of methane and nitrous oxide. Management of ecosystems has the potential to significantly modify concentrations of a number of greenhouse gases, although this potential is small in comparison to IPCC scenarios of fossil fuel emissions over the next century (*high certainty*). Ecosystems influence the main anthropogenic greenhouse gases in several ways:

- **Carbon dioxide**—Preindustrial concentration, 280 parts per million; concentration in 2000, 370 ppm. About 40% of the emissions over the last two centuries and about 20% of the CO_2 emissions during the 1990s originated from changes in land use and land management, primarily deforestation. Terrestrial ecosystems have been a sink for about a third of cumulative historical emissions and a third of the 1990s total (energy plus land use) emissions. The sink may be explained partially by afforestation/reforestation/forest management in North America, Europe, China, and other regions, and partially by the fertilizing effects of nitrogen deposition and increasing atmospheric CO_2. Ecosystems were on average a net source of CO_2 during the nineteenth and early twentieth century and became a net sink sometime around the middle of the last century (*high certainty*).
- **Methane**—Preindustrial concentration, 700 parts per billion; concentration in late 1990s, 1750 ppb. Natural processes in wetland ecosystems account for 25–30% of current CH_4 emissions, and about 30% of emissions are due to agriculture (ruminant animals and rice paddies).
- **Nitrous oxide**—Preindustrial concentration, 270 ppb; concentration in late 1990s, 314 ppb. Ecosystem sources account for about 90% of current N_2O emissions, with 35% of emissions from agricultural systems, primarily driven by fertilizer use.
- **Tropospheric ozone**—Preindustrial, 25 Dobson Units; late 1990s, 34 DU. Several gases emitted by ecosystems, primarily due to biomass burning, act as precursors for tropospheric ozone. Dry deposition in ecosystems accounts for about half the tropospheric ozone sink. The net global effect of ecosystems is a sink for tropospheric ozone.

Land cover changes between 1750 and the present have increased the reflectivity to solar radiation (albedo) of the land surface (*medium certainty*), partially offsetting the warming effect of associated CO_2 emissions. Deforestation and desertification in the tropics and sub-tropics leads to a reduction in regional rainfall (*high certainty*). The biophysical effects of ecosystem changes on climate depend on geographical location and season. With *high certainty*:

- Deforestation in seasonally snow-covered regions leads to regional cooling during the snow season due to an increase in surface albedo and leads to warming during summer due to reduction in evapotranspiration.
- Large-scale tropical deforestation (hundreds of kilometers) reduces regional rainfall, primarily due to decreased evapotranspiration.
- Desertification in tropical and sub-tropical drylands leads to decrease in regional rainfall due to reduced evapotranspiration and increased surface albedo.

Biophysical effects such as this need to be accounted for in the assessment of options for mitigating climate change. For example, the warming effect of reforestation in seasonally snow-covered regions due to albedo decrease is likely to exceed the cooling effect of additional carbon storage in biomass.

Ecosystems are currently a net sink for several atmospheric pollutants, including tropospheric ozone (which causes respiratory problems and plant damage), CO_2 (which leads to ocean acidification, with negative effects on calcifying organisms such as corals and coccoliths), and ammonia (which contributes to health problems, eutrophication of lakes, and acidification of N-saturated ecosystems). Fertilizer use has led to increased ecosystem emissions of N gases (which contribute to acid rain and eutrophication of lakes). The net effect of ecosystems on acid rain and stratospheric ozone depletion are small compared with industrial emissions.

Vegetation burning, both natural and human-induced, is a major cause of air pollution. Particulates, tropospheric ozone, and carbon monoxide are toxic to humans at levels reached as a result of biomass burning. In the 1990s, biomass burning was responsible for about a quarter of global carbon monoxide emissions, just under half of particulate aerosol emissions, and a large but poorly quantified fraction of tropospheric ozone precursor emissions. Smoke plumes cause changes in plant productivity (generally decreases), changes in rainfall (generally decreases), and economic losses due reduced visibility (affecting transport, for example).

The self-cleansing ability of the atmosphere is fundamental to the removal of many pollutants and is affected by ecosystem sources and sinks of various gases. Removal of pollutants involves chemical reactions with the hydroxyl radical. OH concentration and hence atmospheric cleansing capacity has declined since preindustrial times but likely not by more than 10%. The net contribution of ecosystem changes to this decline is currently unknown. The reactions are complex, but generally emissions of NO_x and hydrocarbons from biomass burning increase tropospheric ozone and OH concentrations, and emissions of CH_4 and carbon monoxide from wetlands, agricultural practices, and biomass burning decrease OH concentration.

The most important ecosystem drivers of change in climate and air quality in the past two centuries have been deforestation (net CO_2 emissions, net increase in surface albedo, and rainfall reduction), agricultural practices (increasing emissions of CH_4, N_2O, and other N gases), and biomass burning (emissions of toxic pollutants). Wetland draining has decreased CH_4 emissions but increased emissions of CO_2 and N_2O. The net short-term (20–100 year) effect on radiative forcing is cooling (*medium certainty*), while the long-term effect is probably warming (*low certainty*). Management of drylands to increase vegetation cover reduces soil carbon loss, reduces dust emissions, and increases water recycling. Loss of species richness has probably not had significant impacts on climate and air quality in the recent past, but shifts in functional types—such as trees versus grasses, deciduous versus evergreen trees, or calcifying versus non-calcifying plankton—could alter the biological storage of carbon and trace gas emissions in the future.

Ecosystem interactions with the atmosphere are highly nonlinear, with many feedbacks and thresholds that, if passed, may lead to abrupt changes in climate and land cover. Human-induced land cover changes may become irreversible due to ecosystem-climate feedbacks. For example, in the Sahara-Sahel region, two alternative land cover types are theoretically sustainable: savanna and desert. If a threshold in loss of vegetation cover contributing to rainfall reduction is crossed, the desert state becomes self-sustaining (*low certainty*). The complexity and incomplete understanding of the feedbacks make it hard to predict thresholds and their future changes.

13.1 Introduction

Living matter builds bodies of organisms out of atmospheric gases such as oxygen, carbon dioxide and water, together with compounds of nitrogen and sulphur, converting these gases into liquid and solid combustibles that collect the cosmic energy of the sun. After death, it restores these elements to the atmosphere by means of life's processes . . . Such a close correspondence between terrestrial gases and life strongly suggest that the breathing of organisms has primary importance in the gaseous system of the biosphere; in other words, it must be a planetary phenomenon.

(Vernadsky 1926)

The composition of the atmosphere and the climate we experience are products of the co-evolution of the biosphere, atmosphere, and geosphere over billions of years (Vernadsky 1926; Zavarzin 2001). The climate and the concentration of various gases in the atmosphere are determined by the flow of energy (radiation, heat) and materials (such as water, carbon, nitrogen, trace gases, aerosols) between the atmosphere, ocean, soils, and vegetation. These interlinking components are referred to collectively as the Earth System to stress their inter-dependence. (See Box 13.1.) Lovelock and Margulis (1974) proposed the Gaia Hypothesis: that biospheric feedbacks regulate the climate within a range suitable for life. Although not universally accepted, Gaia remains an inspirational idea in Earth System science (Lenton 1998; Watson 1999; Kirchner 2003).

Ecosystems alter atmospheric chemistry, providing both sources and sinks for many atmospheric constituents that affect air quality or that affect climate by changing radiative forcing. In this chapter we refer to these as ''biogeochemical effects.'' Ecosystems further influence climate through the effects of their physical properties on water fluxes (such as rainfall) and energy balance (such as temperature). (See Figure 13.1.) We refer to these as ''biophysical effects.''

The ability of ecosystems to modify climate and air quality and thereby provide a service to humans occurs both through natural processes and as a result of ecosystem management. For example, the conversion of carbon dioxide and water to oxygen by ecosystems billions of years ago could be considered the fundamental ecosystem service, enabling evolution and maintenance of a breathable atmosphere. Not all impacts of ecosystems on the atmosphere and climate are beneficial to human well-being, and the effects often depend on the location and magnitude of the impact. A change in magnitude can change the sign—for example, a small temperature increase may help some people at some locations by, say, extending the crop-growing season or potential area, but a large temperature increase is detrimental to the majority of people in the majority of locations through, for instance, damage to crops and human health (IPCC 2001d).

This chapter assesses all major effects of ecosystems on climate and air quality, be it ''good'' or ''bad'' for human well-being. The impacts of climate and air quality on ecosystems and human well-being, in contrast, are dealt with in detail by other assessments (e.g., IPCC 2001b, 2001d; WHO 2002; WMO 2003; Brasseur et al. 2003a; Emberson et al. 2003) and are not the focus of the MA other than as drivers of ecosystem change (which are summarized in Chapter 3 and in MA *Scenarios,* Chapter 7, in several sections later in this chapter, and in relevant sections of other chapters). For more detailed reviews of the science behind global climate change see IPCC (2001a); see also Kabat et al. (2004) and Kedziora and Olejnik (2002) on biophysical mechanisms and impacts and Brasseur et al. (2003a) on atmospheric chemistry.

During the Quaternary period (approximately the past 2.5 million years), the Earth System has shown a persistent pattern of glacial-interglacial cycles during which the climate and atmospheric composition varied between fairly consistent bounds, as shown by ice core measurements (Petit et al. 1999, EPICA community members 2004). These quasi-periodic cycles are triggered primarily by variations in Earth's orbit. The associated changes in climate and in carbon dioxide, methane, and other atmospheric constituents are controlled by mechanisms involving both terrestrial and ocean ecosystems (IPCC 2001a; Prentice and Raynaud 2001; Steffen et al. 2004; Joos and Prentice 2004). However, the balance of these mechanisms is not well understood, and this implies uncertainties in predicting future changes, especially on time scales of centuries or longer.

Burning fossil fuels, changes in land cover, increasing fertilizer use, and industrial emissions over the past two centuries have propelled the Earth System outside the boundaries of the natural system dynamics of the Quaternary period (*high certainty*). The current concentration of carbon dioxide and methane are unprecedented in the last 420,000 years and possibly in the last 20 million years, and the rate of increase is unprecedented in at least the last 20,000 years (IPCC 2001a, 2001d; see also MA *Scenarios,* Chapter 7). The increase in temperature in the twentieth century was the largest of any 100 years in the last 1,000 years (IPCC 2001a, 2001d). The Intergovernmental Panel on Climate Change concluded that ''there is newer and stronger evidence that most of the warming observed over the last 50 years is attributable to human activities'' (IPCC 2001a, 2001d).

Human intervention in global biogeochemical cycles has triggered a chain of biogeochemical and biophysical mechanisms that will continue to affect both atmospheric chemistry and climate on time scales from years to millennia (*high certainty*). Even if emissions ceased today, past emissions would continue to have an impact in the future related to the lifetime of the emitted gas in the

BOX 13.1

The Earth System, Thresholds, and Feedbacks

The "Earth System" has several interacting components: the atmosphere, ocean, terrestrial and marine biosphere, cryosphere (ice, including permafrost), the pedosphere (soils), and humans. These components are tightly linked with each other. Ecosystems are an integral part of the Earth System; they provide different services to the climate system via numerous physical and chemical mechanisms that control fluxes of energy (radiation, heat), water, and atmospheric constituents.

The Earth System is highly nonlinear: climate, air quality, and ecosystem distribution across the planet may change quite abruptly in response to smooth changes in external forcing (as occurred, for example, during the last deglaciation about 15,000 years ago). Current theories support the possibility of multiple stable states (regimes of a particular balance of components that are resistant to change) and abrupt transitions between these different states or regimes (as with desert and vegetation in the Sahara/Sahel region). These transitions are reinforced by positive (amplifying) feedback loops between components of the Earth System, whereby a small change in one component can cause changes in other components that continue to push the system away from its previous state and toward a new one. Conversely, negative (stabilizing) feedbacks can maintain stable states by preventing the system moving beyond certain thresholds.

Numerous examples of feedbacks between ecosystems, climate, and atmospheric constituents are mentioned throughout this chapter.

- **Climate–greenhouse gases, positive feedback.** Warming enhances emissions of CH_4, N_2O, and tropospheric ozone precursors (NO_x and VOCs) (*very certain*). Warming reduces inorganic ocean uptake of CO_2, increases soil emissions of CO_2, and has been predicted to reduce carbon storage in terrestrial and ocean ecosystems; the net result is an increase in atmospheric CO_2 (*high certainty*). Increasing concentration of greenhouse gases causes further warming.
- **CO_2** fertilization–CO_2 uptake, negative feedback. Increased atmospheric concentration of CO_2 has a fertilizing effect on plants, increasing uptake of CO_2 and reducing atmospheric concentrations (*high certainty*).
- **Taiga-tundra albedo-temperature, positive feedback.** Afforestation of snow-covered regions due to northward movement of forest boundaries in a warmer world, or due to tree planting, reduces albedo, leading to further warming, less snow, and further reduced albedo (*high certainty*).
- **Tropical rainforest–precipitation, positive feedback.** Large-scale reduction in tropical rainforest cover reduces regional precipitation, potentially causing further forest loss and precipitation reduction (*high certainty*).
- **Sahara-Sahel vegetation–precipitation, positive feedback.** Decreased vegetation cover increases albedo, reduces soil-atmosphere water recycling, and reduces monsoon circulation, decreasing precipitation, all of which further suppress vegetation cover (*high certainty*).
- **DMS-cloudiness, negative feedback.** Emissions of DMS by ocean ecosystems (and of VOCs by terrestrial ecosystems) increase cloud condensation nuclei, cooling Earth, reducing photosynthesis and emissions of DMS (and VOCs), and increasing thermal stability, reducing cloud formation (*medium certainty*).
- **Tropical forest–tropospheric ozone, positive feedback.** High levels of tropospheric ozone have a deleterious effect on vegetation, compromising further uptake of tropospheric ozone (*medium certainty*).
- **Pollution–reduction in cleansing capacity, positive feedback.** For example, CH_4 in the atmosphere reduces OH concentration and atmospheric cleansing capacity, increasing lifetime and atmospheric concentrations of CH_4 (*high certainty*).

atmosphere, atmospheric chemistry, and inertia in different parts of the Earth System (such as the uptake and mixing of carbon dioxide in the ocean and the response of sea level rise to temperature and ice melting) (IPCC 2001d Figure 5.2).

A summary of the main ecosystem effects on climate and air quality, the drivers, and the impacts on human well-being that are discussed in this chapter is presented in Figure 13.2. Changes in climate or air quality are often simultaneously affected by several atmospheric constituents. Likewise, a particular atmospheric constituent can affect both climate and air quality. Furthermore, ecosystem drivers (such as deforestation, biomass burning, and agricultural practices) often simultaneously affect biogeochemical and biophysical properties, and their effects can work in the same or opposite directions. Thus it is often not possible to quantify cause and effect. Each atmospheric constituent and vegetation property considered in this chapter is summarized in Table 13.1, along with its magnitude and distribution, main drivers, and impacts.

13.2 Biogeochemical Effects of Ecosystems on Climate: Greenhouse Gases and Aerosols

Many atmospheric constituents determine the radiative forcing of Earth's climate (IPCC 2001a, 2001d). (Radiative forcing is the change in net vertical irradiance (radiation or energy) of the tropopause (upper troposphere), with an increase in radiative forcing implying an increase in global temperature. Global warming potential is an index, relative to CO_2, describing the radiative properties of greenhouse gases based on their effectiveness at absorbing long-wave radiation, and the time they remain in the atmosphere. For more detailed explanations of these terms, see IPCC (2001a, 2001d).)

Key atmospheric compounds that have an ecosystem source or sink include:

- greenhouse gases that absorb long-wave radiation from Earth's surface, leading to warming—carbon dioxide, methane, tropospheric ozone (formed from precursors NO_x, methane, and volatile organic compounds), and nitrous oxide; and
- aerosols, of which some types (such as sulfate aerosols) reflect solar radiation leading to cooling, while others (such as black carbon) trap radiation leading to warming.

Ecosystems have played a significant role in past radiative forcing (see Figure 13.3A) and in current sources and sinks of greenhouse gases and aerosols (see Figure 13.3B). The net biochemical contribution of ecosystems to historical radiative forcing has been to increase global warming, accounting for about 10–30% of the radiative forcing of CO_2 from 1750 to the present (Brovkin et al. 2004) and a large proportion of the warming due to CH_4 and N_2O, while reducing tropospheric ozone forcing. Ecosystems are currently a net sink for CO_2 and tropospheric ozone, while they remain a net source of CH_4 and N_2O.

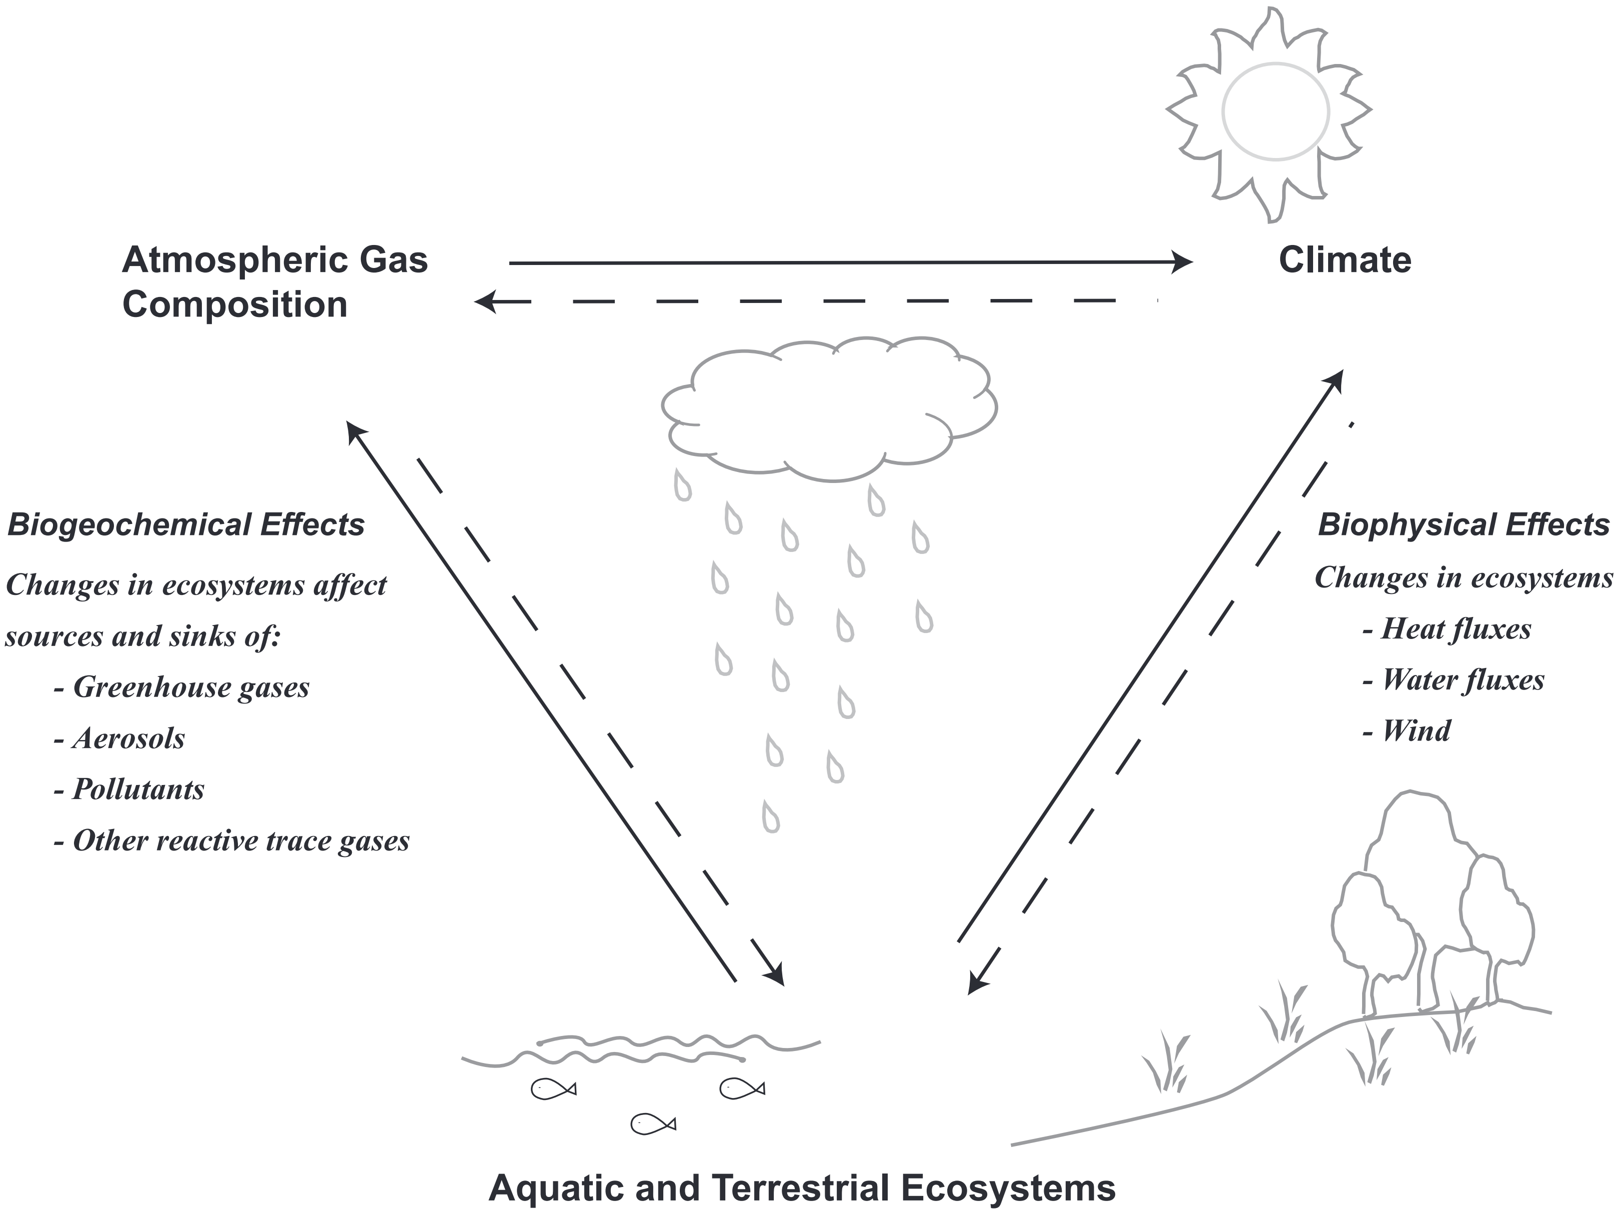

Figure 13.1. Ecosystem Effects on the Atmosphere and Climate. Ecosystems, the concentration of many atmospheric gases/species, and the climate all strongly interact. However, it is the effect of ecosystems on atmospheric air quality (as sources and sinks of pollutants) and on the climate (both directly due to biophysical properties of vegetation, and indirectly as a source and sink of greenhouse gases and aerosols) that is the focus of this chapter, as indicated by the solid arrows.

13.2.1 Carbon Dioxide

Increasing carbon dioxide concentration has had more impact on historical radiative forcing than any other greenhouse gas. In addition, CO_2 has a fertilizing effect on most land plants, while rapid injection of CO_2 into the atmosphere causes acidification of the global ocean, with negative implications for calcifying organisms. Ecosystems are both a source and sink for CO_2. Management of ecosystems for carbon storage is currently regarded as an important ecosystem service by policy-makers, therefore more information is included for this gas than for others. A summary of pertinent details of the carbon cycle is presented in this section; for more details, see Prentice et al. (2001), Kondratyev et al. (2003), and Field and Raupach (2004).

Carbon, the basic building block of all animal and plant cells, is converted to carbohydrates by the process of plant photosynthesis. Terrestrial plants capture CO_2 from the atmosphere; marine plants (phytoplankton) take up carbon from seawater, which exchanges CO_2 with the atmosphere. Plant, soil, and animal respiration returns carbon to the atmosphere, as does burning biomass. Burning fossilized biomass (fossil fuels) also returns carbon, captured by plants in Earth's geological history, to the atmosphere.

CO_2 is continuously exchanged between the atmosphere and the ocean; it dissolves in surface waters and is then transported into the deep ocean (the "solubility pump"). It takes roughly one year for CO_2 concentration in surface waters to equilibrate with the atmosphere, but subsequent mixing between surface waters and deep waters, which drives the ongoing uptake of increased atmospheric CO_2, takes decades to centuries. Some of the dissolved carbon that is taken up by marine plants sinks in the form of dead organisms, particles, and dissolved organic carbon (the "biological pump"). A small amount remains in ocean sediments; the rest is respired at depth and eventually recirculated to the surface. The biological pump acts as a net sink for CO_2 by increasing the concentration of CO_2 at depth, where it is isolated from the atmosphere for decades to centuries, causing the concentration of CO_2 in the atmosphere to be about 200 parts per million lower than it would be in the absence of marine life (Sarmiento and Toggweiler 1984; Maier-Reimer et al 1996).

It has been widely assumed that ocean ecosystems are at steady state at present, although there is now much evidence of large-scale trends and variations (Beaugrand et al. 2002; Chavez et al. 2003; Richardson and Schoeman 2004). Changes in marine ecosystems, such as increased phytoplankton growth rate due to the fertilizing effect of iron in dust (see section 13.4.4.3) and shifts in species composition due to ocean acidification (see section 13.4.2.1) or for other reasons, have the potential to alter the oceanic carbon sink. The net impact of changes in ocean biology on global CO_2 fluxes is unknown.

CO_2 concentration varied within consistent bounds of 180 to 300 ppm during glacial-interglacial cycles. Prior to the industrial

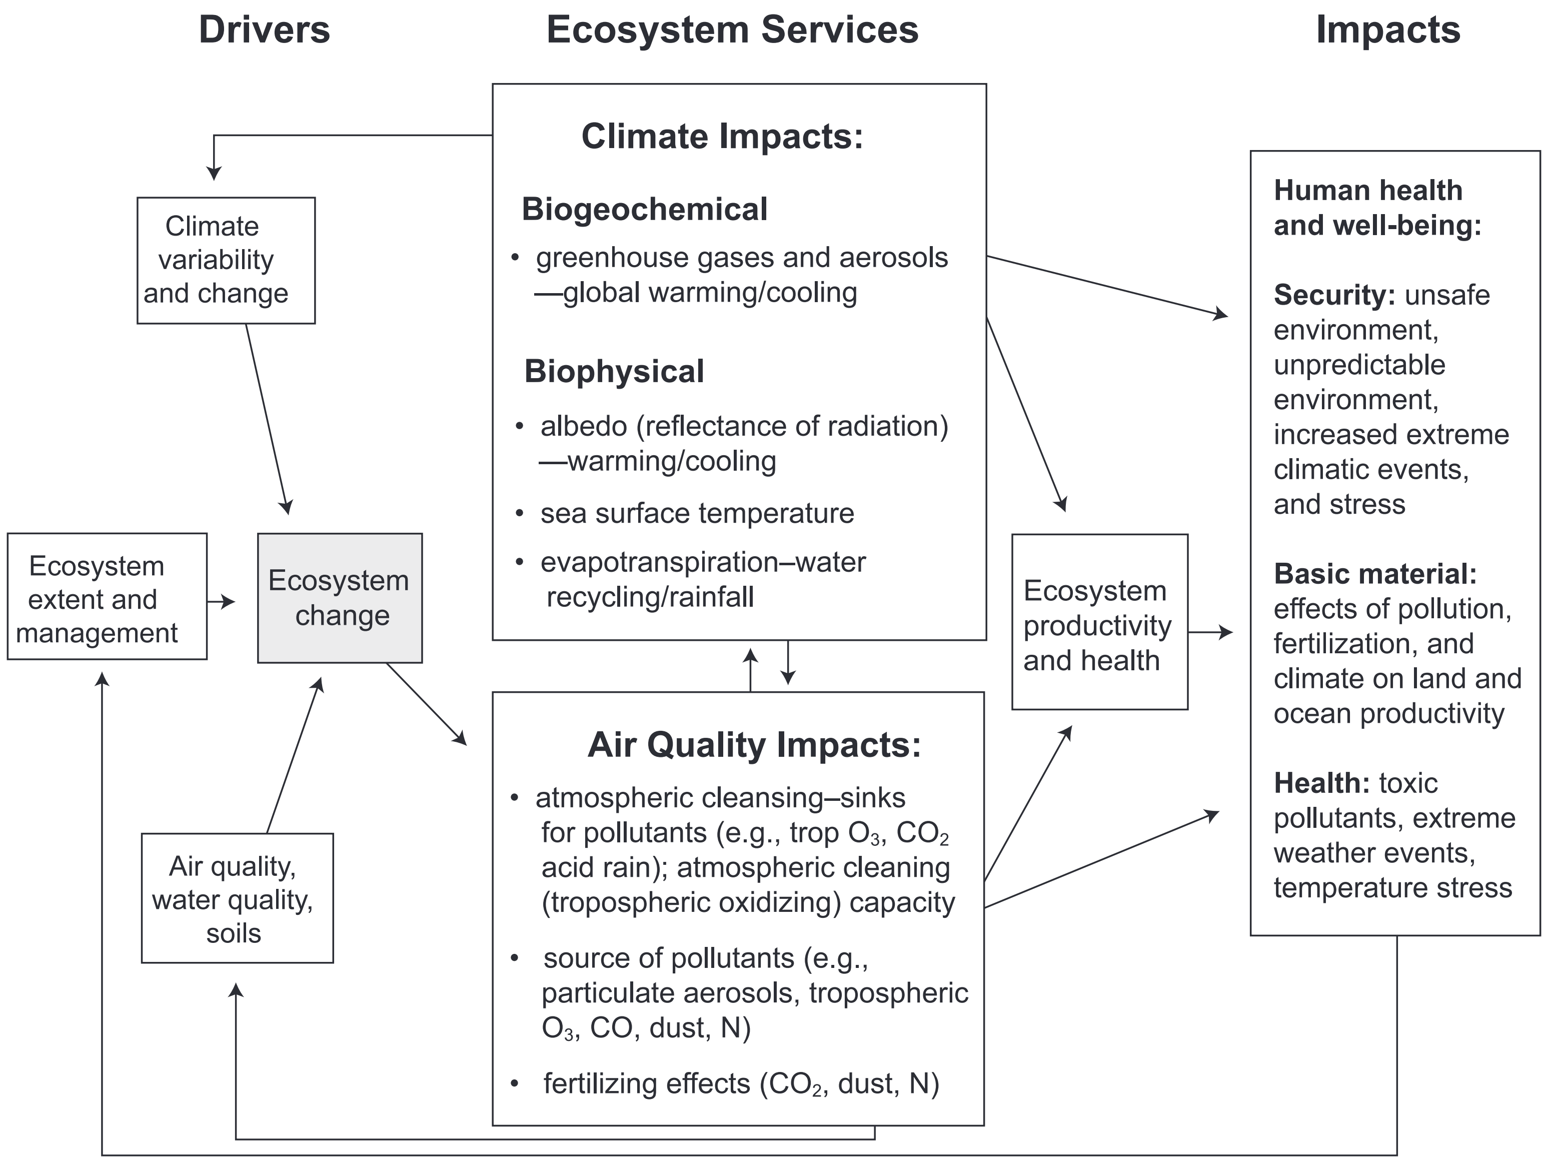

Figure 13.2. Ecosystem Effects on Climate and Air Quality: Services, Drivers, and Impacts on Human Well-being. This figure summarizes the services, drivers, and impacts discussed in this chapter. Arrows represent a direct impact on human health and well-being of the two ecosystems services of this chapter (climate regulation and regulation of atmospheric composition). Note: not all arrows are shown, for simplicity (e.g., direct impacts of climate change on atmospheric composition through changes in atmospheric chemistry).

revolution (that is, before 1750), CO_2 concentration was about 280 ppm, and since then it has risen rapidly, reaching 370 ppm in 2000 (MA *Scenarios,* Chapter 7). It has been estimated that about 40% of CO_2 emissions over the last two centuries came from land use change (primarily deforestation), while 60% came from fossil fuel burning (DeFries et al. 1999). (See Figure 13.4.) About 40% of total CO_2 emissions have remained in the atmosphere.

Oceans are estimated to have taken up approximately a quarter, an amount that can be fully accounted for by the solubility pump. This means that terrestrial ecosystems took up about a third of all emissions (Prentice et al. 2001, House et al. 2002) through a combination of ecosystem processes whose relative importance is still not firmly established but that probably include growth of replacement vegetation on cleared land (e.g., Dixon et al. 1994; Houghton et al. 1998; McGuire et al. 2001; Goodale et al. 2002); agricultural and forest management (e.g., Spiecker et al. 1996; Houghton et al. 1999); other land management practices, such as fire suppression leading to woody encroachment (e.g., Houghton et al. 1999); and fertilizing effects of elevated CO_2 and nitrogen deposition (e.g., Lloyd 1999; Holland et al. 1997).

Analyses of historical atmospheric CO_2 concentrations preserved in ice cores and more recent atmospheric measurements suggest that the land was a net source of CO_2 during the nineteenth and early twentieth centuries (that is, emissions exceeded uptake), and that land changed to a net sink around the 1940s (Bruno and Joos 1997; Joos et al. 1999). Model analyses with reconstructed land use and environmental data indicate a later change from source to sink (1960s to 1970s), due to decreasing deforestation in the tropics, forest regrowth in North America and Asia (Houghton 2003; McGuire et al. 2001; Ramankutty and Foley 1999; Brovkin et al. 2004), and increased uptake of CO_2 by extant ecosystems (McGuire et al. 2001). However, there are uncertainties in modeling the magnitude of changes in the terrestrial carbon budget resulting from several sources: differences in land cover data sets; the lack of systematic global inventory data for vegetation and soil carbon density; and poor quantification of N and CO_2 fertilization effects and climate impacts on ecosystems (Prentice et al. 2001; House et al. 2003).

Measured fluxes of CO_2 during the 1980s and 1990s are shown in Table 13.2. During this period, ecosystems were a net CO_2 sink. Model results indicate that, during the 1990s, terrestrial ecosystems accounted for about 20% of the total emissions (land plus fossil fuels) but were a sink for about a third of the total emissions. Figure 13.5 (in Appendix A) shows a reconstruction of the spatial distribution of ocean and terrestrial net fluxes in the latter half of the 1990s, based on atmospheric measurements (Rödenbeck et al. 2003). These net fluxes are not broken down into source/sink terms or their underlying drivers. Information on regional fluxes due to different drivers assessed by different methods is reviewed in House et al. (2003). Generally, areas of deforestation and forest degradation in the tropics are losing carbon, while areas of afforestation and forest growth in North America and Europe are gaining carbon (House et al. 2003).

Table 13.1. Summary Table of Atmospheric Constituents and Biophysical Factors Affected by Ecosystems: Trends, Drivers, and Impacts on Ecosystem and Human Well-being[a]

Atmospheric Constituents	Sources	Sinks	Trends	Ecosystem Drivers	Impacts
CO_2	*Ecosystem:* land use change (mainly deforestation) ≈1.6 (0.5 to 3.0) PgC/yr (net land flux uptake of 1.2 ± 0.9 PgC/yr) *Other:* fossil fuel 6.3 ± 0.4 PgC/yr *[note: numbers updated since IPCC 2001a, b; see Table 13.2]*	*Ecosystem:* terrestrial uptake (photosynthesis) ≈ 2.8 (0.9 to 5.0) PgC/yr *Other:* ocean uptake (dissolution and mixing) 1.9 ± 0.7 PgC/yr	*Atmospheric concentration:* Increased from preindustrial 280 ppm to 370 ppm (2000). Increased by 3.2 ± 0.1 PgC/yr during 1990s. Average annual rate of increase rising. Projected to continue rapid increase due to fossil fuel burning and long atmospheric lifetime: ≈ 250 years, but a small amount persists for much longer. *Ecosystem:* Terrestrial source until around middle of last century, then increasing sink. Sink likely to decline due to limited management opportunities, saturation of CO_2 fertilization effect, and climate impacts. Ocean ecosystems show evidence of large-scale trends and variations, but the net impact of these changes on CO_2 fluxes is unknown. Non-biological uptake by the ocean will continue, but the rate will decline with increasing CO_2 concentration and warmer climate.	– climate change – land use and land management: deforestation, afforestation, reforestation, forest management, agricultural management – biomass burning – N fertilization – Fe fertilization (dust) – CO_2 fertilization effects	– climate: positive radiative forcing (heating) – ocean acidification: reduced growth of oceanic calcifying organisms including corals, potential negative impacts on fish production – “fertilizing” effect on plants
CH_4	*Ecosystem:* peatlands/wetlands 92–237 TgC/yr ruminants 80–115 TgC/yr rice 25–100 TgC/yr termites 20 TgC/yr oceans 10–15 TgC/yr biomass burning 23–55 TgC/yr *Other:* energy 75–110 TgC/yr, landfills 35–73 TgC/yr waste treatment 14–25 TgC/yr methane hydrates 5–10 TgC/yr	*Ecosystem:* soil uptake 30 TgC/yr *Other:* tropospheric OH reactions 506 TgC/yr stratospheric loss 40 TgC/yr	*Atmospheric concentration:* Increased from preindustrial 700 ppb to 1,745 ppb in 1998. Increased 7.0 ppb/yr during 1990s. Atmospheric lifetime: 8.4 years. Growth rate peaked in 1981 at 17 ppb/yr but is highly variable from year to year. *Ecosystem:* Increasing terrestrial source; sink relatively small contribution to the overall trend; growth rate slowed 1990–96 partly due to decreased northern wetland emissions rates from anomalously low surface temperatures and reduction in OH from strat. O_3 depletion; removal rates increased 1990–2000 by +0.5%/yr.	– climate change – land use and land management: agricultural practices, wetland draining – biomass burning – flooding	– climate: positive radiative forcing (greenhouse gas, heating) – tropospheric ozone formation – stratospheric ozone formation – tropospheric oxidizing capacity reduction
CO	*Ecosystem:* mostly tropical sources vegetation 150 TgC/yr oceans 50 TgC/yr biomass burning 700 TgC/yr *Other:* oxidation of: – CH_4 800 TgC/yr – VOCs 430 TgC/yr fossil/domestic fuel 650 TgC/yr	*Ecosystem:* dry (surface) deposition 190 TgC/yr (Hauglustaine et al. 1998) *Other:* OH reaction 1920 TgC/yr (Hauglustaine et al. 1998)	*Atmospheric concentration:* Preindustrial concentration unknown, 1998 concentration 80 ppb. Increasing 6 ppb/yr during 1990s. Atmospheric Lifetime: 0.08–0.25 years. Slowly increasing till late 1980s, then decreased possibly due to catalytic converters decreasing automobile emissions, increased again late 1990s. Increase may be mostly in Northern Hemisphere (Haan et al. 1996), which already contains twice as much CO as Southern Hemisphere.	– biomass burning – ecosystem uptake – land use and land management: vegetation cover	– human health: hypoxia, neurological problems, cardiovascular disease – tropospheric ozone precursor – tropospheric oxidizing capacity reduction, removal of OH – indirect climate impacts: reacts with other greenhouse gases
N_2O	*Ecosystem:* tropical soils 4.0 TgN/yr temperate soils 2.0 TgN/yr agricultural soils 4.2 TgN/yr ocean 3 TgN/yr cattle/feedlots 2.1 TgN/yr biomass burning 0.5 TgN/yr *Other:* industrial 1.3 TgN/yr atmosphere (NH_3 oxid.) 0.6 TgN/yr	*Ecosystem:* N_2O uptake by soils and conversion to N_2 (relatively small) *Other:* stratospheric reactions that deplete ozone 12.3 TgN/yr	*Atmospheric concentration:* Increased from preindustrial 270 ppb to 314 ppb in 1998. Increased by 0.8ppb/yr during 1990s. Increase rate slower in 1990s than 1980s. Atmospheric lifetime: 120 years. *Ecosystem:* Terrestrial and oceanic sources, exponential rise in concentration since preindustrial. Agricultural emissions increased fourfold from 1900 to 1994 (Kroeze et al. 1999).	– climate change: emission higher in wetter soils – land use and management: acceleration of the global N cycle due to fertilizer use and agricultural N fixation, animal production – biomass burning – N deposition – atmospheric NO_x pollution	– climate: positive radiative forcing (greenhouse gas, heating) – stratospheric ozone depletion

Table 13.1. *continued*

Atmospheric Constituents	Sources	Sinks	Trends	Ecosystem Drivers	Impacts
NO_x (NO and NO_2) (precursors of nitrate)	*Ecosystem:* soils (mostly tropical) 13–21 TgN/yr biomass burning 7.1 TgN/yr *Other:* fossil fuel 33.0 TgN/yr aircraft 0.7 TgN/yr lightning 5.0 TgN/yr stratosphere <0.5 TgN/yr	*Ecosystem:* canopy uptake of soil emissions 4.7–8TgN/yr and of wet and dry deposition *Other:* reaction with OH to form nitric acid (HNO_3), which collects on aerosols (dry deposition) or dissolves in precipitation (wet deposition)	*Atmospheric Concentration:* Difficult to quantify because of the tremendous spatial and vertical variability. Atmospheric Lifetime: <0.01–0.03 years. Nitrate concentrations declined recently due to emission controls. *Ecosystem:* Difficult to quantify trend, largely stable.	– climate change: warming increases emissions – land use and management: tropical deforestation reduces soil emissions, but reduces canopy uptake more so net emissions increase. Acceleration of global N cycle due to fertilizer use, etc. – biomass burning	– human health: direct respiratory effects and respiratory effects of aerosols – tropospheric ozone precursor – tropospheric oxidizing capacity increase – acid rain formation – fertilization of plants (deposition) – eutrophication of lakes (deposition and nitrate leaching)
NH_3	*Ecosystem:* domestic animals 22 TgN/yr fertilizer use 9 TgN/yr crops (+ decomposition) 4 TgN/yr natural soils 2 TgN/yr oceans 8 TgN/yr biomass burning 6 TgN/yr	*Ecosystem:* direct soil and plant uptake wet and dry deposition (affected by vegetation cover) *Other:* reaction with OH (very small percentage)	*Atmospheric Concentration:* Documentation of trends is challenging because of the relatively short atmospheric lifetime. Atmospheric lifetime: 1 day–1 week. *Ecosystem:* Rise in agricultural sources exponential, much of the growth occurring since 1950. Main source areas Europe and North America (fertilizer use) and India (cattle).	– land use and management: acceleration of global N cycle due to fertilizer use, agricultural intensification/management; land cover change – biomass burning	– human health: hypoxia, pfisteria, respiratory effects – eutrophication of lakes (deposition and nitrate leaching) – acid neutralization and production – aerosol/particulate formation
SO_2/SO_4/H_2S DMS (dimethylsulfide) (precursors of sulfate aerosols)	*Ecosystem:* biomass burning [SO_2] 2.2 Tg/yr land biota [H_2S] 1.0 Tg S/yr marine plankton [DMS] 24 Tg S/yr *Other:* fossil fuel emissions [SO_2] 76 Tg S/yr volcanoes [SO_2] 9.3 Tg S/yr	*Ecosystem:* direct soil and plant uptake wet and dry deposition (affected by vegetation cover) ecosystems are a sink for about 30% of SO_2 emissions and sulphate aerosols *Other:* reaction with OH	*Atmospheric concentration:* Sulfate concentration in 1960s four times that of preindustrial, but declined recently due to stringent emissions regulations. Patchy distribution around source areas — polluted regions North America, Europe, and China. SO_2 emissions declining in North America and Europe, rising in South and East Asia. Emissions are projected to decrease substantially over the next century. *Ecosystem:* Mostly stable.	– climate change – land use and management; land cover change – biomass burning	– human health: respiratory effects of aerosols – climate: negative radiative forcing (cooling) – indirect climate impacts: cloud condensation nuclei – acid rain – reduced NPP though reduced solar radiation
VOCs (volatile organic compounds)	*Ecosystem:* vegetation (mostly tropical): isoprene 220 TgC/yr terpene 127 TgC/yr acetone 50 TgC /yr methanol 70–350 Tg/yr biomass burning 33 TgC/yr *Other:* fossil fuel 161 TgC/yr	*Ecosystem:* direct soil and plant uptake wet and dry deposition (affected by vegetation cover) *Other:* reaction with OH	*Atmospheric concentration:* Difficult to quantify because of the tremendous spatial and vertical variability. Atmospheric lifetime: < 1 day to >1 week. Emissions probably increased due to increasing use of gasoline and other hydrocarbon products. *Ecosystem:* Deforestation has probably decreased natural emissions.	– climate change (warming increases emissions) – land use and management: forest cover change, agricultural management, use of fertilizers – biomass burning – N deposition	– human health: aerosol precursor (terpene), respiratory effects – indirect climate impacts: cloud condensation nuclei – tropospheric ozone formation (isoprene) – tropospheric oxidizing capacity (increase) – organic acid formation – acid rain
Aerosols: organic matter	*Ecosystem:* biomass burning 54 Tg/yr biogenic (VOC oxidation, plant debris, humic matter and microbial particles) 56 Tg/yr *Other:* fossil fuel 28 Tg/yr	wet and dry deposition (affected by vegetation cover)	*Ecosystem:* Biogenic aerosols increasing due to increase in oxidizing agents, e.g., NO_3 and O_3, possible three- to fourfold increase since preindustrial times (Kanakidou et al. 2000). Not much is known about emissions from plants, microbes, and humic matter, but likely to be strongly affected by land use change.	– land use and management – biomass burning	– human health: respiratory effects – climate impacts: negative radiative forcing (cooling) – indirect climate impacts: cloud condensation nuclei – reduced NPP though reduced solar radiation

(continues over)

Table 13.1. *continued*

Atmospheric Constituents	Sources	Sinks	Trends	Ecosystem Drivers	Impacts
Aerosols: black carbon (0–2 μm)	*Ecosystem:* biomass burning 5.7 Tg/yr *Other:* fossil fuel 6.6 Tg/yr	wet and dry deposition (affected by vegetation cover)	*Atmospheric concentration:* Concentration and trend uncertain.	– land use and management: vegetation cover – biomass burning	– climate: positive radiative forcing (heating) – human health: respiratory effects – reduced NPP though reduced solar radiation
Aerosols: dust	*Ecosystem:* mineral (soil) dust 2000 Tg/yr (1–2 μm 300 Tg/yr); mainly from desert/dryland areas, <10 % from disturbed soil surfaces (Tegen et al. 2004) *Other:* industrial dust (>1 μm) 100 Tg/yr	wet and dry deposition (affected by vegetation cover)	*Atmospheric concentration:* Concentration and trend uncertain. *Ecosystem:* Decrease in North American emissions since dust bowl years due to changes in management. Emissions from Sahara/Sahel increased significantly since 1960s, possibly due to changing wind patterns and desertification. Chinese desert areas and loess plateau variable, trend and causes not clear. Climate change impacts–model results inconclusive.	– climate variability – climate change – land use and management: reduction in land cover, agricultural management – desertification	– human health: respiratory effects, irritation – climate impacts: radiative forcing net sign and magnitude unclear as reflects incoming radiation and traps outgoing radiation – fertilizing effects of iron in ocean and phosphate on land in some regions, increasing productivity, indirect climate effect as CO_2 sink – reduced NPP though reduced solar radiation – visibility reduction
Tropospheric ozone	*Ecosystem:* ecosystem precursors VOCs (isoprene), NO_x, CH_4, CO primarily from biomass burning in the tropics *Other:* transport from stratosphere 475 Tg O_3/yr precursors in urban pollution	*Ecosystem:* dry deposition: 620–1178 Tg O_3/yr *Other:* stratosphere/troposphere exchange: 400–1440 Tg O_3/yr	*Atmospheric Concentration:* Increased from preindustrial conc. 25 DU (Dobson units) to 34 DU (370 Tg O_3) in late 1990s. Increased from 1970 to 1980 but no clear trend from 1980 to 1996. Difficult to quantify due to the high reactivity and spatial and temporal variability of sources, but satellite measurements may improve quantification. Models predict increasing tropospheric O_3 driven regionally by increasing emissions of pollutants. Atmospheric lifetime: 0.01–0.05 years. Concentrated over areas of urban pollution and biomass burning.	– emissions of key precursor trace species including VOCs, CH_4, NO_x, CO – climate change: warming increases concentration – biomass burning	– human health: UV exposure – climate: positive radiative forcing (heating) – troposphere oxidizing capacity – stratospheric ozone production
OH radical	reactions between tropospheric ozone, non-methane hydrocarbons, and NO_x in UV light	reactions with many reduced compounds, especially CO and CH_4	Probably declining since preindustrial but not by more than 10%.	– emissions of key precursors and sinks	– reduced OH leads to reduced tropospheric oxidizing capacity

Biophysical Surface Properties	Non-Forests	Forests	Trends	Ecosystem Drivers	Impacts
Surface albedo	snow-free: 0.16 (tall grasslands) to 0.6 (sand desert) snow-covered: 0.5 to 0.8	snow-free: 0.11 (tropical evergreen) to 0.2 (deciduous) snow-covered: 0.2 to 0.25	Increase in mid-latitudes due to deforestation until middle of twentieth century, now decrease due to regrowth in some mid-latitude areas. Increase in tropics.	– land use and management: primarily forest cover	– climate: radiative forcing (higher albedo = more reflection = cooling)
Water fluxes (evapotranspiration)	up to 5 mm/day	up to 10 mm/day	Evapotranspiration decrease, especially in tropics, due to deforestation.	– land use and management: primarily forest cover	– climate: direct impacts on radiative forcing and indirect impactsvia clouds – hydrological cycle
Surface roughness	up to 0.1m	1.0–2.5m	Decrease, especially in tropics, due to deforestation.	– land use and management: primarily forest cover	– climate: atmospheric circulation (wind)

[a] All numbers relate to the 1990s and are from IPPC 2001b unless otherwise stated.

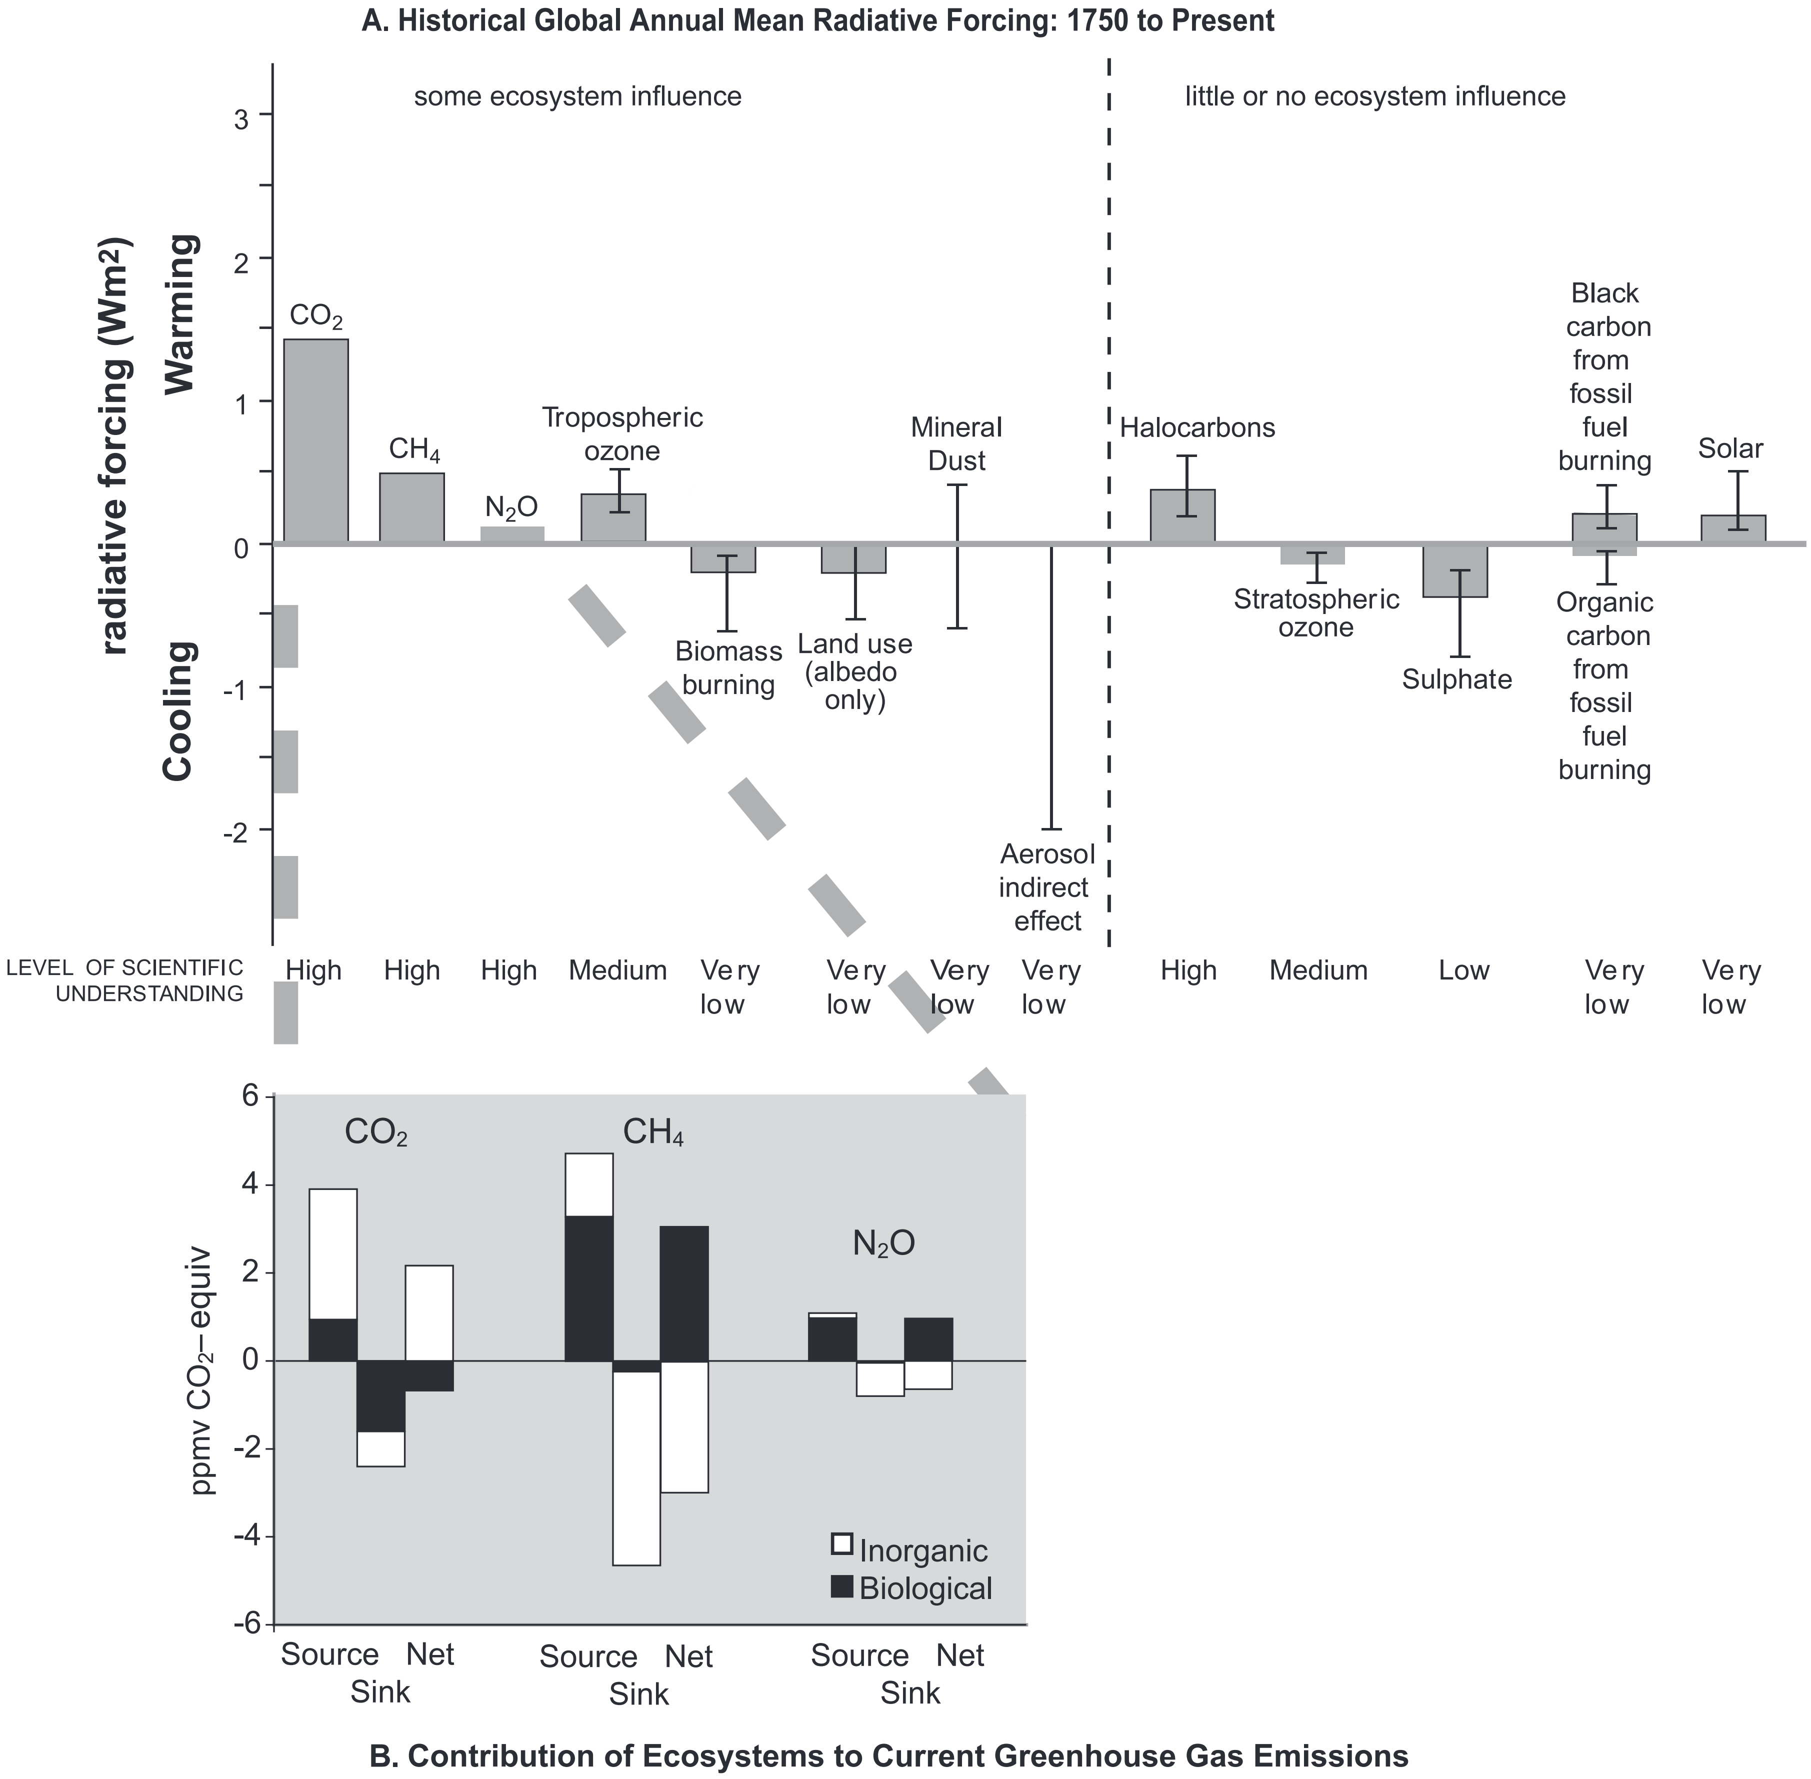

Figure 13.3. Contribution of Ecosystems to Historical Radiative Forcing and Current Greenhouse Gas Emissions (Adapted from IPCC 2001a, 2001b). Figure A is the radiative forcing caused by changes in atmospheric composition, alteration in land surface reflectance (albedo), and variation in the output of the sun for the year 2000 relative to the conditions in 1750. The height of the bar represents a best estimate, and the accompanying vertical line a likely range of values. We have separated factors with a significant ecosystem influence from those without. The indirect effect of aerosols shown is their effect on cloud droplet size and number, not cloud lifetime. Some of the radiative components are well mixed over the globe, such as CO_2, thereby perturbing the global heat balance. Others represent perturbations with stronger regional signatures because of their spatial distribution, such as aerosols. Radiative forcing continues to be a useful tool to estimate to a first order, the relative climate impacts such as the relative global mean surface temperature response due to radiatively induced perturbations, but these global mean forcing estimates are not necessarily indicators of the detailed aspects of the potential climate responses (e.g., regional climate change). Figure B is the relative contribution of ecosystems to sources, sinks, and net change of three of the main greenhouse gases. These can be compared by conversion into CO_2–equivalent values, based on the global warming potential (radiative impact times atmospheric lifetime) of the different gases. For CH_4 and N_2O, a 100-year time scale was assumed; a shorter time scale would increase the relative value compared with CO_2 and a longer time scale would reduce it. Ecosystems are also a net sink for tropospheric ozone, but it is difficult to calculate emissions in CO_2–equivalent values.

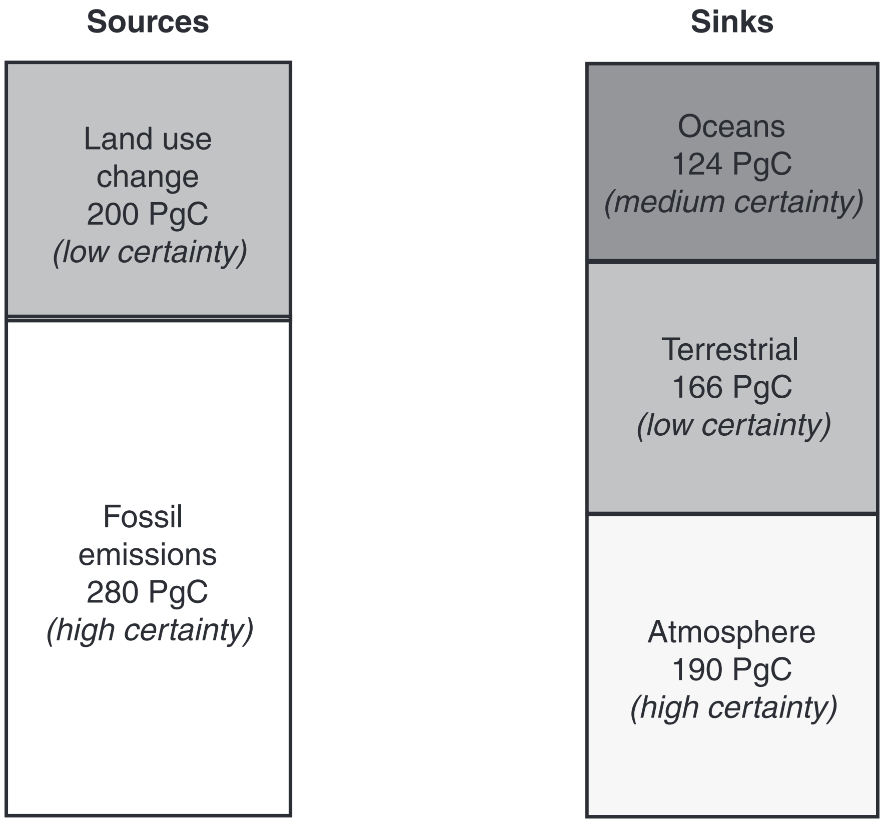

Figure 13.4. Carbon Sources and Sinks over the Last Two Centuries. Total carbon losses to the atmosphere due to historical land use change have been estimated at around 200 PgC (DeFries et al. 1999): two thirds to three quarters of this loss was due to conversion of forestland to cropland or other land uses; other carbon losses included degradation of grasslands and shrublands and the conversion of non-forestland to cropland. Fossil fuel emissions from pre-industrial times to 2000 are estimated as 280 PgC (Marland et al. 2000, update in Prentice et al. 2001), but the atmospheric increase during the same period was only 190 PgC. About 124 PgC, or ≈26% of the total emissions, were taken up by the oceans primarily as a result of chemical and physical processes (dissolution and mixing) (House et al. 2002 based on Gruber 1998; Sabine et al. 1999, 2002; Prentice et al. 2001; Langenfelds et al. 1999; Manning 2001). The remaining 166 PgC or ~34% was absorbed by the land biosphere. In this analysis, historical land use change is responsible for about 40% of the observed growth in atmospheric CO_2; Brovkin et al. (2004) estimate a range of 25–49%, with the lower end of this range being more likely.

Concern about global warming and the implementation of the Kyoto Protocol has led to carbon uptake for climate regulation being considered as an important ecosystem service (MA *Policy Responses,* Chapter 13). Forests can be managed as a sink (including preventing deforestation and promoting afforestation, reforestation, and improved forest management). This approach implies that once the forests stop growing, they must be protected to avoid loss of most of the carbon store (and to encourage long-term storage in soil carbon pools). Alternatively, forest biomass can be used to produce long-lived products that store carbon (such as furniture), or as a substitute for materials that are energy-intensive to produce (such as aluminum and plastics), or as biomass fuels that are used instead of fossil fuels.

In these ways, an area of forest can continue to offset CO_2 emissions indefinitely and may provide other services at the same time. The potential trade-offs with other environmental and socioeconomic values are also relevant—for example, biodiversity maintenance. (See Chapter 9 and MA *Policy Responses,* Chapter 13). The prospect of carbon trading under the Clean Development Mechanism, along with public and industry awareness of climate change issues, is already promoting small-scale forest activities with a view to carbon sequestration and the production of modern biomass fuels.

Forest degradation resulting from overexploitation can result in substantial carbon losses. For example, about 0.5 megagrams of carbon per hectare per year is being lost in Southeast Asia (Kim Phat et al. 2004) by this mechanism. Forest fragmentation leads to increased rates of big tree mortality, decomposition, and fire, causing carbon losses greater than deforestation in some areas (Nascimento and Laurance 2004). In central Amazonia, model estimates for the first half of this century suggest annual fragmentation losses of 4–5 megagrams of carbon per hectare per year. Timber removal from extant Amazonian forests is likely to account for a loss equal to about 10–20 megagrams of carbon per hectare per year, and fires for double that amount (Nepstad et al. 1999). Agroforestry systems have an annual sequestration capacity of 0.2–0.3 megagrams of carbon per hectare per year, and about 400 million hectares of degraded land are potentially suitable for agroforestry systems globally (IPCC 2000). One North Indian agroforestry system sequestered up to 19.6 megagrams of carbon per hectare per year (Singh et al. 2000).

Agricultural management alters the amount of carbon contained in soils and also affects other greenhouse gases such as nitrous oxide and methane (e.g., Rosenberg et al. 1998; Paustian et al. 2000; West and Post 2002; Witt et al. 2000). Soil carbon is lost when land is cleared and tilled, but it can be regained through low-tillage agriculture and other methods (Lal et al. 2004). It remains uncertain how much carbon contained in soil eroded from agricultural landscapes is delivered to the atmosphere in policy-relevant timescales (Renwick et al. 2004). Actions taken to promote carbon sequestration in soils would reduce dust emissions, which have a fertilizing effect on the ocean, thus reducing the uptake of CO_2 by the ocean and diminishing the effectiveness of this response strategy to an unknown degree (Ridgwell et al. 2002). Complex interactions of this type highlight the need to consider all implications of management options (see MA *Policy Responses,* Chapter 13). In the lowland tropics and sub-tropical areas where rice is now grown continuously throughout the year (continuous flooding), soil carbon has been seen to increase (Bronson et al. 1997; Cheng 1984). With intensive management typical of these high-yield continuous rice systems, net carbon sequestration rates of 0.7–1.0 megagrams of carbon per hectare per year have been measured (Witt et al. 2000). (See Chapter 26.)

Management of marine ecosystems to increase oceanic carbon sequestration (''ocean engineering,'' for instance via iron fertilization) has some theoretical potential, but very little is known about potential ecological and geochemical risks of such an endeavor. Due to its comparatively low estimated cost (probably in the range of a few dollars per ton of CO_2), the approach is financially attractive but the capacity is too small to slow down anthropogenic CO_2 increase significantly. Early upper limit calculations show that the potential for reducing atmospheric CO_2 is limited to a few tens of parts per million (Peng and Broecker 1991; Joos et al. 1991), in agreement with the most recent high-resolution ice core data of dust deposition and atmospheric CO_2 (Röthlisberger et al. 2004). More recent calculations put the maximum potential at around 1.0 petagrams (1.0 billion tons) of carbon per year for a maximum of 100–150 years, although it is likely to be much smaller, say less than 0.2 petagrams of carbon per year (Matear and Elliott 2004; Caldeira et al. 2004).

Future trends in atmospheric CO_2 are likely to depend more on fossil fuel emissions than on ecosystem change. Although land use management can have a significant impact on CO_2 concentra-

Table 13.2. Annual Fluxes of Carbon Dioxide over the Last Two Decades. Positive values represent atmospheric increase (or ocean/land sources); negative numbers represent atmospheric decrease (ocean/land sinks). Land and ocean uptake of CO_2 can be separated using atmospheric measurements of oxygen (O_2) in addition to CO_2 because biological processes on land involve simultaneous exchange of O_2 with CO_2, while ocean uptake does not (ocean ecosystems are assumed to be in equilibrium for the purposes of this calculation). While this technique allows quantification of the net contribution of terrestrial ecosystems, breaking this down into sources and sinks requires modeling. The CO_2 released due to land use change during the 1980s has been estimated as the range across different modeling approaches. The difference between the modeled land use change emissions and the net land-atmosphere flux can then be interpreted as uptake by terrestrial ecosystems (the "residual terrestrial sink"). (IPCC data from Prentice et al. 2001)

	IPCC		Update[a]	
Source of Flux	1980s	1990s	1980s	1990s
		(gigatons of carbon equivalent per year)		
Atmospheric increase	+3.3 ± 0.1	+3.2 ± 0.1		
Anthropogenic emissions (fossil fuel, cement)	+5.4 ± 0.3	+6.3 ± 0.4		
Ocean-atmosphere flux	–1.9 ± 0.6	–1.7 ± 0.5	–1.8 ± 0.8	–1.9 ± 0.7
Land–atmosphere flux:	–0.2 ± 0.7	–1.4 ± 0.7	–0.3 ± 0.9	–1.2 ± 0.9
—Land use change[b]	+1.7 (+0.6 to +2.5)	incomplete	+1.3 (+0.3 to 2.8)	+1.6 (+0.5 to +3.0)
—Residual terrestrial sink	–1.9 (–3.8 to +0.3)	incomplete	–1.6 (–4.0 to –0.0)	–2.8 (–5.0 to –0.9)

[a] Same data as Prentice et al. 2001 but including a correction for the air-sea flux of oxygen caused by changes in ocean circulation (Le Quéré et al. 2003). Other estimates of the air-sea oxygen correction have given slightly different results for the 1990s, mostly due to the fact that direct observations of heat change in the ocean have not yet been compiled for after 1998 (Keeling and Garcia 2002; Plattner et al. 2002; Bopp et al. 2002).

[b] The IPCC estimated range for the land use change flux is based on the full range of Houghton's bookkeeping model approach (Houghton 1999) and the CCMLP ecosystem model intercomparison (McGuire et al. 2001). The update is based on the full range of Houghton (2003) and DeFries et al. (2002); the CCMCP analysis only extended to 1995.

tions in the short term (Prentice et al. 2001), the maximum feasible reforestation and afforestation activities over the next 50 years would result in a reduction in CO_2 concentration of only about 15–30 ppm by the end of the century (IPCC 2000). Even if all the carbon released so far by anthropogenic land use changes throughout history could be restored to the terrestrial biosphere, atmospheric CO_2 concentration at the end of the century would be about 40–70 ppm less than it would be if no such intervention had occurred (Prentice et al. 2001, House et al. 2002). Conversely, complete global deforestation over the same time frame would increase atmospheric concentrations by about 130–290 ppm (House et al. 2002).

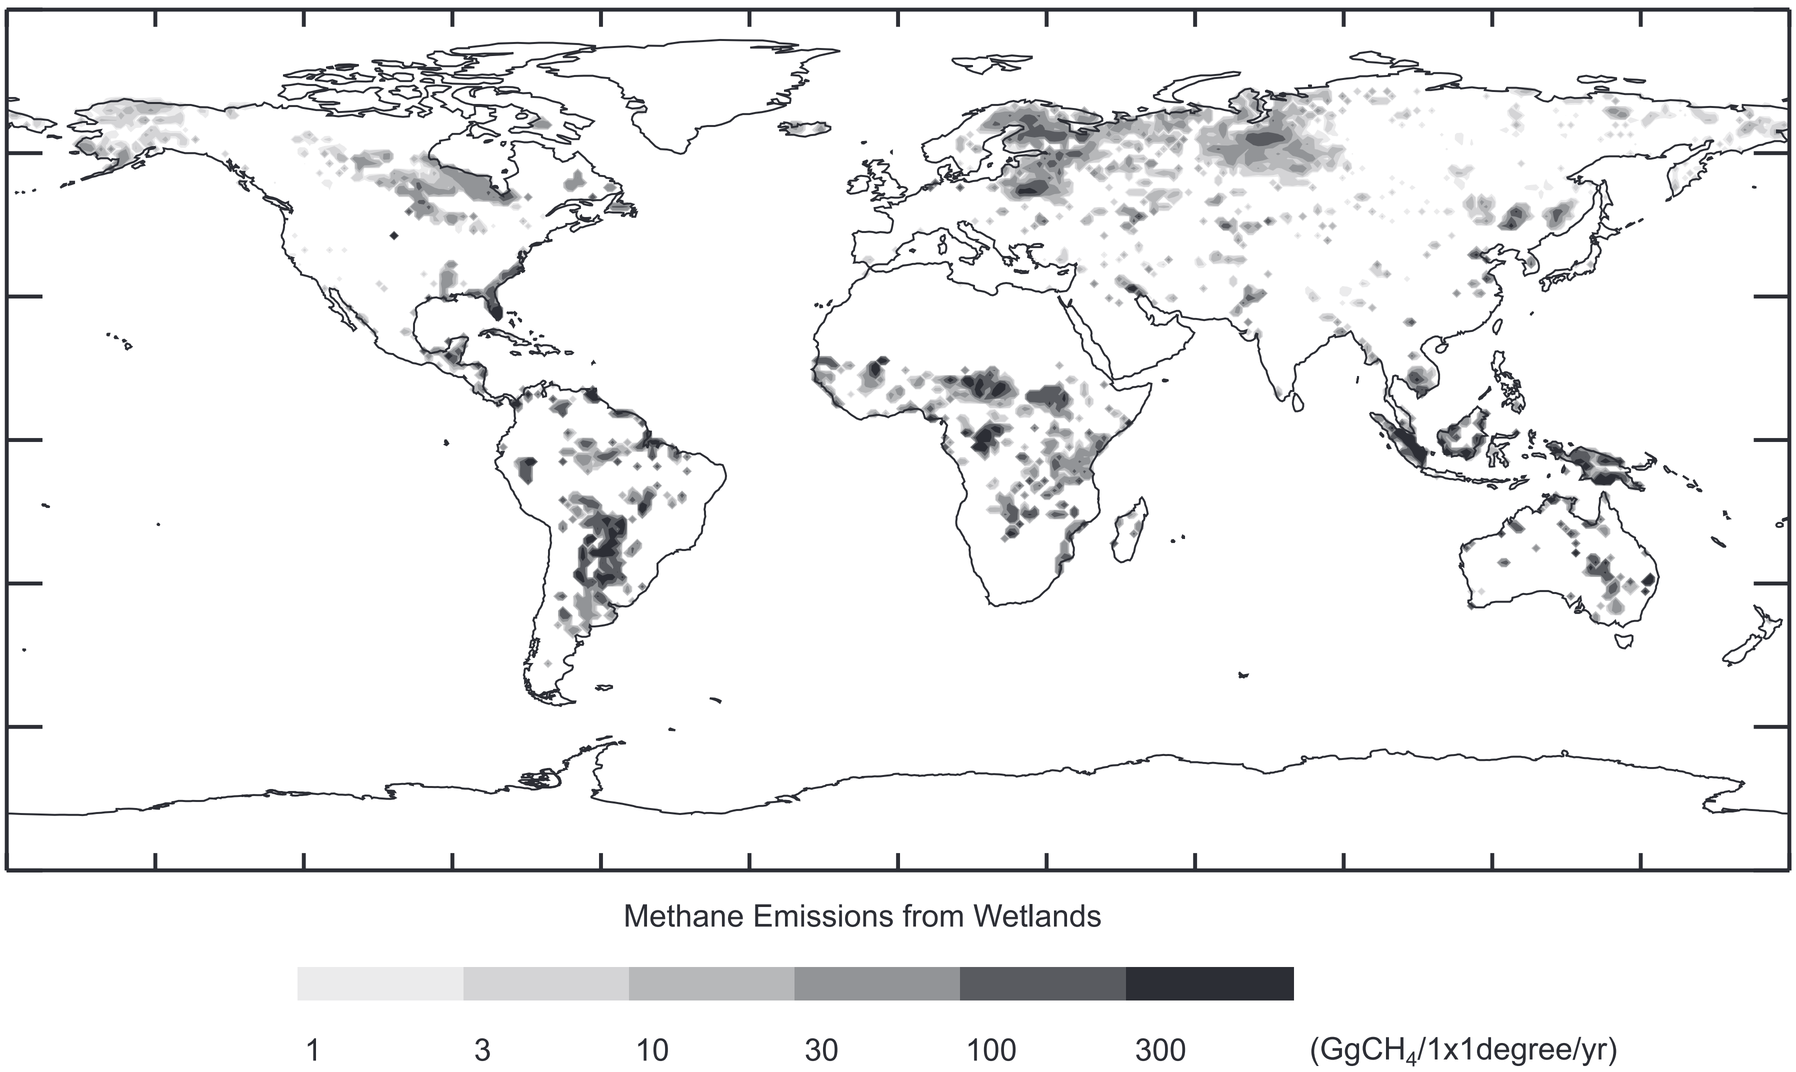
This compares with the projected range of CO_2 concentrations in 2100, under emissions scenarios developed for the IPCC, of 170–600 ppm above 2000 levels, mostly due to fossil fuel emissions (Prentice et al. 2001). The ability of the land and ocean to take up additional increments of carbon decreases as the CO_2 concentration rises, primarily due to the finite buffering capacity and rate at which ocean water can take up CO_2, as well as the saturation of the CO_2 fertilization response of plant growth (Cox et al. 2000; Prentice et al. 2001). Global warming is predicted to have a strong positive feedback on the carbon cycle due, for example, to increases in soil organic matter decomposition and a reduction in inorganic ocean uptake due to reduced CO_2 solubility and ocean stratification at higher temperatures, as described later.

13.2.2 Methane

Methane is a greenhouse gas and an energy source (natural gas). It is involved in many atmospheric chemistry reactions, including formation of tropospheric and stratospheric ozone and the reduction of atmospheric cleansing capacity (see section 13.4.1). The major source of methane is microorganisms living in a variety of anaerobic environments such as flooded wetlands and rice paddies, the guts of termites and ruminant animals, the ocean, landfill sites, and waste treatment plants. Other soil bacteria re-oxidize CH_4, preventing much of the CH_4 produced in anaerobic (wet) soils from reaching the atmosphere and accounting for a small but significant sink of atmospheric CH_4 in soils remote from methane sources.

The current atmospheric concentration of CH_4 is more than twice that of preindustrial times, as Table 13.1 indicated (see also MA *Scenarios,* Chapter 7). The growth rate peaked in 1981 and has declined since (Prather et al. 2001), with no increase in the concentration between 1999 and 2002 (Dlugokencky et al. 2003). The observed values are subject to high interannual variability due to changes in sources, sinks, atmospheric transport, atmospheric chemistry, and climate variability. Emissions from ecosystems account for about 70% of total emissions (Prather et al. 2001), with about 30% from wetlands and 30% from agriculture. The spatial distribution of emissions from natural wetlands and agriculture (based on modeling) is shown in Figure 13.6. While northern wetlands are rather well studied with respect to magnitude and drivers of CH_4 emissions, the lack of data from tropical wetlands is a major knowledge gap.

Agriculture (ruminant animals and rice paddies) is the most important anthropogenic driver of CH_4 emissions. In pastoral countries such as Bolivia, Uruguay, and New Zealand, CH_4 emissions by ruminant livestock are responsible for over 40% of all greenhouse gas emissions (when expressed as CO_2 equivalents)



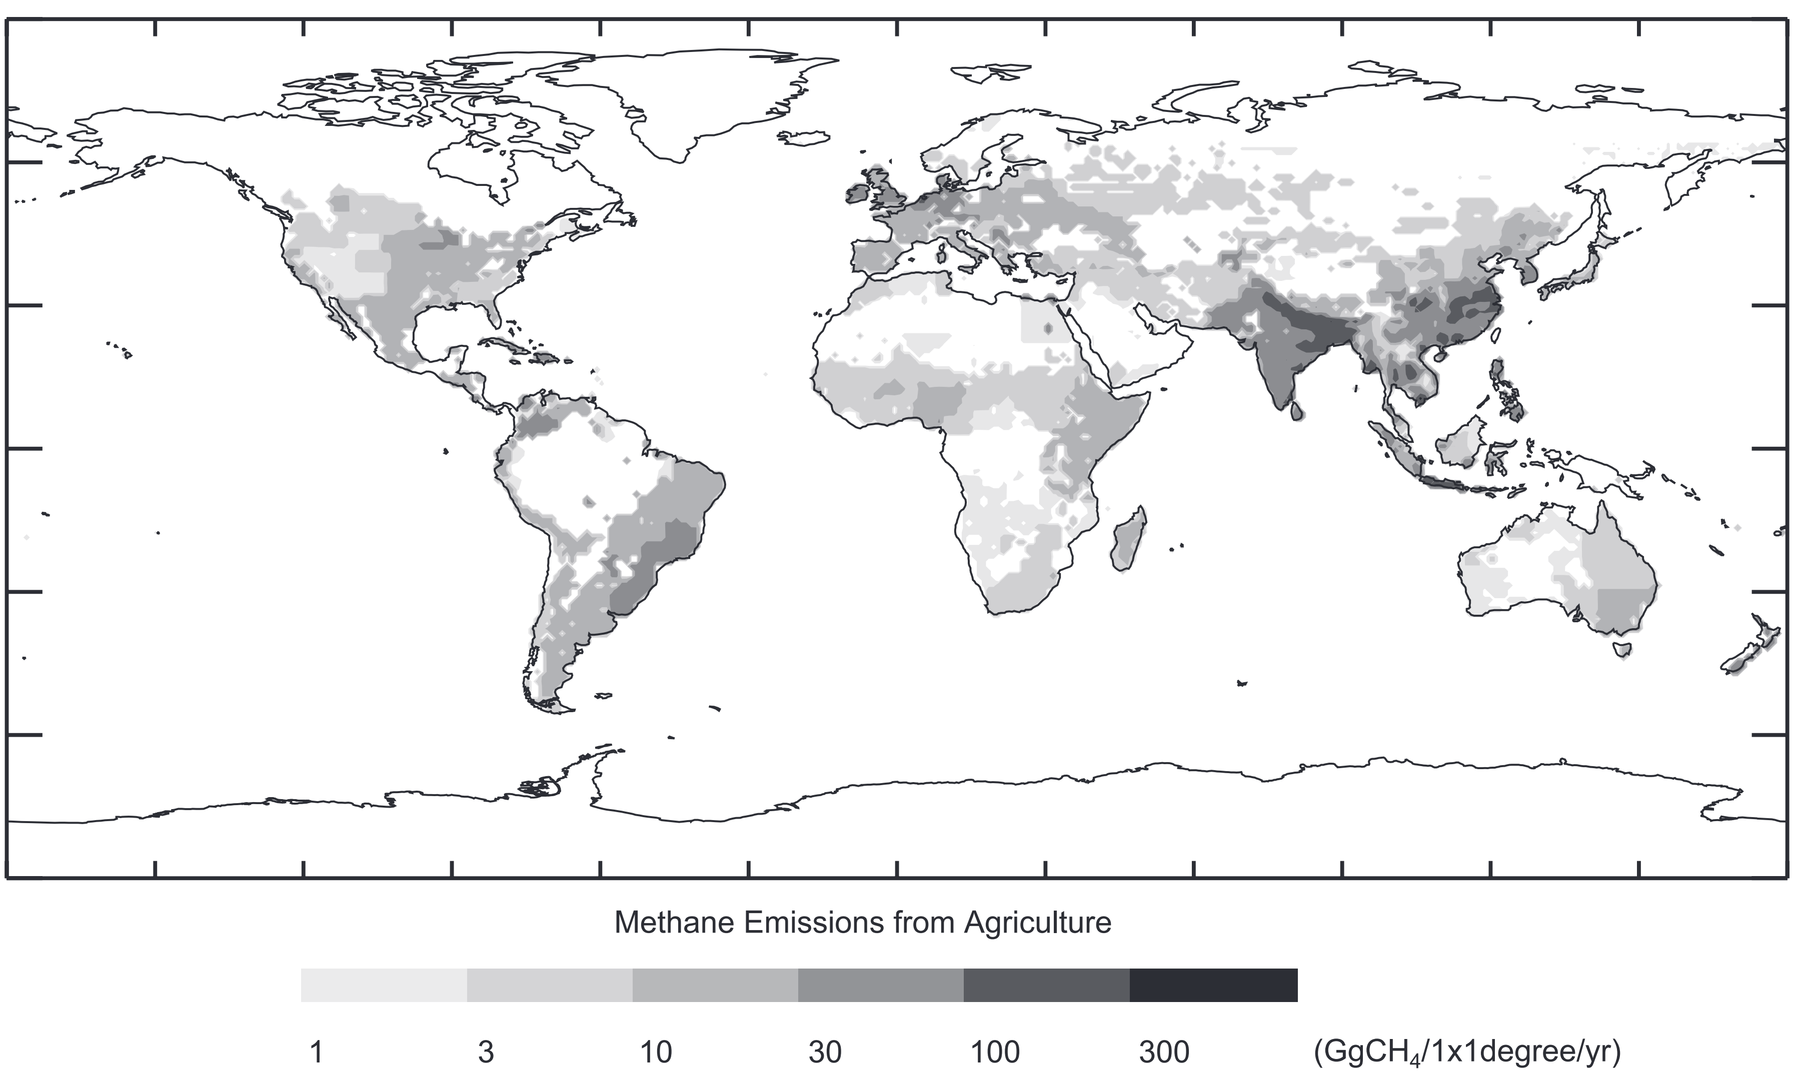


Figure 13.6. Map of Methane Fluxes from Wetlands and Agriculture Models. The top figure shows the spatial location of methane fluxes from natural wetlands according to Walter and Heimann (2000). The total emissions are probably too high; a maximum of about 160–170 $GgCH_4$/yr may be more realistic (Houweling et al. 2000). The bottom figure shows emissions from agriculture sources (rice paddies, animals and animal wastes) according to the model EDGAR (v3.2) (Olivier et al. 1994).

(UNFCCC at ghg.unfccc.int). Control of this methane source through changing diet is being examined as a potential control on global warming. Methane emissions from lowland, irrigated rice systems are affected by various management practices. For example, the use of green manures can substantially increase CH_4 emissions compared with the use of inorganic N fertilizers (Wassmann et al. 2000a, 2000b). (More detailed discussion of rice paddies can be found in Chapter 26.)

Wetland and peatland soils under waterlogged or seasonally frozen conditions tend to store carbon fixed by plants during photosynthesis. This is because in waterlogged soils, decomposition of plant material is slower than in aerated soils and is accompanied by a relatively slow release of CH_4 compared to the faster CO_2 efflux of aerobic soils. Wetland draining for agriculture, for forestation, or due to water extraction leads to a decrease in CH_4 production but a rapid increase in CO_2 release from soils that are often very rich in organic matter. The current consensus is that, while some areas are carbon sinks and some are carbon sources, most wetlands—in particular, the northern peat-forming ones—have a carbon balance close to zero (Callaghan et al. 2004).

CH_4 has a higher global warming potential than CO_2 (23:1 on a 100-year time horizon), although CO_2 is much longer-lived in the atmosphere. In the short term (20–100 years), CH_4 emissions have a more powerful effect on the climate per unit mass than CO_2. Thus as most wetlands are currently sources of CH_4, they are also net sources of radiative forcing (*medium certainty*) (Friborg et al. 2003). Draining of wetlands leads to a decrease in radiative forcing (cooling) in the short term, but in the long term the opposite may be true (*low certainty*) (IPCC 2001a; Christensen and Keller 2003).

The climate change impacts on peatlands have different feedbacks depending on the location and extent of global warming. Some regions, such as northern Alaska, are predicted to experience—and are indeed already experiencing—soil drying, leading to net losses of carbon as CO_2 and decreases in CH_4 emissions (Chapter 25). In the subarctic, however, where recent decadal warming has led to the loss of permafrost with thermokarst erosion and a wetting of the soils as a consequence, a significant increase in CH_4 emissions has been seen (Christensen et al. 2004), with the overall effect of an increase in radiative forcing. In tropical regions, the key issue is what changes will occur to seasonal flooding—draining will lower the impact on radiative forcing as the CH_4 emissions are very high, yet the carbon store in peat is insufficient for emissions of CO_2 to overwhelm this in the long term.

Preliminary model results of changes in wetland areas under future climate (e.g., Cox et al. 2000) suggest that the northern wetlands will increase their carbon storage and subsequent CH_4 emissions while tropical ones will lose significant amounts of carbon and decrease CH_4 emissions. Furthermore, rising soil temperature and enhanced microbial rates could increase methane emissions, amplifying global warming by 3.5–5% by the end of this century (Gedney and Cox 2003; Gedney et al. 2004).

13.2.3 Nitrous Oxide

Ecosystems are a source of nitrogen in various gaseous forms, each with different effects on climate and air quality. They are also a sink for atmospheric nitrogen, taking up N_2 directly from the atmosphere (nitrogen fixation) or reactive nitrogen after deposition (wet deposition–rained out, or dry deposition). For a detailed explanation of the nitrogen cycle and the role of ecosystems, see Chapter 12. The nitrogen cycle has been profoundly altered by use of synthetic fertilizers. (See Chapter 26.)

Nitrous oxide is a powerful, long-lived greenhouse gas (GWP 296:1 on a 100-year time horizon), which (unlike other N oxides) is unreactive in the troposphere. Atmospheric concentrations of N_2O have increased since preindustrial times from 270 ppb to 314 ppb (MA *Scenarios,* Chapter 7). Ecosystem sources—primarily soil microorganisms in an array of environments—account for about 90% of N_2O emissions and a small fraction of N_2O uptake (Prather et al. 2001). Enhanced ecosystem N_2O emissions are mainly driven by increased fertilizer use, agricultural nitrogen fixation, and atmospheric nitrogen deposition (Nevison and Holland 1997; Prather et al. 2001). Wetland draining also increases N_2O emissions. Fertilizer use and nitrogen deposition are projected to increase substantially in the tropics (Matson et al. 1999; Prather et al. 2001).

13.2.4 Tropospheric Ozone

Besides being a greenhouse gas, tropospheric ozone is a toxic pollutant. It is highly reactive in the atmosphere and also helps maintain the atmospheric cleansing capacity. It is formed in the atmosphere in the presence of light from precursors: mainly volatile organic compounds (the most important VOC being isoprene), nitrogen oxides (NO and NO_2, collectively denoted as NO_x), CH_4, and carbon monoxide. Biomass burning is an ecosystem source of precursors, but urban pollution sources dominate, with very high concentrations of ozone mostly appearing downwind of urban areas. In addition to being a source of tropospheric ozone precursors, ecosystems account for about half the total sink for tropospheric ozone, through dry deposition (Prather et al. 2001). Ecosystems are thus currently a net sink for tropospheric ozone. Deforestation reduces this sink (see Figure 13.7): NO_x soil emissions decline, but canopy uptake declines more. Where forests are replaced with agriculture, NO_x emissions increase further.

The concentration, sources, and sinks of tropospheric ozone are difficult to quantify due to its high reactivity and the spatial and temporal variability of sources and sinks. Most surface measuring stations show an increase from 1970 to 1980, but no clear trend from 1980 to 1996. Models predict increasing tropospheric ozone in the future, driven regionally by increasing emissions of its precursors (Prather et al. 2001).

13.2.5 Aerosols

Ecosystems are sources and sinks for a variety of aerosols (or aerosol precursors) that directly affect radiative forcing, causing warming or cooling depending on their properties (such as reflectivity) and location (such as height or the underlying surface) (Penner et al. 2001). Many aerosols affect cloud formation, which in turn affects radiative forcing in complex ways. The net effect of clouds on radiative forcing remains uncertain, but increasing the aerosol load probably, on average, causes cooling. The net effect of aerosols on climate is matter of intensive investigation, and while the field is progressing rapidly, more research is needed before firm conclusions can be drawn.

Sulfur compounds (sulfur dioxide, hydrogen sulfide, and dimethyl sulphide) contribute to the formation of sulfate aerosols with a negative radiative forcing (climate cooling) (MA *Scenarios,* Chapter 7). Industrial sources dominate, despite declines in some regions due to controls and legislation (Rodhe 1999; Penner et al. 2001). Ecosystems are a sink for about 30% of SO_2 emissions and for sulfate aerosols. Dimethyl sulfide, emitted by marine phytoplankton when they die or are eaten, contributes to cloud formation. DMS emissions are quite variable in relation to phytoplankton species and mode of release. Global mean DMS concentration in surface waters is fairly well known, but regional emissions are

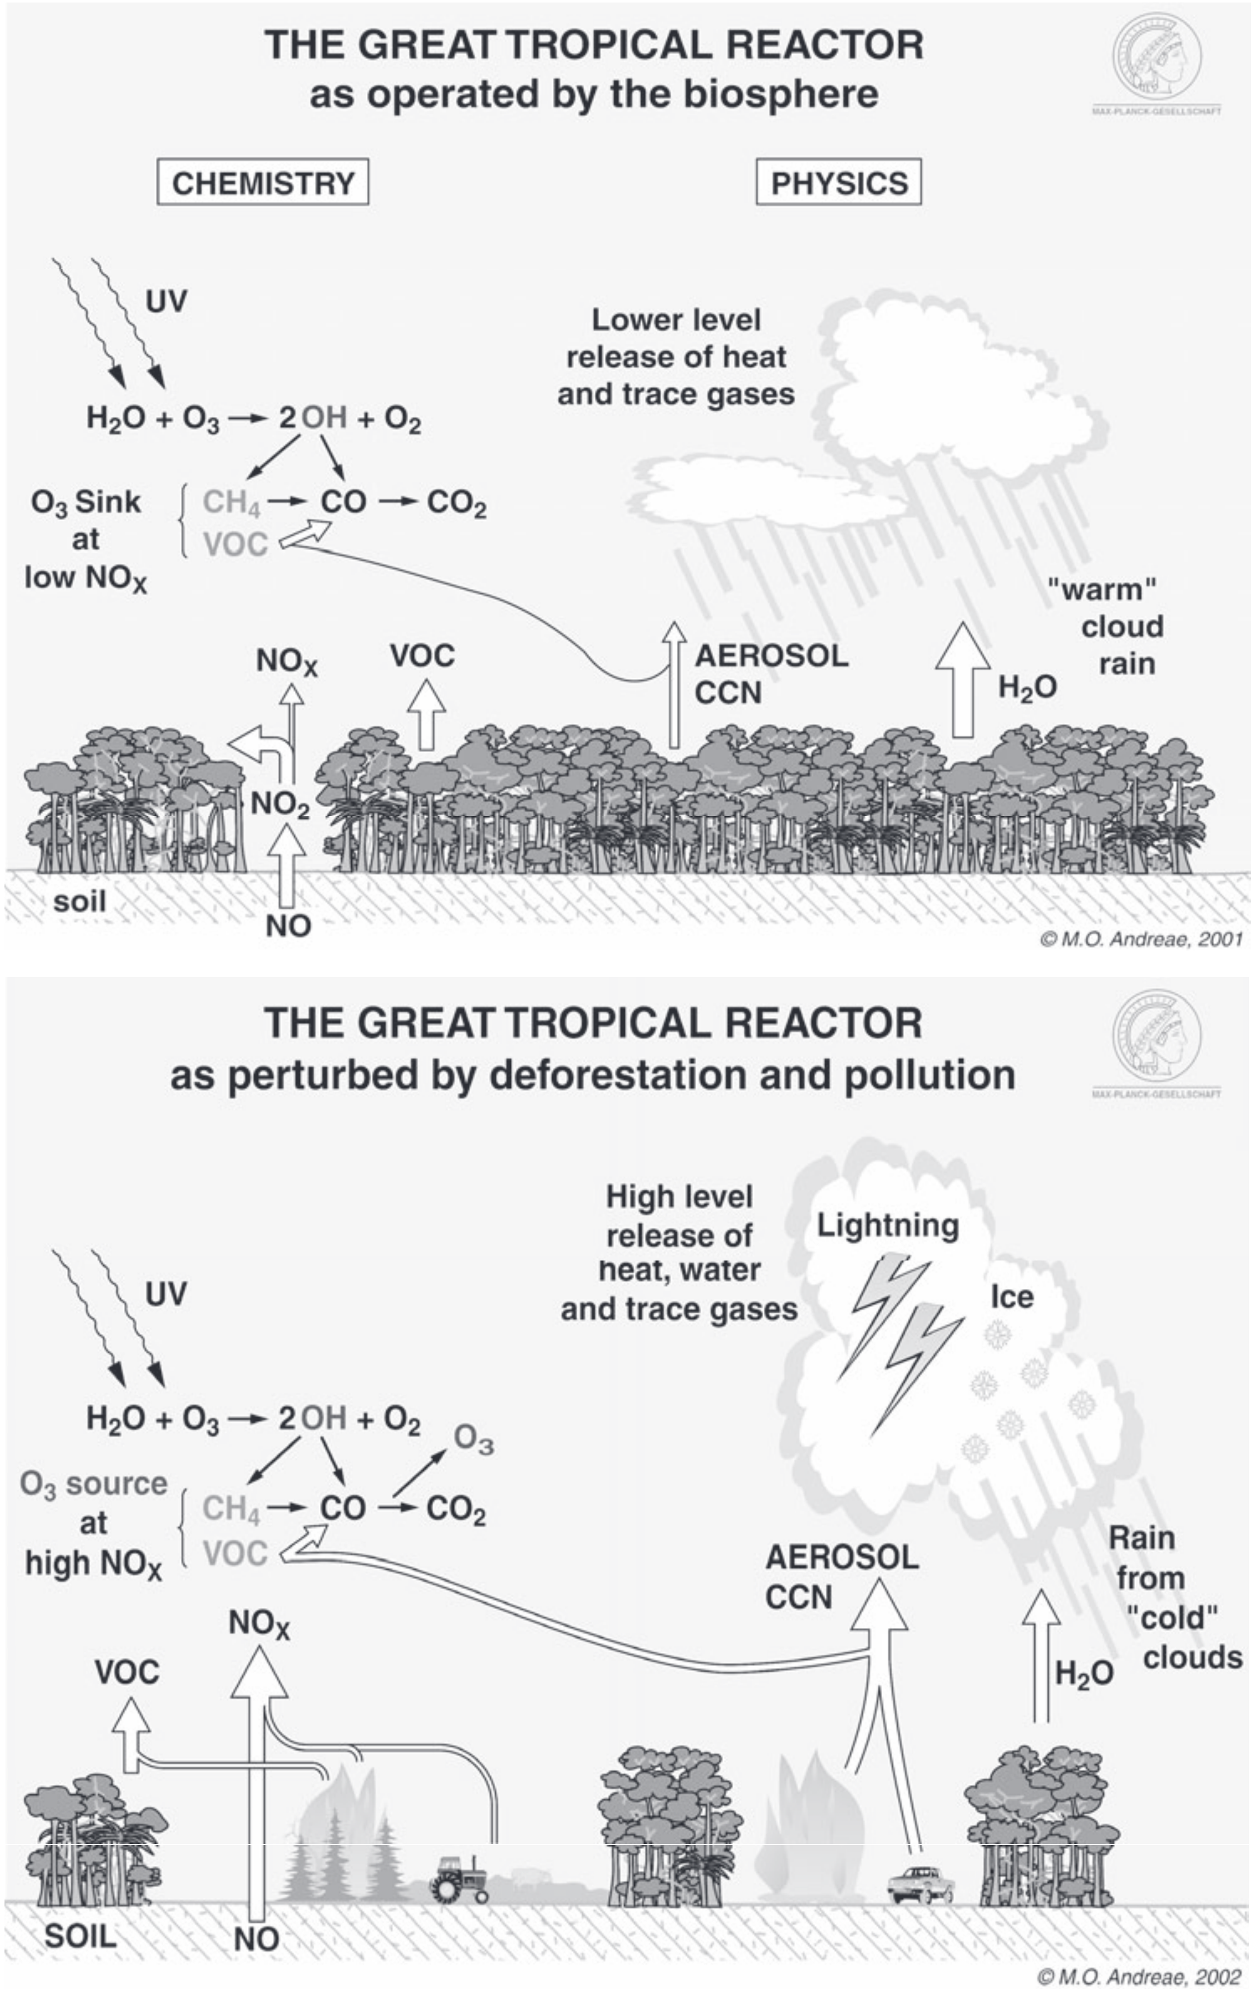

Figure 13.7. The Tropical Reactor—Biochemical and Biophysical Interactions in the Tropics (Andreae 2001). The top figure shows the natural biochemical and biophysical fluxes and interactions over intact forest. The bottom figure shows the fluxes when the natural forest area is subject to deforestation and pollution. The land changes from a net sink of tropospheric ozone to a net source when the canopy does not trap NO_x emissions from soil, and emissions of NO_x from agriculture increase. Aerosols from vegetation fires and pollutions sources (e.g., cars) act as cloud condensation nuclei leading to higher storm clouds. Overall rainfall is reduced due to a reduction or evapotranspiration (water recycling through vegetation).

more uncertain. Climate-related change in surface ocean stratification is bound to affect phytoplankton species distribution and succession, with likely consequences for DMS production and potentially also for cloud formation (Kiene et al. 1996).

Carbonaceous aerosols of many forms are emitted by ecosystems and can cause warming or cooling depending on their composition, size, shape, and location. IPCC (2001a) concluded that biomass-burning aerosols have a net cooling effect (indoor biomass fuel burning was underrepresented in this estimate). But these aerosols can also reduce cloudiness, which is thought to enhance climate warming (Penner et al. 2003). Black carbon (soot from incomplete combustion of biomass and fossil fuels) has been suggested to have a large warming effect on the climate, due in part to various feedbacks (Hansen and Sato 2001; Jacobson 2002), although the magnitude of this effect is disputed (Penner et al. 2003; Roberts and Jones 2004). Air quality impacts of biomass-burning aerosols are dealt with later in this chapter.

There are huge uncertainties regarding emissions and trends of biogenic aerosols (VOC oxidation products, plant debris, humic matter, and microbial particles), thus IPCC (2001a) did not estimate their net radiative warming impacts. Their contribution could be significant in densely vegetated regions of the tropics, and it is under threat as a result of land use change.

Mineral dust is entrained into the atmosphere from sparsely vegetated soils. Dust scatters solar radiation and absorbs terrestrial radiation. Its net impact on radiative forcing is uncertain, but updates since IPCC (2001a) infer that the net effect is cooling (Kaufman et al. 2001). Its trends and drivers are described later in this chapter.

13.3 Biophysical Effects of Ecosystems on Climate

13.3.1 Surface Properties and Climate Processes Affected by Ecosystems

Ecosystems affect climate through the alteration of energy and water fluxes in the lowest atmosphere, or planetary boundary layer (about 1–2.5 kilometers above Earth's surface) (Pitman et al. 2004). Within this layer, vertical profiles of temperature and humidity depend strongly on the partitioning of energy between sensible heat and latent heat. Over land, this partitioning is largely controlled by ecosystems. Over bare, dry land, the energy is transported via sensible heat, resulting in relatively high surface air temperatures. Vegetation canopies transpire water extracted from the root zone, increase the upward latent heat flux, and cool the surface air (Avissar et al. 2004). Modification of the fluxes of water and energy by ecosystems has significant regional effects on precipitation, temperature, and wind. Globally averaged impacts are small, complex, and hard to detect against the background of natural climate variability and anthropogenic climate change. Key physical properties and processes affected by ecosystems are summarized here:

- ***Surface albedo*** is the fraction of solar radiation reflected back into the atmosphere from Earth's surface. Higher albedo means that more energy leaves the planetary boundary layer (net cooling of the atmosphere). Vegetation traps radiation, generally reducing albedo compared with, for instance, snow cover or bare ground in dry lands. In agricultural regions, tillage usually decreases albedo since bare soil in moist climates is generally darker (less reflective) than plant canopies. Forests are very effective at trapping radiation by multiple reflection within the canopy; this effect is particularly strong in snow-covered regions where trees extend above the snow, while short vegetation such as crops and pastures are covered by snow. (See Figure 13.8 in Appendix A.) Phytoplankton modify ocean surface albedo, with different types either reducing (Frouin and Lacobellis 2002) or increasing it (Brown and Yoder 1994; Balch et al. 1991).
- ***Transpiration*** is the flux of water from the ground to the atmosphere through plants, controlled by the opening and closing of tiny pores in the leaf's surface called stomata. The volume of water transpired is determined by vegetation rooting depth, leaf area, soil moisture, temperature, wind, and stomatal conductance (which is biologically regulated). Transpiration drives the hydrological cycle—recycling rain water back to the atmosphere to be rained out elsewhere. Thus terrestrial ecosystems mediate the service of water recycling. Through transpiration and precipitation, water evaporated over the ocean is transported into the interior of continents. A part of the rainfall escapes immediate recycling and forms river runoff; thus the presence of vegetation reduces the fraction of rainfall going into runoff. (See Figure 13.9.) As runoff is part of the freshwater flux into the surface ocean, changes in terrestrial ecosystems can in principle affect ocean dynamics. Transpiration cools the surface during the daytime and increases air humidity in the near-surface atmospheric layer. Increased concentration of water vapor (a greenhouse gas) leads to reduced fluctuations in the diurnal temperature cycle by increasing the night temperatures. Photosynthesis is tightly coupled to transpiration, but while increased atmospheric CO_2 concentration in the future is likely to enhance photosynthesis, it may tend to reduce transpiration due to reduced stomatal conductance (*medium certainty*).
- ***Cloud formation*** has strong but complex effects on global and regional climate (Stocker et al. 2001). Evapotranspiration determines the availability of water vapor for the formation of clouds. Clouds alter the radiation balance (low clouds are cooling while high cirrus clouds are warming), air circulation, and precipitation. Vegetation also affects cloud formation via changes in surface albedo and roughness. Some of the atmospheric constituents with ecosystem sources act as cloud condensation nuclei: in particular DMS emitted by marine plankton, VOCs emitted by some types of vegetation, and some aerosols emitted during biomass burning. Increased concentrations of CCNs produce more and smaller cloud droplets, making clouds more reflective and persistent; this has a cooling effect on Earth. In addition, such clouds tend to rise in the atmosphere, delaying the onset of rain; increasing ice formation, rainfall intensity, and lightning; creating more violent convective storms; and altering energy balances and air circulation (Andreae et al. 2004). The net effect on the total rainfall within a given area is unknown.

Both marine and terrestrial biota naturally regulate CCN concentrations to remain at fairly low levels (Charlson et al. 1997; Williams et al. 2002). Increased DMS and VOC emissions increase CCNs, which reduces radiation and cools the planet; this in turn reduces photosynthesis and emissions of DMS and VOCs and increases thermal stability, thus reducing the probability of cloud formation in a negative feedback loop. The natural regulation mechanism is becoming overwhelmed by anthropogenic emissions of aerosols and deforestation. Some aerosols, such as soot particles, absorb sunlight, which cools the surface and heats the atmosphere, reducing cloud formation.

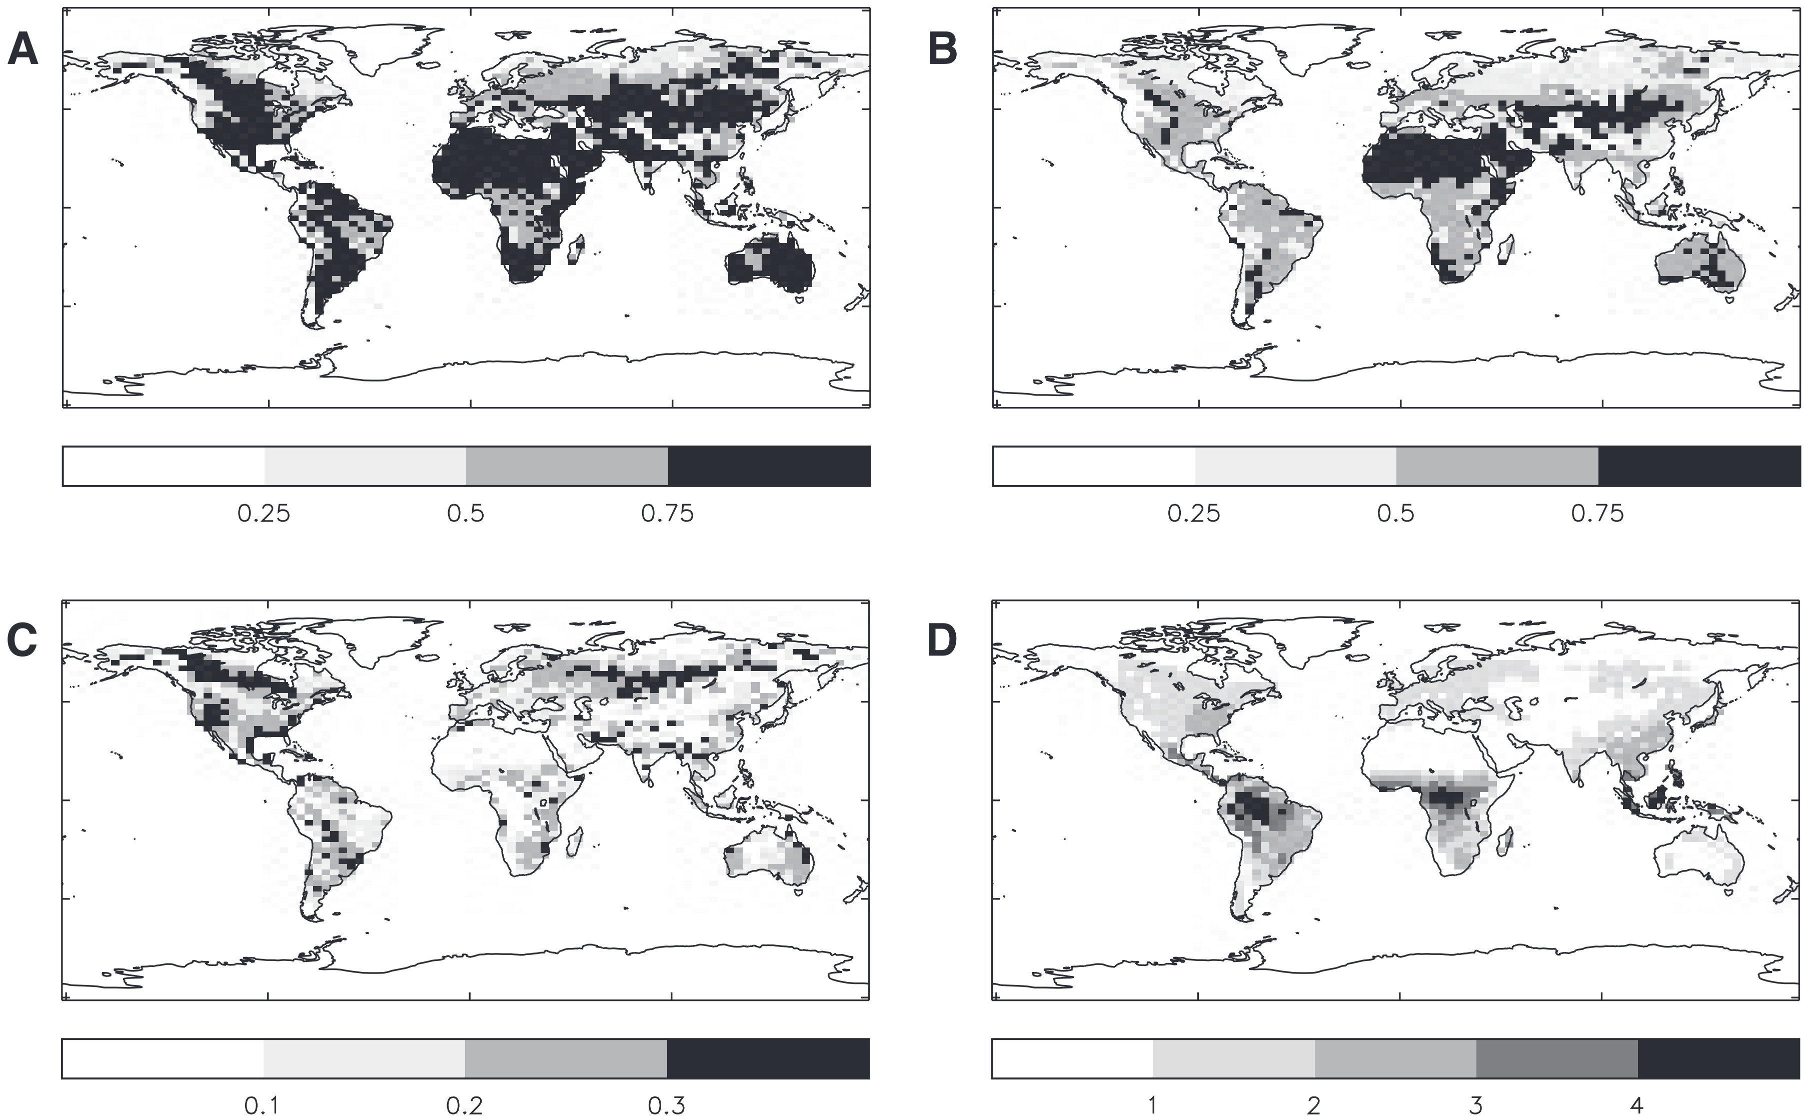

Figure 13.9. The Influence of Terrestrial Vegetation on Water Recycling (in mm/day). A general circulation model of climate has been used to simulate the ratio of land evapotranspiration to precipitation (Betts 1999) with (A) present-day vegetation and (B) all vegetation removed leaving bare soil. The difference between the two (C) illustrates the general increase in recycling of water back into the atmosphere via evapotranspiration when vegetation in present. For reference, (D) shows the absolute rate of evapotranspiration simulated with present-day vegetation.

- ***The aerodynamic properties of the surface*** (roughness length) modify the strength and direction of the surface wind. On land, the height and cover of surface vegetation are the main determinants of roughness length.
- ***Sea surface temperature*** is warmed by phytoplankton that trap radiation within the surface layer. A warmer surface reduces vertical mixing (ocean stratification) and ice cover, with potential feedbacks on regional circulation (Sathyendranath et al. 1991; Miller et al. 2003). Stratification reduces the flow of nutrients, feeding back on phytoplankton growth and composition, CO_2 uptake, and climate.

13.3.2 Biophysical Hotspots

The biophysical impacts of land use on climate are region- and season-specific and are often confounded by other climate drivers (for example, greenhouse gases and aerosols). On the global scale, biophysical effects of historical land cover changes are limited. Most model results indicate a slight biophysical cooling, partly offsetting the biogeochemical warming due to CO_2 emissions from land cover change (Betts 1999; Matthews et al. 2004; Brovkin et al. 2004). Regionally, the biophysical climate effects of ecosystem change can be substantial.

13.3.2.1 Tropical Forests

Tropical forests in South America, Africa, and Southeast Asia are being cleared to make land available for agriculture. (See Chapters 21 and 26.) The change in vegetation from forest to pasture or crops increases surface albedo (leading to cooling of the atmosphere), decreases roughness, and reduces evapotranspiration (reducing rainfall and leading to local warming) (Henderson-Sellers et al. 1993). Measurable impacts can be expected when the area of deforestation is on a scale of a few hundred kilometers. Trees can get access to deep soil water and have been observed to maintain evapotranspiration through the dry season at levels equal to the wet season. Thus extensive deforestation generally leads to decreased regional rainfall (see Box 13.2), although under some conditions rainfall can be higher over areas with partial deforestation compared with areas with no deforestation (Durieux et al. 2003; Avissar et al. 2002). Since forest existence crucially depends on rainfall, the relationship between tropical forests and precipitation forms a positive feedback, which, under certain conditions, theoretically leads to the existence of two steady states: rainforest and savanna (Sternberg 2001; Oyama and Nobre 2003), although some models suggest only one stable climate-vegetation state in the Amazon (Claussen 1998).

Biophysical impacts of tropical deforestation are different in the wet and dry seasons. In the dry season, non-forest areas become hot and dry during the daytime, and air flows from forests to non-forest areas, enhancing thermal turbulence. These conditions favor the formation of shallow rain clouds over non-forest areas. During the wet season, evaporation in forest and pasture are about the same but the forest reflects less radiation due to lower albedo, leading to warming of the planetary boundary layer.

BOX 13.2

Case Study: Deforestation and Rainfall Impacts in the Amazon (Maria Silva Dias, personal communication, 2002)

The state of Rondônia in the southwest Amazon was opened for colonization in the early 1970s by developers, following government incentives. Afonso Andrade was one of the first farmers, clearing an area of about 2,000 hectares for farming cattle and crops like rice, beans, and corn for local consumption. During the first five years, when Andrade's property was mostly surrounded by forest, he would plant a brown bean crop at the end of the wet season. Even if rain was scarce, the seeds would germinate and the crops would grow because dew was very abundant during the nighttime, and "the soil would be wet early in the morning." The flow of moisture from the neighboring forest during daytime would sustain the dew formation during nighttime. As deforestation proceeded, however, the forest was further away in successive years, the atmosphere and the soil became drier during the dry season, and the forest moisture was diluted into a larger area. Now it is very hard to get a crop going during the dry season without irrigation.

Warming generates more thermal turbulence, which favors the formation of clouds and rainfall over forest areas (Nobre et al. 2004). Cloud formation is further affected by aerosols from biomass burning and other sources (Williams et al. 2002).

DeFries et al. (2002) found that projected future land cover change, which is likely to occur mostly in the sub-tropics and tropics, will have a warming effect on climate, driven mostly by decrease in evapotranspiration. Increasing atmospheric CO_2 decreases stomatal conductance in many species. If this effect occurs on a large scale, it will reduce latent heat flux and therefore increase land surface temperature (Sellers 1996). In some cases, agricultural leaf area index (the area of green leaf per unit area of ground) is higher than forest leaf area index, which will reduce the effect of decreased stomatal conductance on large-scale transpiration (Betts et al. 1997). Decreased canopy conductance may contribute to a decrease in precipitation in regions where water recycling by vegetation is important—for example, Amazonia (Betts et al. 2004).

13.3.2.2 Boreal Forests

The presence of forests in boreal regions reduces the albedo of the land surface compared with short tundra vegetation. Solar radiation is trapped within the forest canopy, causing warming (Betts and Ball 1997). This effect is particularly accentuated during the snowy season, when short vegetation becomes fully covered with snow, which strongly reflects solar radiation back to the atmosphere (Harding and Pomeroy 1996; Hall et al. 2004). Increased air temperature leads to earlier snow melt. The treeline boundary is limited by temperature, so the relationship between forest and air temperature forms a positive taiga-tundra feedback. This biophysical mechanism plays a substantial role in Earth System dynamics; for example, a reduction of forest cover may have helped trigger the onset of the last glaciation (Gallimore and Kutzbach 1996; de Noblet et al. 1996), while enhanced forest cover has contributed to the regional warming during the mid-Holocene (Foley et al. 1994).

Boreal deforestation leads to spring cooling and extension of the snow season due to albedo changes. During the growing season, trees have a denser, more productive canopy than herbaceous plants, and therefore they transpire more water, cooling surface air (Pielke et al. 1998). This hydrological effect is of primary importance during the summer, so deforestation leads to summer warming. Model results suggest that for deforestation in most boreal forest areas, the cooling effect of albedo changes dominates over the hydrological warming effect on annual average surface temperature (Chalita and Le Treut 1994; Betts 1999; Brovkin et al. 1999). A sea ice–albedo feedback enhances the cooling effect of boreal deforestation (Bonan et al. 1992; Brovkin et al. 2003).

In the recent past, deforestation in the temperate and boreal regions has likely led to a biophysical cooling that partially offset the warming effect of associated CO_2 emissions. In the future, reforestation of regions permanently covered by snow in winter is likely to lead to an increase in global temperature, as the biophysical warming due to albedo changes outweighs the biogeochemical cooling due to uptake of CO_2 in forest stands (Betts 2000; Claussen et al. 2001). This would be counter to the aims of carbon sequestration schemes in these regions. It is also expected that warming at the high northern latitudes will be substantially amplified through the taiga-tundra feedback (Brovkin et al. 2003), although changes in permafrost, forest fire frequency, and outbreaks of pests complicate projections for vegetation cover dynamics in the boreal and polar regions. (See also Chapters 21 and 25.)

13.3.2.3 Sahel/Sahara

In the Sahel region of North Africa, vegetation cover is almost completely controlled by rainfall. The rainy season lasts between two and four months, during which rainfall is highly unpredictable: rainy days can be followed by weeks with no rainfall. When vegetation is present, it quickly recycles this water, as Figure 13.9 illustrated, generally increasing regional precipitation and, in turn, leading to a denser vegetation canopy (Dickinson 1992; Xue and Shukla 1993). This positive feedback between vegetation cover and precipitation amplifies rainfall variability in the Sahel (Zeng et al. 1999). Model results suggest that land degradation leads to a substantial reduction in water recycling and may have contributed to the observed trend in rainfall reduction in the region over the last 30 years (Xue et al. 2004). Combating degradation should maintain or restore the water recycling service, increasing precipitation and contributing to human well-being in the region. (See Chapter 22.)

The Sahara Desert, to the north of the Sahel, is another important example of ecosystem-climate interactions. While rainfall there is too low to support much vegetation at present, it was not so in the past. During the mid-Holocene, about 9,000–6,000 years ago, Sahelian vegetation was greatly extended to the north (Prentice and Jolly 2000). Changes in Earth's orbit increased summer insolation, enhancing monsoon circulation and increasing moisture inflow into the region, and this effect was greatly enhanced by the reduced albedo of the vegetation itself (Kutzbach et al. 1996; Braconnot et al. 1999; Claussen et al. 1999; Joussaume et al. 1999). A rather abrupt collapse in west Saharan rainfall and vegetation cover occurred about 5,500 years ago (deMenocal et al. 2000). This abrupt change is consistent with the existence of alternative stable states in the climate-vegetation system (Claussen 1998; Brovkin et al. 1998). (See Figure 13.10.)

The Sahara desert today differs from other sub-tropical deserts in its exceptionally high albedo. Net cooling of the atmosphere leads to a horizontal temperature gradient and induces a sinking motion of dry air, suppressing rainfall over the region (Charney 1975). Low precipitation reduces the vegetation cover, increasing bare ground with high albedo. This positive feedback maintains desert conditions. On the other hand, if precipitation increases there is more vegetation, the albedo is lower, surface temperature

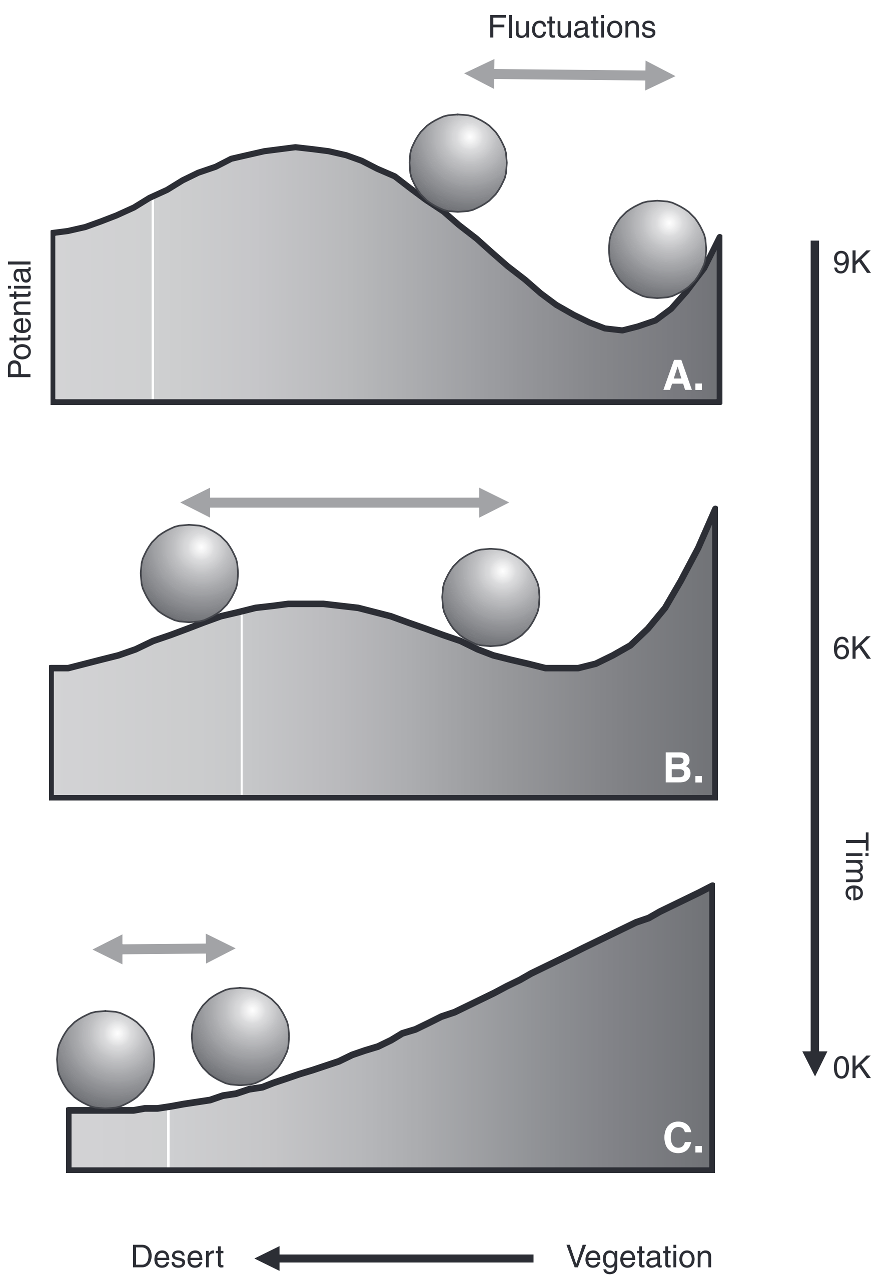

Figure 13.10. Changes in Stability of the Climate-Vegetation System in the Sahara/Sahel Region According to Climate Model Simulations of the Last 9,000 Years (Renssen et al. 2003). Hypothetically, strong positive feedbacks between precipitation and vegetation in the Sahara/Sahel region can lead to the existence of two steady states, desert and "green" (savanna-like). Balls and arrows in the figure indicate the maximum range of the fluctuations induced by large-scale atmospheric and oceanic variability. A) About 9,000 years ago, the system fluctuated in the vicinity of the green state, while the desert state with a shallow potential minimum was also stable. B) About 6,000 years ago, the potential became equal for both states and the system fluctuated between desert and green states. C) Later, the green state lost stability. Desert is the only steady state at present, and precipitation variability is reduced in comparison with the two-state system (A and B).

is higher, and the gradient in temperature between the land and ocean increases—amplifying monsoon circulation and upward air motion over the desert, resulting in increased summer rainfall.

A shift from "green" to "desert" state and vice versa is strongly influenced by externally induced fluctuations in rainfall (Wang and Eltahir 2000; Renssen et al. 2003). In the future, global warming may increase moisture in the Sahara/Sahel region (Brovkin et al. 1998), but it is unlikely that Sahara greening will reach mid-Holocene levels (Claussen et al. 2003).

13.3.2.4 Wetlands

Evapotranspiration of water from wetlands during the day leaves the air above the surface heavy with water vapor, preventing a loss of energy. In sub-tropical regions this is often sufficient to hold night temperatures above freezing point. When wetlands are drained, this ecosystem service is lost. Marshall et al. (2003) showed that the likelihood of agriculturally damaging freezes in southern Florida has increased as a result of the conversion of natural wetlands to agriculture. In January 1997, a rare freeze in southern Florida caused losses to vegetable and sugarcane crops that exceeded $300 million.

13.3.2.5 Cultivated Systems

Intensified agriculture generally increases leaf area index because crops are bred for maximum ability to intercept light. Therefore the effects of past extension of agriculture may, to a certain extent, be reversed by intensification, with increased leaf area during the summer season being a move back toward denser vegetation with characteristics closer to a natural forested state (Gregory et al. 2002). Where seasonal crops replace evergreen vegetation, this will not be the case.

13.4 Effects of Ecosystem on Air Quality

Ecosystems effect the concentrations of many atmospheric compounds that have a direct deleterious effect (for example, pollution) or a beneficial effect (for example, fertilization) on human well-being. Ecosystems are often both sources and sinks for various trace gases that undergo complex atmospheric reactions, simultaneously affecting several aspects of air quality in different ways. It is therefore often hard to quantify the current net effect of ecosystems or of ecosystem change on a particular aspect of air quality. This section concentrates on main net effects, complementing the summary information for each atmospheric constituent that was presented in Table 13.1.

13.4.1 OH and Atmospheric Cleansing Capacity

Some reactive gases released or absorbed by ecosystems are involved in maintaining the ability of the atmosphere to cleanse itself of pollutants through oxidation reactions that involve the hydroxyl radical. (See Box 13.3.) The reactions are complex but, generally, emissions of NO_x and hydrocarbons from biomass burning increase tropospheric ozone and OH concentrations. CH_4 and CO are removed by OH, so emissions of these gases from wetlands, agriculture, and biomass burning decrease OH concentration. Net effects of deforestation are uncertain.

A proxy for estimating atmospheric cleansing capacity (or tropospheric oxidizing capacity) is the concentration of OH, but this is hard to measure directly because of its short lifetime (on the order of seconds). Model estimates, based on measurements of compounds destroyed by OH, indicate a decline in OH concentration since preindustrial times, but the change has probably been less than 10% (Prinn et al. 2001; Jöckel et al. 2003). There is some concern that the pursuit of a hydrogen energy economy could further reduce oxidizing capacity (Schulze et al. 2003; Warwick et al. 2004). A threshold-dependent collapse in atmospheric cleansing capacity would have major implications for air quality (Brasseur et al. 1999). The fundamental importance of tropospheric oxidizing capacity to air quality and atmospheric chemistry means that improving the understanding of OH in the atmosphere, and of the role of ecosystems in regulating OH, is a focus for intensive scientific research.

13.4.2 Pollution Sinks

13.4.2.1 CO_2 and Ocean Acidification

Increased atmospheric CO_2 concentrations are having adverse effects on certain ocean ecosystems, and since terrestrial ecosystems

BOX 13.3

Atmospheric Cleansing (Tropospheric Oxidizing Capacity)

The ability of the atmosphere to cleanse itself of the many compounds emitted from biological and anthropogenic sources is becoming a key issue. Conversion and removal of a large number of environmentally important atmospheric compounds requires one or more chemical reactions involving oxidation taking place in the troposphere (the lower 9–16 kilometers of the atmosphere). The hydroxyl radical is the main oxidizing sink and is often referred to as the "atmospheric detergent." Compounds affected include:

- CH_4 converted to CO;
- removal of NO_x by direct uptake and conversion to HNO_3;
- conversion of CO to CO_2;
- conversion of SO_2 to H_2SO_4;
- removal of some gases responsible for stratospheric ozone depletion, such as methyl bromide; and
- conversion of DMS to SO_2

OH is formed when tropospheric ozone is broken down by UV light to release oxygen atoms that then react with water vapor. Ecosystem emissions of tropospheric O_3 precursors (NO_x, VOCs, CH_4, CO) contribute to OH formation. Ecosystem emissions of compounds oxidized by OH (such as CH_4, CO, hydrocarbons) contribute to the destruction of OH.

are currently a net sink for CO_2 (as described earlier), this could be considered an ecosystem service of benefit to human well-being. The component of anthropogenic CO_2 from fossil fuels and land use change that has dissolved in the ocean has increased the acidity of the ocean to a degree that is unprecedented in recent geological history (Caldeira and Wickett 2003). The global mean surface ocean pH has decreased by 0.12 units since preindustrial times. A further decrease of 0.25 units will occur during this century if atmospheric CO_2 concentration rises to 750 ppmv (Wolf-Gladrow et al. 1999).

Increased acidity changes carbonate chemistry in the surface ocean, with negative impacts on ocean organisms such as corals, coccolithophores, and foraminifera that make their bodies from calcium carbonate. The rate of calcification (growth) of the organisms will decrease (Riebesell et al. 2001), with possible consequences for ecosystem services such as tourism and fish production (Guinotte et al. 2003). A rise in the atmospheric CO_2 concentration to double the preindustrial level may reduce global calcification by as much as 30% (Kleypas et al. 1999). The negative feedback of declining growth of calcifying organisms on the atmospheric CO_2 increase is likely very small (Heinze 2004).

13.4.2.2 Tropospheric Ozone

Sources, sinks, and trends in tropospheric ozone concentration were described earlier in this chapter. Tropospheric ozone can have adverse effects even at relatively low concentrations. Harmful concentrations occur in urban areas but also in the region of vegetation fire events and of high NO_x emissions from fertilizer use, particularly when atmospheric conditions trap air, such as in valleys or temperature inversions. While ecosystems in some regions are a source of ozone precursors, globally they are a net sink. Ozone is destroyed by reacting with plant tissues.

Adverse human health effects of tropospheric ozone include impacts on pulmonary and respiratory function and the aggravation of pre-existing respiratory diseases such as asthma, resulting in increased excess mortality (Thurston and Ito 1999; WHO 2000). Current tropospheric ozone concentrations in Europe and North America cause visible leaf injury and reduced yield of some crops and trees (Mclaughlin and Percy 1999; Braun et al. 1999; Mclaughlin and Downing 1995; Ollinger et al. 1997). It is estimated that for wheat there is a 30% yield reduction for a seasonal seven-hour ozone daily mean of 80 nanomoles per mole, a concentration level that has been found in parts of the United States and Europe (Fuehrer 1996). Economic losses in the Untied States alone may amount to several billion dollars annually. Fowler et al. (1999) estimate that the proportion of global forests exposed to potentially damaging ozone concentrations will increase from about 25% in 1990 to about 50% in 2100.

13.4.2.3 Acid Rain and Acid Regulation

Acid deposition of SO_2, sulfate, NO_x, and nitrate has increased mainly due to industrial emissions (Satake et al. 2000; Rodhe et al. 1995). Biomass burning emissions also affect the chemical composition of rainfall over large areas, while soil emissions of NO_x are as important as industrial emissions in tropical areas, with large increases driven by increasing fertilizer use. Ecosystems are also a sink for NO_x and sulfur compounds. The net effect of ecosystems is probably a sink for compounds that contribute to acid rain. Industrial sources of acid deposition have caused damage to sensitive ecosystems, especially in northern Europe and parts of northeastern North America (Emberson et al. 2003; see also MA *Scenarios,* Chapter 7). Industrial emissions are now declining in these areas due to pollution control, but they continue to rise in other areas, such as Southeast Asia.

Ammonia is the only important gaseous alkaline component in the atmosphere. NH_3 neutralizes many of the acid compounds emitted, forming sulfate and nitrate aerosols. NH_3 in high concentrations is harmful to human health, causes eutrophication of lakes, and can also contribute to acidification in N-saturated ecosystems. Although the quantity of NH_3 volatilized from fertilized fields and animal feedlots can be extremely large (Bouwman et al. 1997), ecosystems as a whole are a net sink for NH_3 (Dentener and Crutzen 1994; Holland et al. 1997).

13.4.2.4 Stratospheric Ozone

Decreases in stratospheric ozone and subsequent increases in ultraviolet (UV-B) radiation have adverse effects on human and animal health, plant growth and mortality, and marine organisms. The net effect of ecosystems on stratospheric ozone is very small compared with industrial emissions, but the effect is probably to reduce the quantity of stratospheric ozone-destroying compounds. As with acid rain, compounds that destroy stratospheric ozone have greatly increased as a result of industrial activities. There are natural ecosystem sources of methyl halides (marine ecosystems and biomass burning), and ecosystems are the primary source of N_2O, which also destroys stratospheric ozone when oxidized in the atmosphere. However, ecosystems are also sinks for halocarbons. As industrial emissions have been controlled by the Montreal Protocol and fallen dramatically, concentrations of most ozone-depleting gases in the atmosphere are now at or near a peak (WMO 2003), while concentrations of N_2O continue to rise.

13.4.3 Pollution Sources

13.4.3.1 Biomass Burning—Vegetation Fires

Vegetation fires are a common natural phenomenon in many regions and vegetation types. Fires maintain vegetation diversity, productivity, and nutrient cycling (although too-frequent fire can lead to impoverishment of nutrients). Fire is also a common land management tool, particularly in the tropics, where it is used to clear land (shifting agriculture, for example, or disposing of residues) (see Box 13.4), to maintain grasslands for cattle grazing, to prevent encroachment of weeds, and to prevent destructive canopy fires and catastrophic wildfires. Prevention of uncontrolled wildfire is an integral component of land use policies: balancing the benefits of controlled use of fire with minimizing the many adverse effects of uncontrolled fires. Several studies have suggested increased fire risk during the twenty-first century (e.g., Flannigan and van Wagner 1991; Price and Rind 1994; Stocks et al. 1998; Mouillot et al. 2002).

Combustion of plant biomass in vegetation fires (or as an energy source, see Chapter 9) produces a mixture of compounds, including greenhouse gases, toxic pollutants, and reactive gases. Toxic pollutants are mostly the result of incomplete combustion; biomass burning is often inefficient, varying with biomass type and load, fire intensity, and weather conditions. Air pollution from biomass burning is associated with a broad spectrum of acute and chronic health effects (Schwela et al. 1999; WHO 2002; Brasseur et al. 2003b). Emissions associated with burning biomass for energy (mostly fuelwood and dung) have been linked to high levels of indoor pollution and major health effects (see Table 13.3); we do not consider this an ecosystem source, however, but rather one arising from use of ecosystem resources. Estimates of the emissions of biomass combustion products in vegetation fires are subject to large uncertainties because of the difficulties inherent in estimating the amount of biomass burned (Andreae and Merlet 2001).

13.4.3.1.1 Particulates

Particles small enough to be inhaled into the lungs, typically less than 10 micrometers (PM10), are associated with the most serious effects on humans, including respiratory disease, bronchitis, reduced lung function, lung cancer, and other cardiopulmonary sources of mortality and morbidity. Studies do not show threshold concentrations below which effects are not observed (WHO 2000, 2002). Particulate levels in plumes associated with large-scale tropical fires can be 2 to 15 times those observed in urban areas (Brauer and Hisham-Hashim 1998), although exposure levels are generally less than those from indoor air pollution.

During the peak of the burning season, the number of particles in the air is an order of magnitude higher than during the rest of the year. Solar radiation reaching the surface is reduced by about 10–30%, lowering both the surface temperature and the light available for plant growth. In China, the effect of atmospheric aerosols and regional haze from all pollution sources is reducing wheat yields by 5–30% (Chameides et al. 1999). In some circumstances, for example in cloudless conditions in areas with high solar radiation (Cohan et al. 2002), plant production could be increased by haze cover. Particulates tend to reduce rainfall but increase the likelihood of intense storms (Andreae et al. 2004). Rainfall reduction has a positive feedback effect, making further fires more likely in, for example, the Amazon (Koren and Kaufman, 2004), but intense rains storms can contribute to putting out fires.

BOX 13.4

Case Study: Biomass Burning in and around the Amazon Basin during the Dry Season

Farmers prepare their crop and pastureland by burning to clear weeds; developers burn the forest to open new farmland. The alternative to burning crop and pasture land is to use herbicides or machinery to cut and mulch the weeds. Herbicides are expensive for the local farmer. The machinery is expensive to buy and operate (but could be bought by cooperatives). Burning is cheap and effective in the short term (two to three years), although it becomes costly to the crop yield in the medium term (three to five years). In areas with poor soils, open areas have been abandoned and a secondary forest is growing back. In areas with less poor soils, fertilizers have been introduced to compensate for the lack of nutrients. In a few places the culture of not burning is beginning to be adopted by more educated farmers.

13.4.3.1.2 Tropospheric ozone

Biomass burning emits tropospheric ozone precursors (VOCs, NO_x, CH_4, and CO). The impacts of tropospheric ozone were described earlier. High levels of tropospheric ozone can accumulate at a regional scale during the biomass-burning season (e.g., Swap et al. 2003). The interannual trends and seasonal cycle of tropospheric ozone concentrations correspond to the seasonal cycle and extent of biomass burning in tropical Africa, Latin America, and Asia (Thompson and Hudson 1999). Ozone concentrations can reach values that are larger than those observed in the most polluted urban areas of the world. Values of 100–120 ppb have been measured during the dry season in the southwest Amazon Basin; background values during the rainy season are around 10–15 ppb (Kirchhoff et al. 1996; Cordova et al. 2004).

13.4.3.1.3 Carbon monoxide

Potential health effects of CO include hypoxia, neurological deficits, neurobehavioral changes, and increases in daily mortality and cardiovascular diseases. CO toxicity is mostly associated with indoor pollution from biomass fuel burning, but some studies show effects of CO even at very low concentrations (WHO 2000; Schwela et al. 1999). Dangerous levels are only occasionally observed during vegetation fires, although fatalities caused by excessive carbon monoxide concentrations alone or in combination with other pollutants have been reported, as in China in 1987 (Schwela et al. 1999).

13.4.3.1.4 Other compounds

Volatile organic compounds, including benzene, toluene and xylene, and polynuclear aromatic hydrocarbons, have been identified in fire smoke plumes (Muraleedharan et al. 2000; Radojevic 2003) and are known or suspected carcinogens, mutagens, and teratogens with the potential to cause serious long-term effects. Volatized heavy metals can also pollute the environment. In 1992, severe wildfires spread into the 30-kilometer exclusion zone around the Chernobyl Power Plant in Belarus, burning radioactively contaminated vegetation and increasing the level of radioactive cesium in aerosols 10 times (Dusha-Gudym 1996).

13.4.3.2 Nitrogen Pollution

Elevated deposition of nitrogen compounds is driven by emissions of various N gases. Ecosystem sources include increased fertilizer use, rice paddies, ruminant animals, and biomass burning. Ecosystem N deposition adds to the burden of nitrate leaching to groundwater due to fertilizer use in agricultural ecosystems, causing changes in the functioning and stability of many sensitive ecosystems (for example, heathlands and bogs), particularly in the most populated parts of the world. In heavily affected areas (the Netherlands, for instance), the drinking water standard for nitrate has been exceeded, and lakes and coastal waters suffer from eutrophication. Episodes of high wet deposition of nitrogen are suspected of occasionally affecting even remote marine ecosystems. Changes in the nitrogen cycle and its impacts are dealt with in detail in Chapter 12.

13.4.3.3 Dust Pollution

Agricultural intensification coupled with increasing population density and climate variability in many areas of Sahelian Africa have led to soil degradation and greater soil exposure to wind erosion, increasing the sources of atmospheric dust in recent years (N'Tchayi 1994; Nicholson 1998). An increase in local dust storms is widely considered to be related to ill health (fever, coughing, sore eyes) and has been implicated in meningococcal meningitis epidemics in the region (Molesworth 2002). Dust emanating from this region and the Sahara has been implicated in respiratory problems as far away as the United States (Prospero 2001). Dust storms cause a strong reduction in visibility, resulting in serious disruptions in ground and air traffic. These conditions not only occur in the dust source regions themselves, they can also be problematic downwind. For example, visibility in Beijing is often adversely affected by dust storms originating in the Gobi Desert in springtime (Sugimoto et al. 2003; Shimuzu et al. 2004).

The major dust source regions are deserts, but semiarid regions where vegetation is sparse and soil surfaces disturbed by human activities also contribute to the atmospheric burden of dust. Soil disturbance has been estimated to account for up to 10% of total dust emissions (Tegen et al. 2004). Long-term increases in dust over the Atlantic are possibly associated with desertification of northern Africa (Prospero and Lamb 2003). There are many land use and climate drivers and feedbacks that are likely to affect dust production in the future, with climate drivers dominating. While both the magnitude and the direction of change in dust are uncertain, some models suggest that dust production could decline in a warming world due to increased vegetation in arid and semiarid regions (Mahowald and Luo 2003; Tegen et al. 2004).

13.4.4 Fertilizing Effects

Carbon dioxide, nitrogen gases (NO_x, NH_3), and nutrients in dust particles can all have fertilizing effects on terrestrial plants, potentially increasing production of services such as food and timber. Fertilization from these sources is one possible contributory mechanism for the increasing terrestrial CO_2 sink in recent years. Estimates of the magnitude of this effect in the past and future are limited by incomplete understanding of soil carbon dynamics, plant nutrient relationships, and plant physiology (Oren 2001; Finzi et al. 2002; Hungate et al. 2003; Zak et al. 2003; Norby et al. 2004; Nowak et al. 2004). Nitrogen and dust deposition on the ocean also have the potential to increase phytoplankton production, and the supply of iron in dust is thought to be a major control on the strength of biological carbon uptake in the ocean (Martin et al. 1991). Ecosystems are currently a net sink for CO_2 and a net source of NO_x, while vegetation cover reduces dust emissions (as described earlier in this chapter).

13.4.4.1 Carbon Dioxide

Carbon dioxide in the atmosphere and ocean is necessary to support plant photosynthesis. Most marine plants are not limited by CO_2 but by nutrients and light. On the other hand, most terrestrial plants are limited to some extent by CO_2 supply, and thus rising atmospheric concentrations can have a fertilizing effect, enhancing productivity both directly (Farquhar et al. 1980) and indirectly though stomatal closure and improvements in water use efficiency (Drake et al. 1997; Farquhar 1997; Körner 2000). The strength of the response in terrestrial plants depends on the photosynthetic pathway. Theoretically, those with a C_3 pathway (trees, cold climate plants, most nontropical grasses, and most agricultural crops, including wheat and rice) respond more strongly than those with a C_4 pathway (most tropical grasses, some desert shrubs, and some crops, including maize and sugarcane), although field experiments suggest a more complex picture (Owensby et al. 1993; Polley et al. 1996; Porter and Navas 2003; Nowak et al. 2004).

Experimental doubling of CO_2 in Free-Air CO_2 Enrichment systems produces an average aboveground biomass increase of 17% for C_3 and C_4 agricultural crops and a 20% increase in agricultural yield under conditions of ample N and water, but there is a wide range of responses among individual studies (Kimball et al. 2002). Increases are generally greater in conditions of low water availability. Trees in open top chambers have shown an enhancement of the annual wood mass increment of about 27% (Norby et al. 1999). This strong response of trees to elevated CO_2 has been confirmed in Free-Air CO_2 Enrichment experiments in young forest plantations (DeLucia et al. 1999; Hamilton et al. 2002; Nowak et al. 2004). However, the response of mature forests may be different from that of young forests for various reasons (Norby et al. 1999; Curtis and Wang 1998).

13.4.4.2 Nitrogen Deposition

Nitrogen limitation to plant production is widespread. (See Chapter 12.) There has been a rapid increase in reactive N deposition over the past 50 years (Vitousek et al. 1997; Holland et al. 1999). There is much field evidence that N deposition increases NPP (e.g., Chapin 1980; Vitousek and Howarth 1991; Bergh et al. 1999; Spieker et al. 1996) and soil carbon storage (Fog 1988; Bryant et al. 1998). When the nitrogen saturation limit is reached, as is thought to have happened in highly polluted areas of Europe, plants can no longer process the additional nitrogen and may suffer from deleterious effects of associated pollution (Shulze et al. 1989; Aber et al. 1998; see also Chapter 7). N addition leads to changes in plant species composition and an overall reduction in diversity. In general, the impacts are most pronounced in nutrient-poor systems, where N deposition enhances growth of the most responsive species, which often outcompete and eliminate rare species that occupy N-deficient habitats (Mooney et al. 1999).

13.4.4.3 Dust as a Fertilizer

Nutrients in dust particles (especially phosphate and iron) can act as fertilizers when deposited on oceans and land (Piketh et al. 2000). Fertilization of the ocean from expanded desert sources, and the resulting increase in ocean ecosystem CO_2 uptake, is thought to be one of the drivers of change in glacial-interglacial atmospheric CO_2 concentrations (Watson et al. 2000; Ridgwell et al. 2002; Bopp et al. 2003). Ice core records indicate decreased dust input in the ocean may account for up to about a quarter of the 80-ppm atmospheric CO_2 increase at the last glacial-interglacial transition (Rothlisberger et al. 2004). A recent synthesis (Piketh et al. 2000) suggests that aerosols derived from the southern African continent are increasing carbon uptake downwind in the Indian Ocean. Changes in dust sources, transport, and deliberate iron fertilization of the ocean could affect marine productivity, future CO_2 uptake (Mahowald and Luo 2003; Tegen et al. 2004), and marine N fixation and N_2O release (Denman et al. 1996), but the magnitude and associated impacts are uncertain. (Sources and drivers of dust are described earlier; see also Chapter 22.)

13.5 Climate Variability and Climate Feedbacks

13.5.1 Interannual Variability

Biological activities are dependent on climatic conditions, and therefore biogenic emissions of gases often show a seasonal cycle and interannual climate variability linked to natural climate variations. In some cases the interannual variability is large—for example, when biological processes are limited by water availability. This variability in turn affects biological sources and sinks of atmospheric compounds and biophysical properties of vegetation. For instance, during recent El Niño events atmospheric CO_2 increase has doubled or tripled compared with other times, partly due to reductions in land uptake caused by the effects of high temperatures, drought, and fire on terrestrial ecosystems in the tropics (Tian et al. 1998; Clark et al. 2004).

Warming enhances emissions of VOCs (which increase by 20–30% per degree Celsius) (Guenther et al. 2000), CH_4, and N gases, which generally tend to increase tropospheric ozone and OH (although these reactions also depend on water and light availability). Changes in OH concentration further affect the variability in concentration of some atmospheric compounds such as CH_4. Effects of interannual variability on biogenic sources and sinks are one of a number of processes that affect CH_4 and tropospheric ozone (Dlugokencky et al. 1998; Warwick et al. 2002; Sudo and Takahashi 2001).

Enhanced biomass associated with the La Niña phase of the El Niño-Southern Oscillation, followed by droughts in the El Niño phase, produce above average biomass burning emissions from savannas in southern Africa (Swap et al. 2003). In 1997–98, fires associated with an exceptional drought caused by ENSO devastated large areas of tropical rain forests worldwide (Siegert et al. 2001). Emissions of associated gases such as CO_2, CO, CH_4, and other trace gases have been correlated with large biomass burning events in tropical and boreal regions (Langenfelds et al. 2002).

13.5.2 Climate Feedbacks on Ecosystems, Climate, and Air Quality

Changes in global and regional climate, partially bought about by ecosystem change, can in turn lead to further changes in ecosystem sources and sinks of gases and biophysical properties. Temperature and moisture changes will cause a variety of changes in sources, sinks, and chemical reactions in the atmosphere, the net effect of which is uncertain and may differ from place to place. The predominant climate feedbacks operate though changes in the carbon cycle and CO_2 emissions, with a strong positive feedback predicted under future climate change. Methane emissions from wetlands are expected to increase under some conditions (such as permafrost melting) and to decrease in others (such as the drying of northern and tropical soils), as described earlier. Nitrous oxide emissions are generally higher in wetter soils. Increased emissions of tropospheric ozone precursors, NO_x and VOCs, occur under warmer conditions.

Where climate change causes shifts in vegetation there will be regional biophysical effects—for example, due to the northward shift of boreal forests and enhanced vegetation cover in the Sahara (Brovkin et al. 2003; Claussen et al. 2003). Vegetation loss could lead to positive climate feedbacks though biophysical effects—for instance, feedback on local drying from Amazon dieback (Betts et al. 2004)—and could lead to increased dust emissions. Changes in water availability affect transpiration, with drought reducing water recycling and rainfall.

On the land, warming increases the rate of decomposition of soil organic matter, thereby reducing carbon storage in soil. Although soil warming experiments have shown an increased rate of decomposition for the first one to three years only (Jarvis and Linder 2000; Oechel et al. 2000; Luo et al. 2001; Rustad et al. 2001), this represents the burning-off of the labile (easily decomposed) component only. The larger pool of more chemically stable soil organic matter is potentially vulnerable to warming over longer time scales (Cramer et al. 2001; Joos et al. 2001; Knorr et al. 2005). The effect of global warming on vegetation cover is highly uncertain but likely also to affect atmospheric CO_2. One coupled climate-carbon cycle model has predicted a dieback of tropical forests in South America, which, along with increased soil organic matter decomposition and subsequent carbon loss, would lead to an additional 200 ppm increase in atmospheric CO_2 (Cox et al. 2000). Another model predicted a smaller feedback (Friedlingstein et al. 2001).

In the oceans, sea surface temperature increase and changes in the global water cycle tend to increase vertical stratification (layering) and to slow down global ocean circulation. Warming reduces the solubility of CO_2 in the ocean. Stratification slows the mixing into deep layers of excess carbon in the surface water. Stratification further reduces nutrient input into the surface zone and leads to a prolonged residence time of phytoplankton at the surface, near light. Models indicate the net effect is reduced phytoplankton productivity (Bopp et al. 2001; Joos et al 1999). Models estimate that the combined effect of warming and circulation changes on ocean physics and biology will reduce the oceanic CO_2 uptake by 6–25% in 1990–2050, thus providing a positive climate feedback (Maier-Reimer et al. 1996; Sarmiento et al. 1998; Matear and Hirst 1999; Joos et al. 1999, Bopp et al. 2001; Plattner et al. 2001).

Changes in ocean circulation, pH, and temperature are also likely to have additional effects on ocean biology that have not been quantified in these models and that may induce further CO_2 feedbacks. These include changes in the community structure, net production, and bio-calcification. The effect of bio-calcification is estimated to increase the ocean carbon sink by less than 2.5% (Riebesell et al. 2001). The quality and magnitude of biological changes will vary over space and time and is highly uncertain. While the combined inorganic and biological changes tend to reduce global uptake of anthropogenic carbon, the global net effect on carbon uptake of the ocean biological changes alone is unknown. Altered size and timing of phytoplankton blooms can also potentially reduce fish production (Chavez et al. 2003; Beaugrand et al. 2002; Platt et al. 2003).

13.6 Impacts of Changes in Climate and Air Quality on Human Well-being

13.6.1 Impacts of Changes in Climate on Human Well-being

According to the IPCC (2001d), "The earth's climate system has demonstrably changed on both global and regional scales since the pre-industrial era, with some of these changes attributable to human activities. . . . Projected climate change will have beneficial and adverse effects on both environmental and socioeconomic systems, but the larger the change and rate of change in climate, the more the adverse effects dominate." Changes in climate are linked to all aspects of human well-being as defined by the Millennium Ecosystem Assessment (MA 2003). This section provides a summary of the detailed results presented by IPCC (2001a, 2001b, 2001c, 2001d) unless otherwise stated.

13.6.1.1 Security

An increase in frequency and severity of floods and droughts has been noted in some areas. A fourfold increases in economic losses for catastrophic weather events from the 1980s to the 1990s (average annual global loss $40 billion in the 1990s) has been partly linked to regional climatic factors and partly to socioeconomic factors. IPCC projections include increasing ecological shocks and stress as well as vulnerability to them, alongside a reduction in the ability to predict and plan for the weather.

13.6.1.2 Health

Many vector-, food-, and water-borne infectious diseases are known to be sensitive to changes in climatic conditions, as are production of spores and pollens and the climatically related production of photochemical air pollutants. Floods increase risk of drowning, diarrhea, respiratory diseases, water-contamination diseases, hunger, and malnutrition. Heat waves in Europe and America have been associated with a significant increase in urban mortality. For example, during the European heat wave of 2003, almost 15,000 additional deaths were estimated to have occurred in France, mostly in elderly people (WHO 2004). Warmer wintertime temperatures can also result in reduced wintertime mortality in cold climates.

Indirect climate effects on human health include changes in water quality, air quality, food availability and quality, population displacement, and economic disruption. Poor understanding of the role of socioeconomic and technological factors in shaping and mitigating health impacts, and the difficulty in separating climate variability impacts from climate change impacts, means that current estimates of the potential health impacts of global warming are based on models with *medium* to *low certainty*.

The World Health Organization (WHO 2002) has estimated that global warming was responsible in 2000 for approximately 2.4% of worldwide diarrhea, 6% of malaria in some middle-income countries, and 7% of dengue fever in some industrial countries. (See Table 13.3.) These factors contribute to the estimated mortality of 154,000 deaths and 5.5 million disability-adjusted life years, mostly in Southeast Asia and Africa. (Such estimates are of high uncertainty, however, due to the difficulties in establishing direct causality.)

Overall, global warming is projected to increase threats to human health, particularly in lower-income populations predominantly within tropical and sub-tropical countries: thermal stress effects amplified with higher projected temperature increases; expansion of areas of potential transmission of malaria and dengue; greater increases in deaths, injuries, and infections from floods and storms; and water quality degraded by higher temperatures and salinization, with changes modified by changes in water flow volume.

13.6.1.3 Basic Material for a Good Life

The impacts of global warming include changes in species distributions, population sizes, the timing of reproduction or life-cycle events, and the frequency of pest and disease outbreaks (IPCC 2001b, 2001d). Growing season has lengthened by one to four days in the Northern Hemisphere during the last 40 years, with earlier onset of life-cycle events (such as flowering, migration, and breeding). Coral reef bleaching has increased in frequency. (See Chapter 19.)

The productivity of ecological systems is highly sensitive to climate change, and projections of change in productivity range from increases to decreases. Models of cereal crops indicate that in some temperate areas, potential yields increase for small increases in temperature but decrease with larger temperature changes. In most tropical and sub-tropical regions, potential yields are projected to decrease for most projected increases in temperature. An increase in frequency of disturbance by fire and insect pests is projected.

Stratification of the ocean at warmer temperatures may reduce phytoplankton productivity and thus fish production (Platt et al. 2003). A further increase in frequency and extent of coral reef bleaching is projected, along with loss of coastal wetlands and erosion of shorelines. Diversity in ecological systems is expected to be affected by climate change and sea level rise, with an increased risk of extinction of some vulnerable species. Projected climate change would exacerbate water shortages and water-quality problems in many water-scarce areas of the world but would alleviate it in others. Some systems—including coral reefs, glaciers, mangroves, boreal and tropical forests, polar and alpine systems, prairie wetlands, and temperate native grasslands—are particularly vulnerable to climate change because of limited adaptive capacity and may undergo significant and irreversible damage (IPCC 2001b, 2001d).

13.6.1.4 Good Social Relations

The impacts just described may compound the risk of conflict over natural resources.

Tropical and dryland regions are likely to incur more detrimental impacts than temperate and cold regions (IPCC 2001b, 2001d). People in poor countries are most vulnerable due to lower adaptive capacity. Climate change is expected to have negative impacts on development, sustainability, and equity (IPCC 2001b, 2001d; Toth 1999). The aggregated market sector effects are estimated to be negative for many developing countries for all magnitudes of global mean temperature increase studied and are estimated to be mixed for industrial countries for up to a few degrees Celsius warming and negative for warming beyond that point.

The global value of the climate regulation services of ecosystems was estimated by Costanza et al. (1997) to be $2 trillion per year, of which $800 billion was attributed to the biological role of ecosystems, principally carbon storage in forests and changes in greenhouse gas emissions and albedo from converting grasslands to agriculture. The remainder was due to nonbiological oceanic uptake of CO_2. This global value is a synthesis of published estimates of ecosystem service values for several different biomes, using a range of valuation techniques. Extrapolating from the biome values to a global aggregate is likely to underestimate the true total value because these are partial valuations in several ways. First of all, not all biomes were represented in the available literature. Second, not all processes (biochemical and biophysical) and feedbacks that generate ecosystem climate services were considered. For example, increasing loss of forests might alter other ecosystems so dramatically as to change their function in the carbon cycle, such as altering temperature in the oceans and net ocean uptake of CO_2.

Damages from reductions in carbon sequestration capacity may be nonlinear, with damages increasing more than proportionally to forest loss. The unit demand for an ecosystem service is likely to increase rapidly as its supply diminishes; in other words, there is reason to expect that the marginal value of forests for climate control may increase with forest loss. In this case, ag-

Table 13.3. Attributable Mortality and Disability-Adjusted Life Years from Environmental Risk Factors, 2000.[a] The risk factors and measured adverse outcomes of exposure are as follows: unsafe water, sanitation, and hygiene–diarrhea; urban air pollution–cardiovascular mortality, respiratory mortality, lung cancer, mortality from acute respiratory infections in children; indoor smoke from solid fuels–acute respiratory infections in children, chronic obstructive pulmonary disease, lung cancer; climate change–diarrhea, flood injury, malaria, malnutrition, dengue fever, cardiovascular mortality, population movement. (WHO 2002)

	World	Africa	North America[b]	South and Central America	Eastern Mediterranean	Europe	Southeast Asia	Western Pacific
					(thousand)			
Mortality								
Unsafe water, sanitation, and hygiene	1,730	608	1	54	270	18	699	77
Urban air pollution	799	32	28	35	59	107	164	373

Climate change[c]	154	54	0	0	21	0	74	3
DALYs								
Unsafe water, sanitation, and hygiene	54,158	18,636	61	2,045	8,932	736	19,727	4,018
Urban air pollution	7,865	485	200	360	727	859	1,852	3,386
Indoor smoke from solid fuels	38,539	12318	6	773	3,572	544	15,227	6,097
Climate change[c]	5,517	1,893	3	94	768	17	2,572	170

[a] Uncertainty ranges (range of coefficient of variation): water and indoor air pollution 0 to 4.9; urban air pollution 10 to 14.9; climate change >15.

[b] North America: United States, Canada, and Cuba.

[c] Climate change impacts are modeled effects on disease, flood risk, and food production for modeled climate in year 2000 compared with mean climate in 1961–90.

gregating the marginal valuation methods used may underestimate the economic value of total forest climate control services. While the direct use of the Costanza et al. (1997) service values is problematic in many policy spheres, which need the marginal values, the review by Balmford et al. (2002) of the relative values of intact and human-modified ecosystems suggests that in general terms, the loss of nonmarketed services associated with ecosystem loss or conversion frequently exceeds the (marketed) benefits.

13.6.2 Impacts of Changes in Air Quality on Human Well-being

Impacts of air pollution on human health can be dramatic, as exemplified by the ''Asian/atmospheric brown cloud'' and the smoke haze generated by 1997–98 fires in Indonesia. Health effects can also be more subtle and are increasingly widespread. Industrial pollution is not the concern of this chapter, but some of its effects were included in Table 13.3 for illustration. Ecosystem emissions, particularly those resulting from biomass burning, can add to the burden of industrial pollution and affect human well-being in nonurban areas, while ecosystem sinks can reduce the negative impacts of industrial air pollution. Some ecosystem air quality effects described earlier in this chapter are summarized below according to the Millennium Ecosystem Assessment (MA 2003) definition of well-being:

13.6.2.1 Security

Vegetation fires can cause damage to property and life, with effects of smoke on transport and effects of toxic pollutants on health. The health implications of changes in clean air are outlined in a following section.

13.6.2.2 Access to Resources

Some pollutants with ecosystem sources and sinks are deleterious to ecosystem health, affecting production of resources such as food and timber. For example, ecosystems are currently a net sink for tropospheric ozone and compounds that contribute to acid rain as well as for CO_2 (ocean acidification and impacts on marine organisms). Agricultural ecosystems are a net source of nitrogen compounds that contribute to acid rain and eutrophication of lakes, decreasing agricultural and fish production. On the other hand, some of these N compounds have a fertilizing effect, increasing plant productivity up to the point where the ecosystems become saturated with that nutrient.

13.6.2.3 Health: Clean Air

Biomass burning is a source of particulates, tropospheric, ozone and CO, all of which have harmful respiratory effects. Smoke pollution generated by vegetation fires occasionally reaches levels with major public health and economic impacts—usually when wildfires or land management fires get out of hand under extreme weather conditions. Vegetation fires particularly enhance the risk of acute respiratory infections in childhood, a major killer of young children in developing countries, and affect the health of women already exposed to high levels of indoor air pollution (Schwela et al. 1999).

Few epidemiological studies investigate short-term and long-term implications of vegetation fires for human health. The health impacts of burning biomass (mainly fuelwood or dung) as an energy source in indoor cookstoves has been studied in more detail. (See also Chapter 9.) Exposures are far more concentrated and chronic than for vegetation fires, but since many of the compounds emitted are the same, it is useful to note the impacts for comparison. WHO has estimated that 1.6 million deaths and 39 million DALYs worldwide were attributable to indoor biomass burning, with women and children particularly at risk (WHO 2002). Ecosystems are a net sink for tropospheric ozone, reducing the impacts of urban air pollution. Dust adversely affects respiration and is reduced by vegetation cover.

13.6.2.4 Good Social Relations

Ecosystem reduction of air pollution, such as acid rain and ocean acidification, can limit damage to ecosystems valuable for aesthetic, cultural, religious, recreational, or educational purposes. On the other hand, the detrimental impacts of some wildfires on economies, human health, and safety have consequences comparable in severity to other major natural hazards and could lead to transboundary conflicts. In addition to the air quality impacts of fire mentioned already, wildfire can lead to the destruction of ecologically or economically important resources (such as timber and biodiversity), adding to rapid environmental changes and degradation. Smoke plumes can cause visibility problems, resulting in accidents and economic loss including closure of airports and marine traffic.

Fires can be catastrophic in areas that have been long protected from them, allowing a buildup of fuel, and where human settlement has extended into forest areas. In the 1980s and 1990s, the most serious pollution problems were noted in the Amazon Basin and in Southeast Asia. Land use fires and uncontrolled wildfires in Indonesia and neighboring countries in 1991, 1994, and 1997 created regional smog layers that lasted for several weeks. Box 13.5 provides examples of impacts and losses of particular fire events. Advances in satellite data and atmospheric transport models are expected to improve monitoring, evaluation, and early warning systems to prevent fires or manage impacts. (See Chapter 16 for more information on fire impacts other than air quality.)

BOX 13.5

Recent Major Fire Episodes and Losses

- Regional haze episodes caused by forest fires occurred in SE Asia on several occasions during the 1990s (Radojevic 2003). Measurements in Brunei in 1998 during a particularly severe haze episode caused mainly by local fires recorded many compounds, including VOCs (such as benzene and toluene), aldehydes, cresol, phenol, acetic acid, polynuclear aromatic hydrocarbons, heavy metals, and levels of particulates exceeding air quality guidelines (Muraleedharan et al. 2000). In 1994, the fires burning in Indonesia caused the visibility to drop to as low as 500 meters in Singapore. During the 1997 South East Asian smog episode, when particle levels in some areas were up to 15 times higher than normal, the Malaysian government was close to evacuating the 300,000 inhabitants of the city of Kuching (Brauer and Hisham-Hashim 1998), and the loss of an aircraft and 234 human lives in Sumatra was partially attributed to air traffic control problems caused by the smog.
- On the Indonesian islands of Kalimantan and Sumatra during 1997–98, an estimated 9 million hectares of vegetation burned. Some 20 million people in Indonesia alone suffered from respiratory problems, mainly asthma, upper respiratory tract illness, and skin and eye irritation during the episode, with nearly four times as many acute respiratory illnesses as normal reported in South Sumatra (Heil and Goldammer 2001). A first assessment of costs of damages caused by the fire episode on 4–5 million hectares was $4.5 billion (short-term health damages; loss of industrial production, tourism, air, ground and maritime transportation; fishing decline; cloud seeding and fire-fighting costs; losses of agricultural products, and timber; and direct and indirect forest benefits) (EEPSEA 1998).
- The fires burning in Mexico during the 1998 episode forced the local government to shut down industrial production in order to decrease additional industrial pollution during the fire-generated smog. Daily production losses were about $8 million (Schwela et al. 1999).
- In 2002, forest and peat fires in the Moscow region resulted in the worst haze seen in Moscow in 30 years. This has caused severe cardiovascular and respiratory problems among the population of Moscow, especially among children (GFMC 2003).

13.7 Synthesis: Effects of Ecosystem Change and Management on Climate and Air Quality Services

Table 13.4 provides a synthesis of the different biochemical and biophysical effects of each MA ecosystem type on climate and air quality. This section addresses the most pertinent types of ecosystem change and management due to the scale of their impacts or their relevance to the MA.

13.7.1 Changes in Ecosystem Cover and Management

The largest effects of ecosystems on air quality and climate due to human-induced changes in land cover and management have been associated with deforestation, agricultural management (fertilizer use, cattle, and irrigation), and biomass burning. Deforestation and agricultural practices are mainly driven by population growth, urbanization, and economic development and are modified by policies and subsidies. Chapter 7 in the *Scenarios* volume (and Chapter 3 here, more briefly) describes many of these direct and indirect driver and linkages. While industrial countries have been responsible for most of the industrial impacts on climate and air quality in the past, management of tropical ecosystems in particular has played a role and will likely continue to have a significant impact in the future.

13.7.1.1 Forest Cover and Management

Change in forest cover has had a larger impact on global and regional climate than any other ecosystem driver. Deforestation has been a major source of CO_2, only partially offset by reforestation, afforestation, and forest management activities and by the fertilizing effects of N and CO_2. Immediately after deforestation, tropical soils are a source of N_2O, although emissions decline to original level or below after 15–20 years. Tropical forests are also an important source of VOCs; therefore deforestation reduces VOC emissions, although this will depend on the emission rate of the replacement vegetation. Deforestation reduces the sink for tropospheric ozone and N gases (Ganzeveld and Lelieveld 2004).

Forest cover affects albedo, particularly in boreal snow-covered regions. Deforestation increases albedo (cooling). Model results suggest that historical deforestation has led to a cooling of the land surface (Betts 2001; Govindasamy et al. 2001) comparable to the warming caused by CO_2 emissions resulting from the same deforestation (Brovkin et al. 2004), and that this biophysical effect of historical deforestation is necessary to explain the observed climate during the second half of the nineteenth century (Crowley 2000; Bauer et al. 2003). Loss of forest cover profoundly affects the water cycle, reducing water recycling and local rainfall, but the net hydrological effect of deforestation is less certain, especially on a global scale (Rind 1996).

Table 13.4. Summary of Important Ecosystem Fluxes and Biophysical Properties, by Ecosystem Type

Biome	Major Biochemical Impacts	Major Biophysical Impacts
Cultivated systems	CO_2 source: conversion to cropland, management sink: management (e.g., low tillage) CH_4 source: rice paddies, ruminant animals, termites sink: upland soils N_2O source: soils, cattle/feedlots, fertilizer use NO_x source: soils NH_3 source: cattle, feedlots, fertilizer, plants, soils VOCs source: oxygenated VOCs (e.g., methanol, ethanol, acetone) dust source: disturbed soil surfaces and reduced vegetation cover	albedo: increase when forest conversion to cropland, decrease in case of irrigation, decrease where leaf area index higher than natural vegetation transpiration: decrease in case of forest conversion to cropland, increase for irrigated systems
Dryland systems (including savannas and grasslands)	CO_2 source: biomass burning, devegetation, sink: woody encroachment CH_4 source: biomass burning, ruminants, termites sink: upland soils CO source: biomass burning N_2O source: soils NO_x source: soils NH_3 source: plants, animal waste, soils VOCs source: plants, biomass burning S source: biomass burning particulates source: biomass burning tropospheric O_3 source: biomass burning CO source: biomass burning dust source: devegetation, degradation, and erosion	albedo: increase in case of desertification surface runoff: increase in case of desertification

13.7.1.2 Agriculture

Agriculture is a significant source of greenhouse gases, accounting for about 5% of total CO_2 emissions (Rosenberg et al. 1998), about a quarter of CH_4 emissions (rice paddies and ruminant animals) (Praether et al. 2001), and about a third of N_2O emissions (agricultural soils and cattle/feedlots) (Praether et al. 2001). Agricultural management can reduce carbon loss or promote storage to some extent (Lal et al. 2004; Renwick et al. 2004). The use of nitrogen fertilizers profoundly alters the nitrogen cycle, leading to increased emissions of N gases that, in addition to contributing to global warming, contribute to acid rain and eutrophication of lakes, increase the atmospheric cleansing capacity, destroy stratospheric ozone, and may cause respiratory and other health problems. Dust is lost from cultivated and denuded soil surfaces. Agricultural crops often have a higher leaf area index than natural vegetation, reducing albedo. Irrigation increases water recycling, raising latent heat flux and cooling the surface.

13.7.1.3 Wetlands

Wetland draining for agriculture, forestry, or water extraction leads to a decrease in CH_4 production and an increase in CO_2 and N_2O emissions, probably with a net decrease in radiative forcing on short time-frames (20–100 years), but in the longer term the opposite may be true (*low certainty*) (IPCC 2001a; Christensen and Keller 2003). The same will be true for wetlands experiencing drying due to global warming, such as Northern Alaska (now and in the future), and for tropical seasonally flooded areas (if they dry in the future) (*low certainty*). Where climate change has led to loss of permafrost, the net effect is increased CH_4 emissions that will likely continue in the future.

13.7.1.4 Dryland Management and Degradation

Management of drylands to increase vegetation cover and reduce soil erosion increases carbon storage, reduces dust sources, and increases rainfall recycling. Potential impacts are significant given the very large areas involved. Drylands store more carbon in soils than in biomass and are thus more vulnerable to carbon loss through soil erosion, but with good potential for increasing belowground carbon storage (IPCC 2000). (See Chapter 22.)

13.7.1.5 Biomass Burning

Biomass burning is a major source of toxic pollutants, greenhouse gases, and reactive gases—causing major health and visibility problems and contributing to global warming. Greenhouse gases emitted during fires are CO_2, CH_4 (5–10% of all sources), N_2O, and tropospheric ozone precursors: NO_x (just over 10% of all sources), CO (a quarter of all sources), and VOCs. Aerosols from biomass burning have a net cooling effect. Fire suppression reduces emissions from burning and encourages woody plant biomass to increase and act as a carbon sink. (In the United States, for example, this may have amounted to a sink of 0.2 petagrams of carbon per year during the 1980s (Houghton et al. 1999).) However, fire suppression can also increase the risk of future, catastrophic wildfires (Schwela et al. 1999). Pollutants include particulates, precursors of tropospheric ozone, and CO, plus a number of trace gases and compounds (such as polynuclear aromatic com-

Table 13.4. *continued*

Biome	Major Biochemical Impacts	Major Biophysical Impacts
Forest and woodland systems	CO_2 source: deforestation sink: afforestation, reforestation, forest management CH_4 source: biomass burning, termites sink: upland soils CO source: biomass burning, decomposition N_2O source: soils NO_x source: soils sink: canopy NH_3 source: plants, animal waste, soils VOCs source: plants, biomass burning S source: biomass burning particulates source: biomass burning tropospheric O_3 source: biomass burning CO source: biomass burning	albedo: increase in case of deforestation, decrease due to afforestation transpiration: decrease in case of deforestation, increase for afforestation
Urban systems	CO_2 source: biomass (fuel) burning? CH_4 source: landfill, biogas N_2O source: landfills VOCs source: landfills S source: landfills tropospheric O_3 source: indoor biomass fuel burning CO source: indoor biomass fuel burning particulates: indoor biomass fuel burning	"heat island" effect albedo: increase with expansion and vegetation replacement transpiration: decreases with expansion and vegetation replacement
Inland water systems	CH_4 source: intermittent flooding of vegetation (remineralization)	freshwater incursions to ocean and effects on ocean circulation
Coastal systems	CO_2 sink: biological pump source: upwelling net balance unknown CH_4 source: remineralization N_2O source: denitrification	
Marine systems	CO_2 sink: biological and solubility pumps N_2O source: remineralization CH_4 source: remineralization DMS source: plankton	phytoplankton blooms—reduced albedo (warming sea surface temperatures)
Polar systems	CO_2 source: permafrost melting CH_4 source: permafrost melting	reduced ice cover due to warmer surface and longer growing season—decreased albedo and further warming
Mountain systems	CO_2, CH_4 and N_2O production under snowpack can constitute a significant proportion of the annual trace gas budget	reduced ice cover due to warmer surface and longer growing season—decreased albedo and further warming, shift in treeline
Island systems	Depends on land cover as above, no specific impacts	deforestation changes in wind patterns alters ocean upwelling, warming sea surface temperatures
Wetlands	CH_4 source: anaerobic respiration—decreased by draining CO_2 source: peatland burning, aerobic respiration after draining CO source: peatland burning N_2O source: soils	reduced evapotranspiration in case of draining

pounds, aldehydes, organic acids, sulfur dioxide, and methyl halides (stratospheric ozone depletion)).

13.7.2 Changes in Biodiversity, Invasive Species, and Disease

Change in species diversity in the strict sense is thought not to have a large influence on climate and air quality, although climate, climate change, and air quality conditions have a large influence on biodiversity. (See Chapters 4 and 11.) Changes in the relative abundance of different functional types (such as needle-leaved versus deciduous trees, shrubs versus grasses, and diatoms versus cocolithophorids), however, may have substantial impacts on sources and sinks of gases and on other ecosystem properties (e.g., Riebesell et al. 2001; Scherer-Lorenzen et al. 2005). Loss of biodiversity could further affect the adaptability and resilience of ecosystems and their ability to migrate with changing climate (Schulze and Mooney 1993; Tilman et al. 1997; Nepstad et al. 1999; Loreau et al. 2001; Kim Phat et al. 2004).

Furthermore, the loss of particular species could have a substantial impact on ecosystem functioning. Such ''keystone species'' or ''ecosystem engineers'' (Jones et al. 1994) may not necessarily be identified in advance, which makes preventive mitigation policy difficult. For a review of climate-biodiversity interactions, see Gitay et al. (2002) as well as Chapters 4 and 11. Some examples of drivers of change in functional type abundance are provided here, including climate change, species invasions, and disease.

Encroachment of invasive woody species is generally an additional sink of CO_2, changes biophysical properties (increases LAI, increases transpiration, and reduces albedo), and may reduce biodiversity—for example, Mesquite (*Prosopis* sp.) invasions in Texas in the United States (Archer et al. 2001; Dugas et al. 1996; Gibbens 1996).

The ''fertilizing'' effect of increased CO_2 levels benefit some species (most trees) more than others (such as grasses) (Nowak et al. 2004), giving them a competitive edge. For example, Smith et al. (2000) showed that elevated CO_2 increased the success of an invasive C_4 grass species in the Mojave Desert, potentially reducing biodiversity and altering ecosystem function. As with invasive tree species, this functional shift from grass to trees will also affect biophysical properties, biodiversity, and sources/sinks of various trace gases. Trees are not always the winners; for example, lianas respond more strongly than trees to the fertilizing effects of increased atmospheric CO_2 concentration (Condon et al. 1992; Granados and Koner 2002; Phillips et al. 2002.). Lianas enhance tree mortality and suppress tree growth, which could ultimately reduce carbon storage in forests.

The chestnut blight in the United States around the 1900s caused a switch from chestnut trees, which do not emit isoprene (a VOC involved in tropospheric ozone formation), to oaks, which do, approximately doubling the biomass of isoprene-emitting species (Lerdau and Keller 1997).

Regime shifts of marine pelagic ecosystems, which have occurred in Arctic waters since the mid-1980s, have caused major breakdown in fishery production. Diatom-dominated phytoplankton communities were replaced by extensive coccolithophorid blooms in the Barents Sea and the eastern Bering Sea (Smyth et al. 2004), causing massive changes in ecosystem structure. With coccolithophores being predominant producers of DMS, the observed regime shifts are likely to have altered the sulfur cycle and cloud formation in these areas, affecting air quality and water recycling.

Certain types of marine organisms (calcifiers—coccolithophorids, foaminifera, and corals) form shells of calcium carbonate ($CaCO_3$). This process releases CO_2 to the ambient seawater, countering part of the photosynthetic CO_2 drawdown (that is, the drawdown of CO_2 by coccolithophorids is much smaller than that of non-calcifying phytoplankton). A shift in species composition away from coccolithophorids, for example due to changes in ocean acidity, would increase the ocean's CO_2 storage capacity. On the other hand, biogenic particles containing $CaCO_3$ and SiO_2 sink faster than other particles, which implies that the plankton (coccolithophorids and diatoms) producing these two minerals should increase the drawdown of carbon from surface to depth in the ocean. Thus shifts in composition of the marine ecosystems have the potential to influence the oceanic carbon sink (Francois et al. 2002; Klaas and Archer 2002), but at present we cannot quantify the probability, extent, or direction of the likely future changes or their consequences for climate.

Main Messages

According to the World Health Organization, infectious diseases still account for close to one quarter of the global burden of disease. Major tropical diseases, particularly malaria, meningitis, leishmaniasis, dengue, Japanese encephalitis, African trypanosomiasis, Chagas disease, schistosomiasis, filariasis, and diarrheal diseases still infect millions of people throughout the world (*very certain*).

The magnitude and direction of altered disease incidence due to ecosystem changes depend on the particular ecosystems, type of land use change, disease-specific transmission dynamics, and the susceptibility of human populations. Anthropogenic drivers that especially affect infectious disease risk include destruction or encroachment into wildlife habitat, particularly through logging and road building; changes in the distribution and availability of surface waters, such as through dam construction, irrigation, or stream diversion; agricultural land use changes, including proliferation of both livestock and crops; deposition of chemical pollutants, including nutrients, fertilizers, and pesticides; uncontrolled urbanization or urban sprawl; climate variability and change; migration and international travel and trade; and either accidental or intentional human introduction of pathogens (*medium certainty*).

There are inherent trade-offs in many types of ecosystem changes associated with economic development, where the costs of disease emergence or resurgence must be weighed against a project's benefits to health and well-being. Such trade-offs particularly exist between infectious disease risk and development projects geared to food production, electrical power, and economic gain. To the extent that many of the risk mechanisms are understood, disease prevention or risk reduction can be achieved though strategic environmental management or measures of individual and group protection (*high certainty*).

Intact ecosystems play an important role in regulating the transmission of many infectious diseases. The reasons for the emergence or reemergence of some diseases are unknown, but the main biological mechanisms that have altered the incidence of many infectious diseases include altered habitat, leading to changes in the number of vector breeding sites or reservoir host distribution; niche invasions or interspecies host transfers; changes in biodiversity (including loss of predator species and changes in host population density); human-induced genetic changes of disease vectors or pathogens (such as mosquito resistance to pesticides or the emergence of antibiotic-resistant bacteria); and environmental contamination of infectious disease agents (*high certainty*).

Disease/ecosystem relationships that best illustrate these biological mechanisms include the following examples with *high certainty* (unless stated otherwise):

- Dams and irrigation canals provide ideal habitat for snails that serve as the intermediate reservoir host species for schistosomiasis; irrigated rice fields increase the extent of mosquito breeding areas, leading to greater transmission of mosquito-borne malaria, lymphatic filariasis, Japanese encephalitis, and Rift Valley fever.
- Deforestation alters malaria risk, depending on the region of the world. Deforestation has increased the risk of malaria in Africa and South America (*medium certainty*).
- Natural systems with intact structure and characteristics generally resist the introduction of invasive human and animal pathogens brought by human migration and settlement. This seems to be the case for cholera, kala-azar, and schistosomiasis, which have not become established in the Amazonian forest ecosystem (*medium certainty*).
- Uncontrolled urbanization of forest areas has been associated with mosquito-borne viruses (arboviruses) in the Amazon, and lymphatic filariasis in Africa. Tropical urban areas with poor water supply systems and lack of shelter promote transmission of dengue fever.
- There is evidence that habitat fragmentation, with subsequent biodiversity loss, increases the prevalence of the bacteria that causes Lyme disease in North America in ticks (*medium certainty*).
- Zoonotic pathogens (complete natural life cycle in animals) are a significant cause of both historical diseases (including HIV and tuberculosis) and newly emerging infectious diseases affecting humans (such as SARS, West Nile virus, and Hendra virus).
- Intensive livestock agriculture that uses subtherapeutic doses of antibiotics has led to the emergence of antibiotic strains of *Salmonella, Campylobacter,* and *Escherichia coli* bacteria. Overcrowded and mixed livestock practices, as well as trade in bushmeat, can facilitate interspecies host transfer of disease agents, leading to dangerous novel pathogens, such as SARS and new strains of influenza.

Human contact with natural ecosystems containing foci of infections increases the risk of human infections. Contact zones between systems are frequently sites for the transfer of pathogens and vectors (whenever indirect transmission occurs) to susceptible human populations such as urban-forest borders (malaria and yellow fever) and agricultural-forest boundaries (hemorrhagic fevers, such as hantavirus) (*high certainty*). The different types and subtypes of systems (natural, cultivated, and urban) may contain a unique set of infectious diseases (such as kala-azar or plague in drylands, dengue fever in urban systems, and cutaneous leishmaniasis in forest systems), but some major diseases are ubiquitous, occurring across many ecosystems (such as malaria and yellow fever) (*very certain*).

Tropical developing countries are more likely to be affected than richer nations in the future due to their greater exposure to the vectors of infectious disease transmission and environments where they occur. Such populations have a scarcity of resources to respond to and plan environmental modifications associated with economic activities (*high certainty*). However, international trade and transport leave no country entirely unaffected.

The following diseases (*high certainty*) are ranked as high priority for their large global burden of disease and their high sensitivity to ecological change:

- malaria across most ecological systems;
- schistosomiasis, lymphatic filariasis, and Japanese encephalitis in cultivated and inland water systems in the tropics;
- dengue fever in tropical urban centers;
- leishmaniasis and Chagas disease in forest and dryland systems;
- meningitis in the Sahel;
- cholera in coastal, freshwater, and urban systems; and
- West Nile virus and Lyme disease in urban and suburban systems of Europe and North America.

14.1 Introduction

This chapter focuses on infectious diseases whose incidence has been shown or is suspected to be related to anthropogenic ecological change. Mechanisms of change occur through a variety of ways, including altered habitats or breeding sites for disease vectors or reservoirs, niche invasions, loss of predator species, biodiversity change, host transfer, and changes in (intermediate) host population density.

Infectious diseases stemming from health infrastructural deficiencies, such as poor sanitation and lack of adequate vaccine coverage, as well as those linked to specific sociocultural factors, such as airborne and sexually transmitted diseases, are not covered in this chapter, even though these lead to a large global burden of disease. Readers should refer to Chapter 5 of this volume and Chapter 12 of *Policy Responses* for an assessment of noninfectious disease and related health topics.

Ecosystems affect human health in many ways, either directly or indirectly. Many major pharmaceuticals, including aspirin, digitalis, quinine, and tamoxifin, originated from plants. (See Chapter 10.) Intact ecosystems protect against mortality and injuries from floods and mudslides. (See Chapter 16.) Human health depends on access to food, clean water, clean air, and sanitation. (See also Chapters 8, 7, 13, and 27.) Watershed conditions influence water quality and wetlands help remove toxins from water—increased soil runoff following deforestation, for example, has led to mercury contamination of Amazonian fish. (See Chapter 20.) Toxic algal blooms threaten food safety. (See Chapter 19). Watershed protection has been used to offset the cost of drinking water treatment facilities. (See MA, *Policy Responses,* Chapter 7.) Finally, a broad range of noninfectious disease health risks and prevention strategies are detailed in Chapter 16 of *Policy Responses*.

Infectious diseases account for 29 of the 96 major causes of human morbidity and mortality listed by the World Health Organization, representing 24% of the global burden of disease (WHO 2004). As numerous reports address the health effects of poor sanitation and drinking water treatment, this chapter focuses more specifically on diseases with known links to anthropogenic ecological change. Table 14.1 and Figure 14.1 (in Appendix A) show the current extent and distribution of infectious and parasitic diseases around the globe.

The incidence of many of these diseases is not declining. According to WHO (WHO 2002), African trypanosomiasis, dengue, and leishmaniasis are emerging and expanding and do not yet have a standardized control program in place. In addition, malaria, schistosomiasis, and tuberculosis persist even though active control programs have been established. Comparison of disease-burden figures published in WHO's latest *World Health Report* (2004) with the same statistics from the previous report (WHO 2002) shows that malaria, meningitis, leishmaniasis, dengue, and Japanese encephalitis are increasing. Tropical diseases with essentially no change include diarrheal diseases, trypanosomiasis, Chagas disease, schistosomiasis, and filariasis. However, onchocerciasis (river blindness) shows a declining trend.

While this chapter summarizes known links between ecological degradation and altered infectious disease transmission or emergence, natural systems can also be a source of pathogens, and destruction of an ecosystem may, in some cases, reduce the prevalence of disease in an area. Destroyed ecosystems have led to the disappearance of foci of disease, but this has resulted more from economic development rather than from any planned disease control. Yet environmental modification has been, for millennia, a key means for controlling disease vectors—from the drainage of swamps in Rome to reduce mosquitoes to deforestation in Zimbabwe to protect cattle from trypanosomiasis. At this point in history, however, the scale of ecological change may be leading to disease emergence or reemergence, and this is the issue to which the assessment in this chapter is directed.

14.1.1 Historical Perspective on Infectious Diseases and Development

Over the millennia, people have used and changed the habitable environment. Ten thousand years ago, agriculture and large settlements developed. Several of today's most pervasive diseases originally stemmed from domestication of livestock. Tuberculosis, measles, and smallpox, for example, emerged following the domestication of wild cattle. Infectious agents or pathogens of vertebrate mammals that infect humans as incidental hosts are called zoonotic, and the resultant diseases are zoonoses. Many pathogens that are currently passed from person to person (anthroponotic), including some influenza viruses and HIV, were formerly zoonotic but have diverged genetically from their ancestors that occurred in animal hosts. Many diseases thought to be caused by noninfectious agents, including genetically based and chronic diseases, are now known to be influenced or directly caused by infectious agents (UNEP in press).

In the last two centuries, the spread of industrial and post-industrial change, rapid population growth, and population movements have quickened the pace and extensiveness of ecological change. New diseases have emerged even as some pathogens that have been around for a long time are eradicated or rendered insignificant, such as smallpox. Environmental and ecological change, pollutants, the widespread loss of top predators, persistent economic and social crises, and international travel that drives a great movement of potential hosts have progressively altered disease ecology, affecting pathogens across a wide taxonomic range of animals and plants (Epstein 1995).

14.1.2 Ecology of Infectious Diseases

Intact ecosystems maintain a diversity of species in equilibrium and can often provide a disease-regulating effect if any of these species are either directly or indirectly involved in the life cycle of an infectious disease and occupy an ecological niche that prevents the invasion of a species involved in infectious disease transmission or maintenance. Disease agents with much of their life cycle occurring external to the human host, such as water- and vector-borne diseases, are subjected to environmental conditions, and it is these diseases for which most linkages to ecosystem conditions have been found (Patz et al. 2000).

Infectious diseases are a product of the pathogen, vector, host, and environment. Thus, understanding the nature of epidemic and endemic diseases and emerging pathogens is essentially a study of the population biology of these three types of organisms, as well as of environmental factors. In addition to ecologically mediated influences on disease, changes in the level of infectious diseases can themselves disrupt ecosystems (such as bird populations or predator-prey relationships altered by West Nile virus) (Daszak et al. 2000; Epstein et al. 2003).

Recent interest in infectious disease threats to public health has focused on emerging and reemerging pathogens. From a scientific perspective, looking at emerging infectious diseases is useful, as they display different adaptive mechanisms of evolution that have been "successful" in leading to the survival or even increased spread of a microorganism. In a narrow sense, the study of the ecology of emerging infectious diseases tries to understand (and possibly also predict) the mechanisms that lead to the ability

Table 14.1. Burden of Infectious and Parasitic Disease in 2003, by WHO Region and Mortality Stratum. Mortality stratum is a way of dividing up the WHO regions, which are based on geography, into units which are more similar in terms of health performance (i.e., separating Australia, Japan, and New Zealand out from China, the Philippines, and others in the Western Pacific Region, and Canada, the United States, and Cuba from the rest of the Americas, where health status is poorer). They are based on WHO estimates of adult and child mortality, with some arbitrary threshold to group them into different classes (see second column in the table). The data are based on nationally reported health statistics, although there is sometimes some estimation by WHO if national statistics are poor or non-existent. (WHO 2004)

Region	Mortality Stratum	Total DALYs[a]	DALYs from Infectious and Parasitic Diseases	Infectious and Parasitic Diseases as Share of Total
		(thousand)	*(thousand)*	*(percent)*
Africa	high child, high adult	160,415	75,966	47.4
	high child, very high adult	200,961	111,483	
Americas	very low child, very low adult	46,868	1,228	2.6
	low child, low adult	81,589	6,719	8.2
	high child, high adult	17,130	3,944	23.0
Southeast Asia	low child, very low adult	62,463	10,598	17.0
	high child, high adult	364,110	78,355	21.5
Europe	very low child, very low adult	51,725	891	1.7
	low child, low adult	37,697	2,040	5.4
	low child, high adult	60,900	2,734	4.5
Eastern Mediterranean	low child, low adult	24,074	1,529	6.4
	high child, high adult	115,005	30,881	26.9

	low child, low adult	248,495	23,349	9.4
Total		**1,487,816**	**350,039**	**23.5**

[a] Disability-adjusted life year: years of healthy life lost, a measure of disease burden for the gap between actual health of a population compared with an ideal situation where everyone lives in full health into old age. (WHO World Health Report 2004)

to switch hosts and establish in a new host—from the perspective of a given pathogen (as described later in this chapter).

Definitions of the term ''emerging'' are given early in the literature (e.g., Krause 1981; Lederberg et al. 1992). Emerging diseases are those that have recently increased in incidence, impact, or geographic or host range (Lyme disease, tuberculosis, West Nile virus, and Nipah virus, respectively); that are caused by pathogens that have recently evolved (such as new strains of influenza virus, SARS, or drug-resistant strains of malaria); that are newly discovered (Hendra virus or Ebola virus); or that have recently changed their clinical presentation (hantavirus pulmonary syndrome, for instance). Many authors vary in their definitions of ''recent,'' but most agree that emerging infectious diseases are those that have developed within the last 20–30 years (Lederberg et al. 1992). ''Reemerging'' diseases are a subclass of emerging diseases that historically occurred at significant levels but that became less significant due to control efforts and only recently increased in incidence again, such as dengue fever and cholera.

14.1.3 Trade-offs

While preservation of natural ecosystems can prevent disease emergence or spread, there are recognized trade-offs between ecological preservation and human disease. Malaria control efforts, for example, which relied heavily on the insecticide DDT, caused enormous damage to wetland systems and beyond. (See MA *Policy Responses,* Chapter 12.)

Probably the best documented examples of trade-offs involving ecosystem change, development, and disease are associated with water supply projects for agriculture or electrical power. (See Box 14.1.) Dams and irrigation systems were one of the most visible symbols of water resources development and management in the twentieth century. Irrigation systems are estimated to consume 70–80% of the world's surface freshwater resources and produce roughly 40% of its food crops. (See Chapter 7.) The pace of irrigation development has increased rapidly over the past half-century, in order to meet the increasing food requirements of human populations. But irrigation and dam construction can also increase transmission of diseases such as schistosomiasis, Japanese encephalitis, and malaria.

Such trade-offs also have an important temporal aspect. For example, draining wetlands can reduce mosquito breeding sites for immediate benefit, but the wetland services of filtering, detoxifying, or providing species habitat will be lost.

14.1.4 Ecosystem Services Relevant to Human Health

The relationships between ecological systems, their services, human society, and infectious diseases are complex. (See Figure 14.2.) The primary drivers of ecosystem changes are linked to population growth and economic development. These changes trigger several ecological mechanisms that can often increase the risk of infectious disease transmission or can change conditions of vulnerability, such as malnutrition, stress and trauma (in floods and storms, for example), immunosuppression, and respiratory ailments associated with poor air quality.

BOX 14.1

Trade-offs: Dams—Food and Power versus Disease

From 1930 to 1970, dams were synonymous with economic development, consuming an estimated $3 trillion in global investments but providing food security, power, local employment, and the expansion of physical and social infrastructure such as roads and schools (WCD 2000). Apart from their direct benefits, dams also are recognized to mediate indirect benefits, both economic and social, that are often ignored in quantifications of economic benefits focused on crop production. These include the use of water for horticulture, livestock farming, fisheries, and domestic purposes.

Case studies done for the World Commission on Dams show services and benefits ranging from irrigation and electricity generation for domestic and industrial purposes to flood protection, tourism, fisheries, local employment, and water supply. At the household level it is accepted that irrigation projects, and implicitly large irrigation dams, have contributed to greater food security and improved nutrition. The magnitude of the impact at the national level is less clear. In India (one of the largest builders of irrigation dams), for instance, estimates of total food increase attributable to new land brought under irrigation range from 10% to 30% and nutrition levels have improved by 14% over the past 25 years. Over the past 50 years, the country has achieved a marginal per capita increase in food availability and a decrease in the proportion of rural population below the poverty line (people without the capacity to purchase their own food requirements). However, the absolute number of people below the poverty line has increased by approximately 120 million people (WCD 2000).

The financial and economic profitability of large dam projects also presents a mixed picture. The WCD's evaluation of 14 large dam projects showed a shortfall of roughly 5% in the average economic internal rate of return, between the appraisal estimate and the evaluation estimate, with 4 projects falling below the 10% rate of return that is deemed acceptable in a developing-country economic context. The WCD concluded that irrigation dam projects have "all too often" failed to deliver on the economic profitability promised, even when defined narrowly in terms of direct project costs and benefits. However, added to the direct costs are additional costs in terms of adverse economic, social, environmental, and health impacts, such as the loss of thousands of hectares of tropical forests and their associated flora and fauna, the suffering of physically and livelihood-displaced communities, the loss of downstream fisheries and agricultural productivity, and impaired health due to water-related diseases.

Diseases such as malaria, schistosomiasis, onchocerciasis, lymphatic filariasis, and Japanese encephalitis have at various times scourged humankind in different parts of the world, and together with diarrheal and intestinal diseases caused by microbial agents and helminths they continue to be a serious threat to human health. There is an extensive literature on disease outbreaks or increased endemicity occurring in the aftermath of large-scale water resources development over the past 50–75 years (for example, Surtees 1975; Service 1984, 1989; Gratz 1987; Hunter et al. 1993; Jobin 1999). However, there is a serious lack of comparative burden of disease estimations and economic cost estimations relating to these disease outbreaks or increased endemicity.

There is a wide spectrum of human disturbances to ecosystems and their services that may change disease risk via biological mechanisms described in the next section. Of course, human activities not associated with environmental modifications may also have a role in the production of infectious diseases, both in their emergence or resurgence. This is the case of the infectious processes associated with human behavior, such as those transmitted by direct contact (such as AIDS or skin infections), airborne infections, and some food-borne infections.

Ecosystem changes can mediate the influence of anthropogenic activities in changing the epidemiological patterns of human infectious diseases by reducing or increasing disease incidence. (See Box 14.2.) Most ecological systems have a unique set of infectious diseases; however, some diseases, such as malaria, are more ubiquitous and can be found across ecological systems such as drylands, forests, and wetlands, although with somewhat different dynamics.

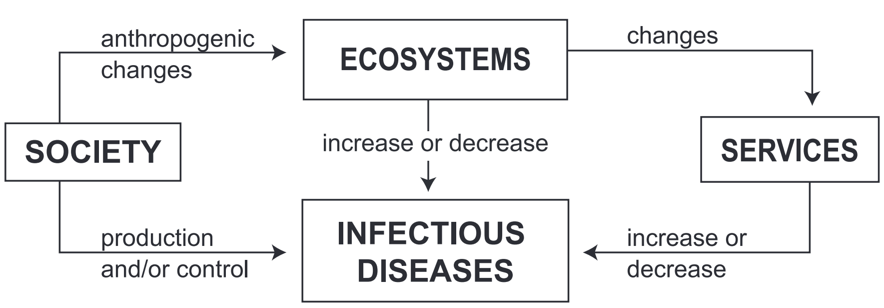

Figure 14.2. Relationships between Society, Ecosystem Services, and Human Infectious Diseases

14.2 Trends and Drivers of Changes in Disease Risk

Most emerging diseases are driven by human activities that modify the environment or otherwise spread pathogens into new ecological niches (Taylor et al. 2001). Examples of direct anthropogenic drivers that affect disease risk include wildlife habitat destruction, conversion, or encroachment, particularly through deforestation and reforestation; changes in the distribution and availability of surface waters, such as through dam construction, irrigation, and stream diversion; agricultural land use changes, including proliferation of both livestock and crops; deposition of chemical pollutants, including nutrients, fertilizers, and pesticides; uncontrolled urbanization; urban sprawl; climate variability and change; migration and international travel and trade; and either accidental or intentional human introduction of pathogens. (See also Chapter 3.)

These anthropogenic drivers of ecosystem disturbance can lead to specific changes in ecosystems that may or may not lead to disease emergence via mechanisms that are more directly relevant to life cycles or transmission of infectious diseases. There is concern that the extent of ecosystem changes in recent decades and the multiple ways in which habitats and biodiversity are being altered are increasing the odds that infectious diseases will be affected at some level. The specific biological mechanisms altering disease incidence, emergence, or reemergence are described here and, by way of illustration, disease case studies in this chapter are organized according to these biological mechanisms.

The relationship between infectious diseases and ecological changes is shown in Figure 14.3.

Disturbance or degradation of ecosystems can have biological effects that are highly relevant to infectious disease transmission. The reasons for the emergence or reemergence of some diseases

BOX 14.2

The Resilience of the Amazon Forest in Preventing the Establishment of Infectious Diseases

The Amazon forest system in Brazil has been the subject of successive cycles of occupation and development since the last quarter of the nineteenth century, starting with the rubber boom up to the 1980s, when road building and the expansion of cattle ranching also became important drivers. These developments attracted human migrations from other parts of the country, either for temporary work or permanent settlement (Confalonieri 2001). Most of the migrants came from northeastern Brazil, which is endemic for diseases like kala-azar, schistosomiasis, and Chagas disease.

As for the introduction of schistosomiasis, both infected humans and snail intermediate hosts have been found in the region (Sioli 1953). However, the foci of the disease were established only in the periphery of a few major cities, in snail breeding sites created by humans, such as pools, ponds, and channels. No foci of transmission of the disease were created among the riverine populations, some including infected human migrants. The main reason was the absence of the snail species *Biomphalaria spp,* which were not able to develop probably due to the characteristics of the fresh water of the natural systems, which do not have the appropriate mineral salts necessary for the formation of the shell of the snails (Sioli 1953).

A similar situation has been observed with kala-azar, which is endemic in rural areas of the Brazilian northeast, involving humans, sand flies, dogs, and wild canids as reservoir animals. So far the disease has become established only in two geographically restricted areas of the Brazilian Amazon: in a savanna area in the northern part and in a periurban setting in the central part (Confalonieri 2000). In both situations it seems that the dogs are the only reservoir species involved in the transmission cycle, and the pathogen did not pass to wild populations of vertebrates (Guerra 2004; Silveira et al. 1997).

In the early 1990s, cholera entered Brazil through the Peruvian border and moved down the Amazon River and its tributaries, where a few small outbreaks occurred. When the "cholera wave" reached the major cities in the Amazon region, hundreds or even thousands of people were affected. In the "rural"/riverine areas of western Brazilian Amazon, the disease affected people only for a few months and vanished without any significant control measures being implemented. The suspected major reasons for this, in addition to the low human population density in the area, was that the left margin tributaries of the Amazon River were unsuitable for the survival of *Vibrio cholerae,* due especially to their low pH.

These case studies are good example of the "nonreceptiveness" of natural systems—and the people living on them—to the introduction of alien pathogens or parasites and their invertebrate carriers, which did not evolve in these environments due to a natural resilience. This has important implications both for public health and for conservation.

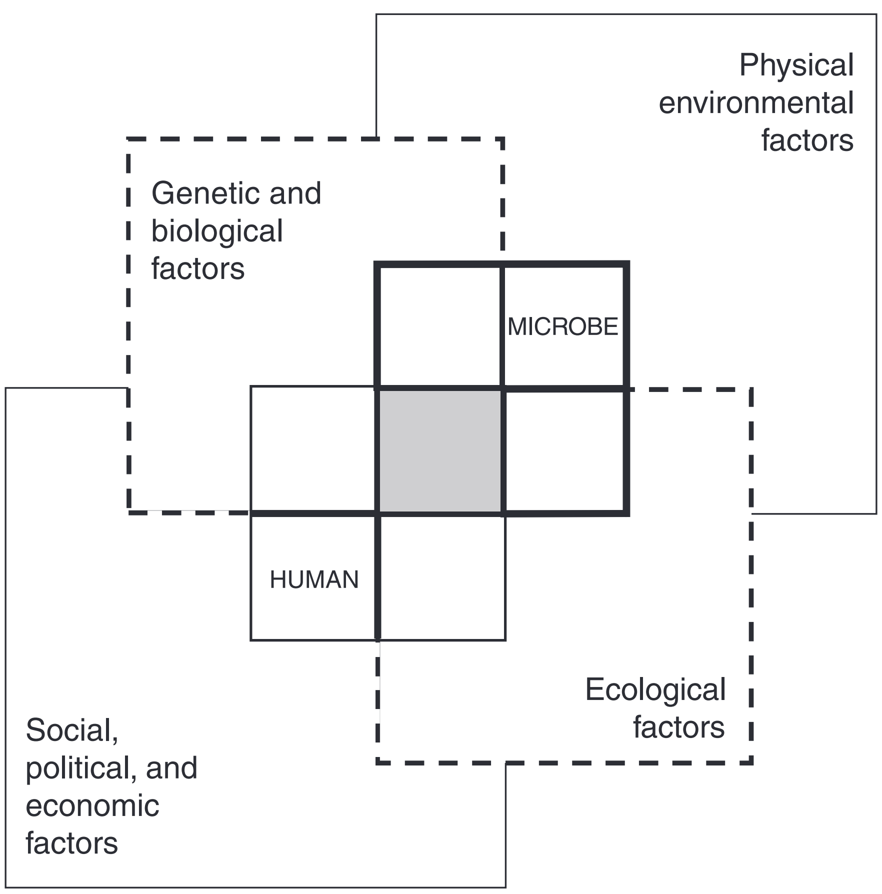

Figure 14.3. Convergence Model for the Emergence of Infectious Diseases, Combining Multiple Causes of Disease Emergence or Reemergence (Institute of Medicine 2003)

are unknown, but the following mechanisms have been proposed and have altered the incidence of many diseases (Molyneux 1997; Daszak et al. 2000; Patz et al. 2004):

- altered habitat leading to changes in the number of vector breeding sites or reservoir host distribution;
- niche invasions or transfer of interspecies hosts;
- biodiversity change (including loss of predator species and changes in host population density);
- human-induced genetic changes in disease vectors or pathogens (such as mosquito resistance to pesticides or the emergence of antibiotic-resistant bacteria); and
- environmental contamination by infectious disease agents (such as fecal contamination of source waters).

While the rest of this chapter is organized according to these mechanisms (see Table 14.2), it is important to recognize that in many instances these often overlap or act in combination, sometimes resulting in non-linear or synergistic effects on disease transmission. It should be noted that emerging or resurging diseases may occur across many ecosystems even though they have been grouped here according to the major ecosystem in which they are prevalent.

14.2.1 Altered Habitat/Breeding Sites: Effect on Infectious Disease Transmission

Disturbance of habitats due to alterations in land cover or climatic change is considered to be the largest factor altering the risk of infectious diseases—for example, by affecting breeding sites of disease vectors or the biodiversity of vectors or reservoir hosts. Examples of diseases emerging or resurging due to habitat change that occur across many ecosystems are described here for cultivated, drylands, forest, urban, and coastal systems.

14.2.1.1 Irrigation and Water Development in Cultivated Systems

According to the FAOSTAT database (apps.fao.org/default.jsp), the global extent of irrigated agricultural land increased from 138 million hectares in 1961 to 271 million hectares in 2000. In 1950, there were an estimated 5,000 large irrigation and multipurpose dams in the world, which has now increased to more than 45,000. These provide water for 30–40% of irrigated agricultural land and

Table 14.2. Mechanisms of Disease Emergence and Examples of Diseases across Ecosystems

Mechanisms	Ecosystems				
	Cultivated Systems	Dryland Systems	Forest Systems	Urban Systems	Coastal Systems

Environmental contamination of infections agents	cryptosporidiosis leptospriosis			leptospirosis	diarrheal diseases

generate 19% of global electricity supplies. (See Chapter 8 for more on water impoundment and offtake for irrigation.)

Inevitably, this growing trend in water resources development has resulted in qualitative and quantitative changes in natural biodiversity and in changed levels of interaction between humans, vectors, and disease agents. Large-scale human resettlement, which usually occurs in conjunction with irrigation development, has resulted in exposure to disease in nonimmune populations. Furthermore, multiple cropping has changed movement patterns of temporary agricultural labor, increasing risks of disease transmission and dissemination, while overcrowding and low nutritional status has increased susceptibility to infection. Water resources development has often been accompanied by invasions of new disease-carrying vectors or population changes in existing vectors, as well as similar changes in disease agents, which have increased the risks of disease (Bradley and Narayan 1988).

Global statistics on major microbial and parasitic diseases associated with water resource development show differential degrees of mortality and morbidity due to different diseases. Comparisons in terms of disability-adjusted life years (DALYs) show that infectious and parasitic diseases contribute 23.5% (340 million DALYs) of the total global burden of disease.

Unfortunately, DALY estimates only exist for global and regional scales at present, and it is not possible to use these to make direct spatial or temporal comparisons of disease burdens associated with large-scale water resources developments. Such information would be needed to evaluate properly the impact of water resource developments on human health. A similar caveat applies to economic indicators that point to significant impacts. For instance, malaria alone is estimated to reduce the economic growth rate in seriously affected countries by 1.3% per year and to cost these countries billions of dollars a year (Malaney et al. 2004). Once again, however, such figures cannot be disaggregated to determine the economic costs associated with water resources development in particular.

Small dams, below 15 meters in height, are far more numerous than large dams and are closely linked to agriculture. They have been advocated by the international financing community as manageable and practical solutions to land and water conservation. They serve more purposes than large dams: for example, a small multipurpose project may provide water for domestic supplies, fishing, cattle, and irrigation while providing flood control. Although there is no accurate estimate of the number of small dams in the world, it is likely that their collective volume is greater than that of large dams. In Nigeria and Zimbabwe, for instance, the shore length of small dams has been estimated to be 8–10 times that of the large reservoirs (Jewsbury and Imevbore 1988).

Similarly, it is estimated that small dams have an equal or greater impact on human health than large dams. There is usually a high degree of water contact with people and animals, so disease transmission rates are high (Hunter et al. 1993). However, there have been relatively few epidemiological studies on disease trends around small dams in tropical countries, despite available data that show a strong association between small dams and substantial increase in disease. For instance, intense transmission of diseases such as schistosomiasis, onchocerciasis, malaria, lymphatic filariasis, and dracunculosis are associated with small dams in many African countries, including Cameroon, Kenya, Ghana, Mali, Rwanda, and Zambia (Hunter et al. 1993). As in the case of large water resource developments, comparative health statistics in terms of DALYs or other useful parameters such as years of life lost or years lived with disability are yet to be determined.

14.2.1.1.1 Schistosomiasis

Irrigation canals are known to provide ideal habitat for the snails that serve as an intermediate reservoir host for schistosomiasis. For example, reduced salinity and increased alkalinity of water associated with irrigation development along the Senegal River have been shown to increase fecundity and growth of freshwater snails (Southgate 1997).

A literature review of the association between schistosomiasis and the development of irrigation projects along the Tana River in Kenya has been provided by Mutero (2002). Two species of the genus *Schistosoma* occur in Africa, namely *S. haematobium* and *S. mansoni*. Clinical signs for the two infections are blood in the urine and blood in the stools, respectively. *S. haematobium* has the highest prevalence along the lower Tana, where the now largely abandoned Hola irrigation scheme is situated. In 1956, when the scheme began, there were no snail vectors of *S. haematobium* due to a lack of suitable habitat because of the scheme's elevation above the river. A decade later, there was a 70% prevalence of urinary schistosomiasis among local children, which rose to 90% by 1982 due to poorly maintained irrigation channels.

14.2.1.1.2 Mosquito-borne diseases and tropical rice irrigation

There are many examples worldwide of vector-borne disease problems linked to water resources development (see reviews of Bradley 1977; Mather and That 1984; Service 1984). (See Box 14.3.) Tropical rice irrigation systems, in particular, have been linked to vector-borne diseases such as malaria and Japanese encephalitis (reviews by Lacey and Lacey 1990; Amerasinghe 2003). Major ecological impacts of irrigated rice include an enormous increase in the extent of mosquito breeding surface and an increase in the availability of habitat where multiple cropping occurs. These factors may selectively favor some species and displace or change the relative dominance of certain species or genotypes.

With malaria, in particular, the result can be marked changes in disease equilibrium, which may increase or decrease depending on the transmission capability of a particular mosquito species (Akogbeto 2000). The varied epidemiology of malaria in different cultivated systems in Africa is aptly reviewed by Ijumba and Lindsay (2001), who coined the phrase "paddies paradox" to describe situations where irrigation increases vector populations but may or may not increase malaria.

This anomaly has been largely attributed to differences in socioeconomic and ecological environments inside and outside irrigation schemes. For instance, villages surrounded by irrigated rice fields in Kenya showed a 30- to 300-fold increase in the number of the local malaria vector, *Anopheles arabiensis,* compared with those without rice irrigation, yet malaria prevalence was significantly lower in these villages (0–9% versus 17–54%) (Mutero et al. 2003). The most plausible explanation for this appeared to be the tendency of *An. arabiensis* to feed more on cattle than people in irrigated villages.

BOX 14.3

Irrigation: Infectious Disease Case Studies from Sri Lanka and India

Two of the most recently documented examples of ecosystem disturbance and mosquito-borne disease are from South Asia, and they provide contrasting examples of the aggravation of health problems resulting from irrigation development in a tropical environment (Sri Lanka) and a more northern desert region (India).

In Sri Lanka, the Accelerated Mahaweli Development Project developed 165,000 hectares of land (much of it forested land previously unoccupied by humans) for irrigated rice cultivation, resulting in the settlement of 1 million persons into the malaria-endemic lowland dry zone of the country between 1980 and 1990. Varied impacts of mosquito-borne diseases were observed in the irrigated rice systems. Malaria increased two- to fivefold in all systems within the first two to three years of settlement (Samarasinghe 1986). *Plasmodium falciparum* infections increased from the normal 5% of infections to 24% in some regions. Some systems have remained highly malarious 10–15 years later, but the disease burden has decreased in other areas. Upstream impacts also were recorded, with outbreaks of malaria in villages along the banks of the Mahaweli River in normally non-malarious hill country areas—a consequence of decreased water flow, pooling, and vector breeding as a result of water impoundment at upstream dams (Wijesundera 1988).

The major vector of malaria in Sri Lanka is *Anopheles culicifacies,* but in areas of the Mahaweli Project it was observed that additional species such as *An. annularis* and *An. subpictus* also played a significant role in transmission, as their populations increased due to the availability of suitable breeding habitats (Amerasinghe et al. 1992; Ramasamy et al. 1992).

On top of the malaria burden came Sri Lanka's first major epidemic of Japanese encephalitis in System-H of the Mahaweli in 1985–86 (more than 400 cases and 76 deaths), followed by a second epidemic in 1987–88 (more than 760 cases and 138 deaths). The catalyst appears to have been the promotion of smallholder pig husbandry in a misguided attempt to generate supplementary income among farmers. In a rice irrigation system where *Culex tritaeniorhynchus* and other *Culex* vectors of Japanese encephalitis were breeding prolifically, the outcome was catastrophic.

The Mahaweli represents a complex of gross physical ecosystem disturbance in terms of forest clearing, dam, reservoir and canal construction, and the maintenance of standing or flowing water virtually throughout the year, which erased the normal trend of wet and dry periods. Added to this was biological disturbance in terms of the replacement of a diverse natural forest flora and fauna by the introduction of a virtual crop monoculture (rice), and a dominant large mammal population (humans, often from areas nonendemic to diseases such as malaria and Japanese encephalitis), together with fellow-traveler species (garden plants, vegetables, fruit trees, livestock, domestic pets, poultry, rodents, and so on). Whether overall plant and animal biodiversity was diminished or not is debatable, but it is clear that the natural biodiversity was replaced by a crop-related one that afforded opportunities for disease causing–organisms and their vectors to have an impact.

The development of irrigated agriculture in the Thar Desert, Rajasthan, in northwestern India provides another telling example of ecosystem disturbance exacerbating disease burden. Here, the major change was the provision of surface water to a desert area.

The Thar Desert was traditionally only mildly prone to malaria, but in the last six decades it has undergone drastic change in physiography and microclimate concomitant with irrigation development. Contrasting trends in the balance between *An. culicifacies* (an efficient vector) and *An. stephensi* (a poor vector) have occurred in the Thar Desert, with *An. stephensi* constituting 94% of the two species in desert areas, but the opposite situation (overwhelmingly more *An. culicifacies*) holding in the irrigated areas. As a result, the prevalence of malaria in the irrigated areas has increased almost fourfold between the 1960s and today, with several epidemics in the past 15 years. As in Sri Lanka, this has been accompanied by a high incidence of *P. falciparum* infections in the irrigated areas, rising from 12% in 1986 to 63% by 1994 (Tyagi 2002).

Although excessive rainfall triggered by the El Niño Southern/Oscillation has probably contributed to malaria epidemics in the Thar Desert, Tyagi (2002) relates most of the recent epidemics to the phenomenon of "inundative vectorism"—the sudden ushering of one or more vector species in prodigiously high densities in virgin areas such as a recently irrigated desert). Malaria in the Thar Desert is now effectively transmitted in three ways: in the irrigated area it is transmitted in tandem by the native *An. stephensi* and invader *An. culicifacies*; in the dryland areas, by *An. stephensi*; and in the non-command flood-prone southern areas, mainly by *An. culicifacies.*

In rural India during the 1990s, "irrigation malaria" was responsible for endemic transmission in a population of about 200 million people (according to Sharma 1996). This has been attributed to poorly maintained irrigation systems, illegal irrigation, water seepages, poor drainage, and a rise in water tables associated with irrigation that created conditions suitable for the breeding of the major vector *An. culicifacies* and slow running streams that favor another vector, *An. fluviatilis.*

Japanese encephalitis is confined to Asia and is almost always associated with rice ecosystems. Region-wide, with an estimated 50,000 cases per year and 20% fatality and disability rates, the disease takes a considerable social and economic toll (Hoke and Gingrich 1994). The primary vector, *Culex tritaeniorhynchus,* occurs throughout Asia and breeds abundantly in flooded rice fields, as does another important vector, *C. vishnui* (India, Thailand, Taiwan). Other vectors, such as *C. gelidus* (in Indonesia, Sri Lanka, Thailand, and Viet Nam), *C. fuscocephala* (in Malaysia, Thailand, Taiwan, and Sri Lanka), and *C. annulus* (in Taiwan), breed in a variety of habitats, some of them associated with irrigated rice.

The transmission cycle of Japanese encephalitis involves an amplifying host, which is usually the domestic pig (in some instances, birds of the heron family (Ardeidae) are also involved) (Hoke and Gingrich 1994). Thus, irrigated riceland communities in which pig husbandry is traditionally carried out are likely sites for the disease, as both vector and amplifying host are brought together. The disease is endemic in irrigated ricelands in Thailand and China. Explosive outbreaks of Japanese encephalitis in new irrigation systems have been reported from the Terai region of Nepal and in Sri Lanka (Joshi 1986; Peiris et al. 1992). Extensive use of synthetic nitrogenous fertilizers in Indian rice fields has been blamed for significant increases in the populations of this disease's vectors; elevated nitrogen in the rice field water increases the density of mosquito larvae (Victor and Reuben 2000; Sunish and Reuben 2001).

Another disease linked to irrigation developments is lymphatic filariasis. Commonly called "elephantiasis," filariasis is caused by a mosquito-borne helminth. Outbreaks often occur from rising water tables following water project developments. In Ghana, for instance, rates of infection, worm load, annual bites per person, and annual transmission potential have been found to be higher in irrigated areas than in communities without irrigation (Appawu et al. 2001). This was also confirmed by another observation, where opening irrigation channels during the dry season resulted in a significant increase of filariasis vectors (Dzodzomenyo et al. 1999). On the other hand, conversion of swamps into rice fields on Java Island, Indonesia, resulted in a decrease of breeding sites for vectors and therefore a decrease in disease transmission (Oemijati et al. 1978).

14.2.1.1.3 African trypanosomiasis (African sleeping sickness)

Tsetse flies are widely distributed in West and Central Africa and parts of East Africa; they are the vectors of animal and human trypanosomes that cause African sleeping sickness. They are a highly adaptable group of generalized vectors feeding on available hosts throughout their distribution and are associated with the ability to adapt rapidly to changing habitats and vegetation. For instance, in Kenya in 1964 an outbreak of sleeping sickness was associated with the spread of flies from the natural shoreline habitats of Lake Victoria to vegetation within settlements characterized by thickets of *Lantana camara*; flies were feeding on humans and cattle, with cattle acting as the reservoir host of the parasite. More recently, during the 1980s an epidemic in Busoga, Uganda, was the result of civil unrest and abandonment of traditional agricultural practices and crops (coffee and cotton), followed by the spread of *L. camara* along village edges (UNEP in press).

In West Africa the behavior of tsetse flies in Southeast Nigeria and Côte d'Ivoire peridomestic populations has been closely associated with villages with a high population of domestic pigs and, again, *Lantana* as well as other vegetation (coconuts, yams, and bananas). In West Africa, *Glossina palpalis* and *G. tachinoides* appear to feed preferentially on pigs, where they act as a "dilution host"—reducing the risk of sleeping sickness to humans, as do cattle in Uganda (UNEP in press).

14.2.1.1.4 Rodent-borne hemorrhagic viruses

These infections are caused by different species of arenaviruses, with wild rodents of the genera *Calomys, Sigmodon, Akodon,* and *Zygodontomys* acting as their natural hosts and reservoirs. They have been especially recorded in Argentina (Junin virus), Bolivia (Machupo virus), and Venezuela (Guanarito virus) (Simpson 1978; Salas et al. 1991; Maiztegui 1975; de Manzione et al. 1998).

These infections often occur in outbreaks involving a few dozen to thousands of cases, mainly in rural populations, and humans become infected through contact with the urine and feces of infected rodents. In the specific case of Junin virus infections there is an additional occupational component: agricultural workers risk excess exposure during the harvesting of corn.

Human infection of the three diseases occurs in both villages and the wider countryside, primarily due to the contact between susceptible human hosts and the naturally infected rodent species in agro-ecosystems. In short, these viral infections are linked to the expansion of agriculture into natural systems in South America.

14.2.1.2 Habitat Change and Disease in Drylands and Grasslands

As with other systems, drylands have specific components and services that are relevant to human health issues. (See Box 14.4.) These can be grouped in two general categories: those that are part of natural systems (either biological or nonbiological) that can pose risks to human health and those associated with social interventions to promote human livelihoods in dry environments.

Water availability is the major limiting factor in drylands—not only for the survival of wild species and for agricultural and livestock production systems (see Chapter 22), but also for human health. Water scarcity and the poor quality of available water can increase the risk of transmission of pathogens associated with poor hygiene practices, leading to food-borne and water-borne diseases, which are major health problems in impoverished communities living in these areas. The greatest impacts are most often experienced by the more vulnerable social segments, such as high morbidity and mortality rates in children due to diarrheas. These infections are aggravated by the already existing chronic physical health problems common in impoverished communities, such as malnutrition, as well as a lack of adequate medical care in what are often marginalized communities.

Climate extremes such as droughts can have severe impacts on human health via different pathways, both direct and indirect. Direct effects are basically associated with the exacerbation of water scarcity as well as with food deprivation, resulting in famines. Droughts also have indirect effects that are mediated by social and demographic mechanisms such as individual and population stress and migrations. Movements of rural communities deprived of water and food in extreme situations can become an important determinant of the spatial redistribution of endemic infectious diseases. This is the case of kala-azar in northeastern

BOX 14.4

Meningitis in West Africa and Its Connection to Ecology, Overgrazing, and Dust Clouds

No animal reservoirs of infections are involved in the transmission of meningococcal meningitis in Africa. This is an airborne disease, transmitted from person to person through aerosols that are inhaled. The disease occurs in high endemic levels in Africa only in the so called meningitis belt, which is a large dry area in the Sahel. The specific environmental mechanisms involved in determining the biological vulnerability of the human population to this infection is not well known, but it is generally assumed that the low relative humidity is an important factor in decreasing the resistance of the upper respiratory tract. The role of dust storms is also being investigated (Molesworth et al. 2002).

The countries of Sahelian Africa sandwiched between the hot dry Saharan Desert and the moist humid forests of the Guinea Coast are among the poorest in the world. The region includes significant portions of Senegal, Mauritania, Mali, Burkina Faso, Niger, Chad, Sudan, and Eritrea, which roughly correspond to the zone receiving between 200 and 600 millimeters of annual rainfall. In this region, approximately 90% of the population depends on subsistence agriculture. As a result of rapid demographic change, climate variability, and economic drivers, farmers have expanded their cropping areas to increase production.

Agricultural intensification (often resulting in overgrazing) coupled with higher population densities in many areas has led to fallow periods that are insufficient to recuperate the soil. This has resulted in the loss of topsoil due to wind erosion, thus increasing the sources of atmospheric dust. Wind erosion may cause three types of agricultural damage: sedimentation at undesired places, crop damage, and soil degradation (Stark 2003).

Wind erosion has resulted in an increase in local dust storms, widely considered to be related to ill health during the dry season. For instance, in a detailed study of farmers' perceptions on the causes and consequences of wind erosion in Niger, its impact on health (fever, coughing, and sore eyes) was of greater concern than its contribution to crop damage or loss of topsoil (Bielders 2001). Dramatic increases in atmospheric dust in Sahelian West Africa have been noted in recent years (Ben Mohamed 1986; N'tchayi 1994; Nicholson 1998); atmospheric dust emanating from this region and the Sahara has been implicated in respiratory problems many thousands of miles away (Prospero 2001).

Dust storms have also been implicated in changes in the spatial and temporal dynamics of meningococcal meningitis epidemics in the region (Molesworth 2002). Key factors that have been identified as determinants of areas at risk of epidemic meningitis are land cover and absolute humidity (Molesworth 2003). The identification of these determinants has significant implications for directing essential monitoring and intervention activities and health policy. It also provides a basis for monitoring the impact of climate variability and environmental change on epidemic occurrence in Africa.

Brazil. In the major droughts of the early 1980s and 1990s, massive intraregional migrations of people from endemic rural areas to cities in search of subsistence and governmental assistance created new foci of the disease. This has resulted in outbreaks of infectious diseases at the periphery of major cities (Confalonieri 2001).

Besides natural biotic and abiotic factors, anthropogenic environmental modifications in dryland areas can also create conditions for the emergence of health problems related to development projects in these areas. This is the case of the efforts to increase food production in drylands by designing schemes for the provision of water, such as irrigation, and the building of dams has resulted in an increase in the incidence of tropical diseases, as mentioned earlier.

Wild fauna and insect ecology is also important for some infectious diseases located in dryland systems, including plague in the scrublands of southwestern United States, northeastern Brazil, and Peru and in regions of India and southern Africa. Another focal infection is kala-azar (*Leishmania donovani*), which is present mostly in arid areas such as Sudan (Thomson et al. 1999), Mediterranean countries, and South America.

14.2.1.2.1 Hantavirus

Rodent-borne hantavirus occurs both in arid grasslands (for example, in North America), as well as agricultural systems (particularly in South America and Asia). One of the best-known outbreaks occurred in the spring and summer of 1993, when acute respiratory distress with a high fatality rate was diagnosed among previously healthy individuals in the Four Corners region of the southwestern United States (Engelthaler et al. 1999). The disease, hantavirus pulmonary syndrome (HPS), was traced to infection by a previously unrecognized hantavirus. The virus (Sin Nombre virus) was found to be maintained and transmitted primarily within populations of a common native field rodent, the deer mouse Peromyscus spp. Transmission to humans is thought to occur through contact with virus in secretions and excretions of infected mice.

Recent studies have now shown that the El Niño effects during 1991–92 helped boost the reservoir populations of rodents in the region (Engelthaler et al. 1999; Glass et al. 2000). Unseasonal rains during the usually dry summer months in 1992 produced favorable environmental conditions in the spring and summer of 1992 that led to the outbreak of HPS. Parmenter and colleagues reported that populations of deer mice at the Long-Term Ecological Research station approximately 90 kilometers south of Albuquerque, New Mexico, were ten- to fifteenfold higher during the HPS outbreak period than the previous 20-year average (Parmenter et al. 1993). Glass and colleagues (2000) further showed the potential of using remotely sensed data to monitor conditions and identify high-risk areas up to a year in advance of anticipated disease outbreaks.

14.2.1.2.2 Rift Valley Fever

Extensive Rift Valley Fever outbreaks were not reported until 1951, when an estimated 20,000 people were infected during an epidemic among cattle and sheep in South Africa. Outbreaks were reported exclusively from sub-Saharan Africa until 1977–78, when 18,000 people were infected and 598 deaths were reported in Egypt (CDC 2002).

All known Rift Valley Fever virus outbreaks in East Africa from 1950 to May 1998, and probably earlier, followed periods of abnormally high rainfall (Woods et al. 2002). Analysis of these records and of Pacific and Indian Ocean sea surface temperature anomalies, coupled with vegetation data from satellites, showed that accurate predictions of Rift Valley Fever outbreaks in East Africa could be made up to five months in advance. Concurrent near-real-time monitoring with such data may identify actual affected areas (Linthicum et al. 1999).

Dams and irrigation can increase the breeding sites of the Rift Valley Fever vector, exacerbating the effect of extreme rainfall. (See Figure 14.4.) Several ecological changes have been reported in the epidemic region in Mauritania following dam construction, irrigation, and heavy rainfall (Jouan et al. 1990). Environmental factors, such as hydroelectric projects, and low-grade transmission among domestic animals could have enhanced the disease's survival and subsequent outbreaks (Lefevre 1997).

14.2.1.3 Habitat Change and Disease in Forest Systems

The major vector-borne diseases are focused in the tropics. There is a significant overlap between the distribution of the majority of important vectors of human and animal diseases and the biological richness of tropical rain forest ecosystems, woodland savannas, and boundaries of these ecosystems. (See Box 14.5.) It is the degradation of these ecosystems, the behavior and ecology of the vectors at the forest edge, the impact of deforestation on the interactions between humans with vectors, and reservoir hosts at the interface that determine the epidemiology of human infective agents. Additional factors are the behavior and degrees of immunity of local or migrant populations, their interaction with and the behavior of reservoir hosts, and the availability and effectiveness of surveillance systems and quality of local health care (UNEP in press).

14.2.1.3.1 Malaria

Deforestation, with subsequent changes in land use and human settlement patterns, has coincided with an upsurge of malaria or its vectors in Africa (Coluzzi et al. 1979, 1984, 1994), Asia (Bunnag et al. 1979), and Latin America (Vittor et al. in press; Tadei et al. 1998). (See Box 14.6.)

The capacity of different *Anopheles* mosquitoes to transmit malaria varies between species. Anopheline species themselves also occupy a variety of ecological niches. *An. darlingi* in South America, *An. gambiae* in Africa, and *An. dirus* in Southeast Asia are the predominant and highly effective vectors in their respective regions.

When tropical forests are cleared for human activities, they are typically converted into agricultural or grazing lands. This process is usually exacerbated by construction of roads, causing erosion and allowing previously inaccessible areas to become colonized (Kalliola and Paitan 1998) and anopheline mosquitoes to invade. Cleared lands and culverts that collect rainwater are far more suitable breeding sites for malaria-transmitting anopheline mosquitoes than forest (Tyssul Jones 1951; Marques 1987; Charlwood and Alecrim 1989). Forest-dwelling *Anopheles* species either adapt to newly changed environmental conditions or disappear from the area, which offers other anophelines a new ecological niche (Povoa et al. 2001).

14.2.1.3.2 Forest Arboviruses in the Amazon

A wide variety of arboviruses occurs in the Amazon forest, a consequence of the extreme diversity of both arthropod vectors and wild vertebrates.

Thirty-two arbovirus types have been associated with human disease in the Brazilian Amazon region. Of these, four are important in public health because of their link to epidemics: the Oropouche virus (family *Bunyaviridae),* dengue and yellow fever viruses (*Flaviviridae*), and Mayaro virus (*Togaviridae).* It is noteworthy that Oropouche and dengue viruses are associated with human epidemics in urban areas while Mayaro and yellow fever occur in rural areas. All arboviruses (except dengue) that have been isolated in the Brazilian Amazon are maintained within complex cycles in the forest, where many species of blood-sucking arthropods act as vectors and several wild vertebrates act as reservoir hosts.

There have been historical changes in the Amazonian environment due to natural cyclical processes such as climate variability and as the result of human economic and geopolitical activities. The latter, which includes deforestation, construction of dams and highways, and mining, can disrupt to a greater extent the fragile equilibrium of the forest ecosystem, with impacts in the dynamics of virus transmission (Dégallier et al. 1989; Shope 1997; Vasconcelos et al. 2001).

Dam construction has been associated with the emergence of several different arboviruses, some of them responsible for human disease while others were previously unknown (Vasconcelos et al. 2001b).

Comparative studies carried in the 1970s and 1980s in Altamira and Tucurui municipalities prior, during, and after the construction of the Tucurui Dam in the State of Pará, Brazil, showed that inadequate management of the environment can cause an increase in the occurrence of a known virus or the appearance of a new one (Pinheiro et al. 1977; Dégallier et al. 1989). Examples

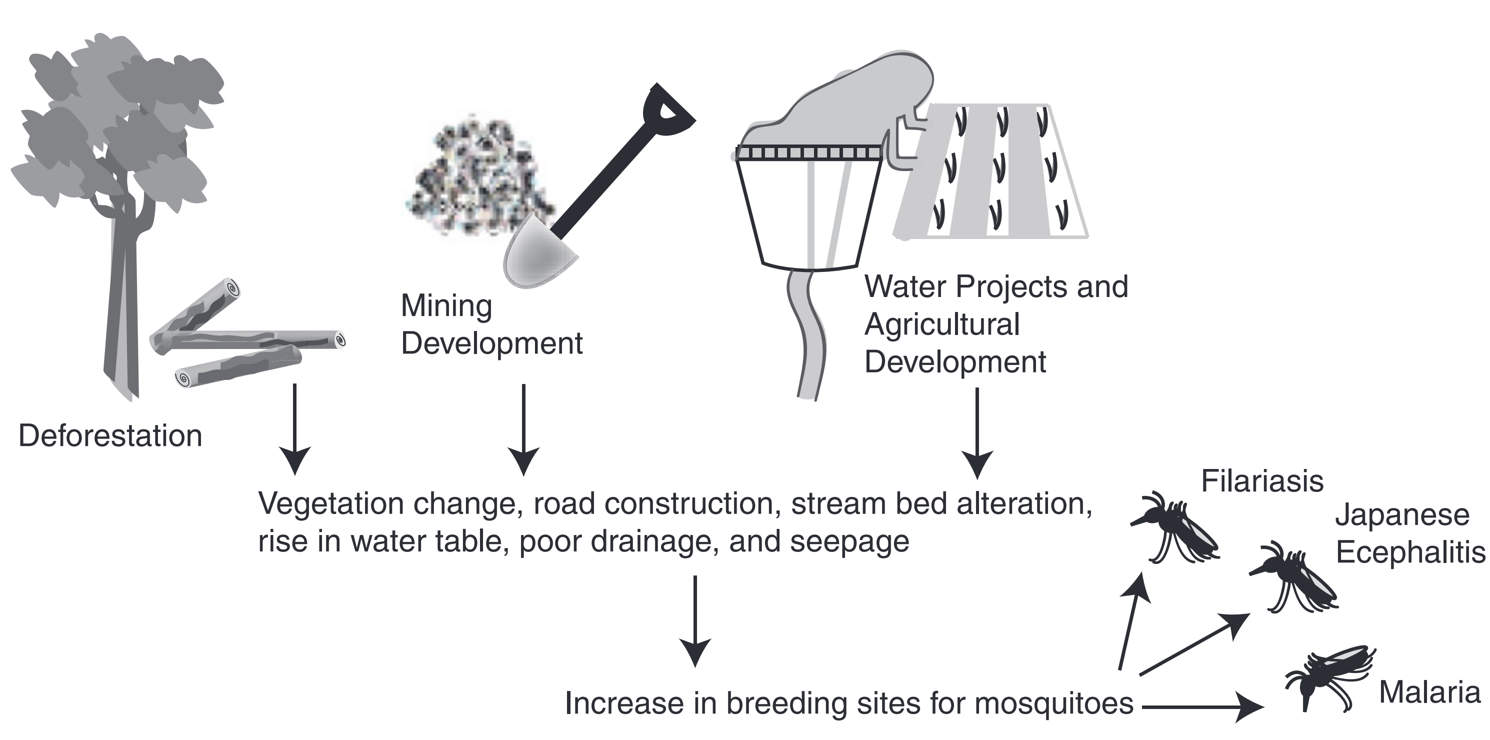

Figure 14.4. Habitat Change and Vector-borne Diseases

BOX 14.5

Reemergence of Onchocerciasis Related to Deforestation in Africa

Prior to the 1970s, onchocerciasis (also known as river blindness) was a neglected disease. Its devastating effects were largely borne by rural populations of West Africa living near the fast-flowing rivers of the Sahel. When the Onchocerciasis Control Programme was started in 1974, some of West Africa's richest riparian lands were uninhabited. In villages sited in river valleys near to the white water rapids that form the major breeding sites of the blackfly vector, it was not unusual to find 60% of adults afflicted with the disease and 3–5% blind. As a direct consequence of the disease, communities were forced to abandon their villages en masse. Today, 30 years and $600 million after the program was first launched, the disease has been controlled through one of the most successful public health campaigns in history (Benton 2002).

The filarial worm that causes the disease (*Onchocerca volvulus*) is transmitted in West Africa solely by blackflies, which are members of the *Simulium damnsum* species complex. Understanding the spatial and temporal distribution of the vectors of onchocerciasis has been key to their successful control (Boakye et al. 1998), given that the *S. damnosum* species complex comprises many distinct sibling species with varying capacities to transmit *O. volvulus.* The savanna species *S. sirbanum* and *S. damnosum* s.str. were identified early on in the program as the species associated with the blinding form of the disease. The distribution of the different members of the *S. damnosum* species complex is generally related to vegetation zones, forest, and savanna, but seasonal changes in their distribution occurs on an annual cycle as the monsoon winds and their accompanying rainfall aid dispersal and result in enhanced river flow and the creation of breeding sites. According to Baker (Baker et al. 1990), members of the *S. damnosum* complex move average distances of 15–20 kilometers daily and may migrate over a total distance of 400–500 kilometers.

From the beginning of the control program, vector control has been dogged by "reinvasion"—the long-range northwards movement of female blackflies with the potential to reestablish breeding grounds in savanna areas during the wet season and to carry *O. volvulus* parasite back into vector-cleared areas. Flies are known to be carried from more southerly permanent breeding sites on a generally northeasterly tack across West Africa by the associated winds. In the late 1980s, a reverse form of migration was also noted in which savanna flies, both *S. sirbarnum* and *S. damnosum* s.str., appeared to have extended their range into areas previously only inhabited by forest species (Thomson et al. 1996). The migrations of savanna species of *S. damnosum* s.l. into the forest zones was considered a serious threat to the health of populations living in the forested area, as it suggested that the blinding, savanna form of the disease may spread to the forested areas.

In 1988 a Task Force of the Onchocerciasis Control Programme in Sierra Leone determined that breeding sites there were the source of the annual invasion of savanna species of *S. damnosum* that were actively recolonizing the controlled breeding sites of Mali each rainy season. The Task Force also found that the savanna fly *S. sirbarnum* was widely distributed throughout the country, including many forested areas (Baker 1989). This has led to the speculation on the possible role of deforestation and rainfall decline on the distribution of different species of *S. damnosum* s.l. (Walsh et al. 1993), a role that was later confirmed by a detailed cytotaxonomic study of *S. damosum* larvae found breeding in a deforested area in Ghana (Wilson et al. 2002).

Deforestation in West Africa has been implicated in the southward movement of the savanna species of *S. damnosum* s.l. in the region—the most significant vectors of the blinding form of onchocerciasis (Wilson 2002; Thomson and Connor 1996). This has important implications for the newly developed African Programme for Onchocerciasis Control; unlike its predecessor, the Onchocerciasis Control Programme that successfully controlled savannah species of *S. damnosum* s.l. using insecticides, the new program is heavily dependant on the widespread distribution of the micro-filaricidal drug ivermectin. Should current control measures fail, then emergence of the blinding disease in deforested areas can be expected. Curiously, forest cover has further implications to the success of new program, as the recent distribution of ivermectin in forested areas has resulted in a number of deaths—thought to be related to the presence of yet another filarial worm, *Loa loa.* This parasite, which has emerged from obscurity, is now considered a major impediment to the success of the control program, and mapping its potential distribution has become a priority activity and may also be relevant to the control of other filarial worms in the region, such as lymphatic filariasis (Thomson and Connor 2000).

The exact effect of land cover changes, especially deforestation, on the composition of the vector population differs from place to place. However, as a net effect an increase of the more virulent vector and therefore an increase of morbidity from onchocerciasis can be noted.

of arboviruses that emerged or reemerged in the Brazilian Amazon region and the factors responsible are shown in Table 14.3.

Uncontrolled urbanization or colonization near forest areas has been typically associated with the emergence of Oropouche fever and Mayaro fever viruses (Vasconcelos et al. 2001a). The Oropouche virus has been responsible for at least 500,000 infections in the last 40 years in the Amazon, and it is spreading.

Current modifications to the forest ecosystem are likely to result in the spread of infections if vectors and reservoirs find better ecological conditions. This mechanism may explain the large epidemics of Oropouche fever virus in the Brazilian Amazon from 1960 to 1990, as well as in other Latin American countries, especially Peru and Panama (Pinheiro et al. 1998; Watts et al. 1998; Saeed et al. 2000). Alternatively, if the ecological changes are detrimental to the nonhuman carriers of the virus, they will probably disappear due to the absence of the basic elements necessary for their survival. This could explain the absence of many previously identified virus species that are no longer found despite continued surveillance (Vasconcelos et al. 2001a).

Deforestation for agricultural expansion has been the most important factor associated with the spread of yellow fever in Africa and its reemergence in Brazil (in the state of Goiás), although climatic extremes are also important, for instance Brazil in 2000 (Vasconcelos et al. 2001b). Yellow fever is maintained by a sylvatic cycle between primates and mosquitoes in the forest. Evidence from epidemics in Côte d'Ivoire (1982), Burkina Faso (1983), Nigeria (1986 and 1987), and Mali (1987) and other, long-term, studies have established a clear link between deforestation and yellow fever's increasing area of endemicity (Cordellier 1991). However, it should be noted that yellow fever epidemics occur in urban and dry savanna areas as well and can be transmitted by different mosquito species more adapted to these environments.

14.2.1.4 Habitat Change and Infectious Diseases in Urban Systems

Uncontrolled urbanization has many adverse human health consequences, primarily due to health infrastructure problems and

BOX 14.6
Gold Mining and Malaria in Venezuela

Bolívar state in southern Venezuela near the border with Brazil and Guyana covers an area of 24 million hectares (the size of the United Kingdom), 70% of which is forested. It is presently affected by deforestation mainly associated with logging, agriculture, dam construction, and gold mining. Before 1980, malaria was occasionally reported from this state among the indigenous population. Malaria in this area was classified by Gabaldon (1983) as difficult to control since the vector, *An. darlingi,* was found to bite mostly outside houses (thus harder to spray with insecticides). Also, the human populations were mainly Amerindians with seminomadic habits in remote areas (Gabaldon 1983).

During the late 1950s, construction was started on a road to connect Ciudad Bolívar, capital of Bolivar state, to Boa Vista, capital of Roraima state in Brazil. The road construction brought workers from all over the country and opened new opportunities for people seeking land for agriculture, gold and diamond mining, and forest exploitation. In the 1980s, the boom of gold and diamonds attracted a wave of migrants from different parts of the country as well as illegal migrants from Brazil, Guyana, Colombia, and Dominican Republic, among others. Malaria started to increase steadily, reaching the highest peak of over 30,000 cases in 1988, with over 60% cases due to *P. falciparum* (MSDS 2000). Malaria has since become endemic-epidemic in Bolívar state.

Studies carried out in several villages spanning 1999–2000 showed that only three species of anophelines were caught on human landing catches: *An. darlingi, An. marajoara,* and *An. neomaculipalpus* (Moreno et al. 2002). In general, biting densities were low (fewer that two bites per person per hour). Nevertheless, there was a strong correlation between *An. darlingi* density and malaria incidence ($P<0.001$). In this area, studies on breeding places showed that up to 13 species of anophelines were present, with *An. triannulatus* being the most abundant. The most productive breeding sites in terms of anophelines species diversity and density were the abandoned mine dug outs, which vary in size from a few meters in diameter to several kilometers, followed by lagoons created by flooding of streams on artificial and natural depressions of terrain (Moreno et al. 2000).

overcrowded, unsanitary conditions. This section focuses on infectious diseases linked to urbanization.

14.2.1.4.1 Lymphatic filariasis

Lymphatic filariasis is one of the most prevalent tropical diseases, with some 120 million people infected, primarily in India and Africa, where there has been no decline in the incidence of the disease for the past decade. The disease is reported to be responsible for 5 million DALYs lost annually, ranking third after malaria and tuberculosis (WHO/TDR 2002).

Distribution and transmission of the lymphatic filariasis are closely associated with socioeconomic and behavioral factors in endemic populations. In Southeast Asia, urban Bancroftian filariasis *Wuchereria bancrofti* infection, a filarial nematode, is related to poor urban sanitation, which leads to intense breeding of *C. quiquefasciatus,* its principal mosquito vector (Mak 1987). In Sri Lanka, *C. quinquefasciatus* was not originally present in a forested environment, but rapidly invaded as soon as forest clearing began and settlement expanded (Asmerasinghe in press). In urban East Africa, filariasis is also transmitted by *C. quinquefasciatus,* but in rural areas across tropical Africa it is spread by the same anopheline mosquito species that transmit malaria (Manga 2002).

Table 14.3. Probable Factors in Emergence of Arbovirus in Brazilian Amazon Region and Association with Human Disease (Vasconcelos et al. 2001)

Virus	Probable Factors for Emergence	Disease in Humans
Dengue	poor mosquito control; increased urbanization in tropics	yes, epidemic
Guaroa	flooding of dam[a]	yes, sporadic cases
Gamboa	flooding of dam[a]; migrating birds	not yet
Mayaro	deforestation	yes, limited outbreak
Oropouche	deforestation; increase of colonization and urbanization in Amazon	yes, epidemic
Triniti	flooding of dam[a]	not yet
Yellow fever	urbanization in tropics; deforestation; lack of widespread immunization	yes, epidemic
Anopheles A viruses[b]	flooding of dam[a]	not yet
Changuinola viruses[c]	flooding of dam[a]; deforestation; use of subsoil	not yet

[a] During construction of dam in Tucurui, Pará State, millions of hematophagous insects were obtained in a few days, from which several strains of previously known and new arboviruses were obtained

[b] In this serogroup of family *Bunyaviridae*, the new viruses Arumateua, Caraipé, and Tucurui were isolated, and there was also an increase in circulation of Lukuni and Trombetas viruses.

[c] In this serogroup of family *Reoviridae*, 27 new arboviruses were isolated in Tucurui, 4 in Carajas (use of subsoil), and 8 in Altamira (deforestation for several purposes) from phlebotominae sandflies.

14.2.1.4.2 Dengue fever

In terms of morbidity and mortality, dengue fever—caused by a virus that has four serotypes or genetic variants—is the most important human viral disease carried by mosquitoes. It is caused by a flavivirus and is endemic in about 100 countries and found in all continents except Europe (WHO/TDR 2004). Around 80 million cases are reported every year, of which 550,000 people need hospital treatment and about 20,000 die. Although dengue is primarily a tropical disease, it has become a great concern in countries with temperate climates because of an increased number of imported cases, resulting from increased air travel and the introduction of *Aedes albopictus,* an exotic vector adapted to a cold climate (Kuno 1994).

However, the primary vector of large dengue epidemics is *Ae. aegypti,* a day-biting mosquito that prefers to feed on humans and that breeds at sites typically found in the urban environment: discarded tires, cans, and other trash that accumulates rainwater; water storage devices in houses; flower pots and even plants that collect water. This species has made extraordinary evolutionary adjustments to coexist with human beings since its origins in Africa as a forest species feeding principally on wild animals (rodents and so on) and laying eggs in tree holes containing rainwater.

One subspecies—*Ae. aegypti aegypti*—evolved to become highly adapted to indoor or peridomestic environs, breeding in artificial containers, and followed humankind on its journeys and migrations throughout the globe (Monath 1994).

The spread of the disease is associated with the geographical expansion of the vector species, favored by current housing and water supply conditions as well as garbage collection practices in developing countries. Therefore, uncontrolled urbanization, which is frequently associated with population growth and poverty (resulting in substandard housing and inadequate water and waste management systems), plays a major role in creating the conditions for dengue epidemics. Analysis of associations between social and economic variables, such as income and education level, in residential urban areas and the incidence of dengue infection has shown that low-income neighborhoods have the highest levels of infection (Costa and Natal 1998). Moreover, communities with high infestations of *Ae. aegypti,* especially if they are near forests that maintain yellow fever virus, face a significant risk of yellow fever epidemics.

14.2.1.4.3 Other diseases linked to urbanization

Soil disturbance from building construction in arid environments can encourage coccidioidomycosis, a fungal pneumonia. Increased aridity and eventual desertification due to increasing global temperatures may increase the potential for infection. Coccidioidomycosis is spread by dust, and disease outbreaks are often preceded by increased rain, followed by dry periods, and especially in the wake of soil disturbances. A well-documented outbreak followed the 1994 Northridge, California, earthquake, when 317 cases resulted (Schneider et al. 1997). In a study in Greece, factors thought to contribute to the extraordinary increases in cases were a drought lasting five to six years, abundant rain in 1991 and 1992, construction of new buildings, and arrival of new susceptible residents to the endemic areas (Pappagianis 1994)

Leishmaniasis has been associated with urban settlements in forested regions and is widespread in 22 countries in the New World and in 66 in the Old World (WHO, TDR 2004). There are two major types of leishmaniasis: cutaneous and visceral (kala-azar). Cutaneous leishmaniasis is originally a forest disease but may adapt to urban settings with some vegetation and cycling in dogs.

Uncontrolled urbanization or colonization near forest areas has been typically associated with the emergence of Oropouche fever and Mayaro fever viruses (Vasconcelos et al. 2001a). The relationship between malaria and urbanization in two cities is presented in Box 14.7.

BOX 14.7

Malaria and Urbanization in Brazil

The transmission of malaria in urban areas in the Americas occurs when urbanization invades the habitat of vectors. These phenomena have been observed in cities of Brazil such as Belém (Pará state) located near the mouth of the Amazon River and in Manaus (Amazonas state).

In a recent study comparing malaria transmission and epidemiology over 60 years in Belém, Póvoa et al. (2002) showed that the incriminated vectors in the 1940s, *An. aquasalis* and *An. darlingi,* are still currently important vectors. The anopheline species diversity has increased from 2 in the 1930s to 6 in the 1940s to 10 in the 1990s. *An. darlingi* was eliminated from Belém in the 1960s and was absent for approximately 20 years, probably due to the destruction of breeding sites in forested areas as urbanization increased. During this period the reported malaria cases were attributed to human immigration from rural areas into Belém (Marques 1986) or people from Belém traveling to endemic areas during the holidays and returning with malaria parasites in their blood (Souza 1995). Nevertheless, *An. aquasalis* was present in coastal areas influenced by tides.

The population of Belém increased from 206,331 in 1942–43 to 934,322 in 1980–89 and then to 1,367,677 in 1996. The number of malaria cases went from 363 in 1942–43 to 1,197 in 1980–89 and 2,716 in 1996. Approximately 80% of the original forest has been destroyed (Povoa et al. 2002), but the expansion of the city (particularly the District of Daent) toward the forested protected area and low coastal swampy areas provided new larval habitats, resulting in a higher mosquito diversity and closer proximity between human dwellings and mosquito habitat, which increases the transmission of malaria.

A similar situation has occurred in Manaus, where the process of urbanization eliminated *An. darlingi* from the city by 1976 (Tadei et al. 1998). Nevertheless, the accelerated expansion of the suburbs into the surrounding jungle reestablished the contact between the human population and the principal vector, *An. darlingi,* which by 1988 colonized the city again and triggered malaria epidemics. Vectors are also adapting to new circumstances; for example, mosquitoes have varied their feeding time in areas where humans have intervened (Tadei et al. 1998). At present, malaria cases continue to be reported from the periurban areas of Manaus.

14.2.1.5 Ecological Change and Infectious Disease in Coastal and Freshwater Systems

Cholera and severe forms of gastroenteritis are caused by *Vibrio cholerae* and *V. parahaemolyticus.* In tropical areas, cases are reported year-round. In temperate areas, cases are mainly reported in the warmest season. The seventh cholera pandemic is currently spreading across Asia, Africa, and South America. In 1992, a new strain or serogroup (*V. cholerae O139*) appeared and has been responsible for epidemics in Asia. During the 1997/98 El Niño, excessive flooding caused cholera epidemics in Djibouti, Somalia, Kenya, Tanzania, and Mozambique. Warming of the African Great Lakes due to climate change may create conditions that increase the risk of cholera transmission in the surrounding countries.

Pathogens are often found in coastal waters, and transmission occurs through consumption of shellfish or brackish water or through bathing. Coastal waters in both industrial and developing countries are frequently contaminated with untreated sewage (see Chapter 19), and warmth encourages microorganism proliferation. The presence and increased transmission of *Vibrio spp.* (some of which are pathogens that cause diarrhea), such as *V. vulnificus,* a naturally occurring estuarine bacterium, has been associated with higher sea surface temperatures. Phytoplankton organisms respond rapidly to changes in environmental conditions and are therefore sensitive biological indicators of the combined influences of climate change and soil and water pollution. Algal blooms are associated with several environmental factors, including sunlight, pH, ocean currents, winds, sea surface temperatures, and runoff (which affects nutrient levels), as described in Chapters 12 and 19.

V. cholerae and other gram-negative bacteria can be harbored in many forms of algae or phytoplankton. *V. cholerae* can assume a noncultivable but viable state, returning to a cultivable, infectious state with the same conditions that promote algal blooms (Colwell 1996). Some species of copepod zooplankton apparently provide an additional marine reservoir for *V. cholerae,* facilitating its long-term persistence in certain regions, such as in the estuaries of the Ganges and Brahmaputra in India. According to this theory, the seasonality of cholera epidemics may be linked to the seasonality of plankton (algal blooms) and the marine food chain. Studies using remote sensing data of chlorophyll-containing phytoplankton have shown a correlation between cholera cases and sea surface temperatures in the Bay of Bengal. Interannual variability in cholera incidence in Bangladesh is also linked to El Niño/Southern Oscillation and regional temperature anomalies (Lobitz et al. 2000), and cholera prevalence has been associated with progressively stronger El Niño events spanning a 70-year period (Rodo et al. 2002).

14.2.2 Niche Invasion or Interspecies Host Transfer Effects on Infectious Disease Transmission

The emergence of many diseases has been linked to the interface between tropical forest communities, with their high levels of biodiversity, and agricultural communities, with their relatively homogenous genetic makeup but high population densities of humans, domestic animals, and crops. For instance, expanding ecotourism and forest encroachment have increased opportunities for interactions between wild nonhuman primates and humans in tropical forest habitats, leading to pathogen exchange through various routes of transmission (Wolfe et al. 2000). (See Box 14.8.)

14.2.2.1 Cultivated Systems and Niche Invasion

Intensive farming practices have seen the emergence of several devastating herd and flock diseases, including Nipah virus, bovine spongiform encephalopathy, foot and mouth disease, severe acute respiratory syndrome, and avian influenza.

14.2.2.1.1 Nipah virus in Malaysia

The emergence of many diseases can be viewed as a pathogen invading a new or recently vacated niche. For example, Nipah virus emerged in Malaysia in 1999, causing over 100 human deaths (Chua et al. 2000). This highly pathogenic virus (with a case fatality rate greater than 40 %) was previously unknown as a human pathogen, and emerged from its natural reservoir hosts (fruit bats) via domestic animal (pig) amplifier hosts.

The ecological changes that caused this virus to invade a new niche appear to be a complex series of anthropogenic alterations to fruit bat habitat and agriculture set in a background of increasing ENSO-caused drought (Daszak et al. 2001; Field et al. 2001; Chua et al. 2002). First, the virus appears not to be able to move directly from bats to humans, so the development of a pig industry in Malaysia has been a crucial driver of emergence. Second, fruit bat habitat has been largely replaced in peninsular Malaysia by crop plants such as oil palm. Third, deforestation in Sumatra coupled with increasing amplitude, intensity, and duration of ENSO-driven drought has led to repeated, significant seasonal haze events that cover Malaysia. These events reduce the flowering and fruiting of forest trees that are the natural food of fruit bats and may have changed the fruit bats' migration patterns and ability to find food.

These interrelated events are theorized to have coincided just prior to the Nipah virus outbreaks, when the large mid-1990s

BOX 14.8

The Importance of Ecological Change and Zoonotic Diseases

Zoonotic pathogens are the most significant cause of emerging infectious diseases affecting humans in terms of both their proportion and their impact. Some 1,415 species of infectious organisms are known to be pathogenic to humans; 61% of these are zoonotic and 75% of those considered as emerging pathogens are zoonotic (Taylor et al. 2001). More important, zoonotic pathogens cause a series of EIDs with high case fatality rates and no reliable cure, vaccine, or therapy (such as Ebola virus disease, Nipah virus disease, and hantavirus pulmonary syndrome). They also cause diseases that have the highest incidence rates globally (such as AIDS). AIDS is a special case, because it is caused by a pathogen that jumped host from nonhuman primates and then evolved into a new virus. Thus it is essentially a zoonosis (Hahn et al. 2000) and is thought to have infected the highest number of human individuals of any disease in history.

Viruses such as Junin, Machupo, and Guanarito hemorrhagic fever agents in Argentina, Bolivia, and Venezuela, transmitted to humans through the urine of wild rodents, came through the expansion of agricultural practices to new areas; hantaviruses, initially recognized in Korea, came through the urine of infected rodents and were then identified in Asia and Europe. The Junin virus, which causes a hemorrhagic fever, also emerged when the production of vegetables that serve as food source for rodents increased in Argentina in 1957.

Because of the key role of zoonoses in current public health threats, wildlife and domestic animals play a key role in the process by providing a "zoonotic pool" from which previously unknown pathogens may emerge (Daszak et al. 2001). The influenza virus is an example, which causes pandemics in humans after periodic exchange of genes between the viruses of wild and domestic birds, pigs, and humans. Fruit bats are involved in a high-profile group of EIDs that include rabies and other lyssaviruses, Hendra virus, Menangle virus (Australia), and Nipah virus (Malaysia and Singapore). This has implications for further zoonotic disease emergence. A number of species are endemic to remote oceanic islands, and these may harbor enzootic and potentially zoonotic pathogens (Daszak et al. 2000).

The current major infectious disease threats to human health are therefore emerging and reemerging diseases, with a particular emphasis on zoonotic pathogens jumping host from wildlife and domestic animals. A common, defining theme for all EIDs (of humans, wildlife, domestic animals, and plants) is that they are driven to emerge by anthropogenic changes to the environment. Because threats to wildlife habitat are so extensive and pervading, it follows that many of the currently important human EIDs (such as AIDS and Nipah virus disease) are driven by anthropogenic changes to wildlife habitat such as encroachment, deforestation, and others. This is essentially a process of natural selection in which anthropogenic environmental changes perturb the host-parasite dynamic equilibrium, driving the expansion of those strains suited to the new environmental conditions and driving expansion of others into new host species (Cunningham et al. in press). The selection process acts on the immense pool of varied pathogen strains circulating within the population (c.f. the "zoonotic pool," Morse 1993).

Thus, very few EIDs are caused by newly evolved pathogens, although notable exceptions include drug-resistant pathogens, newly re-assorted influenza strains, and pathogens with point mutations that increase their virulence (such as canine parvovirus, Parrish et al. 1985). Even in these examples, it is possible that the new strains were already present in the pathogen population. For example, recent work shows that drug-resistant strains of some common microbes circulate within rodent populations in areas outside normal contact with antibiotics (Gilliver et al. 1999).

ENSO event was associated with a drop in fruit production and the appearance of *Pteropus vampyrus* (the key Nipah virus reservoir) for the first time at the index farms, where Nipah virus was initially identified (Chua et al. 2002).

14.2.2.1.2 Bovine spongiform encephalopathy (''mad cow'' disease)

The background of the BSE epidemic is well known. In order to improve the protein content in the diet of cattle, ground-up sheep and cattle remains—including of the brain and spinal cord—were fed to cattle. This practice was claimed as economically rational because it turned a waste product into a valuable food. But from an ecological perspective it was anything but rational; cattle are normally vegetarian, and are certainly not cannibals (Prusiner 1997).

While it was originally argued that this practice is harmless, a similar disease in sheep (scrapie) was known for centuries, and one in humans (kuru), transmitted through the ritual cannibalism of human brains, was already known in New Guinea. In time, the causal agent of BSE, an unusual protein called a prion, was transmitted to humans, causing a devastating, rapidly progressive, still untreatable brain disease, called new variant Creutzfeldt-Jakob disease. So far, the size of this human epidemic has been modest, but transmission is probably still occurring through blood transfusions (Llewelyn et al. 2004) and surgical instruments that cannot be sterilized. As well as these human health effects, the BSE epidemic had an immense economic and psychological cost to farmers, as millions of cattle were slaughtered prematurely.

14.2.2.1.3 Severe acute respiratory syndrome

SARS gained international attention during an outbreak that began sometime during November 2001 in China. Wet markets, a known source of influenza viruses since the 1970s, were found to be the source of the bulk of the infections (Webster 2004). (Live-animal markets, termed ''wet markets,'' are common in most Asian societies and specialize in many varieties of live small mammals, poultry, fish, and reptiles (Brieman et al. 2003).) The majority of the earliest reported cases of SARS were of people who worked with the sale and handling of wild animals. The species at the center of the SARS epidemic are palm civet cats (Paguna larvata), raccoon dogs (Nyctereutes procuyoinboides), and Chinese ferret badgers (Melogale moschata) (Bell at al. 2004). As of July 2003, there had been 8,096 cases and 774 deaths reported worldwide (WHO 2004).

14.2.2.1.4 Avian influenza

Avian influenza virus has caused fatalities in humans, highlighting the potential risk that this type of infection poses to public health (Capua and Alexander 2004). Genetic reassortment within a person coinfected with human and avian strains of influenza virus could potentially link the high transmissibility associated with human-adapted viruses with the high rates of mortality observed in the avian cases, thus triggering a potentially devastating pandemic (Ferguson et al. 2004). The ''Spanish flu'' pandemic of 1918–19 was the largest infectious disease event in recorded history, killing over 20 million people. Recently a single gene coding for the viral haemagglutinin protein from the 1918 pandemic influenza A strain was identified and produced extraordinary virulence in a mouse model (Kobasa et al. 2004). Such highly virulent recombinant viruses will continue to pose a threat through agricultural practices.

14.2.2.2 Forest Systems and Interspecies Host Transfer

14.2.2.2.1 Bushmeat hunting and disease emergence

The global trade in bushmeat is quite extensive. In Central Africa, 1–3.4 million tons of bushmeat are harvested annually (Fa and Peres 2001). Also, in West Africa, a large share of protein in the diet comes from bushmeat; in Côte d'Ivoire, for example, 83,000 tons are eaten each year (Feer 1993) and in Liberia, 75% of meat comes from wildlife (105,000 tons consumed a year) (Fa and Peres 2001). The bushmeat harvest in West Africa includes significant numbers of primates, so the opportunity for interspecies disease transfer between humans and non-human primates is not a trivial risk.

Contact between humans and other animals can provide the opportunity for cross-species transmission and the emergence of novel microbes into the human population. Road building is linked to the expansion of bushmeat consumption that may have played a key role in the early emergence of human immunodeficiency virus types 1 and 2 (Wolfe et al. 2000). Simian foamy virus has been found in bushmeat hunters (Wolfe et al. 2004), and workers collecting and preparing chimpanzee meat have become infected with Ebola (WHO 1996). The initiation of a local epidemic of monkeypox (an orthopoxvirus similar to smallpox), which continued for four generations of human-to-human contact, has been attributed to the hunting of a red colobus monkey (Jezek et al. 1986). Also, there are other specific human activities that pose risks similar to those of wildlife hunting and butchering. For example, in the Tai forest in Côte d'Ivoire, a researcher performing a necropsy on a chimpanzee contracted Ebola (Le Guenno et al. 1995).

The Taxonomic Transmission Rule states that the probability of successful cross-species infection increases the closer hosts are genetically related (chimpanzees are closer genetically to humans, for example, than birds or fish are), since related hosts are more likely to share susceptibility to the same range of potential pathogens (Wolfe et al. 2000). Surveillance of nonhuman primates—reservoirs or sources for microbial emergence—can flag emerging pathogens (Wolfe et al. 1998).

14.2.2.2.2 Diseases transferred from human hosts to wildlife

Cross-species transmission also increases the probability that endangered nonhuman primate species and other wildlife will come into contact with human pathogens. The parasitic disease Giardia was introduced to the Ugandan mountain gorilla, *Gorilla gorilla beringei,* by humans through ecotourism and conservation activities (Nizeyi et al. 1999). Gorillas in Uganda also have been found with human strains of *Cryptosporidium* parasites, presumably from ecotourists (Graczyk at al 2001). The invasion of human tuberculosis into the banded mongoose (Alexander et al. 2001) represents another case of a human pathogen invading a free-ranging wildlife species.

These host transfer and emergence events not only affect ecosystem function, they could possibly result in a more virulent form of a human pathogen circling back into the human population from a wildlife host and may also allow the development of other transmission cycles to develop outside human-to-human contact.

14.2.3 Biodiversity Change Effects of Infectious Disease Transmission

Biodiversity change includes issues of species replacement, loss of key predator species, and variation in species population density. (See Chapter 4.) The equilibrium among predators and prey, hosts, vectors, and parasites is an essential service provided by ecosystems. (See Chapter 11.) It plays the role of controlling the emergence and spread of infectious diseases, although it is only recently that this protective function of biodiversity has been acknowledged (Chivian 2001).

14.2.3.1 Biodiversity Change at the Forest/Urban System Interface

Lyme disease can be used as a model system to illustrate some effects of biodiversity change on infectious disease transmission. In eastern U.S. oak forests, studies on the interactions between acorns, white-footed mice (*Peromyscus leucopus*), moths, deer, and ticks have linked defoliation by gypsy moths with the risk of Lyme disease (Jones et al. 1998). Most vectors feed on a variety of host species that differ dramatically in their function as a reservoir—that is, their probability of transmitting the infection from host to vector. Increasing species richness has been found to reduce disease risk (Schmidt and Ostfeld 2001), and the involvement of a diverse collection of vertebrates in this cases may dilute the impact of the main reservoir, the white-footed mouse (Ostfeld and Keesing 2000a).

Habitat fragmentation also plays a part in disease emergence; mouse populations that are isolated in fragments seem to fluctuate, unregulated by biotic interactions. Moreover, predators tend to be absent in small woodlots, and probable competitors occur at lower densities in these areas than in more continuous habitat. Therefore, habitat fragmentation causes a reduction in biodiversity within the host communities, increasing disease risk though the increase in both the absolute and relative density of the primary reservoir.

The same conclusions may apply to a number of other diseases, including cutaneous leishmaniasis, Chagas disease, human granulocytic ehrlichiosis, babesiosis, plague, louping ill, tularemia, relapsing fever, Crimean Congo hemorrhagic fever, and LaCrosse virus (Ostfeld and Keesing 2000b).

14.2.3.2 Biodiversity Change in Forest Systems: Variation in Population Density

Most of the human cases of rabies acquired from bat bites in Brazil result from isolated attacks, usually by sick bats that drop from their resting places or fly into houses and are unwisely grasped by a person. But over the last few decades several reports have been published of outbreaks of vampire bat (*Desmodus rotundus*) attacks on humans in Latin America, occasionally transmitting rabies (Thomas and Haran 1981; Schneider and Burgoa 1995).

Recently compiled data show that vampire bats were the second most frequent species transmitting rabies to humans in Brazil (25% of all cases) in 1993, second only to dogs (Schneider and Burgoa 1995); this was also true previously in Mexico (Anonymous 1991). In the majority of vampire bat attacks, the underlying motive for the attacks seemed to be the same: bat populations deprived of their abundant and readily obtained primary food sources (animals) sought alternative hosts (humans) to feed on. In rural areas, it has happened when animals such as cattle or pigs were rapidly eliminated from an area (MacCarthy 1989; Schneider 1991; Lopez 1992; Costa et al. 1993).

Similar attacks can occur when wild vertebrates are reduced following establishment of human settlements in remote areas (Almansa and Garcia 1980; Schneider 1991). For example, massive attacks by bats have occurred in the gold mining camps in the Amazon, where wild animal species that served as food sources for the bats were depleted due to overhunting or were chased away by the noise produced by water pumps and airplanes (Uieda et al. 1992; Coelho 1995; Schneider et al. 1996; Confalonieri 2001).

In this context, bat attacks on humans are a direct consequence of human-induced environmental modifications caused by the elimination of native species of animals in natural landscapes, with a consequent host shift and an increase in the likelihood of rabies transmission.

14.2.4 Human-induced Genetic Changes of Disease Vectors or Pathogens

One of the key properties of microbes that have successfully managed a ''host transfer,'' migrating into a new ecological niche, is the potential for mutability. This mutagenic potential of the microbe is exploited once selection pressure (through ecological change) is exerted on the microbe. For example, Brault et al. (2004) have associated genetic shifts in the Venezuelan encephalitis virus with epidemics in animal hosts in southern Mexico due to extensive deforestation and habitat changes, where the subsequent replacement of mosquito vector species is exerting new evolutionary pressures on the virus.

14.2.4.1 Resistant Bacteria from the Use of Antibiotics in Animal Feed

Intensive animal production (both agriculture and aquaculture) has many impacts on ecosystems and human well-being. (See Chapters 19 and 26.) Antibiotics are routinely used for prophylaxis and growth promotion in high-production livestock agriculture rather than being used sparingly for medical purposes. Such subtherapeutic levels exert selective pressure on the emergence of resistant bacteria. *Campylobacter* bacteria sampled from pigs in South Australia, for example, show widespread resistance (60–100%) to antibiotics such as erythromycin, ampicillin, and tetracycline, and *E. coli* strains showed widespread resistance to multiple antibiotics (Hart et al. 2004). Livestock have also been shown to be reservoirs of drug-resistant *Salmonella* bacteria (Busani et al. 2004) and other *E. coli* that are resistant even to newer-generation antibiotics, like cephalosporins (Shiraki et al. 2004).

Salmonella enteritidis likely stemmed from antibiotic prophylaxis in the poultry industry that led to removal of *S. gallinarum* and *S. pullorum* during the 1960s and the creation of a vacant niche in the gut, which was subsequently filled by *S. enteritidis*. These three pathogens share a common surface antigen; thus, flock immunity prior to removal of the former two species would have prevented the latter from becoming established.

14.2.4.2 Genetic Changes in Disease Vectors at Forest/Urban Interface

Chagas disease is a deadly disease transmitted by triatomine beetles in South and Central America. The niche and trophic relationships of these insects have direct epidemiological importance, and pesticide resistance is changing the ecology and transmission of this disease.

Only a few cases of typical insecticide resistance have been reported (Busvine 1970; Cockburn 1972), but important niche adaptations to houses and domestic areas seem to have taken place, particularly for the *Triatoma infestans* beetle (Dujardin et al. 1997a, 1997b; Gorla et al. 1997; Noireau et al. 1997; Panzera et al. 1997; Schofield et al. 1997). Domiciliary adaptation generally involves genetic simplification (Schofield 1994; Dujardin et al. 1998; Rabinovich et al. 2001), including the loss of genetic material that may make triatomines highly susceptible to chemical control (Borges et al. 1999) and may cause simplification of some specific characteristics, such as a reduction in body size and sexual dimorphism (Steindel 1999). Specific markers can differentiate populations that have survived chemical control from invasive populations (Costa 1999).

Triatomine ''ecological successions'' (replacement of some species by other species) follows control programs and environmental changes such as deforestation (Costa 1999). For instance, *T. sordida* has progressively replaced *T. infestans* because of elimination of the latter from houses. And *T. pseudomaculata,* which is predominantly peridomiciliary (around dwellings), has replaced *T. brasiliensis* in some areas treated with insecticides (Diotaiuti et al. 1998). The Brazilian Amazon, where Chagas disease was always considered endemic in wild animals, presently has at least 18 triatomine species reported, 10 of which are infected by *Trypanosoma cruzi,* the deadly human form of the disease (Coura et al. 2002; Teixeira et al. 2000).

14.2.5 Environmental Contamination of Infectious Agents of Diseases

14.2.5.1 Cryptosporidiosis

Cryptosporidium, a protozoan that completes its life cycle within the intestine of mammals, sheds high numbers of infectious oocysts that are dispersed in feces. One hundred and fifty-two species of mammals have been reported to be infected with *C. parvum,* which causes diarrhea and gastrointestinal illness. *C. parvum* infections of humans were first reported in 1976 and have since been reported from 90 countries. It is highly prevalent in ruminants and readily transmitted to humans. *Cryptosporidium* oocysts are very small (~3 microns) and are difficult to remove from water; another study found 13% of treated water in the United States still contained *Cryptosporidium* oocysts, indicating some passage of microorganisms from source to treated drinking water (LeChevallier and Norton 1995).

In a survey of farms in the state of Pennsylvania, 64% returned at least one bovine stool sample that was positive for *C. parvum,* and all samples were positive at 44% of farms. All cattle had full access to water courses that could be contaminated with these parasites (Graczyk et al. 2000). Environmental factors such as land use, climate extremes, and inadequate water treatment are now recognized as contributing factors in the spread of cryptosporidiosis (Rose et al. 2002).

The extent of the problem of *C. parvum* in tropical environments where water supplies are less well controlled is unknown. However, the impact of changing climate patterns and increased frequency of severe weather events on watershed and water storage facilities is likely to increase the level of oocyst contamination (Graczyk et al. 2000).

14.2.5.2 Leptospirosis

Leptospirosis is a bacterial waterborne disease disseminated by mammals, which shed the pathogen in their urine. Leptospirosis occurs across the globe. In tropical areas, the disease usually occurs as outbreaks during the rainy season, due to the flooding of densely populated low-lying areas infested with domestic rats, which breed prolifically because of poor garbage collection practices. In Rio de Janeiro, for example, epidemics have always been associated with seasonal increases in rainfall (Roberts et al. 2001). Outbreaks in rural areas are not as common as in urban areas.

14.2.6 Synergies between Malnutrition and Infectious Diseases

Malnutrition, as a consequence of environmental degradation, has a huge global impact on morbidity and mortality due to infectious diseases. For children under five years of age in the developing world, being underweight equates to about half the mortality risk of the main infectious diseases such as diarrhea, malaria, pneumonia, and measles. (See Chapter 8 for more on the health impacts of malnutrition). (See also Box 14.9.)

BOX 14.9

Nomadic Lifestyle, Land Cover Change, and Infectious Diseases

Nomads often face a different spectrum of health problems than nonnomadic populations. Their adaptation to a specific environment—often one that supports human settlement only on a transient basis—makes them sensitive indicators of land cover changes. Important inequalities between nomadic and nonnomadic populations exist not only with regard to the disease spectrum, but even more important with regard to access to health care (Sheik-Mohamed and Velena 1999). Nomadic lifestyle interferes with issues of compliance and adherence, but health care as an instrument of control used by settled populations is also an issue. Primary health care for nomads would have to be adapted to their life-style and needs. Continuous drought, for example, may force nomads into living conditions that threaten their health as well as their whole lifestyle (Loutan and Lamotte 1984). Becoming sedentary carries a major risk of mortality and infectious disease for nomadic populations in the African rain forest.

Nomadic populations live in the semiarid regions of the African continent or in the rain forest regions of Africa, South America, and Asia. Two big groups that can be distinguished are pastoralists (in the semiarid regions) and hunters/collectors (in rain forests). Kalahari Bushmen or Australian Aborigines would also be part of the hunters/collectors group.

For nomadic populations in the semiarid regions of Africa, water supply and management is a crucial issue. Water is also an essential part in many land cover changes and is of course essential to health. Child mortality in the Sahel region of Africa was found to be higher, and general access to health care was found to be limited. Infectious disease prevalence in pastoralists differs from settled populations with a profile that is directed toward diseases that have a reservoir in cattle, such as tuberculosis or brucellosis, and those that require long-term treatment, such as some sexually transmitted diseases and again tuberculosis (Niamir-Fuller and Turner 1999).

Pygmies in the Central African rain forest have been protected against some infectious diseases (including HIV1) due to their partial isolation. However, they are fully susceptible when coming into contact with carriers. Major land cover changes like deforestation in the Central African basin increase contact between different populations. Infections that require long-term treatment, like leprosy or tuberculosis, are difficult to target in nomadic populations in the rain forest.

14.3 New Tools and Methods for Assessment of Ecosystem Change and Human Disease

Table 14.4 summarizes the published literature on the link between ecological change and human disease. New tools applied across these ecologically linked diseases will improve understanding of these linkages and of the emergence of infectious diseases. Time-series analysis, geographic information systems, and spatial analysis (which encompass a range of technologies and approaches, including digital mapping, analysis of remotely sensed imagery, spatial statistics, ecological niche modeling, and the use of global positioning systems), for example, have proved useful in studying diseases emerging from land use change. (See also Chapter 3.) There have also been a number of significant reviews of tools that have been applied specifically to public health (Beck et al. 2000; Thomson and Connor 2000; Hay 2000).

Table 14.4. Infectious Diseases and Mechanisms of Potential Changing Incidence as Related to Ecosystem Changes

Disease	Cases per Year	DALYs[a]	Emergence Mechanism	Anthropogenic Drivers	Geographical Distribution	Expected Variation from Ecological Change	Confidence Level
		(thousand)					
Malaria	350 million	46,486	niche invasion; vector expansion	deforestation; water projects	tropical (America, Asia, and Africa)	+ + + +	+ + +
Lymphatic filariasis	120 million	5,777	habitat alteration	water projects; urbanization	tropical America and Africa	+	+ + +
Schistosomiasis	120 million	1,702	intermediate host expansion	dam building; irrigation	America; Africa; Asia	+ + + +	+ + + +
Dengue fever	80 million	616	vector expansion	urbanization; poor housing conditions	tropical	+ + +	+ +
HIV	42 million	84,458	host transfer	forest encroachment; bushmeat hunting; human behavior	global	+	+ +
Onchocerciasis	18 million	484	habitat alteration	spillways of dams	Africa; tropical America	+ +	+ + +
Chagas disease	16–18 million	667	habitat alteration	deforestation; urban sprawl and encroachment	Americas	+ +	+ + +
Leishmaniasis	12 million	2,090	host transfer; habitat alteration	deforestation; agricultural development	tropical Americas; Europe and Middle East	+ + + +	+ + +
Meningitis	223,000 (in 2002)	6,192	habitat alteration; dust storms	desertification	Saharan Africa	+ +	+ +
Hantavirus	200,000	–	variations in population density of natural food sources	climate variability		+ +	+ +
Rabies	35,000 deaths	1,160	biodiversity loss, altered host selection	deforestation and mining	tropical	+ +	+ +
Trypanosomiasis	30,000–500,000	1,525	habitat alteration	deforestation	Africa	+ + +	+ +
Japanese encephalitis	30,000–50,000	709	vector expansion	irrigated rice fields	Southeast Asia	+ + +	+ + +
Rift Valley fever	27,500 (Kenya 1998)		heavy rains	climate variability and change; dam building	Africa; Middle East	+ + +	+ +
Lyme disease	23,763 (U.S. 2002)		depletion of predators; biodiversity loss; reservoir expansion	habitat fragmentation	North America and Europe	+ +	+ +
SARS	8,098[e]		host transfer	intensive livestock operations mixing wild and domestic animals	global	+	+

Ecological niche modeling is an approach used in biogeography to predict the distributional range of species from existing occurrence data (Anderson et al. 2003). Using genetic algorithms as a decision tool in a GIS containing layers of environmental information (such as topography, climate, and vegetation), epidemiological and spatial risk stratification can be achieved from data on the location of vectors or pathogens. This approach has been successfully used in the case of Chagas disease and for vectors of leishmaniasis and filovirus infections (Peterson et al. 2002, 2004a, 2004b).

Increasingly in recent years, meteorological satellite data have been used to help model the spatial and seasonal dynamics of disease transmission and develop early warning systems (Connor et al. 1998). These relatively low cost and easy-to-use data sources have become familiar to public health services in Africa. For example, environmental data indicating areas at risk of malaria epidemics are beginning to be routinely incorporated into the WHO/UNICEF-supported disease surveillance software HealthMapper that is widely used by ministries of health (WHO 2001).

Table 14.4. *continued*

Disease	Cases per Year	DALYs[a] (thousand)	Emergence Mechanism	Anthropogenic Drivers	Geographical Distribution	Expected Variation from Ecological Change	Confidence Level
West Nile virus and other encephalitides	5,483 (U.S. average 2002–04)	–	niche invasion	international travel; climate variability	Americas; Eurasia	+ +	+
BSE	133[d]		host transfer	intensive livestock farming	Europe	+	+
Cholera	[b]	[c]	sea surface temperature rising	climate variability and change	global (tropical)	+ + +	+ +
Cryptosporidiosis	[b]	[c]	contamination by oocystes	poor watershed management where livestock exist	global	+ + +	+ + + +
Coccidioidomycosis	–	–	disturbing soils	climate variability	global	+ +	+ + +
Ebola	–		forest encroachment; bushmeat hunting	forest encroachment	Africa	+	+
Guanarito; Junin; Machupo	–	–	biodiversity loss; reservoir expansion	monoculture in agriculture after deforestation	South America	+ +	+ + +
Oropouche/ Mayaro virus in Brazil	–	–	vector expansion	forest encroachment; urbanization	South America	+ + +	+ + +
Leptospirosis	–	–	habitat alteration	agricultural development; urban sprawl	global (tropical)	+ +	+ + +
Nipah/Hendra viruses	–		niche invasion	industrial food production; deforestation; climate abnormalities	Australia; Southeast Asia	+ + +	+
Salmonellosis	–		niche invasions	antibiotic resistance from using antibiotics in animal feed	global	+	+

Key:
+ low
+ + moderate
+ + + high
+ + + + very high

[a] Disability-adjusted life year: years of healthy life lost, a measure of disease burden for the gap between actual health of a population compared with an ideal situation where everyone lives in full health into old age. (WHO World Health Report 2004)

[b] and [c] Diarheal disease (aggregated) deaths and DALYs respectively: 1,798 ˘ 1,000 cases and 61,966 ˘ 1,000 DALYs.

[d] Human cases from 1995 to 2002.

[e] From November 2002 to July 2003, probable cases of SARS reported to the World Health Organization.

Main Messages

Ecosystem processes may act to reduce concentrations of substances that are directly or indirectly harmful to humans. This capacity is finite, has been exceeded locally in many places, and is exceeded across some whole regions. The cases of stratospheric ozone depletion by chlorofluorocarbons and climate change due to greenhouse gas buildup demonstrate that the capacity to alter the environment in harmful ways through by-products of human activities has now reached global proportions.

Humankind produces a large variety of wastes that are introduced into the environment either by accident or by design. Wastes are by-products of human activity and include human excrement wastes, agricultural wastes, energy and manufacturing wastes, industrial and consumer chemical products, medical and veterinary products, and transportation emissions.

All cases of wastewater-borne disease, human health impairment due to contaminants, environmental degradation due to waste discharges, and contaminant-caused impacts on biota are failures in waste management. The management of wastes is an important function of human societies and essential to the promotion of human well-being. The mismanagement, or neglect of management, for any of the many waste types leads to impairment of human health, to economic losses, to aesthetic value loss, and to damages to ecosystems, biodiversity, and ecosystem function.

Deferring waste management actions until the problems become large is not an effective management approach. The costs of trying to reverse damages to waste-degraded ecosystems or remove toxins from the environment, if possible at all, can be extremely large and burdensome on society.

The capacity of an environment to adsorb wastes without damage to human well-being or to ecosystems depends on the ecosystems' ability to detoxify, process, or sequester (that is, isolate from the biosphere) waste contaminants. The no-damage limit or capacity for assimilation is highly variable. This variability is a result of the properties of different contaminants and the differing characteristics of specific ecosystems. Loading limits also depend on human judgments as to what is an acceptable level of human health risk or alteration of an ecosystem.

The levels of a waste chemical that are harmful to the ecosystem may be either much higher or much lower than for human health. For example, by the time human health effects are noticed, there may already have been substantial changes in the ecosystem and vice versa. Further, the sensitivity of different organisms within ecosystems may be very different for a particular contaminant. Different waste contaminants may have local, regional, or global impacts.

Some waste contaminants (such as metals and salts) cannot be converted to harmless materials and will remain in the environment permanently. With continued introduction into an environment, the concentrations of such contaminants will continue to increase. Many other contaminants (such as organic chemicals and pathogens) can be degraded to harmless components. And depending on the properties of the contaminant and its locations in the environment, degradation can occur at relatively fast or extremely slow rates. The more slowly a contaminant is detoxified (that is, the more persistent it is), the greater the possibility that harmful concentrations of the contaminant will be reached in the environment either locally or globally.

Some wastes, such as nutrients and organic matter, are normal components of natural ecosystem processes but can reach harmful levels due to human activities. Inputs of these materials may sufficiently exceed natural rates so that ecosystem functions are modified or impaired. Nutrients and organic matter, when applied at appropriate rates and locations, are an important resource for the improvement of agricultural soils.

The fate and effects of chemicals introduced into the environment can be predicted (in most cases with useful accuracy), so as to allow informed waste management decisions to be made. Due to the great number of possible contaminants, as well as the continuous generation of new compounds, and to the complex interactions within ecosystems, our understanding of the consequences of some contaminants is incomplete.

The problems associated with wastes and contaminants are in general growing worldwide. Some wastes are produced in nearly direct proportion to population size, such as sewage wastes. Other wastes and contaminants reflect the affluence of society. An affluent society uses and generates a larger volume of waste-producing materials such as domestic trash and home-use chemicals. Where there is significant economic development, loadings of certain wastes are expected to increase faster than population growth. The generation of some wastes, such as industrial ones, does not necessarily increase with population or development state. These wastes may often be reduced through regulation aimed at encouraging producers to clean discharges or to seek alternate manufacturing processes.

It is not possible at this stage to state whether the intrinsic waste detoxification capability of Earth will increase or decrease with a changing environment. The detoxification capabilities of individual locations change with changing conditions. However, it is certain that at high waste-loading rates, the intrinsic capability of ecosystems can be overwhelmed such that wastes build up in the environment to the detriment of human well-being and the loss of ecosystem biodiversity and functions.

15.1 Introduction

This chapter addresses two major topics: the general characteristics and patterns of waste production and the capacity of ecosystems to detoxify or otherwise adsorb human-produced wastes. The first is addressed by showing some trends in major categories of wastes, attempting to indicate in particular the relationships between population and level of development and waste production. The second topic is complex due to the wide variety of types of wastes produced by human activities and to the complex set of ecosystem processes that determine the fate and effects of wastes in various ecosystems. The chapter shows how ecosystem processing of wastes and waste loadings interact to determine the damages of particular wastes.

The term ''wastes'' in this chapter refers to materials for which there is no immediate use and that may be discharged into the environment. It includes materials that might otherwise be useful if they were not in the environment, such as oil after an oil spill or pesticides once they are no longer at their site of application. The term ''pollutant'' is not generally used here. A waste in the environment is a contaminant but not necessarily a pollutant in the sense of loss of use of ecosystem services.

Although there is no attempt here to systematically assemble and estimate the damage to humans and ecosystems done by past waste releases, a few examples of the types, issues involved, and magnitude of damages of wastes that exceeded ecosystems' capacity are provided in order to illustrate the importance of managing wastes.

The intent of this chapter is to lay down a foundation for decisions regarding wastes and to establish the importance of waste management for human well-being at both the local and the global scale.

15.1.1 Humanity's Many Types of Wastes

Human activities discharge many types of materials into the environment:

- *Industrial by-products resulting from the production of durable goods, pharmaceuticals, and other manufactured goods* used by society: Some of these materials are novel to natural systems (xenobiotic), which means they did not exist on Earth before being manufactured by humans. Ecosystems may be very ineffective in detoxifying novel chemicals, and so they may be particularly persistent and thus accumulate in the environment.
- *Nondegradable wastes, which cannot be broken down to harmless materials*: These can only be diluted. This category includes metals and salt wastes. Typically, salts are not a problem once they reach the ocean, but metals cause problems in any ecosystem.
- *Pesticides*: These may indiscriminately kill even beneficial insects, and persistent pesticides may accumulate in organisms and have harmful effects on other organisms in the food web.
- *Fertilizers,* the most important of which, quantitatively, are nitrogen and phosphorus compounds.
- *Excrement, or sewage wastes,* rich in organic matter and in nitrogen and phosphorus (plant fertilizers or nutrients) and carrying pathogens: The organic matter in sewage can remove oxygen from aquatic systems, and the nutrients may stimulate plant growth and alter ecosystem structure and function.
- *Natural materials,* which are often released at rates that greatly increase environmental concentrations, thereby often harming ecosystems and human health: Included here are toxic metals, salt wastes, acid wastes, reactive nitrogen, carcinogenic polycyclic aromatic hydrocarbons (found in smoke and exhaust), and petroleum products.
- *The by-products of day-to-day human activities*: This category includes materials made from paper, plastics, glass, metals, and products such as household chemicals, and pharmaceuticals, which become wastes after they are used and, in one form or another, end up in the environment.

Table 15.1 provides a more detailed listing of the major categories of wastes introduced into the environment. The individual materials within a category may have different behaviors in the environment and represent very different types and levels of risks. It should be recognized that some of the categories in the table include a great number of different types of materials. For example, the Registry of Toxic Effects of Chemical Substances (MDL 2003) lists over 150,000 chemicals. Another compendium, *The Merck Index* (O'Neill et al. 2003), lists over 10,000 individual biologically active pharmaceuticals, chemicals, and biological compounds. Further, thousands of new compounds are being synthesized and manufactured each year.

Wastes may be classified as either ''point source'' or ''non-point source.'' Point source wastes are those discharged from a specific facility or at a specific location. Typical of these facilities are industrial operations or sewage processing facilities where the discharge location is readily identifiable, often a single pipe or smokestack. (It should be noted that a sewage treatment plant is not the actual source, but a collecting point for wastes.) The other major category, non-point source wastes, includes urban runoff, acid rain, and agricultural runoff. The distinction between point and non-point sources is somewhat arbitrary, however, as the place in time and space at which a large number of small point sources become non-point source is subjective.

Different types of wastes are also often mixed together, making management of wastes more difficult. For example, the mixing of industrial effluents with domestic sewage impairs possible beneficial uses of waste waters. Domestic sewage, properly treated to kill pathogens, may make suitable fertilizer and soil enhancers for agricultural purposes. However, metals or chemicals often contaminate centrally collected sewage, precluding the use of the sewage for such beneficial purposes. Many household chemicals such as pesticides, pharmaceuticals, and cleaners may also render domestic sewage unsuitable. For example, irrigation with industrial waste waters has been associated with enlarged livers, cancers, and malformation rates in areas in China (Yaun 1993) and with cadmium poisoning in Japan (WHO 1992).

Reuse of domestic waste waters is easier when grey waters (those, for example, from washing) are not mixed with black waters (those containing excrement). The grey waters can be used especially for small-scale irrigation with low risk of disease transmission (Faruqui et al. 2004). If mixed wastes (such as municipal wastes) are incinerated, special technology is required to prevent potentially harmful materials (such as noncombustible metals) from entering the incinerator's air emissions and causing air pollution. The ash of incinerated mixed waste may also have high levels of contaminants, requiring careful disposal.

15.1.2 Types of Damage Caused by Wastes

Wastes can cause harm in many different ways. It is convenient to consider three general different types of harm:

- direct impairment of human health;
- damage to ecosystems or organisms that creates economic losses; and
- damage to organisms in an ecosystem, with loss of biodiversity.

15.1.2.1 Impact of Wastes on Human Health

There are many examples of human health problems associated with wastes:

- Pathogens in sewage wastes transmit diseases. Such pathogens include cholera, typhoid, shigella, and viruses, causing diseases such as diarrhea, polio, meningitis, and hepatitis. It is estimated that 1.8 million children in developing countries (excluding China) died from diarrheal disease in 1998, caused by microorganisms, mostly originating from contaminated food and water (WHO 2003) (some reported food cases may not be from wastes but from direct contamination by other humans and poor hygiene in food preparation). Worldwide, a lack of suitable sanitary waste treatment is estimated to cause 12 million deaths per year (Davidson et al. 1992).
- For metals, the severe health effects of mercury being discharged into the environment were learned in the painful lesson of Minimata Bay Disease (actually not an infectious disease, but mercury poisoning) first identified in the late 1950s, where nearly 3,000 people were stricken with disease or died after mercury was dumped into the environment. Lead is another metal of high concern. Lead has entered the environment as an additive in gasoline and paints. For example, lead exposure in Mexico has resulted in 40–88% of the children in various communities having blood levels of lead higher than exposure guidelines (Romieu et al. 1994, 1995). Lead exposure can reduce growth and cause learning disabilities and neurological problems.
- A number of persistent organic pollutants have become of enough concern to stimulate the generation of international conventions to stop their use (such as the Stockholm Conven-

Table 15.1. Major Categories of Wastes and Contaminants Listed by Source

Category	Types of Wastes	Character of Source	Extent of Impact
Industrial sources			
Energy producers Coal, oil, and gas, production of coking coal Nuclear plants	metals, PAH, fixed nitrogen, waste heat, fly ash, spent fuel, CO_2	point source	local to regional to global
Manufacturing and chemical wastes	wide variety of types; often synthetic chemicals, solvents, and/or metals	point source	local to regional
Mining	metal-contaminated water and soils, acidified water	point source	local to regional
Transportation accidents	oil spills and chemical spills	point source	local to regional
Waste incineration	particulates, PAH, dioxins, fixed nitrogen, phthalates	point source	local to regional
Agricultural sources			
Livestock production systems	pathogens, including species-jumping bacteria/viruses, organics, nutrients, salts; pharmaceuticals, including antibiotics	non-point source	local to regional
Cropping systems	herbicides, fungicides, and insecticides; nonusable plant materials, nitrogen, phosphorus	point and non-point sources	local
Land preparation and rangeland management	PAH, particulates (from set fires)	point and non-point sources	local to regional
Human habitation sources			
Sewage	pathogens, fertilizers, organic matter, residual pharmaceuticals	point and/or non-point sources	local to regional
Heating source emissions	PAH, particulates	non-point source	local to regional
Consumer hazardous materials	cleaners, paints, automotive fluids, pesticides, fertilizers, batteries, cells	point and/or non-point sources	local
Trash	organics, leachates containing nutrients, salts, metals, plastics, glass	point and/or non-point sources	local
Transportation, including shipping, aviation, and automotive sources	PAH, reactive nitrogen, lubricating oils, coolants, lead	non-point source	regional

tion on Persistent Organic Pollutants and the Aarhus Protocol on Persistent Organic Pollutants). For example, the concentrations of polychlorinated biphenyls in fish from certain waters are great enough to warrant official advisories against eating the fish. PCBs have been found in human tissues and human milk throughout the world (Jensen and Slorach 1991).

- It is estimated that air pollution in China causes more than 50,000 premature deaths and 400,000 new cases of chronic bronchitis a year (Harrison and Pearce 2000; UNEP 2000). Air pollution may aggravate asthma, and in the United States approximately 600 children die annually from asthma and 150,000 are hospitalized (CDC 1995). (See also Chapters 13 and 27 for a further assessment of air pollution.)

Humans are exposed to wastes by drinking water containing hazardous substances from waste residues, by ingesting foods with waste residues, by inhaling airborne wastes, or by through-the-skin exposure after physical contact with waste residues. Drinking contaminated water is a common route of exposure for many wastes that are leached into surface or groundwaters. Examples of food exposure routes include agricultural pesticide residues on foods, contamination during food preparation, and bacteria accumulated by edible clams that filter and concentrate particles from water.

Inhalation is a route of exposure for airborne wastes, such as the polycyclic aromatic hydrocarbons in smoke and automotive exhausts, or for pesticides carried downwind of the site of application. Through-the-skin (dermal) exposure is most often associated with worker exposure to materials they are handling, but it is also a route for wastes, such as for residential use pesticides, and for parasites. The dermal and inhalation exposure routes highlight significant overlaps between worker safety issues and waste issues.

15.1.2.2 Economic Losses

Detriment to ecosystems or specific organisms by the introduction of harmful wastes can lead to significant economic losses:

- When a body of water becomes anoxic from eutrophication through excess nutrient inputs, it can no longer support commercial, subsistence, or sport fisheries. Worldwide, there are now at least 146 areas in the coastal environment where low oxygen concentrations occur either chronically, seasonally, or episodically (UNEP 2004).
- A major economic loss has resulted from the use of the antifoulant agent tributyltin used in paints for ship and boat hulls.

Pleasure boats are often kept in high-density moorings and docks in close proximity to where oysters are grown. The species and race used for the oyster aquaculture industry in Europe is about 100 times more sensitive to TBT than are typical aquatic test organisms. As the pleasure boating community adopted TBT-based paints as the hull paints of choice in the 1970s, oyster farming operations throughout Europe experienced huge decreases in yield. For example, in Arcachon Bay, France, annual oyster production dropped from around 13,000 tons to about 3,000 tons between 1977 and 1983. Further, surviving oysters grew deformed, rendering them unsuitable for market. Economic losses for Arcachon Bay over this period were estimated at 800 million francs (Alzieu 1990). Banning the use of TBT paints on small vessels alleviated the immediate threat to the European oyster industry.

- Discharges of wastes into the environment can also cause economic losses even where there may be no clear detriment to the local organisms. For example, in U.S. coastal waters about 15% of potential commercially harvestable shellfish beds are closed due to water quality problems, primarily from sewage discharges (NOAA/ORCM 2003).
- When human health is affected by wastes such that a person is unable to work, there are direct economic consequences.

15.1.2.3 Damage to Ecosystems and Loss of Biodiversity

Wastes present in the environment can harm organisms. Terrestrial organisms may be exposed to wastes through the food chain, through inhalation, or through direct contact. Aquatic organisms may also take up wastes directly from the water.

- Where sufficiently high levels of contamination occur, organisms may receive acutely toxic exposures and die in mass. For example, fish kills have resulted from industrial discharges or runoff of agricultural pesticides (Heileman and Siung-chang 1990). Deaths of aquatic and bird wildlife are often the immediate and visible result of large oil spills, although there may also be long-term residual toxicity resulting from large oil spills (Peterson et al. 2003).
- More subtle and less evident are wastes that change the behavior or the biology of organisms but are not in themselves lethal. A well-known example was the widespread use of DDT and its effects on high-trophic-level birds, which did not die but could not successfully reproduce. Currently, there is concern that other chemicals, such as hormone disrupters, may affect organisms at concentration levels below those causing effects evident in standard toxicity tests. Some of these may disrupt the hormone systems of some organisms, affecting their behavior or reproductive physiology and reducing their capability to survive or reproduce (NTP 2001; deFur et al. 1999).
- Ecosystems can be damaged by changes in their chemical composition. For example, acid rain—a result of sulfur and fixed nitrogen emissions from power plants, motor vehicles, and agriculture—can alter the chemistry of soil. This stresses vegetation and alters the species composition of lakes and streams, sometimes to the point of making the lake unable to support fish life (Driscoll et al. 2001; Galloway 2001).

15.1.2.4 Different Thresholds for Human Health, the Ecosystem, and Economic Loss

The thresholds for effects in the three general types of damage—human health, economic losses, and damage to ecosystems—may be quite different. Acceptable waste concentration limits to protect human health may overwhelm some ecosystems and result in economic losses.

- The effective pesticide DDT has a low acute (short-term) toxicity to humans. From a human perspective, its use was relatively safe and is still used inside households for malaria control, and although there could be significant sublethal human health effects as well, it was primarily DDT's effects on the reproductive capabilities of birds that made its use unacceptable.
- The antifoulant paint ingredient TBT is apparently harmless to mammals (including humans) at environmental concentrations that are lethal to oysters. Although the use of TBT caused economic losses in Europe and harmed some other mollusk populations as well, ingestion of TBT-contaminated organisms was not considered or regulated to address a human health problem.
- The effects of low levels of many carcinogenic chemicals (such as PAH) or ionizing radiation are of great concern for human health where each individual is valued, yet are usually not risks to the health of wildlife populations.

Given the different sensitivity of different species, including humans, to chemical residues, a chemical exposure standard set to reduce human health impacts may not be sufficient to protect wildlife, or vice versa. As such, individual evaluations are required to fully understand the consequences of varying waste concentrations on human health and ecosystems.

15.2 Trends in Waste Production

The amounts of wastes released into the environment in many ways depend on choices made by governments, organizations, and individuals. Trends for some categories of wastes by themselves are not necessarily predictive of future trends, as waste-generating behaviors may change. And the future magnitude of waste problems depends on how wastes are managed in relation to the capacity of ecosystems to detoxify wastes.

In order to understand the actions required for adequate waste management, recognizing the role of ecosystems in waste detoxification, it is useful to examine relationships between waste production and different segments of the human population. The production of some wastes is closely related to population size, while some production is more related to human practices in agriculture and manufacturing, which often correlate with a nation's state of development.

15.2.1 Population-proportional Wastes

The amounts of human excrement wastes (feces and urine) produced are essentially proportional to human population size. Although there may be some differences in the composition and per capita production of excrement depending upon the nutrition status of the population (for example, the nitrogen content of sewage depends on the amount of protein in the diet), the overall variability in composition is relatively small. The total amount of human excrement wastes will increase in proportion to population growth.

The urbanization of populations (see Chapter 27) and the general increase in coastal populations (see Chapter 19) will tend to concentrate the excrement production into relatively limited areas. If damage to ecosystems from the nutrients and organic matter in human sewage is to be prevented, and if sewage-carried pathogens are to be reduced or eliminated, efforts to manage human excrement wastes must increase in proportion to the population size. Where the oxygen demand (mostly due to the decay of carbon compounds in the sewage) and nutrient fertilizers in excrement wastes are not removed from sewage, especially in waste-receiving waters near large urban areas, the loadings to the environment can easily exceed the capacity of ecosystems to adsorb them without causing harm to the environment. Pathogen destruction and the removal of oxygen demand can be managed very effectively by modern sewage treatment. With additional treatments (and often significant expense), the amount of nitrogen and phosphorus discharges may be significantly reduced. (See later description in this chapter, Chapter 12, and MA *Policy Responses,* Chapter 10.)

15.2.2 Development-related Wastes

The amount of consumer or municipal waste produced on a per capita basis has a relationship with the development status of countries. (See Figure 15.1.) In general, poverty reduction would be expected to increase the production of consumer waste even without increasing populations. However, policies and practices may also significantly affect the amount and types of municipal wastes produced as societies develop.

The density and character of solid municipal wastes also differs at different states of development. (See Figure 15.2.) In the United States and Europe, for example, solid waste has a large fraction of light materials, such as carton boxes, paper bags, and plastic bags, whereas in many developing countries there is a larger fraction of higher density solid waste, such as gravels, glass, food wastes, and unusable metals.

There are three different types of agricultural wastes: fertilizers, pesticides, and organic wastes (such as manure). The use patterns of these are different and typically depend on a country's state of development. In industrial nations, fertilizers were applied in increasing amounts per unit area until the late 1980s, when application declined. (See Figure 15.3.) Recognizing the contribution of agricultural runoff to degraded water quality and eutrophication and the expense of unnecessary overfertilization, improved farming practices were introduced in many countries, which reduced the need for more fertilization yet maintained production. In contrast, in many developing countries the application of fertilizer on an area basis is still increasing and has surpassed the rate in industrial countries. There is, however, considerable variation between industrial and developing countries: industrial ones use more pesticides overall. (See Figure 15.4). Hidden within this overall trend are some additional important trends:

- Industrial countries are quicker to move to newer, less toxic (to humans), more environmentally suitable systems and products.
- Developing countries are often still using older, less expensive, more toxic pesticides at significant risk to farm workers, their families, and others in the vicinity of farms (Goldman and Tran 2002), with poverty exasperating such problems.
- Many developing countries have stockpiled wastes that are likely to eventually breach containment and be a source of potential harm if not destroyed or disposed of properly (Goldman and Tran 2002), again a problem exasperated by poverty, which reduces the capacity to deal with such problems.

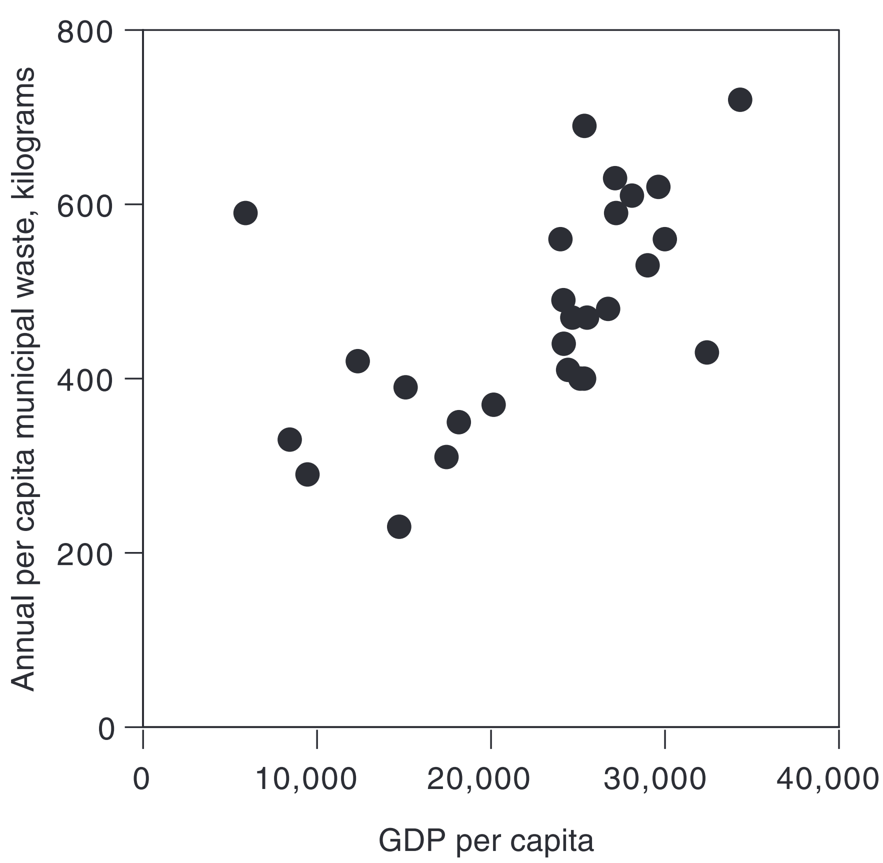

Figure 15.1. Municipal Waste Production in OECD Countries by per Capita GDP (Harrison and Pearce 2001; UNDP 2003)

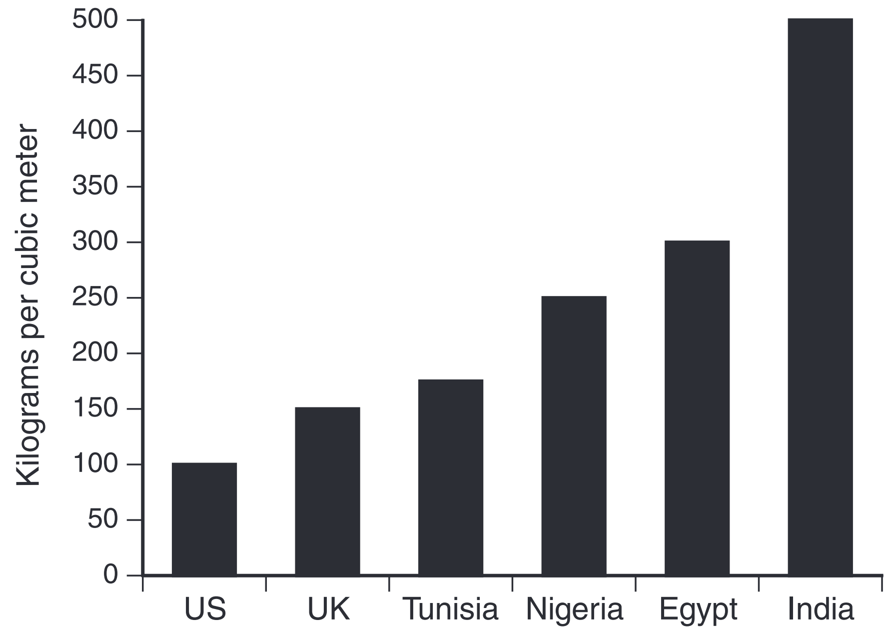

Figure 15.2. Density of Municipal Solid Waste in Selected Countries (UNEP 1996)

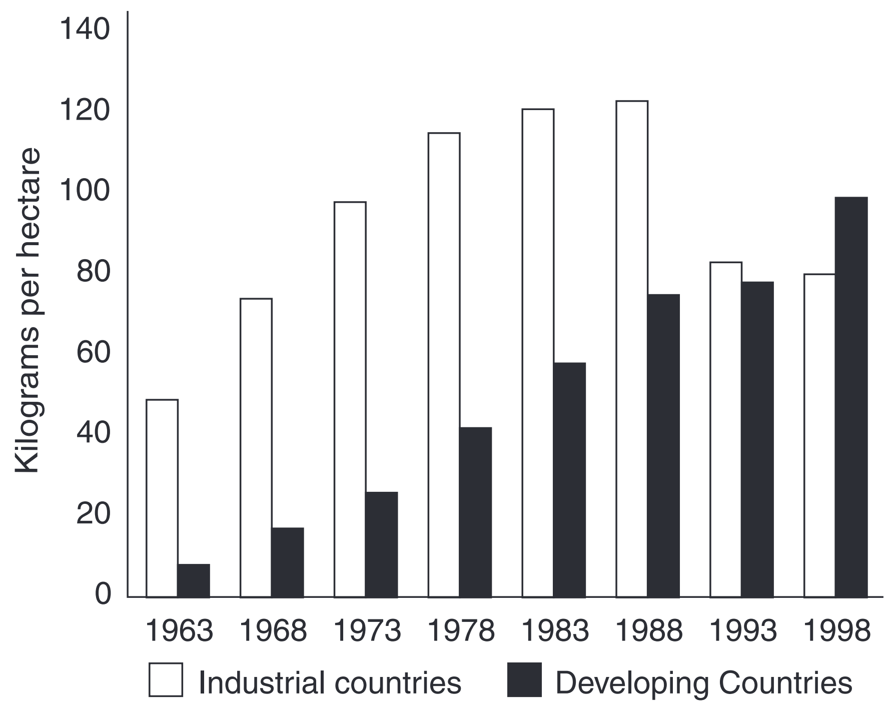

Figure 15.3. Fertilizer Use Trends in Industrial and Developing Countries, 1963–98 (Harrison and Pearce 2001)

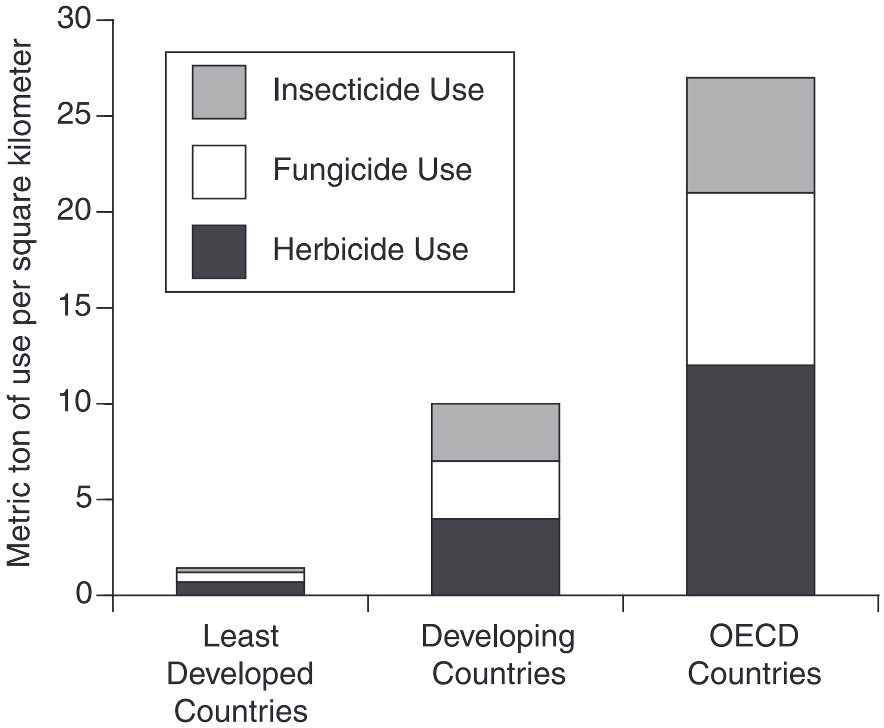

Figure 15.4. Pesticide Use in Countries at Different Levels of Development (Goldman and Tran 2002)

- Many individuals applying pesticides, particularly in developing countries, lack appropriate training. This leads to pesticide poisonings, unnecessary use, and misapplication of pesticides.

15.2.3 Wastes Controlled by Regulations

The amount of industrial wastes produced can be controlled by regulation and good industrial manufacturing practices, and it is not necessarily the case that discharge of industrial wastes grows with increased industrial levels. Figure 15.5 shows that releases of industrial wastes to water do not increase in proportion to the gross domestic product of various countries. The trend is not significantly different if looking only at the waste produced as a function of the fraction of GDP that is attributable to the industry sector.

The prevention of industrial discharges can be required by a strong regulatory framework and can be achieved through treatment of waste streams (or pollution control) and through pollution prevention (often called ''green chemistry'') through modification or selection of manufacturing processes to reduce or eliminate the production of wastes in the manufacturing process while providing the same products (Greer 2000).

15.2.4 Wastes Controlled by a Combination of Factors

Some wastes do not fit into a single one of the categories just described. For example, emissions from cars and trucks include carbon monoxide, reactive forms of nitrogen, soot, PAH, and carbon dioxide. The number of vehicles in any country depends on population size, the wealth of the population, and the policies in place. The emissions from an individual vehicle depend on regulation and enforcement of emission standards and on the kinds of vehicles (that is, the size and engine capacity and type) in use.

15.3 The Necessity of Waste Management

The production of wastes is a normal function of all living organisms, and individuals, groups of organisms, and societies depend on the capacity of ecosystems to detoxify such wastes. Without an ability to manage wastes, organisms cannot live indefinitely. A lesson often taught in introductory biology classes provides a useful illustration. Bacteria inoculated into a rich culture medium will at first grow and multiply. But eventually, as waste products from bacterial metabolism build up in the medium, the bacteria can no longer multiply and may die. The death happens even though there may still be plenty of food for the bacteria. They are poisoned by their wastes.

Higher organisms require systems to process wastes and expend significant energy to deal with wastes. For example, a human body has kidneys, liver, large intestine, and bladder that are primarily committed to waste processing. Further, the circulatory system is just as important for transporting wastes to be processed or eliminated as it is for carrying oxygen and nutrients to cells. Waste management is an important and necessary function of higher organisms.

Similarly, a portion of society's energy must be committed to the important but unglamorous task of waste processing in order to promote health and well-being. In a human-dominated Earth, the practice of placing wastes out of reach is no longer a long-term solution. The dumping of wastes, such as at sea, or the transport of wastes from one country to another does not necessarily prevent the wastes from causing human detriment.

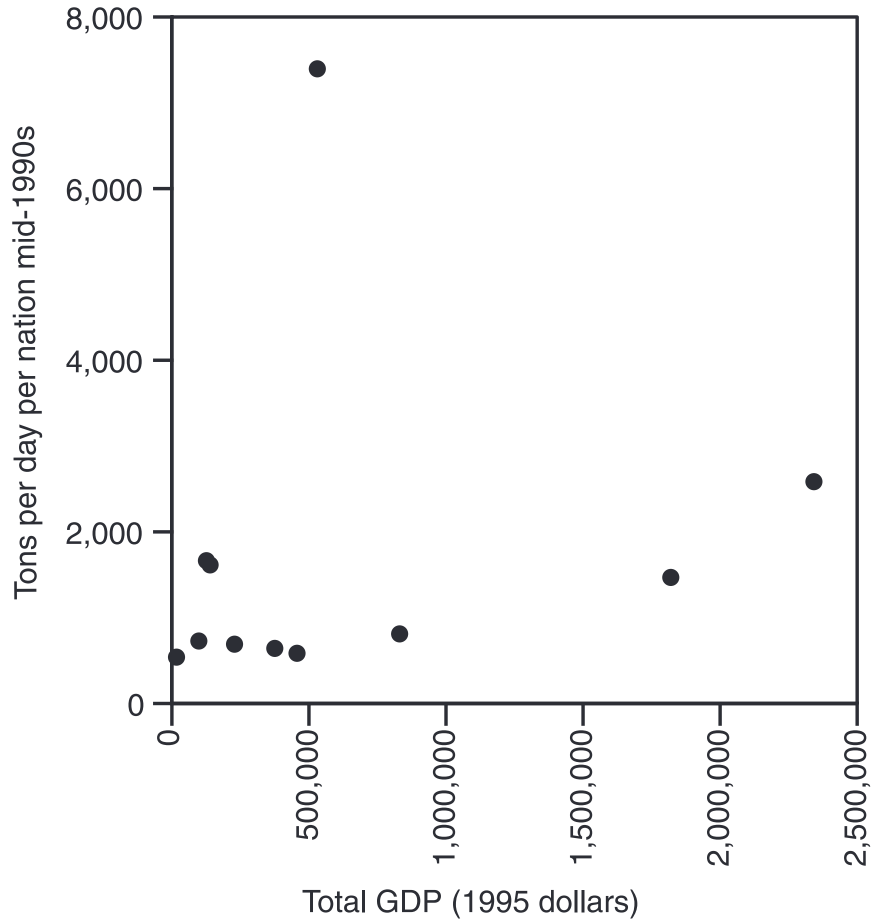

Figure 15.5. National Releases of Organic Water Pollutants in Selected Countries. The nations included (in order of lowest to highest GDP) are Ukraine, Indonesia, Russia, India, Brazil, China, United Kingdom, France, Germany, Japan, and United States. (Harrison and Pearce 2000; WRI 2003)

15.3.1 Local Scale

On the scale of a large city, sewage treatment and solid waste management are particularly important functions. The level of commitment necessary to accomplish these tasks may be illustrated by examination of the expenditures in cities where sewage and solid waste services are considered adequate. In an examination of budgets for some major U.S. cities, for example, the combined expenditures of solid waste disposal and sewage treatment range from about half the costs of police and fire protection (New York and San Diego) to equal to those expenditures (Detroit and Houston). Establishing effective waste management functions is an extremely important development goal, as the poor are particularly susceptible to detrimental exposure to wastes (Goldman and Tran 2002; see also description later in this chapter).

15.3.2 National Scale

Regulatory management of wastes is generally conducted through national governments and through state or provincial authorities. Insufficient regulatory management often leads to human health impairment, economic loss, or ecosystem degradation. The costs of failure to prevent waste problems can be very high, especially those for cleaning up contaminated sites. For example, the U.S. Environmental Protection Agency estimated (EPA 1998) that it would require $32.9 billion in public funds to remediate the 5,664 listed contaminated sites in the United States at that time, which is in addition to the considerable private funds spent on these projects. Another example is the costs of remediation in U.S. coastal waters, where it is estimated that upgrading sewage treatment plants to mitigate nitrogen-caused low oxygen problems in estuaries will cost up to $20 billion for the Chesapeake Bay and about $10 billion for Long Island Sound (Boesch 1996). In addition to such remediation costs, the full cost of failure in waste management includes broader human, ecosystem, and economic costs.

15.3.3 Global Scale

Some contaminants are of global significance, particularly persistent chemicals subject to long-range transport. Accordingly, a number of international conventions and protocols have come into force or been signed to manage such chemicals. Notable among these are:

- the 1979 Geneva Convention on Long-Range Transboundary Air Pollution and its eight protocols;
- the 1985 Vienna Convention for the Protection of the Ozone Layer and its Montreal Protocol on Substances that Deplete the Ozone Layer (plus amendments);
- the 1989 Basel Convention on the Control of Transboundary Movements of Hazardous Wastes and Their Disposal;
- the 1992 United Nations Framework Convention on Climate Change and its Kyoto Protocol;
- the 1998 Rotterdam Convention on the Prior Informed Consent Procedure for Certain Hazardous Chemicals and Pesticides in International Trade; and
- the 2001 Stockholm Convention on Persistent Organic Pollutants.

In addition, there are further efforts to manage chemicals on a global basis, such as the U.N.'s Strategic Approach to International Chemicals Management initiative.

15.4 The Capacity of Ecosystems to Detoxify or Use Wastes

The ability of an ecosystem to reduce waste concentrations depends on both the properties of the waste and the properties of the ecosystem. In order to understand the potential harm of a waste or to determine how much capacity an ecosystem has to assimilate a particular waste, it is necessary to examine the ecosystem processes that are responsible for the fates of wastes. Although there are thousands of types of materials in wastes, ecosystem processes are relatively few in number.

Table 15.2 lists the ecosystem processes that may act to reduce the concentrations or impacts of wastes in an environment over time. There are two fundamentally different types of processes:

- *Processes that act to change wastes into less toxic forms (''detoxification'')*: Some types of wastes may be completely destroyed by processes in the environment or used in the environment in a way that renders them harmless. It should be recognized that while processes that alter waste materials are often on the path to detoxification, the initial alteration of a waste may not reduce the potential of the waste to do harm.
- *Processes that move and transport wastes*: These reduce concentrations of waste by diluting them into larger areas or larger volumes of water. However, some waste transport processes may also concentrate wastes into ''hot spots'' of relatively high waste concentrations.

Different types of waste have different properties and interact with or are subject to different environmental processes. Table 15.3 lists the general detoxification characteristics for different types of waste materials.

15.4.1 Detoxification Processes

15.4.1.1 Microbial Degradation

Organic wastes can usually be broken down or even consumed as food by some organisms. When degraded, the waste may be made less toxic and its harmful effects reduced. Remineralization is the complete breakdown of an organic chemical (for example, into its basic components such as carbon dioxide, nitrogen, phosphorus, and water), such as may occur by microbial digestion. Remineralization completely destroys toxicity inherent in such waste. Most remineralization is conducted by microbes (primarily bacteria and fungi).

The ability of microbes to metabolize and remineralize different wastes is highly variable. Remineralization depends on the type and number of microbes in the total community that are capable of degrading a particular waste. The number of waste-degrading microbes in turn depends on prior exposure to the waste (or similar types of waste) through chronic or single-event exposures. Degradation of the wastes may increase after exposure as a result of an increase in number of waste-degrading microbes or the induction of appropriate enzyme systems.

The rates at which microbes can degrade wastes are influenced by temperature and thus may change seasonally. The presence of oxygen often exerts a strong influence on degradation rates, and wastes may persist for very long periods of time in sediments that have little or no oxygen, even though microbes in oxygen-rich environments may readily degrade the same waste. Marine and aquatic sediments and water-saturated soils in wetlands are often low in oxygen. Hence, the water availability in a specific location, acting through changes in the amount of saturated sediments and soils or even through changes in soil moisture, may have significant effects on contaminant degradation rates.

Some wastes break down in anaerobic conditions. Specifically, the removal of chlorine atoms from PCB molecules, a necessary first step in their remineralization, seems to occur (though slowly) in anaerobic conditions (e.g., Mondello et al. 1997).

High concentrations of waste contaminants may also be toxic to the bacteria and fungi that could otherwise degrade the contaminant were it present in lower concentrations. This restricts the breakdown of a contaminant to the less contaminated areas of a site, slowing the overall degradation.

Table 15.2. Processes Involved in Waste Processing and Detoxification

Processes	Factors Affecting Processes
Contaminant movements in soils	
Sorption to sediments (may reduce bioavailability)	chemical nature of soils; especially organic content and cation exchange capacity, basicity of compound
Leaching by precipitation water flow (transport from and through surface sediments)	porosity of soils, rate and pattern of rainfall, vegetation cover, slope of soil surface, polarity of compound
Groundwater transport	clay content, cation exchange capacity, porosity, hydraulic gradient, polarity of compound
Volatilization and dust transport	vapor pressure of chemical, vegetation cover, moisture content of soils
Soil erosion	vegetation cover, soil moisture content, soil cohesion
Biological transports	bioturbation, bioconcentration, and animal movements and migration
Contaminant movements in water bodies	
Mixing or dilution	volume of receiving waters, stratification
Advection and dispersion	velocity of water, turbulence regime
Water residence time	water input rate, tidal height, salinity distribution
Particle and sediment interactions and scavenging to sediments	solubility of contaminant (Kow), particle deposition rate
Sediment-water exchange	diffusion rate, bioturbation rate, water level fluctuations
Sequestering of chemicals (acid volatile sulfides in sediments)	oxidation state of sediments, availability of sulfides
Scavenging to (accumulation at) sea–air interface	solubility of contaminant
Volatilization	vapor pressure of contaminant, wind speed and water surface roughness
Aerosol formation	breaking waves
Precipitation from solution	solubility limits
Biological transports	uptake by organisms, settling of organic materials, food chain transfers
Contaminant movements in air	
Wind transport	wind speed, particle size and density
Wet deposition	precipitation patterns and solubility
Dry deposition and adsorption	surface area, air turbulence, "strictness" of contaminant
Processes responsible for alteration and destruction of contaminants	
Direct photolysis	strength and wavelength of light
Oxidation/reduction	properties of chemicals, oxidation state of media
Acid, base, and neutral hydrolysis	properties of chemicals, moisture availability
Microbial transformations	type of chemical bonds (e.g., chlorinated/holgenated vs. natural compounds); native community of microbial degraders; microbial degradation rates may depend upon waste concentration, temperature, the presence or absence of oxygen, pH, prior exposure, availability of co-metabolites, and influence of synergism
Radioactive decay	rate of decay intrinsic to radionuclide
Die-off (of pathogens and indicator organisms)	temperature and other conditions in environment, presence of organisms to ingest pathogens, presence of vector organisms

Chemicals that can be used as food by microbes tend to break down more quickly than poor food-quality chemicals. Some organic chemicals are especially slow to break down in the environment. For many of these, their resistance to microbial degradation results from the presence of many attached chlorine or bromine atoms. While there are many naturally occurring organic compounds incorporating chlorine or bromine—which degrade, albeit slowly, naturally—many of those synthesized by the chemical industry are quite resistant to microbial degradation. The chlorine-carbon bonds in these synthetic chemicals are not naturally abundant, and organisms do not have enzymes effective at degrading these chemicals. One group of such resistant chemicals with known toxic effects are the persistent organic pollutants, some of which have been banned from further production by international treaties (as described earlier in this chapter).

The time required for the concentration of POPs in a contaminated area to decrease measurably is typically measured in decades (Wania and Mackay 1995). For example, results from the NOAA Mussel Watch Program show that PCBs (one group of POPs) in Delaware Bay are decreasing at a rate of only about 5% per year (a half-life of about 13 years). This decrease is partly due to slow degradation of the PCBs but also to their dilution and spreading. On a national scale, the average PCB concentration in mussels in the United States is only decreasing at a rate of 2% per year (a half-life of 34 years). Another example is dioxin contamination in Viet Nam, which was a result of defoliant use between 1962 and 1970. Concentrations of dioxin in human milk in Viet Nam have been decreasing with a half-life of about 4 years (calculated from data in Schecter et al. 1995). This decrease is a result of both degradation and slow dispersion of the dioxin. The slow rate of loss, coupled with the high initial exposures, results in dioxin concentrations in human milk some 30 years after the contamination ceased that are still 10 times higher than in nonexposed areas (Schecter et al. 1995).

Where large amounts of waste are present, such as in an oil spill, the degradation rates of the wastes may be limited by factors needed for microbial growth such as nitrogen and phosphorus. If bacteria cannot increase in number, the degradation rates of compounds will remain slow. The physical nature of spills may also inhibit microbial breakdown. If the spilled waste remains in large clumps, or patches, the microbes cannot reach or degrade the interior of the clump, and only the surface of the clump is subject to microbial decay, greatly slowing the digestion of the waste.

For many organic wastes, and particularly large (high molecular weight) compounds, it is important to distinguish between an initial alteration of the chemicals in the waste (a relatively small change in the form of the waste) and complete remineralization. A small alteration of a parent compound may result in persistent and/or toxic daughter products that may be of as much concern as the parent waste chemical.

With such a complex array of factors that can influence biodegradation, it is not usually a simple matter to predict the persistence of a degradable waste in an environment. However, experience with wastes has been gained and models have been developed that allow such predictions to be made with good confidence. In addition, understanding of the process affecting waste degradation has allowed the development of bioremediation techniques that create the right conditions to accelerate biodegradation in some contaminated areas (Alexander 1994) (see MA *Policy Responses,* Chapter 10).

15.4.1.2 Pathogen Die-off

Some human pathogens are rendered harmless in the environment. Many bacteria and some viruses that only grow in condi-

Table 15.3. Detoxification Characteristics for Different Types of Waste Materials. For the types of waste that cannot be destroyed by natural environmental processes, as opposed to dilution or sequestration, no time frame for detoxification is given. Half-life is the time it takes for the concentration of a particular material to reduce by half. The use of half-life is a measure that implies first-order kinetics. It should be recognized that detoxification is usually a biological process that will have much more complex kinetics than first-order. Nevertheless, half-life is a useful simplifying approach.

Type of Waste	Characteristics of Waste and Major Processes for Detoxification	Time Frames for Detoxification, Where Applicable
Airborne sulfur dioxide and sulfates	Component of acid rain. Can be buffered by some soils until buffering capacity of soils is exceeded.	
Airborne oxides of nitrogen	Component of acid rain. Contributor to eutrophication. (see box on eutrophication.)	
Polycyclic aromatic hydrocarbons (PAH)	Many PAH are carcinogenic. PAH may be photodegraded and remineralized by microbes. Many PAH have a high affinity to adsorb onto particles and soils.	Rate of photodegredation of PAH depends upon specific configuration of individual PAH. In air or sunlit waters, half-lives of PAH may range from hours to days. Lower molecular weight PAH can be readily degraded in aerobic soils and sediments, with typical half-lives in days to weeks. Higher molecular weight PAH degrade much more slowly, with half-lives in weeks to months. In anaerobic conditions, PAH may persist indefinitely.
Toxic metals, especially mercury, lead, and cadmium	Cannot be degraded. May be bound to other material (i.e., sulfides) in certain conditions so that toxicity of metals is not exhibited if there is sufficient binding material. Other binding sites include organics, and they may form precipitates such as hydroxides and oxy-hydroxides that may render them less bio-available and in the process reduce their toxicity.	Rate of dilution depends upon environmental setting, while precipitation processes are pH/redox regulated. Many metal-contaminated sites may remain contaminated for decades to centuries.
Halogenated organic compounds, especially DDT and its metabolites, PCB, PCT, dieldrin, and short-chained halogenated aliphatic compounds	Some can be photodegraded. May be degraded by microbes. Many have high affinity to adsorb onto particles and soils. One route of degradation is the volatilization of chemicals from sediments or soils to the atmosphere, where it is degraded by strong UV light.	Due to having halogen-carbon bonds that only occur in trace amounts in nature, microbes do not generally have an ability to degrade these compounds readily. However, general detoxification enzymes within microbes can degrade some of these chemicals, albeit slowly. For example, half-lives of PCBs in contaminated sediments are typically decades.
Petroleum hydrocarbons	Petroleum hydrocarbons are a mixture of primarily alkane compounds and PAH. The alkanes are readily degraded by microbes in the right conditions. PAH are described above. Where petroleum hydrocarbons are introduced into the environment in large quantity, such as an oil spill, the oil may remain in large drops so that bacteria cannot get to most of the oil. In large spills, there may not be sufficient nitrogen and phosphorus in the local environment to permit hydrocarbon-degrading microbes to multiply.	Lighter hydrocarbons can degrade with half-lives of hours to days when found in low concentrations and in aerobic conditions. Heavier components of oil—i.e., that left over after the light hydrocarbons are degraded or volatilized—can persist indefinitely (such as tarballs). Light or heavy hydrocarbons in anaerobic conditions will degrade very slowly if at all. In addition, high concentrations of hydrocarbons may initially exhibit localized toxic effects, causing a delay before degradation proceeds.
Toxins of biological origin from algae, fungi, and bacteria	Presumably these compounds are subject to microbial and/or photodegradation.	Rates of degradation probably rapid, with half-lives in hours or days. The toxicity of a water body disappears soon after the organisms producing the toxins are no longer present.

(continues over)

tions found in the human body lose viability in the relatively harsh conditions of the environment. Both viruses and bacteria may be ingested and utilized for food (therefore remineralized) by other organisms in the environment without detrimental effects. However, other pathogens, such as vector-borne diseases, complete part of their life cycles outside of the human body and are maintained by their in hosts in the environment.

15.4.1.3 Photochemical Degradation

In the atmosphere, and to a lesser extent in surface waters, some compounds are altered by interaction with ultraviolet light or by chemically reactive compounds produced by ultraviolet light, such as ozone or hydroxyl radicals. Some limited groups of organic chemicals have structures (chromophores) that adsorb light energy and are activated into a particularly reactive state, altering their structure. This structural change may not reduce the toxicity and may even create more toxic daughter products, but it may be a first step toward remineralization, which can be followed by microbial degradation. The rates of alteration by photochemical degradation may vary widely between chemicals that have only slightly different structures. Reactive compounds in the atmosphere, especially ozone, may also act to alter the structure of airborne wastes.

15.4.1.4 Sequestration of Wastes

Some waste materials may be sequestered in the environment in such a way that they are not biologically available and do not exhibit toxicity. The sequestration of certain metals in marine and

Table 15.3. *continued*

Type of Waste	Characteristics of Waste and Major Processes for Detoxification	Time Frames for Detoxification, Where Applicable
Nitrogen compounds	Nitrogen exists in different forms and is an essential plant nutrient. The presence of elevated nitrogen concentrations in water can lead to proliferation of algae and other plant species. This can reduce the value of the resource and can affect human health. For example, nitrate levels over 20mg/l are considered the safe upper limit in potable water.	Rates of transformation are dependent on the form. Dentrification can be rapid (hours) in the presence of bio-available carbon and acceptable pH and temperature conditions. Assimilation into plant biomass is light-, temperature-, and plant species-dependent and may be hours to days.
Ammonia toxicity	Ammonia is oxidized to nitrate in aerobic environments. Local pH and salinity conditions can influence the level of toxicity by influencing the ionized and un-ionized fractions.	Rate of oxidation is temperature and oxygen-dependent, with typical half-lives of hours to days.
Phosphorus	An important plant nutrient that is associated with fertilizers and detergents. Phosphates bind with some metals, for example iron and aluminum salts, and can from insoluble salts of calcium and magnesium under high pH conditions in oxidizing conditions. Reducing conditions can result in the release of preciously bound phosphorus. Phosphorus may be removed by plant uptake.	Minutes to hours if chemical precipitation/release processes are involved; days to months in the case of biological uptake being species-dependent.
Organic loading	Most organic matter can be remineralized to carbon dioxide by microbes. Some organic matter is resistant and will degrade much more slowly.	Rate of oxidation is temperature and oxygen-dependent, with typical half lives of hours to days for readily degradable organics and months to years for resistant materials.
Acid wastes	High acid wastes (i.e., low pH wastes) can result in the mobilization of metals that may increase toxicity. Acidity can be buffered in both soils and water until the buffering capacity is exceeded. The presence of sulfur can influence acidity, for example the oxidation of sulfur compounds can lead to a reduction in pH while sulfate reduction through the generation of alkalinity can reduce the acidity , which can be reflected in an increase in the pH.	Hours to weeks if conditions are favorable. Chemical processes are generally more rapid than biologically mediated processes.
Pathogens	Some pathogens may lose viability in environment or may be utilized as food by other organisms. Some pathogens are endemic in the environment and do not lose viability.	Survival half-lives of non-endemic pathogens is typically hours to days.
Radionuclides	Natural radioactive decay to stable isotopes (see metals for associated processes).	Half-lives of most medical-use radionuclides range from hours to weeks. Half-lives for the bulk of radioactive wastes from power plants range from decades to millennia.
Solid salts of alkali metals and alkaline earth metals	Cannot be destroyed.	
Waste heat	Heat loss occurs through dilution and radiation of heat energy to the atmosphere.	

aquatic sediments by acid volatile sulfides is an example. These metals are bound into a mineral form that is not biologically available, and as long as there are sufficient sulfides to bind all the metals, no toxicity is exhibited (Ditoro et al. 1992). Where the concentrations of metals exceed that of sulfides, the sediments exhibit toxicity. Sequestration may be reversible. If conditions are altered, the sequestration may break down and the wastes returned to toxic forms. In the case of acid volatile sulfides, the metal sequestration takes place in anoxic sediments, and if the sediments become oxidized through disturbance or ecosystem change, the metals may be released from their bound state and become available and exhibit toxicity. Some chemicals may also be sequestered within soil or sediment organic matter.

Humans often manage wastes by sequestration or immobilization, such as in managed landfills or high-level radioactive waste storage sites. As with natural sequestration, sufficient time may bring about a change in conditions and release wastes back to the environment.

15.4.1.5 Incineration

Organic wastes are often remineralized by incineration. Efficient incineration can completely destroy the toxicity of an organic or pathogenic waste. Inefficient incineration, however, results in the production of carcinogenic polycyclic aromatic hydrocarbons, dioxins, and furans. If a metal-containing waste is burned, the metals may be emitted to the atmosphere, where they can enter food chains and cause environmental damage and detriment to human health. Incineration in large amounts, especially of sulfur-containing materials (such as some coals) can add acidity to the atmosphere, resulting in acid rain and ecosystem damage. A variety of engineering techniques are available to capture the contaminants and reduce the emissions.

15.4.2 Waste Transport Processes

As noted earlier, there are a number of processes that tend to disperse materials in the environment—for example, pesticide leaching into groundwater, runoff with rainwater to water courses, and evaporation or volatilization into the atmosphere, where it may be carried by winds. Soil and wind erosion may also carry pesticides sorbed to soil particles into water bodies and to downwind areas.

Reduction of waste concentrations in a single body of water is best understood as a result of two processes: dispersion (dilution by mixing into larger volumes of water) and advection (water moving downstream). Both these processes reduce the concentration of the waste at its point of entry in the ecosystem. These also apply to contaminants in air.

Dispersion and advection have been counted on for millennia to manage human wastes. If the wastes can be detoxified by the environment, and the loading rates do not exceed the capacity of the environment to process them without undesirable change to the ecosystem, such an approach can be effective. However, with increasing human population densities and waste loads, coupled with many types of wastes that do not degrade rapidly, such a simple approach is rarely adequate. Even wastes that are diluted into the entire atmosphere of the planet have reached concentrations above acceptable levels. Examples are the upper-atmosphere ozone-depleting chemicals chlorofluorocarbons and methyl bromide, which are now the subject of coordinated efforts to reduce their emissions through the Vienna Convention and the Montreal Protocol.

While there is a natural tendency for all things to disperse and move from areas of high concentration to low concentration, there are also processes that effectively act to concentrate some wastes and create relative hot spots. The next two sections examine these processes in more detail.

15.4.2.1 Partitioning and Scavenging

One particularly important process that influences the fate of chemicals, especially in aquatic systems, is that of chemical partitioning. Many waste chemicals have low solubility in water. Even when present in water at concentrations below their absolute solubility, low-solubility chemicals may be strongly attracted to particles. If a solid surface is available, such as small particles in the water, the chemical will tend to adsorb or attach to the particle. The strength of this affinity is referred to as a partition coefficient (which for organic chemicals correlates with the octanol/water partition coefficient, or Kow). Some authors express this general concentration mechanism as ''solvent switching'' (MacDonald et al. 2002). The particle affinity of metals depends on other factors, especially the oxidation state of the metal.

Particles in the water column tend to settle to the bottom. This may occur in standing water or in areas of low flow, such as upstream of a dam in a river. The adsorption of chemicals to particles and the subsequent settling of particles acts to transport (or scavenge) chemicals from the water column to sediments. In this fashion, relatively high concentrations of chemicals can build up in sediments even in areas that originally had dilute concentrations of waste in the water. The sediments act as a reservoir for wastes, often to the detriment of benthic organisms. And depending on the persistence of the waste, the sediments may remain contaminated even if the inputs are stopped. If the sediments are disturbed by high water flows such as floods or major storms or by mechanical means such as dredging or construction projects, the sediments may become ''new'' sources for wastes.

15.4.2.2 Biological Uptake and Trophic-level Concentration

Many waste chemicals may have a strong affinity for biological tissue, particularly for the lipid (fatty) tissues in organisms. An aquatic organism may move large amounts of water across its metabolic surfaces (gills or equivalent) in order to obtain oxygen. This provides an opportunity for chemicals (especially organic compounds such as the POPs) to be taken up into the organism, concentrating the chemical by another type of solvent switching. As with sediment partitioning, the concentrations in the organism may become much higher than in the water. The magnitude of this effect is usually described as the ''bioconcentration factor.''

The concentrations of wastes can increase in organisms further up the food chain. This process is often called ''bioamplification'' and may be viewed as a ''solvent depletion process'' (MacDonald et al. 2002). (Biomagnification is another term often used in the same sense as bioamplification, although biomagnification is also sometimes used in the same sense as bioconcentration. The use of these terms is not standard.) When a higher trophic level organism ingests a food that has been contaminated (by bioaccumulation), it may digest most of the food but none of the waste. The waste then becomes much more concentrated in the gut, exposing the higher-trophic-level organism to high concentrations of waste. Where upper-trophic-level organisms cannot metabolize or excrete the waste, the waste increases in concentration in bodies of organisms in successively higher trophic levels, and thus bioamplifies. In this fashion, persistent chemicals that were originally present at low, nonharmful levels in the environment build up to harmful levels in the tissues of higher-trophic-level organisms, including humans (MacDonald et al. 2002).

15.5 Determining the Capacity of an Ecosystem to Assimilate Wastes

The assimilative capacity of an ecosystem to adsorb waste may be defined as the amount and rate of a given waste that can be added to an ecosystem before some specified level of detrimental effect is reached. Deciding on a safe or acceptable level is not usually a simple matter, as is clear from the complex set of processes and the wide array of possible waste types just described. Further, the ''acceptable level'' incorporates human value judgments, which may be different for different people and may vary over time.

The human value judgments include such considerations as:

- the level of risk that is acceptable;
- whether environmental standards are based upon some absolute level or whether risks are balanced against benefits;
- the costs of mitigating the effects of wastes;
- the manner in which noneconomic properties of an ecosystem are valued; and
- the allocation of benefits, or risks, to different sectors of Earth's population, and between the present and the future.

Hence the capacity of an ecosystem to assimilate wastes is not usually determined by purely scientific or objective study. Science may be able to clearly describe the consequences of any particular waste loading, but it is the application of human values to the consequences that are responsible for setting a ''safe'' or acceptable limit.

15.5.1 Safe Levels of Exposure

The concept of ''safe'' is reasonably clear for pathogen wastes. If the disease organism is present in water or food, it is not safe to drink the water or eat the food. In practice, however, it is often not easy or routine to directly detect the presence of disease organisms in the environment. A separate test or procedure might be necessary for each species of pathogen, and the culturing of pathogens for test purposes is often difficult and may be dangerous. The presence of nonharmful organisms that are found in human wastes and that are relatively easy to measure are usually used to indicate the possible presence of disease organisms. This approach assumes that pathogenic organisms do not survive longer in the environment than do the indicator organisms, which may not always be the case. Still, the use of indicator organisms has been effective (but not perfect) in protecting human health for many decades. The common use of fecal bacteria for indicators is not useful in predicting the presence of parasitic worms.

Chemical wastes are often divided into two categories: those having threshold effects and those having no threshold effects. For threshold chemicals, there are assumed to be no detrimental effects below a certain level of human exposure, although above that threshold, detrimental effects may be found. For no-threshold chemicals, primarily carcinogens, it is usually assumed that there is detriment at all levels of exposure, no matter how small. For these, the probability of damage is greater with greater levels of exposure.

Establishing a safe level for a contaminant that has a distinct threshold effect is conceptually straightforward, but there may be considerable technical complexities in arriving at a standard, such as how to apply results of laboratory animal studies to humans. In practice, maximum exposure limits are usually set well below the threshold level for the observed effect in order to account for uncertainties in the measurement of the threshold, individual sensitivity, and the possibility of greater than estimated exposures to a waste for some persons. There is always some concern that a chemical may have subtle detrimental effects at low levels of exposure that are hard to identify as being caused by the chemical.

For non-threshold carcinogenic chemicals and for ionizing radiation, the risk increases with exposure. The effects are an increase in probability that the exposed person could get a cancer during his or her lifetime. As cancers may arise from different causes, the cause of a particular case of cancer may not be unequivocally attributable to a particular exposure, and the effects are observed in population statistics of how many persons contract cancer of a particular type. The setting of a "safe" level for a carcinogen requires a value judgment of the level of risk that persons are willing to accept, plus the knowledge of the probability of a cancer developing in an individual from a given dose (that is, the dose-response relationship). An example might be the standard for acceptable concentration of a chemical in drinking water. This standard may be based on a value of an individual's lifetime risk being no more than one chance in a million (usually used by U.S. EPA) or one in 100,000 (usually used by WHO) of contracting cancer from that chemical if they have a lifetime exposure to the chemical at the level of the standard.

The level of exposure that is deemed acceptable varies considerably from chemical to chemical depending on its toxicity. For example, the FAO/WHO *CODEX Alimentarius* standards for maximum residue levels range from 0.05 to 25 milligrams per kilogram for different pesticides on apples.

Where contaminants occur together and have similar mechanisms of detrimental effects, these effects may be additive, acting together so the threshold for effect may be reached at levels that would have no effect for individual chemicals. There is also concern that the effects of some contaminants may be synergistic in that exposure to a combination of two or more contaminants will lead to a much greater effect than would be expected from the simple addition of the effects of the individual contaminants. Finally, the effects of some contaminants may be antagonistic in that together there is less effect than would be expected from the addition of multiple contaminants (Yang 1994).

15.5.2 Predicting and Managing the Risks of Wastes

Determination of human health impairment from exposure to wastes can be very complex. For each waste or each component of a mixed waste stream, an evaluation of the impairment depends on a knowledge of the fate of the wastes in the environment, how much exposure humans will get from the waste, and how much detriment will occur from a given level of exposure.

In evaluating the detrimental effects of a waste or actions taken to reduce exposure and detriment from wastes, it is usually desirable to evaluate the total number of exposed persons in the population—the cumulative human-health impairment. For example, two differing waste management options might protect all individuals from exposures that exceeded standards for individual protection, but the options may differ in the total dose to the population.

Toxicology and risk assessment are developed areas of science, and various national and international bodies have used appropriate techniques to determine health risks and set appropriate standards and guidelines. Professional organizations working on these issues include the Environmental Mutagen Society, Genetic Toxicology Association, Society of Environmental Contamination and Toxicology, Society for Occupational and Environmental Health, and many others (see, for example, www.health.gov/environment/ehpcsites.htm). Although the scientific community has the ability in most cases to predict (with useful accuracy) the fate and effects of chemicals, due to the great number of possible contaminants (as well as the continuous generation of new compounds) and the fact that the specific conditions within a specific ecosystems may not be known, our understanding of the consequences of some contaminants is incomplete.

15.6 Drivers of Change in Waste Processing and Detoxification

At this stage it is not possible to state, on a global scale, whether the capacity of ecosystems will increase or decrease in response to climate change. The change in average local or global temperatures of a few degrees is not thought likely to have much effect on the distribution of waste materials in the environment (MacDonald et al. 2002) or on a temperature-dependent microbial degradation rate.

As described earlier, the capacity for an environment to assimilate wastes is highly dependent upon local conditions. The bacteria and other decomposing organisms that detoxify susceptible chemicals or reuse nutrient wastes are highly dependent upon local conditions such as oxygen availability, moisture, and temperature. Hence, changes in local climate may have significant effects of waste assimilation capacity of different ecosystems. The conditions at some locations may allow the microbial community to be better able to process certain types of wastes. Other locations may suffer a reduced inherent ability to detoxify.

Changing climatic conditions may also have an effect on the susceptibility of organisms to wastes. Organisms living near their physiological temperature limits may be particularly sensitive to stress from waste contaminants. In such cases, small temperature changes may cause significant differences in the effects of contaminants.

A safe generalization for virtually all types of wastes is that the ability of environments to detoxify them can be overwhelmed at high waste loading rates. If waste production increases with growing populations and improved development of nations proceeds faster than waste management efforts, then it seems likely that there will be an increasing number and size of locations on Earth where the detoxification capabilities of the ecosystem will be overwhelmed and waste concentrations will build up to the detriment of human well-being to damage ecosystems with a loss of biodiversity.

It is hard to predict with a high degree of confidence which environments will be most subject to impacts by different types of wastes. Nevertheless, Table 15.4 is an assessment of the likelihood of ecosystems receiving different types of wastes and contaminants. Table 15.5 lists a number of the driving forces acting at the local level and the effects those drivers will have on waste processing and detoxification.

15.7 Selected Waste Issues

This section describes some key waste issues. A great number of waste types and issues could be cited as examples, and it is not possible for this chapter to attempt to detail the entire scope of waste types and issues in similar detail. The selection here is merely representative of this range, and should not be interpreted as suggesting that these wastes are the most important to consider for future waste management actions.

15.7.1 Consumer Household Wastes and Hazardous Materials

15.7.1.1 Household Trash, a Mixed-waste Stream

A multitude of products are used by individual consumer households or in nonindustrial commercial settings. Many of these products generate trash and require disposal. These include food wastes, paper products, plastics, and metals and may also contain harmful chemicals. Depending on local practice, wastes may be combined or attempts may be made to keep the different materials separate. Food wastes, when kept separate, may be used as compost and for soil enrichment. Some paper products, plastics, glass, and metals can be recycled. What is not separated and reused must be disposed of. Once different types of materials are mixed (usually by the individuals or households generating the trash), it is much more difficult to separate them for reuse. Polyethylene wrappers, bags, or sheets are a major problem in Africa as they litter urban areas, are not biodegradable, and do not burn readily.

Common practices are to either landfill (dump) or incinerate the wastes. Both options have drawbacks. Landfilling permanently takes up space, often in short supply in areas of high population density. Improperly designed and managed landfills may attract vermin, may contaminate groundwater, become visual blights, and emit objectionable odors. Although portions of the organic materials in landfills may decay and generate the green-house gas methane (which could be collected and used as a resource), much of the disposed materials does not degrade and will effectively persist permanently.

Incineration generates air pollution, with the amount of pollution dependent upon the investment in technologies to reduce or capture emitted metals and other hazardous materials before they leave the smokestack (NRC 1999). Where open burning is used, the simplest form of incineration, there is no opportunity for recapture of harmful materials in the smoke. Clearly, keeping the different types of wastes separate and reusing those materials is beneficial relative to either landfilling or incineration. However, most community recycling programs reduce the total volume of the domestic waste stream by only 30–50%.

The amount of household refuse is likely to increase with increasing affluence of persons, as indicated earlier in Figure 15.1. There can also be differences in societal practices that would deviate from this trend. Another example of development-dependent use of materials is provided by the per capita use of paper in different countries. (See Figure 15.6).

In parts of the developing world, municipal waste collection is often very ineffective, and much of the wastes are dealt with by a network of urban wastepickers (Furedy 1990, 1994). In most cases, wastepicking is driven by poverty. Picking through wastes of more-affluent people provides access to resources of clothing, fuel, housing, and even jobs for the poorest. The waste stream can be mined for the raw materials to support small-scale industries, but the conditions for the waste pickers are usually very unhealthy (Yhdego 1991). There have been some efforts to organize wastepickers and improve waste collection efficiency, recycling, and conditions for the workers (Furedy 1992; LIFE 1995; Poerbo 1991).

15.7.1.2 Consumer-use Hazardous Materials

Consumers use many products that contain hazardous materials. A partial list of such products sorted into general categories includes the following:

- *Household cleaners*: bleach, ammonia, disinfectants, drain opener, furniture polish and wax, oven cleaner, spot remover
- *Laundry products*: laundry detergent, fabric softener, bleach, perchloroethylene
- *Lawn and garden products*: fertilizer, pesticides, herbicides, gasoline, oil
- *Home maintenance products*: paint, paint thinner, stains, varnish, adhesives, caulk
- *Pesticides*: insecticide, mothballs, pet spray and dip, rat and mouse poison, weed killer, disinfectant, flea collars, insect repellant
- *Health and beauty products*: hairspray, hair remover, fingernail polish, fingernail polish remover, hair coloring products, cosmetics, medications
- *Automotive products*: antifreeze, brake fluid, car wax and cleaners, gasoline, oil filters, transmission fluid, windshield washer fluid, lead-acid batteries, tires
- *Other*: charcoal briquettes, lighter fluid aerosol cans, art and craft materials, lighter fluid, pool chemicals, shoe polish, batteries, electronic components, light bulbs

Many of these products represent potential waste streams and potential impacts on the environment. In addition, some of them may have detrimental effects on sewage treatment systems, especially individual household septic systems. Consumer use may be a significant fraction of chemical use not usually associated with individual consumers. For example, nonagricultural uses of pesticides in the United States represents about 30% of total pesticide sales (Donaldson et al. 2002). At least one pesticide is used in 77% of U.S. households, with most households using multiple types of pesticides (Donaldson et al. 2002). Pesticides are used in homes for nuisance insect control, protection of structures, and (in some countries) for control of insect-borne diseases. The risks of pesticide use in the home are relatively large. Between 1981 an 1990, on average 20,000 pesticide exposures a year were reported in emergency rooms throughout the United States, with 82% of those reportedly due to exposure in the home (Blondell 1990).

Further, many of these products may end up in domestic wastes, as indicated. Where toxic materials are placed in landfills, they represent an additional hazard as they may leach into groundwater and render it unsafe for consumption.

15.7.2 Persistent Organic Pollutants

POPs are a category of waste of special concern because of their longevity and biological effects. One definition of POPs is pro-

vided in the 1998 Aarhus Protocol on Persistent Organic Pollutants of the 1979 Geneva Convention on Long-Range Transboundary Air Pollution: "Persistent organic pollutants (POPs) are organic substances that: (i) possess toxic characteristics; (ii) are persistent; (iii) bioaccumulate; (iv) are prone to long-range transboundary atmospheric transport and deposition; and (v) are likely to cause significant adverse human health or environmental effects near to and distant from their sources."

Further production of these chemicals will be prohibited under international treaty. The Aarhus Protocol and the 2001 Stockholm Convention on Persistent Organic Pollutants ban the production of an initial list of POPs (12 under Stockholm and 16 under Aarhus), including pesticides, industrial chemicals, and industrial by-products, and include provisions for adding other chemicals to the restricted lists. The Aarhus Protocol has 36 signatories and went into force in October 2003. The Stockholm Convention has 151 signatories and entered into force in May 2004.

A common feature of POPs is that they are all heavily chlorinated compounds. Although there are numerous naturally produced chlorine and bromine compounds (Gribble 2003), they occur at low concentrations in ecosystems, and there are few naturally occurring enzymes and metabolic pathways efficient at breaking down these compounds. POPs have a low solubility in water and a high affinity

Table 15.5. Principal Drivers of Change Summarized from Individual Chapters, with a Provisional Assessment of the Implications for Detoxification

System	Driver of Change	Some Considerations for Detoxification
Cultivated systems	change in vegetation (seasonal contribution to inputs) change in exposure (erosion) temperature interruption in nutrient flow changes in moisture regime (irrigation) removal of biomass introduction of inorganic nutrients introduction of herbicides, pesticides salinization aquaculture in coastal areas floodplains (accreting systems) cultivation of floodplains change in soil structure	increase in soil loss with negative consequences for waste/contaminant attenuation due to loss of part of the resource the soil through erosion becomes a waste/contaminant in its own right causing accretion in and loss of wetlands; a change in the nutrient status of receiving water bodies due to P bound to soil and an increase in turbidity can reduce photosynthetic capacity of water, affecting nitrogen/phosphorus cycling possible greater ranges in temperature that affect moisture content (increase in evaporation losses) and rates of particular transformation processes by influencing metabolic rates cropping reduces return nutrient flows due to active removal of vegetation change in nature of nutrients from organically derived to inorganic due to fertilization direct addition of herbicides/pesticides to crops and transfer of these to other ecosystems either by aerosol or elution introduction of irrigation water can result in salinization of soil, if irrigation scheduling and drainage are not managed, etc.; irrigation return flows can result in an increase in salinity and nutrient flows into receiving waters introduction of ponds and fish farming can result in increase in waste loads in affected waters; the ponds themselves may assist in internal transformation processes afforded by the extended hydraulic retention periods regulated flows due to damming can result in dessication and loss of floodplain functionality, with sediments trapped in dams (rather than on floodplains); should the trapped sediments be subjected to anoxic/anaerobic conditions, previously bound phosphorus, for example, could be released and contribute to eutrophication cultivation of floodplains can result in loss of changes in carbon supply and have implications for nutrient cycling and retention change in soil structure and properties, i.e., loss of carbon, changes in carbon exchange capacity, pH, etc. can have implications for contaminant removal
Dryland systems	changes in vegetation cover increased nutrient load (livestock) use of wetlands (water) water retention (dams) change in exposure (erosion) temperature interruption in nutrient flow changes in moisture regime (irrigation) removal of biomass introduction of inorganic nutrients introduction of herbicides, pesticides salinization aquaculture in coastal areas floodplains (accreting systems) cultivation of floodplains fire	soil erosion, loss of capacity to buffer due to there simply being less soil draining of wetlands for cultivation reduces opportunities for sediment trapping and, depending on site-specific circumstances, may actually contribute to sediment loss reduction in P removal, related to sediment loss and dentrification due to loss of anaerobic environments associated with wetland loss the storage of water in impoundments increases opportunity for contaminant degradation/immobilization due to increased opportunities for sedimentation and extended detention periods the loss of floodplains to agriculture as a result of regular flows will reduce their value in terms of sediment accreting and nutrient trapping/release systems water retention–appearance of systems with symptoms of eutrophication is likely to increase as a consequence of nutrient retention, cycling, and internal generation (i.e., C fixation as algae) capacity of drylands to successfully reduce pesticides/herbicides is likely to be compromised by a reduction in area due to conversion to cropping and higher applied loads the risks of salinization both as a result of changes in land use as well as increasing manufacturing and support activities will increase with a further deterioration of dryland systems the increase in aquaculture ponds in drylands in coastal areas will improve the capacity of the system to trap wastes/contaminants, but on the downside this could be to the detriment of people because of bioconcentration/transfer from sediment to harvestable biota
Inland waters	loss of wetlands (cropping) loss of wetlands (irreparable alteration, i.e. reclamation for structures) loss of wetlands water abstraction loss of water changes in land use (e.g., mining) loss of wetlands through modification of hydrology (e.g., high peaks from urban areas, constrictions due to culverts, etc.) abstraction for human use/urban and agriculture storage deterioration due to waste loads deterioration due to increased introduction of waterborne sanitation increase in baseflows salinization	see above for drylands reduction in capacity to detoxify due to direct loss of habitat, increasing loads, and changes in nature of contaminants damming increases capacity to transform wastes, including nutrients, with consequences on water quality; detention times, days to weeks, can lead to eutrophication

(continues over)

Table 15.5. *continued*

System	Driver of Change	Some Considerations for Detoxification
Coastal	interruption of coastal processes by stabilizing rivers direct loss of habitat (urban/harbor) change in structure (e.g., prawn ponds) deterioration due to waste loads deterioration due to increased introduction of waterborne sanitation increase in baseflows stabilization of flows transportation	see urban increasing nutrient loads, both from local as well as regional origin, may lead to impairment of water quality as the capacity of the system to transform the wasted could be compromised; this is already apparent in the presence of anoxic zones, for example, in the Gulf of Mexico
Marine	reduction in biomass transportation (increase in globalization and trade) dumping accidental spills	increased risk of point source waste load due to increase in global shipping trade increase in nutrient load overriding dilution effect
Forest	changes in land use changes in species composition changes in runoff characteristics changes in water quality (sediment) forest loss acidification fire	see cultivation, inland waters
Mountains	land use changes, deforestation, cropping systems industrial use deforestation, overgrazing, and inappropriate cropping practices lead to irreversible losses of soil and ecosystem function	as above
Polar	land use changes atmospheric composition changes infrastructure development, mining ecotourism	increase in waste loads with temperature being limiting factor limited capacity for microbial degradation due to low temperature
Urban	population expansion increase in impervious surfaces simplification of environments hydrololgy (rapid runoff, contained) nutrient load contaminant types loss of habitat due to direct transformation increase in demand for externally sourced resources, e.g., power, water, food, gas, petroleum waste sludge management	increase in nutrient and other wastes reduced "natural" capacity but potential to replace with engineered systems, constrained by finances and political will, different for industrial and developing countries value systems, immediate survival as opposed to high levels, e.g., aesthetics contaminant types and loads reflect socioeconomic status increased conversion of all other ecosystems, e.g., feedlots, energy provision, landfills, industrial development, to support change in lifestyles

for tissue, especially the fats in tissue, so they tend to accumulate in organisms through bioaccumulation from water or food. As these compounds are not metabolized and are only slowly excreted by mammals and birds, the concentrations of POPs tend to bioamplify, so that organisms at high trophic levels, including humans, are particularly susceptible to detrimental effects.

POP-based pesticides were widely used and are still applied. For example, about 2.6 million tons of DDT were used from 1950 to 1993, while the figure for toxaphene during the same period was 1.33 million tons (Voldner and Li 1995). The remarkable efficacy of this class of insecticides, especially in controlling insect-borne diseases such as malaria, coupled with the intensification of agricultural systems led to their production and wide use. However, use of most of these compounds was curtailed in most countries in the 1970s after their toxicity was demonstrated. While primarily active on nerve conduction chemistry, these substances are acknowledged carcinogens and suspected teratogens, immunotoxins, and hormone disrupters (Guillette et al. 1994; Zahm and Ward 1998; Holladay and Smialowicz 2000; Solomon and Schettler 2000). In many parts of the world, DDT is still used for malaria control and chlordane is still the chemical of choice for termite control. A serious problem facing many developing and transition countries is the issue of stocks and reservoirs of obsolete, discarded, and banned POP pesticides and PCBs. There is an estimated 120,000 tons of obsolete stock of pesticides in Africa (FAO 2001; Tanabe 1988; Goldman and Tran 2002).

Polychlorinated biphenyls have been used mainly in electrical transformers, capacitors, hydraulic fluids, adhesives, plasticizers,

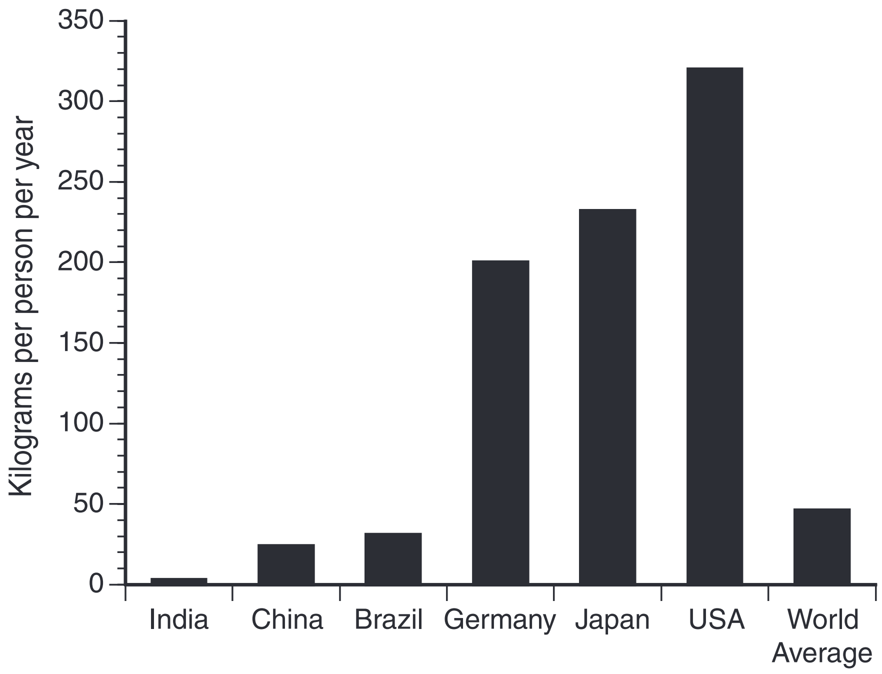

Figure 15.6. Paper Production per Capita in Selected Nations (Brown et al. 1998)

heat transfer fluids, lubricants, cutting oils, and fire-retardants. Global production of PCBs to date has been estimated to be 1.68 million tons (AMAP 2000; UNEP/GEF 2003). PCBs enter the aquatic environment from industrial effluent or urban waste discharges (GESAMP 2001). Dioxins are unintentional products from combustion sources and manufacturing processes such as municipal solid waste incineration, energy production, motor vehicles, smelting, bleaching of paper pulp, and the manufacture of some pesticides and herbicides. Dioxins and the chlorinated furans are also produced naturally during volcano eruption and forest fires (Gullett and Touati 2003).

Volatilization is the principal means of wide dissipation of POPs in the environment. All POPs have a certain vapor pressure or a tendency for the chemical to become a gas and enter the atmosphere. Further, some POPs are initially emitted directly into the atmosphere. POPs may be dispersed over great distances in the air and can now be found anywhere on the globe. They have even reached the polar regions in large quantities through a process called global distillation, where these substances preferentially settle out in the colder air of the polar regions (Wania 2003 and see Chapter 25). POPs also have a strong affinity to associate with particulate matter. In aquatic systems, POPs partition or bind to particles and they sink to bottom sediments, which are their main environmental repository. These legacy POPs can seep back into the water and atmosphere many years or decades after emissions themselves have ceased.

15.7.3 Hydrocarbons

Petroleum hydrocarbons remain the dominant energy source in industrial and most developing countries (UNEP 1994), and yet they are associated with a range of environmental issues. The devastating effects on marine organisms of large oil spills from shipping, oil exploration, and production, for example, are well known (NRC 2003). Management of spilled oil in waters has largely been by attempts to contain and recover oil through use of booms and mechanical skimming and reprocessing of the oil recovered. Unfortunately, in large oil spills most is not recoverable. Unrecovered oil eventually decays in the environment due to microbial degradation, but different fractions of petroleum hydrocarbons are degraded at different rates. The lighter fractions can be degraded relatively rapidly, typically within days to weeks in temperate conditions, except where they are mixed into sediments or soils where there is no oxygen (as described earlier). The heavier fractions are very persistent, requiring weeks to months to be degraded, even under conditions with sufficient oxygen. Hydrocarbons that get mixed into soils and sediments where there is little oxygen persist for years to decades.

One sub-group of hydrocarbons that can cause significant problems are the polycyclic aromatic hydrocarbons. The primary environmental source of these is a residue of combustion processes, though they are also found to some extent in petroleum oils. PAHs—both the parent compounds and alkylated homologues—are carcinogens (and mutagens and teratogens), and though subject to microbial degradation, they are the most environmentally persistent of the hydrocarbons. PAHs emitted into the atmosphere will deposit on land in dry and wet deposition and may accumulate in aquatic sediments through scavenging (GESAMP 2001).

Recent studies have established that land-based sources are the major input of hydrocarbons into the marine environment (GESAMP 2001). The major land-based sources identified are urban runoff, refinery effluents, municipal wastes, and used lubricating oils. Used lubricating oils are often contaminated with metals and high concentrations of PAHs, which makes them particularly hazardous. Pathways through which used oil get into surface water sources include oil dumped down drains that discharges into surface waters and oil poured on the ground and washed into groundwater or surface water.

15.7.4 Salinization

Salinization is a process resulting in an increasing concentration of salts in soils, water, or both. A number of activities can be linked to increases in the salt concentration of surface waters and soils. These include soil disturbance by activities that expose the soil and subsoil to weathering processes and subsequent leaching of salts the nature of which are determined by the composition of the parent material; the use of water for flushing human and industrial wastes; water recycling; water losses due to evaporation or evapotranspiration, such as in irrigation systems; discharge of saline groundwater; and changes in land cover, such as the replacement of trees with grasses, permitting already saline groundwaters to approach the surface due to a reduction in evapotranspiration by deep-rooted trees.

An example of the effects of changes in land use is shown in Figure 15.7, which illustrates increasing conductivity and sulfate concentrations (measures of salinity) in response to open cast (strip) mining in one of the principal coal mining areas in South Africa. The strip mining exposes the soil and subsoil profiles to weathering processes, resulting in the dissolution of minerals, in particular pyrite.

Salts do not degrade, and their concentrations can only be influenced by dilution through the use of sufficient water to move them to where they have less influence—in the ocean, for example. When water with even a low salt content is added continuously to an ecosystem, and when the water is allowed to evaporate or be lost through plant evapotranspiration, the salt remains and accumulates. For example, irrigation water with a salt content of 0.3 grams per liter applied at a rate of 10,000 cubic meters per hectare per year transfers 3,000 kilograms of salt per hectare per year into the soil (Oosterbaan 2003; see also Chapter 22).

Salinization of agricultural soils affects plant growth by restricting the uptake of water by the roots through their high osmotic pressures and by interfering with a balanced absorption of

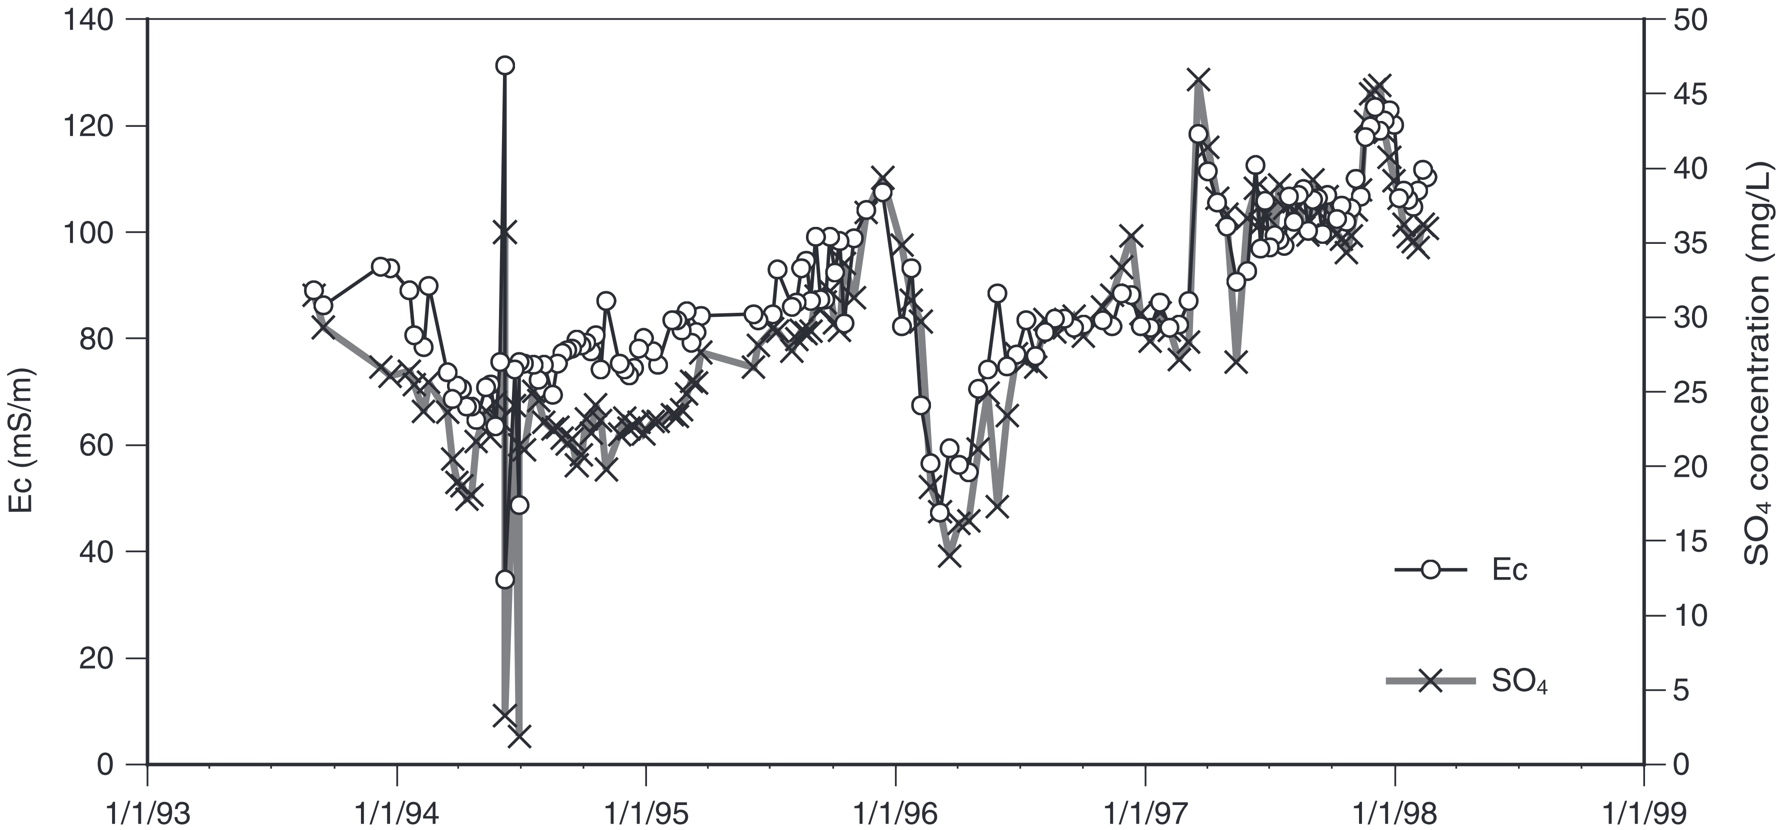

Figure 15.7. Salinization in the Olifant River, South Africa, 1993–98. Changes in electrical conductivity and sulphates measured in the Olifant River showing decreasing quality, attributed largely to coal mining activities. The Ec is a measure of the salt in the water. (S. African Dept. of Water Affairs and Forestry 1999 gauging station B3H017Q01)

essential nutritional ions by the plants. Different plants have different levels of sensitivity, so salinization can cause a shift in local plant communities.

These processes can have local economic consequences. A study on the effects of salinity changes in an irrigation area associated with the Vaal River in South Africa suggested that income of a specific group of farmers could be reduced by up to 84% as a result of crop changes and reductions in yields (Du Preez et al 2000; Viljoen and Armour 2002).

Estimates of the extent of salinization in the world run in the hundreds of millions of hectares, primarily in the more arid regions (Brinckman 1983; see also Chapter 22). The costs of salinization are high, with an estimate provided by the Australian Museum of AUS$500 million a year in Victoria alone (AM 2003).

The economic impact of salinization of surface waters runs beyond agriculture alone; Table 15.6 provides an example of the costs of increasing salinity on various sectors of society in a South African case study (Urban Econ 2000). The costs and factors considered for the identified sectors include:

- *in households*: maintenance costs (water heaters and plumbing), accelerated replacement costs, costs of soaps and detergents as well as the current anticipated salinity level;
- *in agriculture*: cost of water supply, maintenance costs, plant, chemicals;
- *in mining*: evaporative cooling circuits, service water circuits, metallurgical plant circuits, flotation circuits, electrolytic processes, irrigation water circuits, probabilistic distribution of management behavior, cost of water supply, cost of chemicals, cost of water treatment, cost of discharge, costs of scaling, salinity ratio;
- *in industry*: cost of water supply, maintenance costs, cost of chemicals, cost of plant replacement, current anticipated salinity, salinity threshold where expenditure patterns change; and
- *in water services*: cost of water supply, maintenance costs, chemical costs, plant replacement costs, current or anticipated salinity, salinity threshold where expenditure patterns change.

The greatest direct cost implications occur at the household sector, attributed to the fact that this constitutes the largest group of treated water users in the economy, compared with sectors that use predominantly untreated water.

With increasing pressure on surface waters, particularly in arid areas, there is likely to be an increase in the demand for water recycling and reuse (IWA 2004). This will undoubtedly lead to an increase in salinization of water, with associated consequences for downstream users.

15.7.5 Wetlands: Natural Defense Mechanism for Pollution Abatement

Depending on their type, wetlands can improve water quality, provide flood control, provide habitat for young of commercially valuable fish, provide habitat for many types of wildlife, help prevent erosion, and help reduce waterborne disease (see Chapters 7, 14, 19, and 20). Wetlands represent one of the major mechanisms to treat and detoxify a variety of waste products, and there have been many efforts to construct artificial wetlands to obtain these wetland functions.

15.7.5.1 Wetland Processes

One of the key functions that wetlands perform is to reduce concentrations of nitrogen in water. The close proximity of aerobic and anaerobic conditions often found in wetlands create a suitable environment for denitrification to take place. Denitrification converts nitrate, readily used by plants, to nitrogen gas, generally unavailable to plants, thereby reducing eutrophication (as described in the next section). Some wetlands have been found to reduce the concentration of nitrate by 90%, and artificially constructed wetlands have been developed specifically to treat nitrogen-rich sewage effluents.

Wetlands also act as a filter or trap for many waterborne wastes, including metals, organic chemicals, and pathogens. Metals and many organic compounds are adsorbed to the sediments

Table 15.6. Summarized Direct Costs of Salinity Changes on Selected Economic Sectors in South Africa, 1995. Negative values indicate no additional costs due to salinization. The percentages represent the increase in total operating costs due to salinization. For example, the net costs of mining were estimated to increase by 3.17% at 600 milligrams per liter. (Urban Econ 2000)

Sector	Salinity (mg/l TDS) 200	400	600	800	1,000	1,200	Contribution at 600 mg/l
	(milligrams per liter)						*(percent)*
Mining	–7.309	–2.212	0.844	4.863	10.209	17.816	3.17

in the wetlands, and the relatively slow passage of water through many wetlands provides time for pathogens to lose their viability or be consumed by other organisms in the ecosystem. For easily degraded chemicals, their adsorption to sediments and slow passage through wetlands provides time for their degradation. However, for metals and persistent organic chemicals, wetlands become permanent traps, as these wastes either do not degrade or degrade very slowly. Many metals are held in sediments by precipitation with sulfides or as surface oxides (Barnes et al 1991).

Although metals and persistent organic chemicals can build up to high enough concentrations to have detrimental effects on the wetland functions (for example, the impairment of denitrification by metals (Slater and Capone 1984)), moderate waste loadings can generally be tolerated by wetlands without loss of services. Moderate loadings of plant nutrients lead to enrichment (analogous to fertilization of crops or lawns), while severe loadings will lead to a major loss in wetland productivity, structure, and function through eutrophication. Unfortunately, the threshold between where loadings are tolerated and where they will do damage to wetlands is not easily determined and depends on the specific conditions in each wetland.

15.7.5.2 Wetlands and Human Activities

The impact of human activities on wetlands has been drastic, and it is speculated that some 50% of world wetlands have been lost (see Chapter 20), with the greatest changes occurring in industrial countries in the first half of the twentieth century (BEST 2001). Wetlands have been drained for agricultural purposes or filled to create lands suitable for construction. Quite often wetlands have also been used as the end point of wastewater effluent, receiving large volumes of industrial, municipal, and agricultural wastewater. The impact of these effluents on the quality, density, and structure of living communities is substantial, as indicated by diversity indices (Patric 1976; Stevenson 1984). Wastewater effluent can significantly affect phytoplankton species diversity and community structure (Sullivan 1984; Gab Allah 2001), thereby reducing the wetland's capacity to detoxify wastes and to re-oxygenate water. The impairment of wetlands' ability to detoxify of wastes is affecting the quality of groundwater particularly, for example, in northeastern Egypt (Gab Allah 2001), where elevated levels of salinity and high concentrations of heavy metals in groundwater are reported.

15.7.6 Eutrophication

The addition of nitrogen or phosphorus (both essential, and often limiting, in plant growth) can have very undesirable effects on freshwater and marine systems (see Chapters 19 and 20). In freshwater systems, phosphorus is usually in shortest supply. Additions of phosphorus can stimulate large blooms of algal types usually not found in abundance. In some cases, dense filamentous algal mats form, altering the environment to the exclusion of other species and reducing biodiversity. The increased levels of algae sink to the bottom and are broken down by bacteria and other organisms. This decay of the plant material takes up oxygen from the water, and with the decay of enough plant material, the bottom water can become anoxic. The link between phosphorus additions and the undesirable effects on lakes and rivers has been clearly established through both direct experimentation with whole lakes (Schindler et al. 1971; Schindler 1973) and through cross-lake comparisons (Vollenweider 1976).

In coastal and marine systems, nitrogen is usually the limiting nutrient. Additions of any of the various forms of reactive nitrogen usually stimulate plant growth. Reactive nitrogen is nitrogen in the forms of nitrate, nitrite, ammonia, or organic nitrogen that is readily biologically available. Nitrogen gas (N_2 or di-nitrogen), which constitutes 79% of the atmosphere, cannot be used by most plant species. Figure 15.8 shows how the rate of plant production in several coastal marine ecosystems is very strongly influenced by the input of reactive nitrogen nutrients.

As with lakes, the increase in plant material, when settled to the bottom of a bay or estuary, can lead to loss of oxygen and the exclusion of all higher organisms, including the fish, clams, crabs, shrimp, and other valuable harvestable seafood. Eutrophication of coastal waters often stimulates microscopic forms of algae (phytoplankton), which in turn causes a decrease in light penetration to areas that would normally support seagrass beds, an environment that provides a valuable nursery for many desirable species. There is no simple relationship between N loading rates and effects, because the effects depend on the depth, circulation, temperatures, and other characteristics of each system.

Eutrophication in coastal waters has also been linked to the increased prevalence of large blooms of toxic phytoplankton, or red tides (see Chapter 19). The toxins in red tide species may be accumulated in marine organisms and cause significant toxicity to

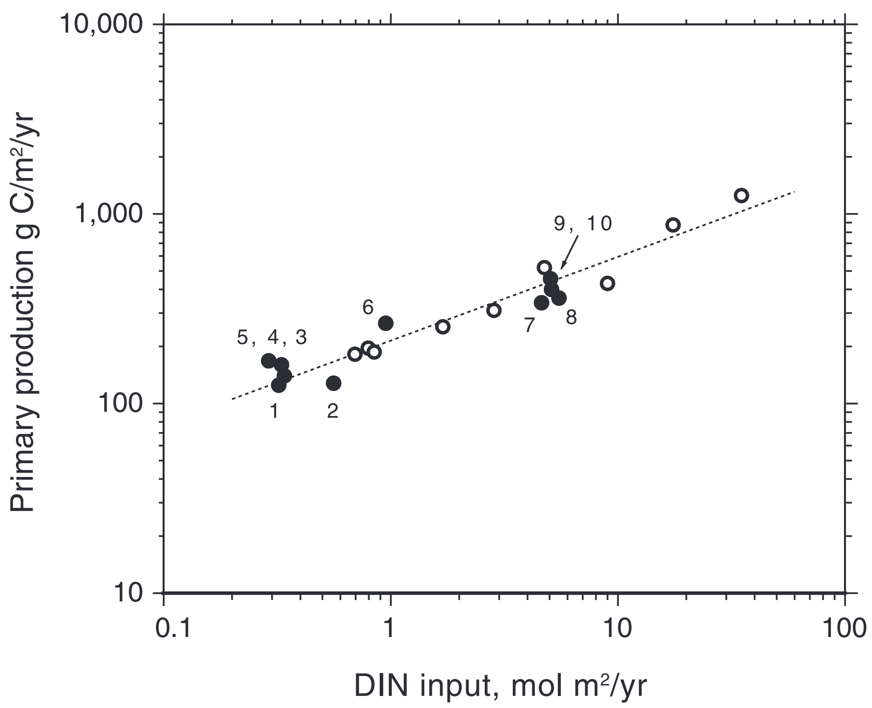

Figure 15.8. Marine Plant Production and Nitrogen Loadings. The increase in phytoplankton production by increased dissolved inorganic nitrogen inputs. Open circles are data from the MEL Marine enclosures. Numbered systems are: 1. Scotian Shelf; 2. Sargasso Sea; 3. North Sea; 4. Baltic Sea; 5. N. Central Pacific; 6. Tomales Bay; 7. Continental Shelf, New York; 8. Outer-Southeast U.S. Continental Shelf; 9. Peru Upwelling; 10. Georges Bank. (Nixon and Pilson 1983)

humans. It should also be noted that some nuisance algal species are not correlated with eutrophication (for examples, see Keller and Rice 1989; Gobler and Sanudo-Wilhelmy 2001; Gobler et al. 2002).

The amount of fixed nitrogen and phosphorus cycling through ecosystems has been greatly increased by human activities (see Chapter 12). Phosphorus is usually mined from mineral deposits. A major source of nitrogen is an industrial process (the Haber process) that converts nitrogen gas from the atmosphere into ammonia. The vast majority of nitrogen fertilizers in use today are from this process. Reactive nitrogen is also generated during combustion processes in industrial, heating, and automotive combustion. Combustion sources produce enough reactive nitrogen in areas of high activity, such as Western Europe and the eastern United States, to elevate atmospheric concentrations of reactive nitrogen to up to 10 times natural concentrations.

The combination of synthetic nitrogen in agricultural fertilizers, nitrogen-rich human sewage inputs, and deposition of atmospheric reactive nitrogen to watersheds has raised the global average river concentrations of nitrogen to five times preindustrial levels, and rivers in heavily populated areas and industrialized areas have nitrogen concentrations some 25 times higher than natural levels (Meybeck 1982). The delivery of this nitrogen to coastal waters has, on a global average, doubled nitrogen concentrations in coastal waters, certainly one of the largest chemical alterations of Earth's ecosystems. The relative importance of the agricultural, combustion, and sewage inputs of nitrogen varies between different watersheds (Hinga et al. 1991), with all three sources being important in some systems. Management of nitrogen eutrophication may require addressing all three sources.

Low levels of eutrophication probably do not adversely affect aquatic ecosystems or impair human well-being. Indeed, as in agricultural systems, fertilization of coastal systems may lead to greater harvests of seafood (Nixon 2003). However, the very large loadings of fertilizers that occur with intense agricultural and industrial activity and dense human population (especially in the coastal zone) have pushed many aquatic systems into conditions that exceed the capability of the system to adsorb the nutrients without detrimental effects. These systems are marked with anoxic conditions and the loss of biodiversity (including coral reefs) and harvestable species. (See Chapters 19 and 20.)

Main Messages

Floods and fires are natural processes occurring in the biosphere that have affected the planet for millennia. As a result of human development and the growth of public and private wealth, these events are having increasing impacts in term of costs and benefits for ecological and human systems.

It is clear that extreme events result in differentiated impacts across ecological and human systems, including impacts on human well-being (such as economic condition, health, happiness, and so on). Different individuals and groups experience different costs and benefits at various spatial and temporal scales.

Under certain circumstances, ecosystem conditions may serve to alleviate the impacts of an extreme event on human systems. For example, the economic impacts of a particular flood event on a community depend largely on the amount of unoccupied floodplains available for flood waters.

Ecosystem conditions may increase or reduce both costs and benefits at various temporal and spatial scales. Examples of these services include sediment and nutrient deposition in floodplains and deltas and natural fire regimes that help to sustain and rejuvenate ecosystems through periodic burning.

Ecosystem conditions that serve to modulate the impacts of extreme events on human well-being have experienced various changes as a result of a variety of drivers that affect ecosystems. The relationships between drivers and their impacts on ecosystem services and extreme events on human well-being are varied and highly complex and are not well understood.

Our knowledge of how ecosystems ameliorate or accentuate the impacts of extreme events on human well-being is limited for a variety of reasons. First, in many parts of the world understanding of the frequency and magnitude of extreme events is not well developed. Second, the collection of trend data on the impacts of extreme events on human well-being has been uneven and the data are often of poor quality. Third, in those cases where good trend data exist they are typically focused on first-order economic impacts and ignore other measures related to human well-being. Fourth, few rigorous quantitative studies have been performed that properly analyze the various factors that explain temporal and spatial patterns of extreme events or trends in impacts. Fifth, very few studies have sought to identify and quantify the services provided by ecosystems in the context of regulation of extreme events such as floods and fires.

Available studies on extreme events, their impacts on human well-being, and the roles of ecosystem services do, however, allow several qualitative assertions to be made:

- Humans are increasingly occupying regions and localities that are exposed to extreme events, establishing settlements, for example, on coasts and floodplains, close to fuelwood plantations, and so on. These actions are exacerbating human vulnerability to extreme events. Many measures of human vulnerability show a general increase, due to growing poverty, mainly in developing countries.

- Impacts of natural hazards are increasing in many regions around the world. Annual economic losses from extreme events increased tenfold from the 1950s to 1990s. From 1992 to 2001, floods were the most frequent natural disaster (43% of the 2,257 disasters), and floods killed 96,507 people and affected more than 1.2 billion people over the decade. A large number of damaging floods occurred in Europe in the last decade. Material flood damage recorded in Europe in 2002 was higher than in any previous year.

- Human vulnerability is usually the primary factor that explains trends in impacts, and, in general, it overwhelms any positive effect on human well-being.

- Interactions of modern human activities with ecosystems have contributed to increasing human vulnerability and to the impact of extreme events on human well-being.

- Appropriate management of ecosystems can be an important tool to reduce vulnerability and can contribute to the reduction of negative impacts of extreme events on human well-being.

16.1 Introduction

The impacts of natural disasters have changed dramatically over the past 30 years. While the number of people reported affected by natural disasters increased from just over 700 million in the 1970s to nearly 2 billion in the 1990s, deaths from natural disasters fell from nearly 2 million in the 1970s to just under 800,000 in the 1990s. The reasons behind these statistics are complex and need further analysis. However, the drop in fatalities can be attributed in part to better disaster preparedness, although most deaths occur in developing countries, where disaster preparedness measures are less well developed.

This chapter examines the role of ecosystems in the context of the impacts of floods and fires on human systems. Floods and fires are considered natural hazards—that is, natural processes or phenomena occurring in the biosphere that may become damaging for human as well as for natural systems. The outcome of a natural hazard becomes a natural disaster as the result of the interaction of human or ecosystem vulnerability and the extent and severity of the damage to the human group or ecosystem receiving it. Many other natural hazards exist that could have been included in the assessment, such as droughts, tropical cyclones, volcanic eruptions, and earthquakes, for example. Only floods and fires are considered here, however, because they are most strongly subject to feedback processes and most directly influenced by human activities such as urbanization and environmental degradation. Deforestation, for example, has a direct effect on the incidence and magnitude of flood events.

This chapter focuses on the roles that ecosystems play in modulating the effects of extreme events, and in particular in protecting human well-being from the impacts of floods and fire. Protection can be defined as contributing to the prevention of harm as well as to the receipt of benefits. It is well understood that extreme events result in differentiated impacts to human well-being, with resulting costs and benefits to people at different spatial and temporal scales (Pielke Jr. 2000a, 2000b). For example, the tropical cyclone that devastates a neighborhood is a disaster to those who lose their homes but also an opportunity for aquifer recharge, especially after a long drought period. In the context of flooding, the impacts of a particular event may be reduced by the presence of unoccupied floodplains that allow flood waters to pass through unpopulated areas. Benefits from flooding may occur through the transport of sediments and nutrients to the coastal zone, although the consequences of this are often negative.

It is of course important to recognize that natural events do not always bring benefits to human well-being; some may result in harms or costs. For example, flood conditions may foster the spread of disease or disease vectors harmful to humans, such as

West Nile virus or hantavirus. Thus, understanding valuation of ecosystem services in the context of extreme events is complicated due to the interacting benefits and costs. Logically, if ecosystems play an intervening role between extreme events and human well-being, then ecosystem services must also provide differentiated impacts on humans.

Understanding the role of ecosystem services in protecting human well-being is further complicated by the diverse array of factors that contribute to protection of and harm to human well-being in the context of extreme events. Such impacts result from the effects of the extreme event itself as well as the vulnerability of human systems. Many of these effects can be considered independent of the intervening role of ecosystems, such as when a powerful tropical cyclone strikes a highly urbanized area. In this case, the economic losses are unavoidable, although human losses can be prevented or minimized.

Ecosystem conditions and their services can play a role in modulating both the event and the human systems that create conditions of vulnerability. This is also true for natural systems. As an example, a perennial grass from a Mediterranean ecosystem might become more vulnerable to extreme wildfires and rainfall events under severe erosion and land degradation conditions (De Luis et al. 2004). In the case of flooding, local or regional ecosystem conditions, such as increased deforestation, may contribute to the magnitude or scope of particular flooding events, setting the stage for increased vulnerability. Human vulnerability is conditioned by the characteristics of local ecosystems, social systems, and human modifications to them.

Figure 16.1 depicts in a highly simplified manner the various inter-relationships of extreme events, human and ecological systems, and the resulting effects (both benefits and costs) to human well-being. Highlighted in red is the role of ecosystem services in contributing to benefits and costs related to human well-being in the context of extreme events. The arrows represent the differentiated impacts of benefits and costs for both ecosystems and human systems. These impacts are modulated by the ecosystem regulating services.

16.1.1 Ecosystem Services in the Context of Regulation of Extreme Events

This section describes the mechanisms by which ecosystems regulate floods and fires, producing benefits to both ecosystems and humans. Table 16.1 describes the mechanisms by which main ecosystems regulate natural hazards.

These mechanisms the role of natural hazards in preserving biodiversity patterns and key biophysical processes in the biosphere (Wohlgemuth et al. 2002). These natural phenomena play an important role in the natural cycle of matter and energy. Fires, for example, are part of the natural behavior of the biosphere, and floods are an efficient mechanism for natural transport of dissolved or suspended material (Pielke Jr. 2000b).

In the case of humans, ecosystem regulation can provide protection from the adverse consequences of natural hazards to human well-being.

16.1.1.1 The Role of Wetlands, Floodplains, and Coastal Ecosystems in the Regulation of Floods

The preservation of natural areas is important for flood attenuation. For example, some natural soils (not affected by human activities) have a large capacity to store water, facilitate transfer of groundwater, and prevent or reduce flooding. The capacity to hold water is dependent on soil texture (size of soil particles and spaces between them) and soil structure (nature and origin of ag-

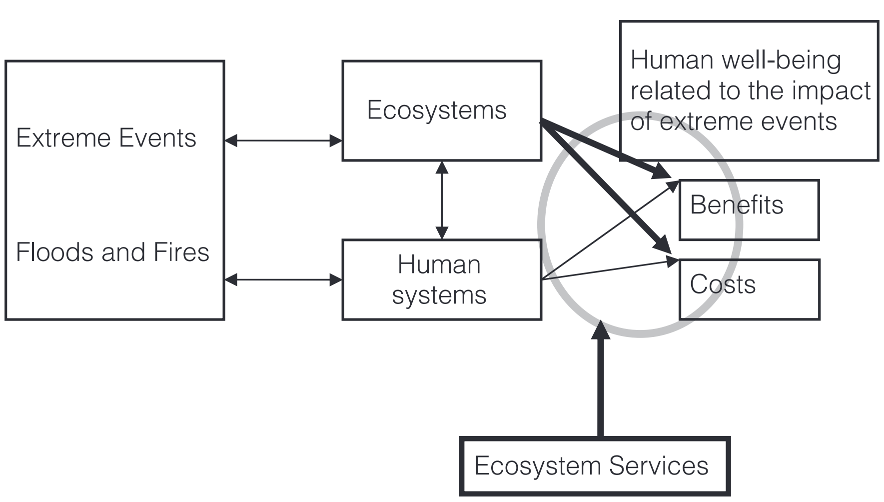

Figure 16.1. Inter-relationships between Extreme Events, Ecosystems, and Social Systems

Table 16.1. Key Role of Ecosystems in Regulating Extreme Events

Ecosystem	Role in Flood Regulation	Role in Fire Regulation
Cultivated	crop cover provides flood protection, conditioned on good management	part of the management of some cropping systems, e.g., sugar cane, timber, etc.
Dryland	protection through vegetation cover; recharge of aquifers	biodiversity issues: adaptation mechanisms to fire
Forest	protection from floods providing flood attenuation and soil loss prevention	part of the natural system; reducing wood fuel accumulation; biodiversity issues
Urban	move people away from flood-prone areas, conditioned on good urban planning	move people away from natural fire-prone areas; scale benefits from more effective fire prevention and control
Inland Waters	provide mechanisms for flood attenuation potential (wetlands, lakes, etc.)	wildfires control, e.g., pit fires control by wetlands
Coastal	benefits from sediment transport to the coastal zone; flood protection provided by coastal ecosystems (barrier beaches, mangroves, etc.)	not applicable
Marine	benefits from nutrient transport to the oceans	not applicable
Polar	discharge regulation to oceans in the Arctic system (freshwater provision to Arctic oceans)	not applicable
Mountains	regulating flood-related events (slope stability)	main source of wood fuel
Islands	benefits from sediment transport to oceans through floods from the mainland; aquifer recharge as main source of fresh water	not applicable

gregates and pores). For instance, clay soils have a larger capacity to hold water than sandy soils due to pore size.

Other intact areas, such as barrier beaches, offer natural flood protection. Important inland water components, such as wetlands and lakes, are key agents of flood attenuation through energy dissipation of runoff peaks. Gosselink et al. (1981) determined that the forested riparian wetlands adjacent to the Mississippi in the United States during pre-settlement times had the capacity to store about 60 days of river discharge. With the subsequent removal of wetlands through canalization, leveeing, and drainage, the remaining wetlands have a current storage capacity of less than 12 days discharge—an 80% reduction of flood storage capacity. The extensive loss of these wetlands was an important factor contributing to the severity and damage of the 1993 flood in the Mississippi Basin, the most severe flooding in recent U.S. history (Daily et al. 1997). Similarly, the floodplain of the Bassee River in France performs a natural service by providing an overflow area when the Seine River floods upstream of Paris. A valuation analysis that highlights the economic need to conserve this natural environment is presented by Laurans (2001).

Wetlands, however, should not be viewed as single units; when examined collectively on a catchment scale, they are all interlinked. Although an isolated wetland may perform a significant flood control function, effective control is more often the result of the combined effect of a series of wetlands within a particular catchment area (Verry and Boelter 1978). Thus, when considered singly, upstream wetlands may appear to have an insignificant effect on flood attenuation. Although upstream wetlands are often numerous, and their cumulative effect may be considerable, most flood control benefits of wetlands are derived from floodplain wetlands (Bullock and Acreman 2003).

Coastal areas, including coastal barrier islands, coastal wetlands, coastal rivers floodplains, and coastal vegetation, all play an important role in reducing the impacts of floodwaters produced by coastal storm events and have been characterized by Leatherman et al. (1995) as a "movable boundary" that continuously responds to fluvial and deltaic fluxes.

Storm regulation in the coastal zone can be achieved by preserving natural buffers such as coral reefs, mangrove forests, sandbars, and so on. When such buffers have been destroyed, management agencies will sometimes try to restore damaged habitats or construct artificial wetlands.

16.1.1.2 The Role of Ecosystems in Regulating Fires

Fire regulation is defined here as the capacity of ecosystems to maintain natural fire frequency and intensity. Fires occur due to a combination of fuel, flammability, ignition, and spread conditions, which are generally related to climate and land cover. For example, precipitation is closely related to fuel load and flammability. Persistent high precipitation allows for increases in fuel by favoring vegetation growth, but leads to conditions that may be too wet to allow fires. Persistent low precipitation, on the other hand, limits plant growth and fuel supply. High temperature and wind speed generally enhance flammability and fire spread. High flammability combined with high fuel load increase the likelihood of intense fires. Temperate regions suffer from catastrophic fires after periods of fuel buildup, whereas tropical forests can store large amounts of fuel, but humid conditions naturally prevent flammability.

In addition to climate and land cover, factors related to economy, education, and technology are also important for fire regulation. For example, economic and educational conditions that determine the use of agricultural techniques other than fires may reduce accidental fires (Nepstad et al. 1999a). Fire regulation can also benefit from investments in systems for monitoring fire risk and activity (Prins et al. 1998) and from disaster-relief mechanisms in cases of catastrophic fires (FEMA 2004). In these cases, one of the most important tools for regulating fires is the use of satellite data.

Remote sensing data can provide fire occurrence information, help improve preparedness, and aid decision-making on fire regulation (Dwyer et al. 2000; Justice et al. 2003; Grégoire et al. 2003). These data are usually reported as "fire pixels" on satellite maps where active burning is highlighted. Several satellite-based systems are in use to monitor fire activity (e.g., Setzer and Malingreau 1996; Prins et al. 1998; Giglio et al. 2000; Justice et al. 2002). For example, the Moderate Resolution Imaging Spectroradiometer (MODIS) Fire Products reports fire activity globally at spatial resolutions as small as 1 kilometer square and temporal resolutions of up to four times per day. (See Figure 16.2 in Appendix A.)

Satellites can also provide information on recent patterns of the area affected by fires, based on comparisons between repeated images. For example, GBA2000 (Grégoire et al. 2003) and GLOBSCAR (Global Burn Scars) (Kempeneers et al. 2002) are inventories of the area burned worldwide in 2000.

When analyzing fire patterns from remote sensing, it is important to consider that some factors can interfere with fire detection. For example, fires occurring at different times to the detection times (Ichoku et al. 2003) or under clouds or forest canopies may not be detected and hence under-recorded (Setzer and Malingreau 1996); exposed soils and solar reflections may be misinterpreted as fires (Giglio et al. 1999); and low spatial resolution can impair the identification of small burned areas (Simon 2002).

Thus to properly interpret satellite fire patterns and improve detection algorithms, comparisons between satellite- and field-based fire data (ground-truthing) are essential. While more studies are needed, there are indications that satellites tend to report fewer active fires than actually occur on the ground and that frequent (sub-daily) temporal sampling is as important as high spatial resolution.

16.1.2 Hazard Regulation and Biodiversity

It is increasingly accepted that a large pool of species is required to sustain the structure and functioning of ecosystems, especially in landscapes with intensive land use. In this context, a group of related hypotheses (Loreau et al. 2001) proposes that biodiversity may act as an insurance or buffer against changing environmental conditions. However, the suggestion that biodiversity controls ecosystem processes, including stability, needs to be analyzed in a much wider array of conditions, since not all ecosystems respond equally to environmental disturbance and since some perturbations may be better buffered by biodiversity than others (Roy 2001).

In the face of major natural disturbances such as fire and flood and an increased probability of their occurrence due to global change, the buffering capacity attributed to biodiversity may play a key factor in ecosystem recovery. The existence of a minimum species richness could help ensure the presence of species or functional groups with dominant roles in biomass production and regulation of nutrient fluxes. (See also Chapters 11 and 12.) A number of observations suggest that after a disturbance or when environmental conditions change, biodiversity richness at larger spatial scales, such as landscapes and regions, can ensure that appropriate key species for ecosystem functioning are recruited to local systems. (See also Chapter 4.)

The importance of natural disturbance processes in the maintenance of landscape diversity has been documented for many protected areas of the world. An example of this is the effect of fires in Yellowstone National Park. In 1988, fires burned a total of 45% (400,000 ha) of the park (Christensen et al. 1989). Reconstructions of the history of fires in Yellowstone suggest that the last time a fire of this magnitude occurred was in the early 1600s. Although plant species richness was still increasing at the scale of sampling plots (less than 10 square meters) five years after the 1988 fires, overall species richness at the landscape level had been unaffected by fires. However, relative abundance varied among species (Turner et al. 1997).

Large-scale disturbance are very important in structuring ecosystems. Changes in this disturbance regime—for example, as a result of climate change—could have substantial implications from the ecological point of view (Turner et al. 1997).

The role of biological diversity in providing insurance, flexibility, and risk distribution across various scales within the context of ecosystem resilience and under conditions of uncertainty is discussed in Chapter 4.

16.2 Magnitude, Distribution, and Changes in the Regulation of Natural Hazards

This section presents the ecosystem components and mechanisms that provide regulating services for floods and fires and their magnitude, distribution, and variability. First we describe key ecosystem components providing regulation of floods and fires at a global scale. Then we present evidence of the historical changes that have occurred in the capacity of ecosystems to provide flood and fire regulation. Changes in the occurrence and magnitude of these natural hazards and their impacts on human well-being provide an indirect measure of the ability of ecosystem conditions to provide regulation services. Unfortunately, data on the direct relationship between the magnitude (frequency and intensity) of natural hazards and changes in the ecosystem conditions as a direct consequence of anthropogenic actions are practically non-existent. Therefore, incidence and trends in natural hazard impacts on ecological and social systems are used as proxy measures of the regulation capacity of ecosystems.

16.2.1 Ecosystem Conditions That Provide Regulatory Services

16.2.1.1 Flood Regulation

Wetlands, floodplains, lakes, and reservoirs are the main providers of flood attenuation potential in the inland water system. Geographic distribution of wetlands is described in different databases (such as Matthews from GISS, University of Kassel, and Ramsar). The University of Kassel in Germany has developed a map of the global distribution of wetlands, lakes, and reservoirs. (See Figure 20.1 in Chapter 20.) Wetlands cover an estimated 6.6% of the global land area (excluding Antarctica and Greenland), and lakes and reservoirs alone cover 2.1% (Lehner and Döll 2004).

Flood attenuation potential can be estimated by the ''residence time'' of rivers, reservoirs, and soils. (See Figure 16.3 in Appendix A.) Residence time is defined as the time taken for water falling as precipitation to pass through a system. The longer the residence time, the larger the buffering capacity to attenuate peak flood events. Larger rivers, such as the Congo and the Amazon, have a greater attenuation capacity than smaller rivers. Data for populations living in different zones of water residence time are presented in Figure 16.4. Nearly 2 billion people live in areas

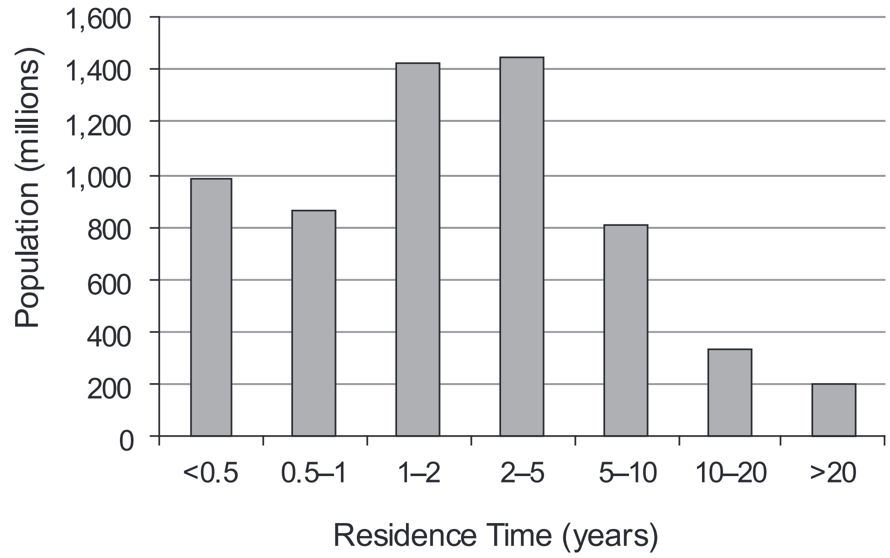

Figure 16.4. Population by Basin for Different Residence Time in Lakes, Reservoirs, Rivers, and Soils (WSAG, University of New Hampshire 2004)

with a residence time of one year or less and are thus located in areas of high flood risk with low attenuation potential. Most of these people live in northern South America, highly populated regions of northern India and South East Asia, Central Europe, and the Southwest coast of Africa.

16.2.1.2 Fire Regulation

Several ecosystem conditions are related to fire regulation—principally the amount of vegetation, and therefore fuel, in the system. Climate, land cover, and land use are important factors linked to these conditions. Climate variability is a dominant factor affecting large wildfires in the western United States, although current fire management practices focus on reducing fuel availability (McKenzie et al. 2004). Regions with climates that present distinct dry and wet seasons have potentially more fires. Under these climates, vegetation growth during the wet season can increase fuel load, and flammable conditions during the dry season can lead to more frequent and intense fires. In addition to seasonality in precipitation, temperature and wind speed are important. Hot conditions and intense winds may promote high fire frequency and intensity by favoring fuel dryness and fire spread.

Land cover and land use are important because they can affect fuel load, flammability, number of ignition events, and spread conditions. For example, forests with deep root systems may take longer to become flammable during dry periods than vegetation with shallow roots. Soils that have low water-holding capacity may lead to flammable conditions after short dry periods. Fire suppression reduces sources of ignition but may favor fuel buildup and the likelihood of more intense fires when they do occur. Land use practices such as pasture maintenance can lead to higher number of trigger events, but the use of firebreaks can help to lower the spread of fire.

16.2.2 Impacts of Ecosystem Changes on Underlying Capacity to Provide a Regulating Service

Direct quantification of the underlying capacity of ecosystems to regulate floods and fires is difficult, and few studies have sought to identify and quantify changes in these regulating services. This section looks at the direct consequences of a reduced capacity to regulate floods and fires, therefore, and presents evidence for changes in flood incidence and flood-related damages as well as changes in fire activity.

16.2.2.1 Evidence for Changes in Flood Incidence and Flood-related Damages

A damaging flood is defined as a flood in which individuals or societies suffer losses related to the event. In almost all cases a damaging flood results from a combination of physical and societal processes (Pielke Jr. 2000b). All types of floods, such as riverine or coastal floods, sudden snow melt floods, or floods after heavy, intense rainfall, have become more destructive in recent years (IFRC 2001). Moreover, projections show that this tendency is likely to become even more pronounced in the future. From 1950 to 1990, annual economic losses from extremes events increased steadily (Swiss Re 2003), largely due to several indirect socioeconomic drivers, including population increase and accumulation of wealth in vulnerable areas, and to some extent direct drivers, such as climate and climate change.

Hydrological variables (precipitation and stream flow, for example) show strong spatial and temporal variability. Occasionally, they take on extremely high values (heavy precipitation occurs, perhaps), with substantial impacts on ecosystems and human society. Thus floods have been a major issue since the beginning of civilization (floods of the Tigris and Euphrates were documented in ancient Babylonian and Sumerian texts, for instance) and continue to be so.

According to data compiled by the International Red Cross (IFRC 2001), floods account for over two thirds of the average of 211 million people a year affected by natural disasters. Every year extreme weather and climate events cause significant morbidity and mortality worldwide. From 1992 to 2001, floods were the most frequent natural disaster (43% of the 2,257 recorded disasters), killing 96,507 people and affecting more than 1.2 billion people (OFDA/CRED 2002). In the Americas, floods accounted for 45% of all deaths from disasters (IFRC 2003). Table 16.2 presents the total number of deaths due to floods and wild fires, by continent, during 1990–99. Asia is the most affected continent in terms of human-related flood losses.

In 2003, flood events did not occur to the same extent as they had in (northern) summer 2002; rather, heat waves dominated, especially in Europe. However, a Swiss Reinsurance Company study found that economic losses from "catastrophes" in 2003 were on the order of $70 billion (Swiss Re 2003). Natural disasters, including floods, accounted for $58 billion. Swiss Re also estimated that "natural and human disasters" claimed 60,000 human lives in 2003. Another study put economic losses at $60 billion and deaths due to extreme events at 75,000 (Munich Re 2003). Significant floods did occur in Nepal, France, Pakistan, and China during the (northern) summer of 2003 (Munich Re 2003).

The majority of large floods have occurred in Asia during the last few decades, but few countries have been free of damaging floods. In many countries at least one destructive flood (including storm surges) has occurred since 1990 (Kundzewicz and Schellnhuber 2004). Pielke and Downton (2000) found an annual increase of 2.93% in the total flood damage in the United States over the period 1932–97. This increase has been attributed to both climate factors, such as increasing precipitation, and socioeconomic factors, such as increasing population and wealth.

Many damaging floods have also occurred in Europe in the last decade. Material damage in 2002 was higher than in any previous year. For instance, the floods in Central Europe in August 2002 caused damage totaling nearly 15 billion euros (Kundzewicz and Schellnhuber 2004). Several destructive floods also occurred in other parts of the world in 2002, including China, Russia, and Venezuela. An evaluation of the damages, by affected area, is presented in Table 16.3.

It is also important to emphasize that damaging floods have occurred in arid and semiarid regions, such as summer floods in Arizona (Hirschboeck 1987).

The number of flood events for each continent and decade since the beginning of last century is shown in Figure 16.5. The data source for this figure is the EM-DAT global disaster database from OFDA/CRED International Disaster Database at the University of Louvein in Belgium (OFDA/CRED 2002). Only events that are classified as disasters are reported in this database. (An event is declared as a disaster if it meets at least one of the following criteria: 10 or more people reported killed; 100 or more people reported affected; international assistance was called; or a state of emergency was declared (OFDA/CRED 2002).) Figure 16.5 shows a clear increase in the number of floods since the 1940s for every continent and a roughly constant rate of increase for each decade. However, it should be noted that although the number has been increasing, the actual reporting and recording of floods have also increased since 1940, due to the improvements in telecommunications and improved coverage of global information.

Regional changes in the timing of floods have been observed in many areas. The maximum daily flow of the River Elbe in Germany (3,000 cubic meters per sec) has been exceeded eight times in winter (most recently in 1940) and only three times in summer (last in 2002) (Mudelsee et al. 2003). Thus, severe winter

Table 16.3. Examples of Floods during the Summer of 2002 (Dartmouth Flood Observatory)

Location and Continent	Duration	Affected Region	Damage
	(days)	*(sq. km.)*	*(dollars per sq. km.)*
C. Europe, Europe	18 (August)	252,300	79,270
S. Russia, Asia	12 (June)	224,600	1,945
W. Venezuela, South America	11 (July)	224,900	13
NW China, Asia	10 (June)	252,000	1,587
NW China, Asia	8 (July)	127,600	287

Table 16.2. Deaths Due to Floods and Wild Fires, by Continent, 1990–99 (IRFC World Disaster Report 2001)

Phenomenon	Oceania	United States and Canada	Rest of Americas	Europe	Africa	Asia	Total
Floods	30	363	35,235	2,839	9,487	55,916	**103,870**
Wild Fires	8	41	60	127	79	260	**575**

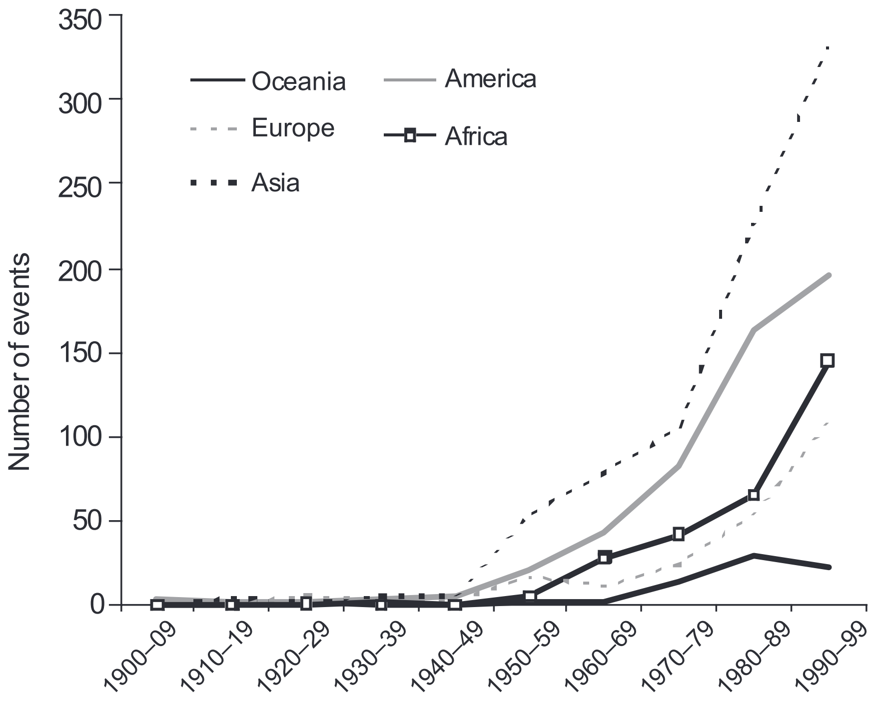

Figure 16.5. Number of Recorded Flood Events by Continent and Decade in Twentieth Century (OFDA/CRED 2002)

floods of the Elbe have not occurred in the last 64 years. Also, as indicated by Kundzewicz et al. (2004), intense and long duration summer precipitation occurred in Central Europe in 1997 and 2002 leading to very damaging floods.

Flood processes are controlled by many factors, climate being one of them. Other nonclimatic factors include changes in terrestrial systems (that is, hydrological and ecological systems) and socioeconomic systems. In Germany, for instance, flood hazards have increased (Van der Plog et al. 2002) partly as a result of changes in engineering practices, agricultural intensification, and urbanization (direct and indirect drivers).

During the 1960s and 1970s, more than 90% of natural disasters in the United States were the result of climate extremes (Changnon and Easterling 2000), and it has been estimated that about 17% of all the urban land in the United States is located within the 100-year (the return period) flood zone (Pielke and Downton 2000). Likewise, in Japan, about 50% of the population and 70% of infrastructure are located on floodplains, which account for only 10% of the land area. On the other hand, in Bangladesh the percentage of flood-prone areas is much higher, and inundation of more than half of the country is not uncommon. For instance, about two thirds of the country was inundated in the 1998 flood (Mirza 2003).

16.2.2.2 Evidence for Changes in Fire Activity

It is difficult to make a complete assessment of the changes in global fire activity because of the diverse methodologies employed and the limited availability of data. At large scales, recent fire activity patterns (during the last 10 years) based on remote sensing data from the satellites are relatively well known (Dwyer et al. 2000; Justice et al. 2002). Data at the local scale are less common and generally only available for specific regions where fire occurrence has been documented from ground-based observations (Schelhaas and Schuck 2002; NIFC 2004). In some cases, these records cover many years (10 to 100) and extend our knowledge on fire patterns further into the past. Tree rings have also been used in the analysis of forest fires for the last few centuries. For longer time scales, fire patterns have been determined from analyses of plant materials in sediments (Clark 1997), which can provide evidence of fires that occurred hundreds to millions of years ago.

Active fire detections from satellite data made from April 1992 to March 1993 showed that most fire activity occurs from July to August and from November to January (Dwyer et al. 2000). Seventy percent of the detected fires were located in the tropics, with 50% of all fires in Africa. Globally, fires affected 19% of savanna areas, 20% of broadleaf forests, 20% of crops and pasture areas, 4% of shrublands, and 4% of grassland areas (Dwyer et al. 2000).

Information on the global area burned in 2000 is available from two satellite-based inventories: the GBA2000 (Grégoire et al. 2003) and the GLOBSCAR (Kempeneers et al. 2002). Based on GBA2000, fires affected $\sim 350 \times 10^6$ ha in 2000; 81% of this area occurred in woodlands and scrublands, 16.5% in grasslands and croplands, 1.5% in coniferous and mixed forests, and 1.2% in broadleaf forests (Bartholomé et al. 2003). Most of the fire activity occurred from July to September and from December to January. Figure 16.6 (in Appendix A) illustrates the global pattern of burned areas based on GBA2000.

According to GLOBSCAR, the global burned area in 2000 was $\approx 200 \times 10^6$ ha (Kempeneers et al. 2002). Of this total, 59% was located in Africa, 11% in Asia, 9% in Australia, 8% in Europe, 7% in South America, and 6% in North America. Most of the fires occurred during June-August and November-January.

Despite the potential to provide large-scale information, satellite-based global fire data sets covering long periods of time are rare (Lepers 2003). However, for tropical regions data on major fires from January 1997 to December 2000 are available from the ATSR World Fire Atlas Project. Based on these data, Lepers (2003) determined that 36% of exceptional or frequent fire events occurred in South America, followed by Africa (30%) and Asia (20%), mostly during El Niño conditions. In Asia and in Central and South America, these fires appear to be associated with areas experiencing deforestation and forest degradation (Lepers 2003). (See Figure 16.7 in Appendix A.)

Independent studies have also shown that high fire activity in tropical regions can be driven by changes in land use. For example, higher fire activity was related to conversion of peat swamp forests in Indonesia (Page et al. 2002). In Amazonia, large-scale fire patterns mirror large-scale patterns of deforestation (Skole and Tucker 1993), road construction (Prins et al. 1998; Laurence et al. 2001; Cardoso et al. 2003), and logging activities (Cochrane et al. 1999a; Nepstad et al. 1999). Consequently, increases in fire activity are likely to occur in response to future development programs in these regions, if the current relationships between fire and land use continue to hold (Cardoso et al. 2003).

At the local scale, important data sets on fire patterns include inventories of areas burned. These data are commonly reported as aggregated state/country statistics. For example, fires in the United States burned an average of 4.1 million hectares a year from 1960 to 2002 (NIFC 2004). In Europe, from 1961 to 1999 forest fires and other woodland burned an average of nearly 450,000 hectares annually (Schelhaas and Schuck 2002). Forest fires in Australia affected on average 360,000 hectares a year from 1956 to 1971 and 480,000 hectares from 1983 to 1996 (Gill and Moore 2002). These are annual averages, but there is significant variability between years.

Differences in methodologies and data availability make it difficult to compare figures from different regions and time periods. Yet the trends in these data sets are informative. For example, records available for extended periods show a general long-term reduction in the area burned. In the United States, the area burned has declined by more than 90% since 1930 (Hurtt et al. 2002) and in Sweden, the area burned fell from ~12,000 to ~ 400 hectares a year between 1876 and 1989 (Pyne and Goldammer 1997). In both countries, fires were reduced due to changes in land use. In Europe as a whole, however, the total extent and the interannual variability of the area of burnt forest are higher for the period 1975–2000 than for the 1960s, due, it is presumed, to changes in land use and climate (Schelhaas and Schuck 2002).

Data on major fire events from OFDA/CRED indicate a global increase in the number of major fire events after 1960. (See Figure 16.8.) According to CRED, changes were greatest in North America, where the number of major fires increased from ~10 during the 1980s to ~45 during the 1990s. CRED data sets only include data on major disasters (as defined by OFDA/CRED 2002) and are compiled from several sources, including U.N. agencies, nongovernmental organizations, insurance companies, research institutes, and press agencies.

Evidence of past fire activity is provided by sediment analyses. Indicators include materials directly affected by or the products of fires, such as charcoal (Sanford et al. 1985), or materials such as pollen that can be used to determine the presence of specific plant species associated with fire regimes (Camill et al. 2003). Data from sediment records are especially important in providing long-term trends in fire activity at large scales. For example, data from sea sediments show that sub-Saharan Africa had low fire activity until about 400,000 years ago and indicate that humans had a significant influence on the occurrence of fire in the Holocene (Bird and Cali 1998). Analyzes from lake sediments show that natural fires have influenced forests in Amazonia for the last 7,000 years, including impacts on current patterns of forest structure (Turcq et al 1998). Data from soils also show that fires have disturbed lowland forests in the Amazonian region for the past 6,000 years (Sanford et al. 1985). In Minnesota, fires have been shown to result from shifts in vegetation caused by climate changes during the Holocene (Camill et al. 2003). An important common result from these studies is the link between high fire activity, dry climates, and fuel accumulation.

16.3 Causes of Changes in the Regulation of Floods and Fires

The complex relationships between direct and indirect drivers are the main causes of change in the regulation of all natural hazards, including floods and fires. Understanding the patterns of distribution of such drivers may be partially achieved by describing which ecosystems are undergoing the most rapid and largest transformations. Such areas are likely to have the most reduced capacity to regulate natural hazards.

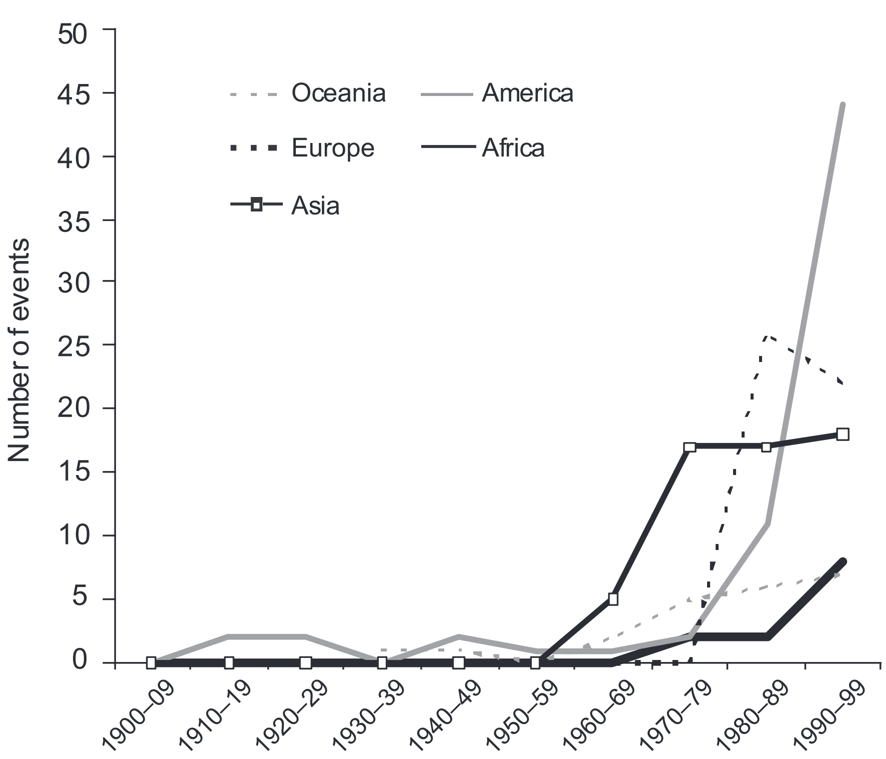

Figure 16.8. Number of Recorded Wild Fires by Continent and Decade in Twentieth Century (OFDA/CRED)

Increased attention has been paid to extreme weather and climate events over the past few years due to increasing losses associated with them. For a more accurate understanding of weather impacts, however, it is necessary to acknowledge the actual and potential impacts of changes in both climate and society (Pielke Jr. et al. 2003). For instance, there are examples where economic impacts of hurricanes have increased dramatically during prolonged periods of rather benign hurricane activity (Pielke and Landsea 1998), and it is thought that a major factor conditioning hurricane losses in the United States is the significant increase in wealth and population in the coastal areas (Landsea et al. 1999).

Human occupancy of the floodplains and the presence of floodwaters produce losses to individuals and society. Different pressures have caused increases in population density in flood-prone areas, especially poverty, which has been responsible for the growth of informal settlements in susceptible areas around megacities in many developing countries.

An immediate question that emerges from the increases in flood damage is the extent to which a rise in flood hazard and vulnerability can be linked to climate variability and change. This has been treated extensively in the Third Assessment Report of the Intergovernmental Panel on Climate Change and recently reviewed by Kundzewicz and Schellnhuber (2004). However, climate change is just one of the many drivers affecting the regulation of floods. A more detailed discussion about drivers affecting flood regulation is given in the next section.

Changes in fire regulation can affect many other ecosystem services—supporting, provisioning, regulating, and cultural services. Supporting services affected by changes in the fire regulation capacity of ecosystems include nutrient cycling (for example, through fluxes and changing stocks of carbon and nitrogen) and primary production (a decrease due to vegetation removal, for instance, or increase by soil fertilization). Provisioning services affected include food production (increased by short-term fertilization, decreased through long-term nutrient losses) and availability of genetic resources (decreased by removal of flora and fauna). Regulating services affected include climate (changes in surface albedo and greenhouse gas emissions) and disease regulation (increase in the likelihood of respiratory diseases due to reduction of air quality). Finally, cultural services affected include recreation opportunities and aesthetic experiences (short-term effects on the landscape in protected areas, for example, or airport closings due to reduced visibility caused by smoke).

16.3.1 Drivers Affecting the Regulation of Floods

In the MA framework a driver is defined as any natural or human-induced factor that directly or indirectly causes a change in an ecosystem, affecting its capacity to provide a service. Evidently, climate variability, climate change, and natural or anthropogenic land cover changes constitute physical and biological factors that directly affect the regulation of floods in terms of both processes and magnitude through changes in extreme rainfall events and peak runoff magnitude. If extreme events become more frequent and intense, the capacity of the system to provide the regulation could be affected. However, the distribution of the impacts of extreme events is not uniform across the world; their impact is greater in poorer and more vulnerable regions.

Precipitation is a critical factor in causing floods, and its characteristics—such as intensity, location, and frequency—appear to be changing. During the twentieth century precipitation increased by 0.5–1.0% per decade in many areas in the mid- and high latitudes of the Northern Hemisphere (IPCC 2001). Moreover, increases in intense precipitation have been reported even in regions where total precipitation has decreased (Kabat et al. 2002). It is difficult to generalize, however, as some regions have shown decreases in both total and intensity of precipitation. Although intense rainfall is a sufficient condition to increase flood hazard, there are a number of other nonclimatic factors that exacerbate flood hazard (Kundzewicz and Schellnhuber 2004).

A conceptual framework for understanding the human- and human-influenced processes contributing to damaging floods is presented in Figure 16.9. The broad integrative framework presented by Pielke and Downton (2000) may be used to understand the role of the drivers (direct or indirect) and policies in determining actual and potential flood outcomes.

Lepers (2003) presented the most rapidly changing areas in terms of deforestation and forest degradation, which are predominately in the tropics. Nearly half of the affected forests are in South America, with 26% in Asia and 12% in Africa. Concurrently, the tropical regions of these three continents have had higher flood incidence and higher relative vulnerability (people killed per million exposed per year) (UNDP 2004).

Figure 16.10 (in Appendix A) shows the number of floods between 1980 and 2000 (OFDA/CRED data set), together with the area of deforestation and forest degradation during the same period. Since there were multiple data sets used to describe deforested areas, the map indicates the number of data sets where deforestation was effectively identified (see Lepers 2003 for more details). The number of flood events is reported as total number of floods by country during the period 1980–2000. Tropical regions, mainly in Asia and South America, have been severely affected by floods and suffered an important loss in forest area and increasing forest degradation, as shown in Figure 16.10.

There are also physical, biological, and anthropogenic factors that influence the regulation of floods, such as land use change and human encroachment of natural areas, such as wetlands, forest, and vegetation in coastal zones. These perturbations of natural areas with the subsequent reduction of ecosystem functions affect flood attenuation potential and soil water storage capacity. It is clear that land conversion, deforestation, and loss of ecosystems such as wetlands have increased in the last decades (see Chapters 20, 21, and 28), but the impact of these drivers is unevenly distributed across different regions. Water extraction and diversion also constitute a direct anthropogenic driver that affects regulation of floods.

The indirect drivers that strongly influence the regulation of floods are population growth, the level of economic, scientific, and technological development, a lack of governance, and population settlement preferences. Impacts vary between countries but are manifest in changes in exposure of human populations to extreme events, in the increase or decrease of GDP (depending on the region), in the capacity of governments to respond to flood-related disasters, and in the commercial and recreational activities developed along major river floodplains. The impacts are more intensely felt in densely populated areas in poorer countries, where farming activities, property, and commercial activities are most at risk.

16.3.2 Drivers Affecting the Regulation of Fires

Direct and indirect drivers can change the capacity of ecosystems to provide fire regulation. For example, climate change is a natu-

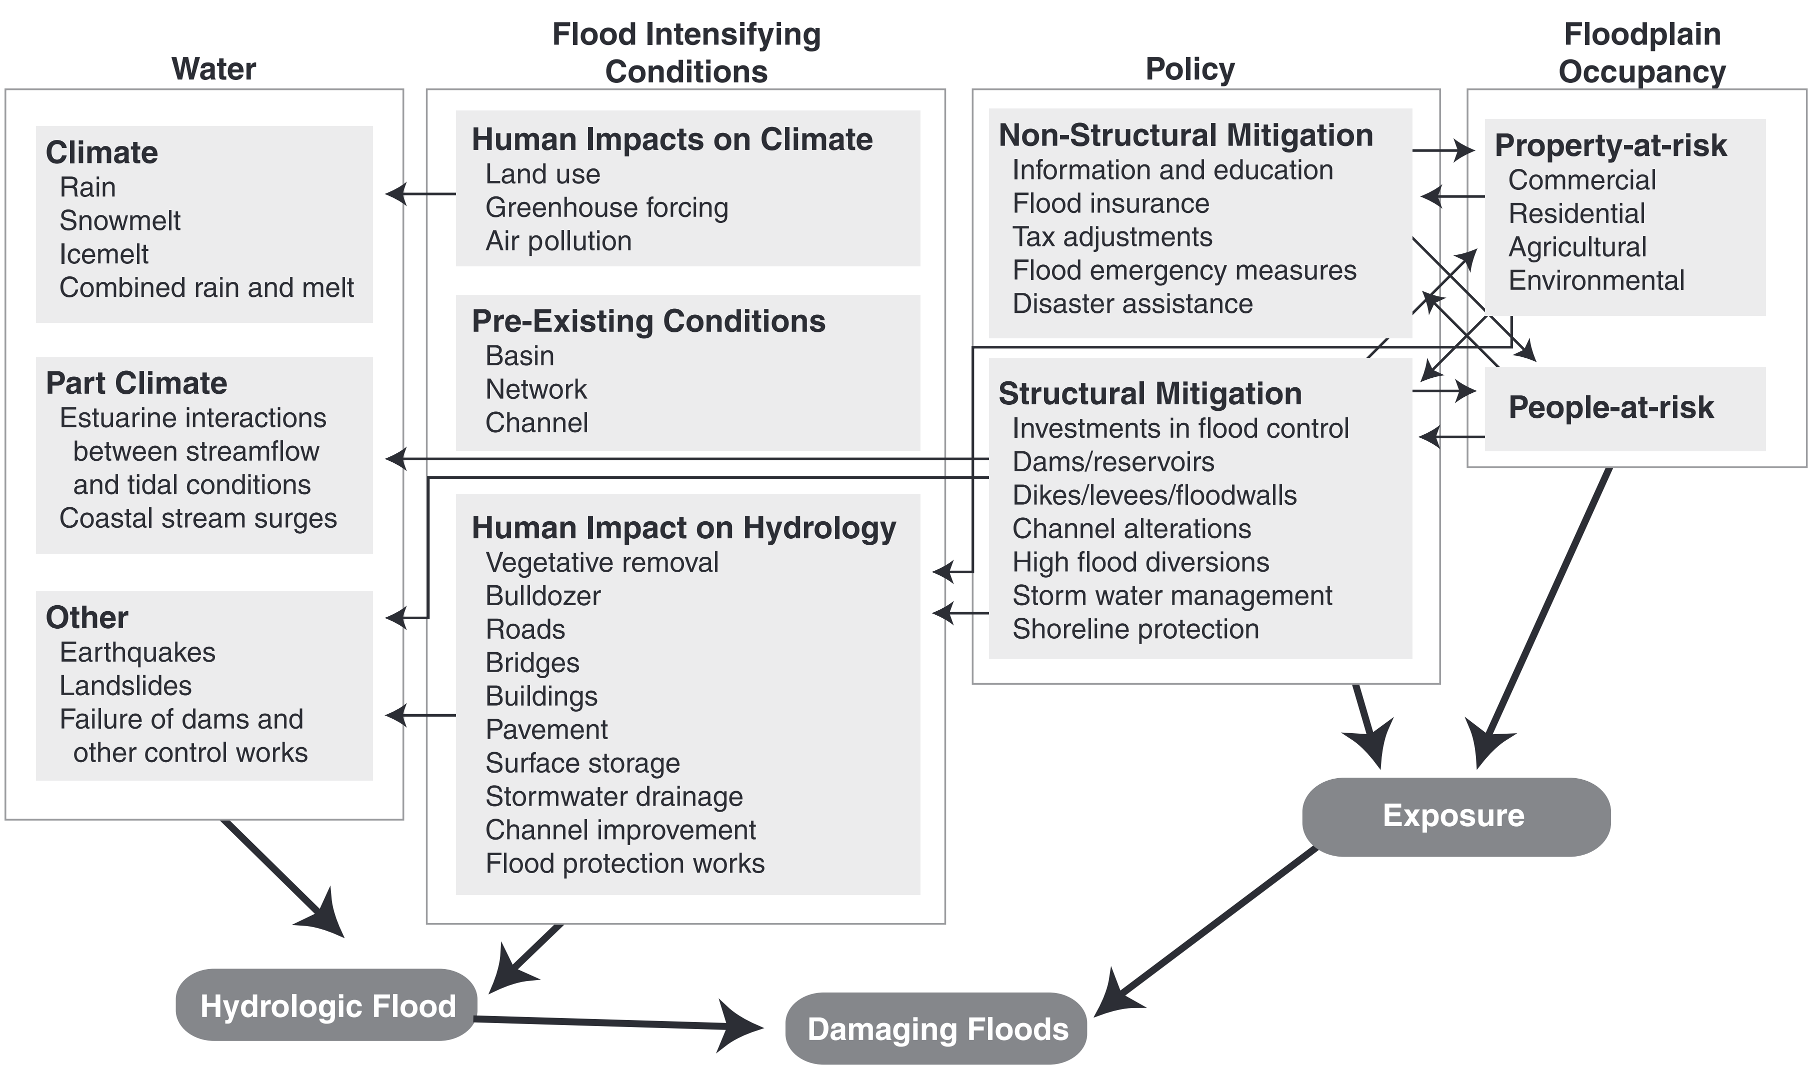

Figure 16.9. Factors Contributing to Damaging Floods (Pielke and Downton 2000)

ral and direct driver that can significantly affect fire regulation. Changes in precipitation variability may affect fire frequency and intensity. Low precipitation is associated with low fire frequency and intensity due to low biomass and fuel conditions. Similarly, high precipitation is associated with low fire frequency and intensity due to extremely wet conditions (Cardoso and Hurtt 2000).

Regions with climates that present distinct dry and wet seasons have potentially more fires. Under these climates, fuel load can increase through vegetation growth during the wet season and the high flammability during the dry season, leading to more frequent and intense fires. In addition to varying precipitation patterns, hotter conditions and more intense winds may promote a higher frequency and intensity of fires by favoring fuel dryness and fire spread. Climate effects may also depend on the state of the ecosystem. Forest trees with deep root systems may resist reduced precipitation longer before becoming flammable compared with trees with shallower roots, such as savannas species (Nepstad et al. 1994). And ecosystems with soils that have low water-holding capacity may become flammable after even short dry periods.

Unfortunately, it is not easy to predict future climate conditions. Although there is evidence that the global average temperature is increasing (IPCC 2001), other climatic data, particularly at a regional, sub-continental scale, are less clear.

Land use and land cover are important direct anthropogenic drivers of fire regulation. Included here are land management, land clearance and agriculture, housing development, logging, harvesting and reforestation, and fire suppression schemes. These can change fuel load, flammability, number of ignition events, and spread conditions. For example, fire suppression seeks to reduce the sources of ignition and short-term fire activity. However, long-term fire suppression may lead to high fuel loads and increase the likelihood of catastrophic fires, as demonstrated in the United States. Fire suppression also leads to lower trigger events, but intentional and accidental fires related to land management lead to a higher number of trigger events. Firebreaks lower spread, but actions that provide fire corridors (such as reforestation) may increase fire spread. Logging and harvesting may reduce fuel loads if biomass is completely removed or may increase fuel loads when biomass debris is left. Changes in land use and land cover have increased in developing regions in the tropics, leading to more fires (Page et al. 2002). In other regions, such as North America, however, land management has reduced fire frequency but increased fuel loads and the likelihood of more intense fires (Hurtt et al. 2002).

Indirect drivers of fire regulation are mainly linked to human activities. These drivers include demographic, economic, sociopolitical, and scientific and technological drivers. (See Chapter 3.) Demographic factors such as changes in population distribution may lead to different land use and land cover patterns, which are direct drivers of fire regulation. Changes in population may also alter property exposure to fire. Increase of population in fire-prone areas can potentially lead to higher exposure to fires, to increased risk of accidental fires, and to economic and human losses that are generally related to the level of preparedness for extreme events in the affected region.

The degree of economic development is also important. Higher levels of economic development generally improve fire regulation. For example, access to machines and technology, such as tractors, offers an alternative to the use of fires as a land clearance tool for land management. Educational programs on fire risks and effects and to alternatives to the use of fire as a land use management tool also tend to improve fire regulation. In addition, higher levels of economic development allow for the use of fire risk and activity monitoring systems and for the development of programs for disaster relief in case of extreme events.

Sociopolitical drivers, such as environmental policy, aid in fire regulation through many processes, including development of legislation and mechanisms of law enforcement and fire research, which leads to better knowledge of fires and how to fight them.

Scientific and technological drivers, such as the monitoring of fire activity, also enhance fire regulation by providing tools that help forecast and track fire activity. Satellite-based data collection systems, for example, provide additional information on fire frequency and behavior, as well as fire times and position. These can help support decisions on fire regulation resources, can improve law enforcement, and can contribute to fire research.

16.4 Consequences for Human Well-being of Changes in the Regulation of Natural Hazards

In this section the consequences and impacts of extreme events on several aspects of human well-being are presented. These impacts result from the reduced capacity of ecosystems to regulate the magnitude and intensity of these events and from the ability of ecosystems and human populations to cope with the consequences of such events—their exposure, sensitivity, and resilience. The latter are all components of ''vulnerability,'' which is a complex and multidimensional concept, intrinsic to ecological and social systems. The degree of vulnerability of an ecosystem or human group will define the impacts of extreme events on society and ecosystems. Vulnerability is discussed extensively in Chapter 6. In this section the vulnerability concept is treated as a tool to understand the differentiated impacts of extreme events on different societal groups.

16.4.1 Security and the Threat of Floods and Fires

16.4.1.1 Floods

Many factors are likely to contribute to the increase of those affected by disasters. One of these is the vulnerability profile of the population. As more people move into urban areas and slum settlements they are increasingly living in susceptible (disaster-prone) regions. Migrants to big cities are normally at greatest risk, since they occupy the most hazard-prone locations on unstable slopes and flood-prone areas. However, urbanization is not necessarily a factor increasing disaster risk if it is managed in an appropriate and adequate way. Local authorities and their interactions with public, private, and civil society may play an important role in urban risk reduction to bridge the gap between national and international risk management players and local communities (UNDP 2004). But this implies a high level of municipal governance.

Environmental degradation increases the negative effects of extreme events on society. While disaster preparedness measures do help save lives, the failure to reduce risks more broadly may be contributing to the higher numbers of disaster-affected people. Unfortunately, data are not uniformly collected, but more information would likely show an increase in the number of affected people, although the definition of ''affected'' varies (IFRC 2003).

16.4.1.2 Fires

The detrimental impacts and consequences of some wildfires on economies, human health, and safety are comparable in severity to other major natural hazards. Unlike the majority of the geological and hydro-meteorological hazards, however, vegetation fires represent a natural and human-caused hazard that can be predicted, controlled, and, in many cases, prevented through the application of appropriate policies. Most countries already have laws, regulations, and action plans for management of forest fires and response procedures in place. These are often insufficient, however, or inadequately implemented.

Loss estimates have been used to quantify the impacts of fires on society. Globally, such losses are difficult to quantify, but data do exist from areas where fire occurrence is well documented. For example, U.S. federal agencies spent an average of $768 million a year in fire suppression between 1994 and 2002 (NIFC 2004). From 1995 to 1999, the annual costs of prescribed fires increased from $20 million to $99 million (NIFC 2004). In 2003, fires in California burned over 750,000 hectares, caused 24 fatalities, and destroyed over 3,000 residences (FEMA 2004).

An analysis of national fire policies concluded that mitigation policies were generally weak, rarely based on reliable data of forest fire extent, causes, or risks, and did not involve landowners most likely to be affected (ECE/FAO 1998). Furthermore, they were sometimes the result of ill-conceived forest management policies, particularly policies aimed at total fire exclusion that led to fuel accumulation and catastrophic fire outbreaks. Future fire policies will need to find a balance between the various ecological, agricultural and energy benefits of biomass burning and environment and health problems.

16.4.2 The Effects of Natural Hazards on Economies, Poverty, and Equity

Economic indicators such as GDP are highly affected by natural disasters, especially in the most vulnerable areas. Thus poorer nations experience lower economic losses but a relatively higher drop in GDP following a natural disaster, while the opposite trend is observed in wealthier nations (MunichRe 2001).

In a recent UNDP report on natural disasters, mortality from floods was inversely correlated with GDP per capita. There was also a negative correlation between deaths from flooding and local density of population (UNDP 2004). This fact, although contradictory, might be explained because of the higher expected mortality in rural and remote areas with limited health care and low disaster preparedness. The most important factors contributing to high risk from floods were low GDP per capita, low density of population, and a high number of exposed people.

In the same study, 147 countries with populations exposed to floods were identified. India, Bangladesh, Pakistan, and China were at the top of the list of countries with high absolute and relative populations exposed to floods. This is a consequence of the large populations living along floodplains and low-lying coasts in this part of the world. Other countries, such as Bhutan and Nepal and the Central American and Andean states, also have large absolute and relative populations exposed to floods because of their mountainous topography and important population centers located on river floodplains (UNDP 2004).

Rural areas with low population density and poor health coverage that are prone to flooding are also more vulnerable to flood-related diseases due to their lower flood evacuation abilities. Disaster reduction measures for these areas can also offer opportunities for these communities, such as involving women in maintaining local social networks focused on risk reduction. In Cox's Bazar (Bangladesh), women's involvement in disaster preparedness activities organized through local networks—including education, reproductive health, and micro-enterprise groups—has resulted in a significant reduction in the number of women killed following tropical cyclones (UNDP 2004).

16.4.3 Impacts of Flood and Fires on Human Health

Natural hazards adversely affect human health both directly and indirectly. The direct physical effects that occur during or after flooding include mortality (mostly from flash floods), injuries (such as sprains or strains, lacerations, contusions), infectious diseases (respiratory illnesses, for example), poisoning (from carbon monoxide, say), diseases related to the physical and emotional stress caused by the flood, and such other effects as hypothermia from loss of shelter. The number of deaths associated with flooding is closely related to the local characteristics of floods and to the behavior of victims (Malilay 1997).

Indirect effects of floods can also cause human injury and disease, such as waterborne infections and vector-borne diseases, acute or chronic effects of exposure due to chemical pollutants released into floodwaters, and food shortages. Studies have also observed increased rates of the most common mental disorders, such as anxiety and depression, following floods (Hajat et al. 2003). These and other psychological effects may continue for months or even years. The physical and health impacts of floods in the United Kingdom have been the subject of longitudinal studies (Tapsell et al. 2003). Flooding events caused adverse physical effects in about two thirds of vulnerable people and adverse mental and physiological effects in more than three quarters. The physical effects lasted about 12 months on average, while the psychological impacts lasted at least twice as long.

Impacts can also be categorized according to when they occurred relative to the event (during the impact phase, immediate post-impact phase, or during the recovery phase). For example, injuries are likely to occur in the aftermath of a flood disaster, as residents return to dwellings to clean up damage and debris.

Although natural hazards cause a significant number of injuries and diseases, the available morbidity data are limited, which restricts our understanding of both the impacts and the possible effective response options.

Campbell-Lendrum et al. (2003) used comparative risk assessment methods to estimate the current and future global mortality burden from coastal flooding due to sea level rise and from inland flooding and mass movement caused by an increase in the frequency of extreme precipitation. As quantitative estimates were not available, longer-term health impacts due to population displacement, economic damage to public health infrastructures, increased risk of infectious disease epidemics, and mental illness were excluded from their analyses, although these impacts are likely to be greater than the acute impacts. Despite this, the global model developed has been shown to be relatively accurate when tested against more detailed assessments at a national level.

The model has other limitations, however. In the absence of detailed data on the relationships between intensity of precipitation, the likelihood of a flood or mudslide disaster, and the magnitude of health impact variables and their effects, it was assumed that flood frequency was proportional to the frequency with which monthly rainfall exceeded the 1-in-10-year limit (that is, upper 99.2% confidence interval) of the baseline climate. It was also assumed that determinants of vulnerability were distributed evenly throughout the population of a region, so that the change in relative risk of health impacts was proportional to per capita change in risk of experiencing such an extreme event. Changes in the frequency of coastal floods were defined using published models that estimate change in sea level for various climate scenarios. These changes were applied to topographical and population distribution maps to estimate the regional change in incidence of exposure to flooding. The regional changes were summed to estimate potential worldwide impacts. The model did not account for changes in the frequency of storm surges.

From the model, it was estimated that the impact of climate change on flooding in 2000 amounted to192,000 disability-adjusted life years, with the Eastern Mediterranean, Latin American and Caribbean, and the Western Pacific regions suffering the largest burdens of flood-related disease (Campbell-Lendrum et al. 2003). Potentially large changes in flood-related mortality were estimated under various climate change scenarios. Subgroups vulnerable to adverse health effects of floods include the elderly, those with prior health problems, the poor, and those with dependents (especially children) (Hajat et al. 2003).

Thus, floods and other extreme weather events should be considered multiple stressors that include the event itself, the disruptions and problems of the recovery period, and the worries or anxieties about the risk of recurrence of the event (Penning-Rowsell and Tapsell 2004). The perceived risk of recurrence can include a perceived failure on the part of relevant authorities to alleviate risk or provide adequate warnings. These sources of stress and anxiety, along with pre-existing health conditions, can have significant impacts on the overall health and well-being of flood victims. Medical authorities, social services departments, insurance companies, and other organizations need to provide better post-event social care for people affected by extreme weather events.

The population at risk, policy-makers, and emergency workers may undertake activities to reduce health risks before, during, and after a flood event. Traditionally, the fields of engineering and urban planning aim to reduce the harmful effects of flooding by limiting the impact of a flood on human health and economic infrastructure. Mitigation measures may reduce, but not eliminate, major damage. Early warning of flood risk and appropriate citizen response has been shown to be effective in reducing disaster-related deaths (Noji 2000). From a public health point of view, planning for floods during the inter-flood phase aims at enabling communities to respond effectively to the health consequences of floods and allows the local and central authorities to organize and effectively coordinate relief activities, including making the best use of local resources and properly managing national and international relief assistance. In addition, medium to long-term interventions may be needed to support populations affected by flooding.

Main Messages

Human culture is strongly influenced by ecosystems, and ecosystem change can have a significant impact on cultural identity and social stability. Human cultures, knowledge systems, religions, heritage values, social interactions, and the linked amenity services (such as aesthetic enjoyment, recreation, artistic and spiritual fulfillment, and intellectual development) have always been influenced and shaped by the nature of the ecosystem and ecosystem conditions in which culture is based. At the same time, humankind has always influenced and shaped its environment. Rapid loss of culturally valued ecosystems and landscapes lead to social disruptions and societal marginalization, now occurring in many parts of the world.

To achieve conservation and sustainable use of ecosystems, ''traditional'' and "formal" knowledge systems need to be linked. There is an emerging need and opportunity for building bridges between these two systems to improve the quality of human life. The complex relationships that exist between ecological systems and cultural systems can be understood only by linking our formal knowledge system, based on a hypothetical-deductive approach and inductive reasoning to understand ecosystems, with the traditional knowledge system, derived from societal experiences and perceptions. Our understanding of the tangible benefits derived from traditional ecological knowledge, such as medicinal plants and local species of food, is relatively well developed. However, our knowledge of the linkages between ecological processes and social processes, and their tangible and intangible benefits (such as spiritual and religious values), and of the influence on sustainable natural resource management at the landscape level needs to be strengthened.

Loss of traditional knowledge systems has many direct and indirect effects on ecosystems and human welfare. The loss of traditional knowledge has a direct effect on the depletion of fauna and flora and the degradation of the habitats and ecosystems generally. Traditional is knowledge is largely oral, and there is significant loss every time an old person dies without leaving a record of what they know. Equally significant is the loss of languages—the vehicles by which cultures are communicated and reproduced. It is estimated that more than 5,000 linguistic groups contain the traditional knowledge of humankind, many of which may disappear by 2020. TK is a key element of sustainable development, particularly in relation to plant medicine and agriculture, which may offer solutions and cures to pandemics such as AIDS and cancer as well as to many other health problems that are emerging with globalization.

The importance of cultural services and values is not currently recognized in landscape planning and management. These fields could benefit from a better understanding of the way in which societies manipulate ecosystems and then relate that to cultural, spiritual, and religious belief systems. This realization is reflected in the emphasis placed by many international organizations, such as UNEP, UNESCO, FAO, IUCN, and WWF, in recognizing "cultural landscapes," "cultural agro-ecosystems," World Heritage Sites, and Biosphere Reserves. The so-called ecosystem approach implicitly recognizes the importance of a socioecological system approach, and policy formulations should empower local people to participate in managing natural resources as part of a cultural landscape, integrating local knowledge and institutions.

In planning and managing ecosystems, a balance must be found between cultural and amenity services. Due to changing cultural values and perceptions, there is an increasing tendency to create landscapes with high amenity values (for aesthetic and recreational use, for example) at the expense of traditional landscapes with high cultural and spiritual values. The remaining traditional landscapes require urgent protection in order to create diversified landscape systems that contribute to strengthening buffering mechanisms and that reduce the vulnerability of ecosystems and human society to environmental change.

Better information is needed on the economic importance of cultural and amenity services. Many cultural and amenity services are not only of direct and indirect importance to human well-being (in terms of improved physical and mental health and well-being), they also represent a considerable economic resource; for example, tourism generates approximately 11% of global GDP and employs over 200 million people. Approximately 30% of these revenues are related to cultural and nature-based tourism. In planning ecosystem use or conversion, these values have not been fully taken into account in the analysis of trade-offs. The costs of the loss of ecosystem services and the benefits of their continued availability should be shared more equitably among all stakeholders.

17.1 Introduction

17.1.1 Nature of the Service

Human cultures have always been influenced and shaped by the nature of the ecosystem (e.g., Ramakrishnan 1998). At the same time, humankind has always influenced and shaped its environment to enhance the availability of certain valued services. While there are specific cultural ''services'' that ecosystems provide (such as aesthetic enjoyment, recreation, spiritual fulfillment, and intellectual development), it is quite artificial to separate these services or their combined influence on human well-being. For example, a jogger in Central Park in New York City obtains a recreational benefit from that ecosystem through aesthetic enjoyment and physical exercise while simultaneously perhaps gaining spiritual benefits from watching a swan land in the lake. Similarly, a farmer in India may have a strong spiritual and religious connection to the local ecosystem and actively protect sanctuaries of forests. As a result, sophisticated health care systems associated with traditional knowledge of herbs often maintained in these forests may develop, and the cultural identity of the local society is maintained through close association with that local ecosystem.

Recognizing that different types of spiritual, intellectual, and physical links between human cultures and ecosystems are inseparable, this chapter seeks to explore the dimensions of the human-ecosystem relationship for the main types of cultural and amenity services provided by ecosystems and landscapes. Based on various literature sources (e.g., De Groot 1992; De Groot et al. 2002; Ramakrishnan et al. 2002; Van Droste et al. 1999) the following six categories have been distinguished:

- cultural identity (that is, the current cultural linkage between humans and their environment;
- heritage values (''memories'' in the landscape from past cultural ties);
- spiritual services (sacred, religious, or other forms of spiritual inspiration derived from ecosystems);
- inspiration (the use of natural motives or artifacts in arts, folklore, and so on);
- aesthetic appreciation of natural and cultivated landscapes; and
- recreation and tourism.

Although cultural services are one of the four main service categories identified by the Millennium Ecosystem Assessment, they cannot be treated independently: cultural and amenity services depend especially on supporting and regulating services; at the same time, the expression of cultural services influences the way ecosystems are viewed in terms of their other services (for instance, fish have a food value but may also have a spiritual value, and fishing may be a traditional way of life).

Throughout this chapter, care has been taken to give a balanced representation of the main ''worldviews'' regarding human-nature relationships, ranging from those of the more traditional and indigenous societies to those of highly industrialized ones. There are striking differences in the way cultural and amenity services are perceived, experienced, and valued by different cultures, which can often be related to differences in the ecosystem conditions in which they originated and the way societies have changed ecosystem conditions and evolved with their environment. The dynamic nature of human-environment interactions leads to continuous changes in the perception and appreciation of cultural and amenity services and greatly contributes to cultural diversification.

17.1.2 Key Questions and Cross-cutting Issues

This chapter addresses how ecosystem changes affect cultural and amenity services and thereby human well-being. For each cultural service considered, three main issues are addressed: current status and dependence on ecosystem condition; observed changes in the availability of ecosystem services, causes for change, and future trends; and the effects on human well-being of changes in the availability of ecosystem services.

Thus for each service, a brief overview is given of its nature, its magnitude and distribution, and its dependence on ecosystem condition, illustrated by means of quantitative data where available on the ecosystem properties providing the service (such as landscape and biodiversity features) and with reference to the systems chapters in this volume (Chapters 18–27). It should be noted that the availability of cultural and amenity services is partly determined by the physical and biotic environment (such as the presence of landscape features with scenic, inspirational, or sacred values), and partly by culture. Thus similar environmental features (species, forests, soil, waterfalls, and so on) will be valued differently by different societies, depending on the cultural background and the way societies have shaped their environment during the course of their development.

In addition, changes in ecosystems in the recent past (since about 1960) and how these have influenced the capacity to provide cultural and amenity services (either positively or negatively) are described, along with predicted trends for the next 10 years. The direct causes for these changes will be briefly described, with reference to the proximate drivers or indirect causes described in Chapter 3.

The importance of a service to human well-being can be described by many different indicators (improved physical and psychological health, for instance, or income). (See Chapter 5.) Where available, examples are given of the economic importance of cultural and amenity services, including monetary data (with reference to Chapter 2, regarding methods and tools for economic valuation of ecosystem services). The consequences of changes in cultural and amenity services for human welfare are discussed near the end of the chapter.

17.1.3 Knowledge Systems

Cultural and amenity services are entirely determined by human perceptions of their environment. Human perceptions, in turn, are the product of the knowledge system of which the individual or community is a part. All knowledge systems, whether ''traditional'' or ''formal'' (or however labeled), reflect the history of ideas as much as some objective body of ''facts.'' (The neutral term traditional is used here; other equivalent terms are local or indigenous, which tend to be much more location-specific. In contrast, ''formal'' knowledge is often referred to as ''scientific.'' One challenge is to validate the former and integrate it into the latter, to the extent possible.) Fundamental is the social context in which the traditional knowledge system of thousands of cultures has evolved. (See Box 17.1.) Important in this social construction is the idea of key paradigms (or mythologies), which even if not scientifically tested in the sense of being based on experiment and verification, are logical and provide insight in understanding how systems, including ecosystems, function (Berger and Luckmann 1966).

While formal knowledge in ecology has largely been a prerogative of natural scientists, analyzing natural phenomena through hypothetico-deductive methods and inductive reasoning, traditional knowledge evolves locally in different communities through an experiential approach, with differences in the way each creates knowledge. Except for some instances involving direct economic values, such as non-timber forest products that may have food, fiber, or medicinal value, the origin and meaning of this knowledge has not been properly documented (Berkes 1999), and there is significant loss every time an old (knowledgeable) person dies without leaving a record of knowledge and experience.

The loss of traditional knowledge has a direct effect on the depletion of fauna and flora and the degradation of the habitats and ecosystems generally. For example, in the transmigration program in Indonesia the traditional knowledge of the transmigrant is of no value under the changed ecological situation, leading to adoption of wrong technologies and ending up in land degradation (Whitten et al. 1987).

Equally significant is the loss of languages, which are the main vehicles by which cultures are communicated and reproduced (in addition to the reflection of human-nature relationships in dance, other art forms, rituals, and architecture, such as in Stonehenge and the Pyramids). It is estimated that there are more than 5,000 indigenous linguistic groups, representing over 350 million people, which contain most of humankind's traditional knowledge. Many of these linguistic groups may disappear by 2020 (United Nations 2004), which is an important obstacle to finding pathways for more sustainable ecosystem management (Berkes et al. 2000). It is also true that much of the traditional knowledge that existed in Europe (such as knowledge on medicinal plants) has gradually eroded due to rapid industrialization during the past century (Hughes 1998).

17.2 Distribution, Magnitude, and Trends in Cultural and Amenity Services

17.2.1 Cultural Identity

Throughout human evolution, human societies have developed in close interaction with the natural environment, which has shaped their cultural identity, value systems (Balee 1989), and economic well-being. However, since the human-nature relationship is influenced by factors such as ownership, ethics, religion, and so on (Hanna and Jentoft 1996), it varies widely across cultures, evolving in both space and time. For instance, for many traditional forest dwellers in the tropics, shifting agriculture is a way of life; for those living in the savanna grasslands of tropical Africa, nomadic pastoralism is a major activity (with limited shifting agriculture), while others living under more extreme climatic conditions, such as the peoples of the Tibetan and central Asian highlands, tend to be nomadic pastoralists and those living in coastal areas and the Arctic regions tend to be depend on fishing. This variety of lifestyles and livelihoods, which are ''dictated'' by

BOX 17.1

Traditional Knowledge Systems

Many traditional societies (including indigenous and tribal) with extended association with nature and natural resources have accumulated empirical knowledge about the natural resources around them, especially food and medicines (National Academy of Sciences 1975; Berlin 1992; Hladik et al. 1993). Many such societies also have accumulated traditional wisdom based on the intrinsic realization that humans and nature form part of an indivisible whole and therefore should live in partnership with each other. This ecocentric view is widely reflected in their reverential attitudes toward plants, animals, rivers, and Earth, often concretized in iconography and imagery of the sculptural forms, a way of transmitting the timeless truths of human-nature ethics (Vatsayan 1993).

Traditional ecological knowledge, although it may have a strong element of the "formal," stands apart in that it is largely derived through societal experiences and perceptions accumulated through a process of trial and error during interactions with nature and natural resources. This implies that while "formal" emphasizes universality of the knowledge created by the given methodology, TEK has a certain degree of location-specificity, but with a strong human element that emphasizes social emancipation (Elzinga 1996). Traditional knowledge enables society to relate to a value system that they understand and appreciate and therefore participate in the process of the quality of life they cherish.

The dichotomy between the universality of formal knowledge and the location-specific nature of TEK hides two distinct elements: the difference between scientific knowledge and common sense (which concerns all societies) and the difference between cultural patterns of thought embedded in the formal knowledge and non-western approaches of the natural and social world. It should be added, however, that below the considerable location-specific diversity, TEK often has undeniable universal characteristics.

In any case, we need to move beyond this perceptional divergence and arrive at generalizations across locations, after validation from an eco-science perspective where required, in order to integrate the two knowledge systems and use them for ecosystem management. For example, traditional systems of medicine such as Ayurveda, which is well developed throughout India, are now getting linked with cultural tourism in this part of the world, which is tending to be of global value. This is in addition to hundreds of ethnic medical practices spread across the world. Similarly, a whole variety of lesser-known plants of food value have not been integrated into our food production systems (National Academy of Sciences 1975).

different ecosystem conditions, led to different knowledge systems and to cultural diversification.

17.2.1.1 Current Status and Dependence on Ecosystem Condition

Language, knowledge, and the environment have been intimately related throughout human history. Local and indigenous languages are the repositories of traditional knowledge about the environment and its systems, its management, and its conservation, which in the contemporary context needs analysis and validation. (See Figure 17.1.) (Ramakrishnan 2001; Ramakrishnan et al. 2004).

Approximately two thirds of the world's languages are linked to forest-dwellers; indeed, almost 50% of all languages are spoken in tropical/sub-tropical moist broad-leaved forest biomes (see www.terralingua.org). Furthermore, nearly 24% of all languages are spoken in tropical and sub-tropical grassland, savanna, and shrubland biomes. But just as with species, the world is now undergoing a massive extinction crisis of languages and cultures. At present, the greatest losses are occurring in high-risk situations, such as where languages are not officially recognized and people are marginalized by rapid industrialization, globalization, depopulation, poor health, low literacy, or considerable ecosystem degradation. Especially threatened are the languages of indigenous peoples, who number 350 million, representing over 5,000 linguistic groups in 70 countries, according to a special UNESCO meeting in New York in May 2004 (see www.unesco.org/culture/indigenous).

External forces, especially national and international development policies, are dispossessing traditional peoples of their land, resources, and lifestyles, forcing them to subsist in highly degraded environments. People who lose their linguistic and cultural identity may lose an essential element in a social process that commonly teaches respect for nature and understanding of the natural environment (Ramakrishnan et al. 1998). Many traditional societies view culture and environment as complementary, and efforts aimed at maintaining cultural identity also often promote environmental conservation (Stevens 1997). The concept of "cultural landscapes" (described in the following section) is an example of traditional societies co-evolving with their environment. (See Box 17.2.)

17.2.1.2 Observed Change, Causes of Change, and Future Trends

Human societies are not immune to changes in their environment. The continuing overconsumption of natural resources is resulting in erosion of time-tested and value-based institutions in many societies. Among the most powerful forces that influence both local cultures and ecosystems are various government policies and the expansion of national, regional, and international markets that stimulate privatization of land and aim to "fix" populations in a particular space, leading to a loss of traditional lifestyles (as with pastoralists and nomadic peoples).

For example, central government policies in Somalia in the 1970s and 1980s sought to "settle" semi-nomadic groups so they could be better "controlled" and provide taxes to government. Another example is government policies that are driven by international market forces determining coffee prices, which in the Western Ghat region in southern India resulted in the extension of coffee plantations into dried zones that are ecologically unsuitable for production, leading eventually to abandonment of the plantations and forest degradation (Ramakrishnan et al. 2002).

The rapid decline in traditional value systems and changing values among the younger generation are linked phenomena that are widespread. Human societies, traditional or otherwise, always tend to perceive the landscape around them as a carved-out cultural landscape. Indeed, now there is a renewed interest even about urban landscapes that could be made self-sustaining to the extent possible through urban agriculture (sometimes referred to as "urbaculture"), a variety of city-based gardens, "bioshelters," green corridors or greenways, and so on (Burel and Baudry 2003).

In the mountain regions of both the developing and the industrial world, there is an increasing realization that the lost cultural landscape should be conserved where they exist or redeveloped where they are already lost (Ramakrishnan et al. 2003; Maurer and Holl 2003). Particularly in the developing-

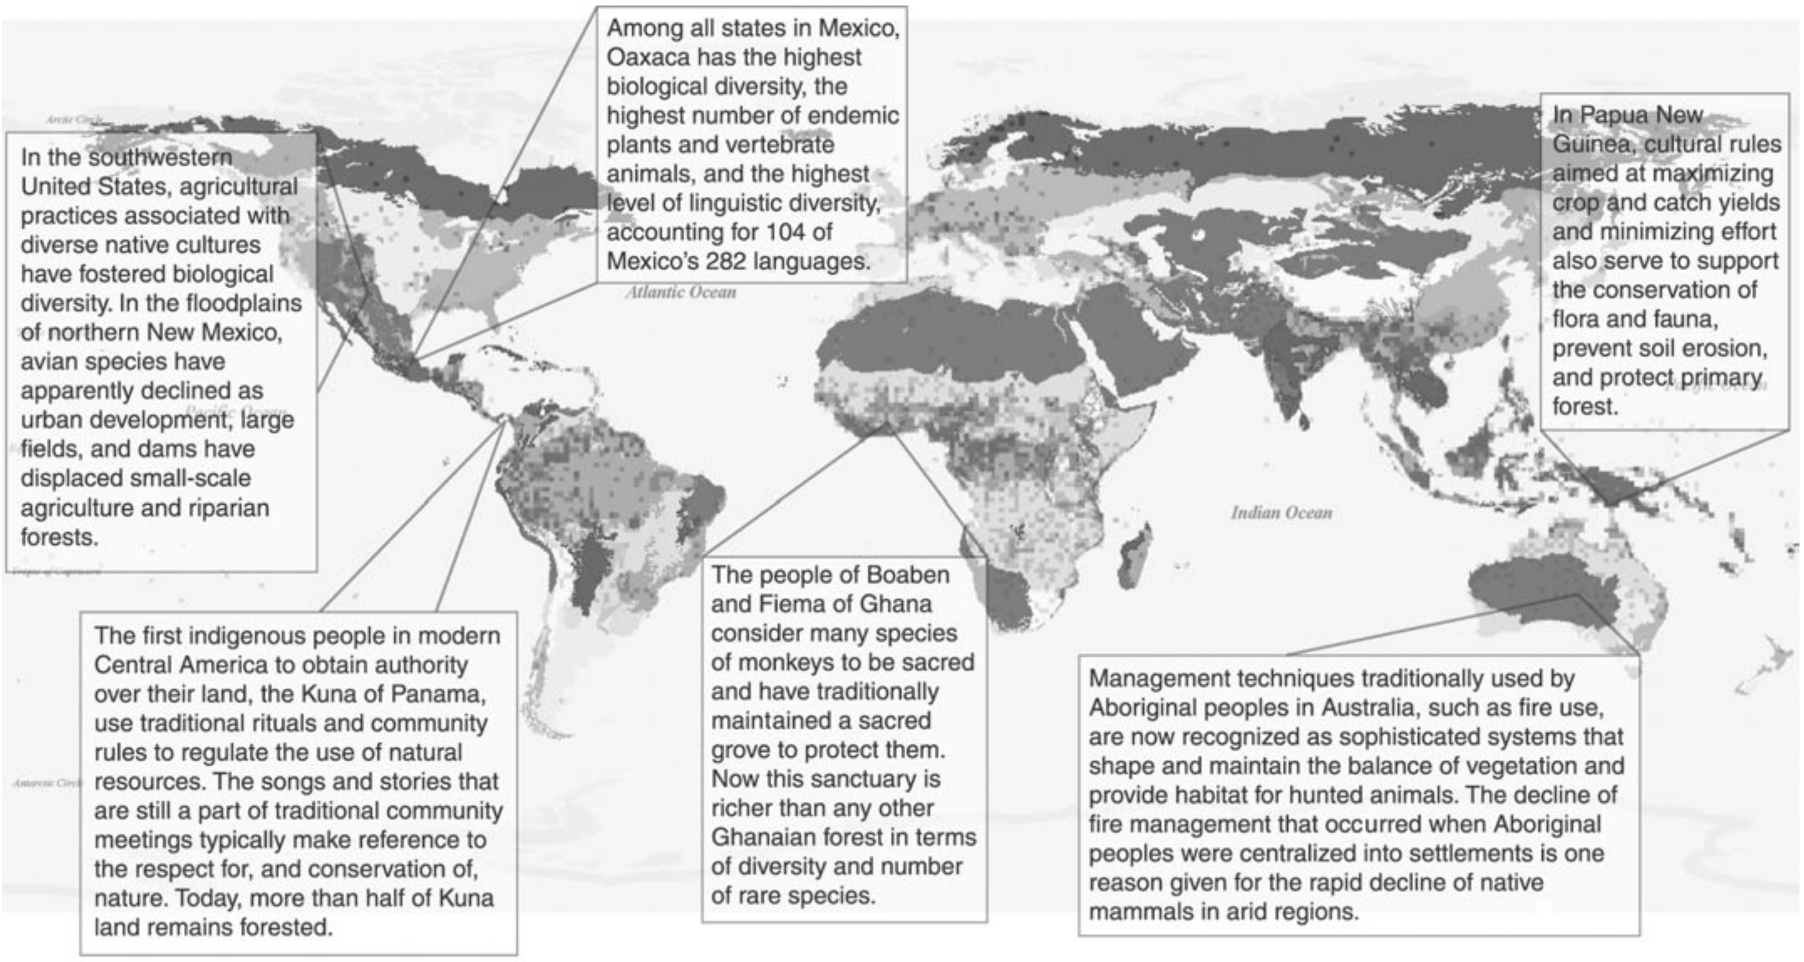

Figure 17.1. Links between Language, Culture, and the Natural Environment: Some Examples (Map produced by Terralingua in partnership with the Conservation Biology Institute; data on the world's languages made available by SIL International; www.terralingua.org)

BOX 17.2

Some Examples of Evolving Human–Nature Relationships

- To Naskapi Indians of Labrador, ownership means shared identity (Henriksen 1986). With deep respect for the harsh environment in which they live, the dependence on nature and natural resources is reflected in the ethnobiological knowledge they possess.
- For others, like the Bushman of Australia, this linkage is reflected in the ritual acts used to kill animals (Campbell 1996).
- For the Lake Racken fishing community concerned with crayfish management, the way in which the formal knowledge system is contextualized with traditional knowledge represents a recent adaptation to combat acidification problems in the lake (Olsson and Folke 2001).
- Combining traditional knowledge with the formal in a complementary fashion, the livelihood needs of the Inuit and Cree communities in the Hudson Bay area of Canada were harmonized in the context of the impact of hydroelectric dams, for effective co-management of natural resources in the area (Fenge 1997).
- In the Great Fish River Valley in South Africa, local Xhosa people place great cultural and utilitarian value on key resource patches such as mountains, forests in various stages of succession, and a variety of grazing lands. In many cases the diversity of resource patches is the consequence of people interacting with the land, where, through a variety of induced disturbances, these resource patches are created. The different types of resource patches provide different kinds of resources, thus satisfying villagers' basic needs. These include both practical, physical needs as well as cultural and spiritual needs (see MA *Multiscale Assessments,* South Africa).

country context, where rural poor abound, the developmental paradigm based on high-energy input monoculture of crops is increasingly debated (Ramakrishnan 2001). Thus, for instance, are we satisfied with having patches of protected biodiversity in the form of nature reserves, placed as islands in a vast ocean of monocultures, or are we looking for more heterogeneity in our landscapes, so that biodiversity is not merely restricted to nature reserves? The latter approach will provide greater resilience to the biosphere by strengthening the internal buffering mechanisms against uncertainties in the environment (see, e.g., Holling 1995).

17.2.1.3 Consequences of Change for Human Well-being

The observed estrangement of people from their land and traditional way of life leads to overexploitation and degradation of ecosystems, which in turn leads to poverty and loss of cultural identity. (For a more in-depth discussion, see Rutten 1992.) Unless ecosystem management is firmly rooted in the local cultural ethos, it can affect the livelihood concerns of large numbers of people, particularly marginalized societies in the developing world, causing social disruptions and ecological degradation. There is an increasing danger of culture-specific land use systems being gradually wiped out, without any viable alternatives in place. If this trend continues, apart from ecological catastrophes, large-scale social disruptions could occur, as is already evident among many traditional societies (United Nations 2004).

For a new perspective to emerge, and to ensure that human well-being and cultural identity remain linked to ecosystem services, there needs to be a reconciliation between ecology, economics, and ethics. The challenge, therefore, lies in learning lessons from the past and in developing an adaptive management strategy that is economically sound and specific to the socioecological system in question.

17.2.2 Cultural Heritage

A large part of our cultural heritage is associated with ecosystems and landscapes with special features that remind us of our historic roots, both collectively and individually (such as special, usually old trees, the remains of traditional cultivation systems, or historic artifacts). These ecosystems and landscape elements give us a sense of continuity and understanding of our place in our natural and cultural environment and are increasingly valued as expressed by the designation of cultural landscapes and sites with special historic interest.

17.2.2.1 Current Status and Dependence on Ecosystem Condition

Cultural landscapes are complex socioeconomic expressions of (mainly) terrestrial ecosystems that have co-evolved under the influence of biophysical factors (such as climate, relief, soil type, water availability, and so on) as well as of human societies at different levels of their cultural, social, and technological development. In many places in the world, long-standing traditions in agri-, silvi-, viti-, and aqua-cultural ecosystem management have contributed to the development of a wide range of productive and characteristic landscapes on cultivated systems. (See also Chapter 26.)

Often this ecosystem management is based on traditional ecological knowledge, sociocultural practices, or religious beliefs, and human perception therefore has a strong influence on defining landscapes. This is echoed by Ellis et al. (2000), whose hierarchical landscape classification system builds upon ecotopes that are defined as ''the smallest homogeneous ecosystem units within landscapes.'' Thus, both natural and cultural features are taken into account when proposing the following definition: ''Cultural landscapes are spatially defined units whose character and functions are defined by the complex and region-specific interaction of natural processes with human activities that are driven by economic, social and environmental forces and values'' (Wascher 2004)

Hence, sustainable cultural landscapes should offer both high heritage values and (relatively) stable ecosystem functions. Ideally, these objectives should be reached on the basis of efficient resource management (wise use), seeking synergy between ecosystem processes and cultural interferences (the latter including economic interests). Table 17.1 illustrates the linkages between cultural landscapes and associated ecosystem functions.

Table 17.1 and several examples illustrate the large variety among cultural landscapes and heritage services in terms of scale and character. In the Netherlands, the historic *slagen* (long stretched land parcels) landscape *Krimpenerwaard* is a specific type of *polder* landscape situated in the ''Green Heart'' of the country. The Green Heart–*polder* is located between Amsterdam, Rotterdam, and the Hague and is a land reclamation system based on a systematic drainage process that determines the characteristic structural and functional landscape patterns of the area. Its characteristic features include long and narrow access roads; straight, parallel drainage ditches in regular sequences linking up with naturally meandering water courses in right-angle patterns; land segregations; blind alleys; and numerous parallel ditches.

In Portugal and Spain, *montado* and *dehesa* landscapes consist of open evergreen forests of cork and holm oaks *Quercus* spp., or open oak savanna, with tree densities ranging from 20 to 60 trees per hectare in an irregular pattern, with relatively open understory or partially closed by shrub encroachment. Despite its use for cork production and multi-functionality with regard to other agricultural management regimes (such as grazing and small-scale cropland), the *montado* and *dehesa* landscapes are also valued for their biological diversity, heterogeneity, and cultural interest due to their strong identity and recreation potential (Ferreira et al. 2003).

Many cultural landscapes, such as the River Ganges and parts of the Himalayas, are defined by their religious significance and are of great importance to a large portion of the world's population, as described later in this chapter.

Thus it is clear that maintenance of cultural heritage is an important service of especially semi-natural and cultivated ecosystems and landscapes. Many European countries have therefore developed specific policies and legislation for the conservation of cultural landscapes, and many private organizations are engaged in their care. In the United Kingdom, for instance, the National Trust owns or manages 200 historic houses, 230 gardens, and 25 industrial monuments plus 240,000 hectares of beautiful countryside and 550 miles of coast. At the global level, initiatives have also emerged to conserve landscapes directly—through, for example, the World Heritage Convention (UNESCO 1972; Rössler 2000). (See Box 17.3.)

Within the European Union, national agricultural legislation typically set objectives for the protection and restoration of landscapes and to provide public access to these landscapes. In addition to regulations and voluntary agreements, many OECD countries adopt economic incentives for agricultural landscape conservation and restoration (see Table 17.2), such as through area payments and management agreements, which can be interpreted as a rough approximation of the ''willingness to pay'' for the maintenance of cultural and heritage values.

Other initiatives target field-based collaborative management at the local and regional levels, including transboundary regions. For instance, the Collaborative Management Working Group within IUCN's Commission on Environmental, Economic and Social Policy promotes and supports field-based co-management initiatives, draws lessons and methods from experience, and supports the development of participatory mechanisms for the management of natural resources through local capacity building (knowledge, skills, attitudes, and institutions) and the elaboration of national, regional, and global policies. Projects address a number of topical areas such as the co-management of protected areas and agricultural landscapes and the involvement of local communities in ecosystem conservation, with an emphasis on poor communities in particularly harsh and fragile ecosystems, such as arid lands, mountains, and coastal areas. (See also MA *Policy Responses,* Chapter 14.)

17.2.2.2 Observed Changes, Causes of Change, and Future Trends

In cultural landscapes, ecosystem processes are mainly driven by human land use changes. Because these have taken place over the entire history of human civilization, it is difficult to introduce objective, widely accepted points of reference. Compared with early cultivation history, however, modern forms of land management and reclamation appear to have more erosive effects on the character and processes of traditional cultural landscapes. Dominant trends include decreasing landscape diversity, altered hydrological systems (drainage and irrigation), intensification of land use, and landscape fragmentation, all of which have affected human social structures, ecosystem functions, and heritage values. Even protected sites, including many of those designated under the World Heritage Convention, are at risk of losing their status due to various internal and external pressures. African, Arab, and Asian UNESCO sites appear to be at higher risk than those in Europe or in North and Latin America. (See Figure 17.2.)

Table 17.1. Examples of Cultural Landscapes, by Biome, with Selected Ecosystem Functions

Biome	Cultural Landscapes	Some Examples of Ecosystem Functions	Ecosystem State and Characteristics
Humid tropical	Salina landscape (Densu Delta, Ghana)	habitat for thousands of wetland species 20 communities with fishing being their primary activity million-dollar salt industry	Ramsar wetland: 6,700 hectares tidal influences extend upstream for some 10km heavily populated with urban estate development
Semiarid tropical	Arnhem land/ dreamland (Australia)	revitalization of native flora and fauna through patch fire management preventing disastrous wild fires tourism main income due to attractivity of Kakadu and Litchfield National Parks	eucalypt grassy woodlands and open tropical savannas pastoral or Aboriginal land management major threats are changes in the fire regime, feral carnivores, cattle grazing, and mining
Humid temperate	hedgerow landscapes (e.g., France, United Kingdom, Germany)	protection against soil erosion wood production grassland farming habitat/corridors for native species acting as natural pest control recreation	regionally distinctive types, regarding patterns, plant compostions, materials, and management threats: agricultural intensification and abandonment
Warm Mediterranean	Dehesa (Spain) and Montada (Portugal)	cork is key export business openland pig farming and transhumance (local products) high biodiversity hunting grounds micro-climate	characteristic pattern of evergreen forest in variable densities of native cork oaks threats: extensification and abandonment, fires, irrigation projects, tree diseases
Semiarid boreal	prairie pothole landscape (Canada)	farmland hunting ("duck factory") biodiversity	mosaic of 4 million small wetlands; 51 percent of all North American breeding ducks threats: agricultural activities (pesticides, nutrients)
Warm desert	farm-based wildlife landscapes (Namibia)	wildlife-based rural development biodiversity (including elephant and endangered black rhinoceros) tourism	75 percent of wildlife is found in these landscapes threats: hunting
Cold desert	Ladakh landscape	unique architecture makes use of local materials such as mud, stone, and wood and of indigenous construction techniques (Gupta 2000)	cold high-altitude desert rainshadow region, cut off Himalaya monsoon clouds chemical reactions in rocks carved fantastic ("lunar") landscapes

Four basic driving forces are considered to affect cultural landscapes: polarization of land use (intensification, extension, abandonment of land, and simplification of land use, which in turn is driven by national and international policies that stimulate monocultures and cash crops); policy responses (site protection, agri-environmental measures, planning schemes, and so on); infrastructure, urbanization, tourism, resource extraction, and energy facilities; and climate change and its effects on ecological, land use, and demographic systems.

During recent years there has been increasing public demand for cultural landscape and associated amenity goods and services linked to rising disposable incomes, more leisure time, and other factors. Public and policy-driven shifts toward greater land use diversification, small-scale developments, and more environmentally friendly land management have also occurred. Increasing awareness of these issues, especially in Europe and Japan, favors multifunctional landscapes that provide humans with food and raw materials, drinking water, space for recreation, a sense of identity, and heritage values (Wascher 2000).

17.2.2.3 Consequences of Change for Human Well-being

Cultural landscapes include living societies as an integral part of their landscape units. From a socioecological viewpoint, these interconnections are significant for ensuring a sustainable livelihood for traditional societies, such as the shifting agricultural societies in the tropics (Ramakrishnan 2001) and in many Central and East European countries, and loss of these cultural landscapes can have many social and economic consequences. (See Box 17.4.)

A review of the past 30 years of implementation of the World Heritage Convention reveals a broad interpretation of the heritage concept. The inclusion of cultural landscapes, and in particular those associated with natural elements rather than material cultural evidence (which may be insignificant or even absent), has changed the perception and the practice of the convention. This evolution in the interpretation of the World Heritage Convention represents a growing recognition of the wealth and complexity of numerous values (including intangible ones) associated with protected areas, and in particular with sites of outstanding ecological or cultural value. Experience has shown that an inclusive approach is crucial for the designation and management of World Heritage sites, for the benefit of the people living in and around them, of the conservation community, and of humanity as a whole (Rössler 2000).

17.2.3 Spiritual Services

Most people feel the need to understand their place in the universe, and they search for spiritual connections to their environ-

BOX 17.3

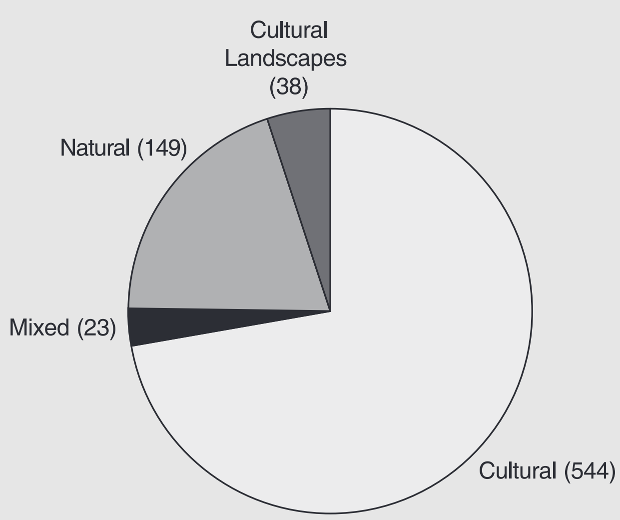
World Heritage Cultural Landscapes

The Convention Concerning the Protection of the World Cultural and Natural Heritage (known as the World Heritage Convention), adopted by the General Conference of UNESCO in 1972, established a unique international instrument that recognizes and protects both the cultural and natural heritage of outstanding universal value (Rössler 2000). The World Heritage Convention's definition of heritage provided an innovative and powerful opportunity for the protection of cultural landscapes as ''works of man or the combined works of nature and man.''

Although there is still debate about the criteria for selecting World Heritage Sites and the type of management imposed on them, the impact of the inclusion of cultural landscapes in the implementation of the World Heritage Convention was considerable in many ways, such as for the recognition of intangible values and of the heritage of local communities and indigenous people; for the importance of protecting biological diversity by maintaining cultural diversity within cultural landscapes; for the management and traditional protection ensuring the conservation of the nominated cultural properties or cultural landscapes; and for the interpretation, presentation, and management of the properties.

Many cultural landscapes have been nominated and inscribed on the World Heritage List since the 1992 landmark decision to include them in the list. (See Figure.) Often they are associative cultural landscapes, which may be physical entities or mental images embedded in a people's spirituality, cultural tradition, and practice.

Distribution of 754 World Heritage properties located in 129 State Parties



World Heritage sites generally are cornerstones in national and international conservation strategies. This far-reaching concept faces new challenges in the future, including:

- creating new institutional networks between international instruments, but also protected area agencies, to fully explore the links between the different categories and protection systems—such a complementary relationship might be formalized through a close link between the World Heritage Convention and other international agreements such as the European Landscape Convention;
- enhancing new partnerships, as recommended by the Venice celebration on 30 years of the World Heritage Convention; and
- enlarging the circle in sharing information about protected area systems and cultural landscapes, in particular on achievements, success stories, and model cases.

One topic to be explored is how World Heritage sites can serve as cornerstones for sustainable local and regional development.

ment both through personal reflection and more organized experiences (as part of religious rules, rituals, and traditional taboos, for example). Ecosystems provide an important measure for this orientation in time and space, which is reflected by spiritual values placed on certain ecosystems (such as ''holy'' forests), species (sacred plants and animals, for instance), and landscape features (such as mountains and waterfalls). (See Box 17.5.)

17.2.3.1 Current Status and Dependence on Ecosystem Condition

The initial impetus among early civilizations and contemporary traditional societies (those living close to nature and natural resources) for biodiversity conservation seems to have arisen out of religious belief systems. The most common element of all religions throughout history has been the inspiration they have drawn from nature (*physis*), leading to a belief in non-physical (usually supernatural) beings (Frazier 1922). The idea of ''unity'' between humans and nature is present in all major religions and influences the management of ecosystems and our attitude toward species. The concept of *Sarvabhutadaya* in Buddhism implies that humans are an integral part of the ecosystem, with a sense of compassion and fellowship—that we give back what we have taken from the biosphere. In the Bible and the Koran, reference is made to the importance of nature as a source of life for humans and their fellow-creatures.

Thus belief systems are a fundamental aspect of people's culture that strongly influences their use of natural resources. The concept of the ''scared grove'' (ecosystem) that traditionally served as an area for religious rituals to appease nature-linked deities (the Wind, Water, Fire, Sun, and so on) as well as a site of worship for ancestral spirits could be viewed as symbolic of the spiritual services derived from nature. Traditional societies all over the world have institutionalized sacred landscapes and ecosystems in a variety of ways, large and small, as part of their belief systems. (See, for example, *Places of Peace and Power* at www.sacredsites.com and *The Sacred Mountains Foundation* at www.sacredmountains.com.) Sacred groves, once strictly protected for cultural and religious reasons, now often remain as islands of biodiversity in an otherwise degraded landscape and are widespread across the globe. (See Box 17.6.)

Perhaps because of their awe-inspiring landscape characteristics, mountains, for instance, have been linked to all major religions in all continents and are sacred to nearly 1 billion people (Wijesuriya 2001; Berbaum 1997). Examples include Mount Kaila (Himalayas), Adams Peak (Sri Lanka), and the Sierra Nevada de Santa Marta (Colombia). There are also sacred or culturally valued species that stand out as a class apart. Sometimes these have restrictions on their usage (see Box 17.7), but in any case such species have implications for management of natural ecosystems with community participation, as described at the end of this chapter.

In addition to the more formalized spiritual ties between humans and nature, there are many other examples of the spiritual importance of ecosystems and species, such as the classic work by Aldo Leopold (1949) on land ethics and the feeling of spiritual enlightenment that many people experience when viewing wildlife (whales, for instance) or ''inspiring'' landscapes.

17.2.3.2 Observed Changes, Causes of Change, and Future Trends

Changes in geographic religious spheres of interest (such as the advent of Christianity in Europe), industrialization and urbanization, and many other social, political, and institutional changes

Table 17.2. Landscape Conservation Schemes and Funding for Selected Countries, 1998. The share of total expenditure on biodiversity, habitats, and landscape as a percentage of the total producer support estimate for 1998 was as follows: Canada: < 1%; Norway: 20%; Poland: < 1%; Switzerland: 4%; and EU: < 1% (the percentage for EU is higher than this, however, as only 9 member states are included in this calculation, while the PSE covers 15 member countries). (OECD 2001)

Scheme	Objective	Area	Share of agricultural area	Funding
		(thousand hectares)	*(percent)*	*(thousand 1998 dollars)*

BOX 17.4

Loss of Ecosystem Functions and Cultural Heritage Values

- Farming in the limestone hills of Southwest Cyprus became economically less rewarding, resulting in the abandonment (shrub growth) and destruction of traditional landscape elements (Dower 2000).
- In *dehesa* landscapes (Spain), the planting of conifers (*Pinus pinaster*) and exotic broad-leaved trees (*Eucalyptus ssp*) brought about the most radical change, entirely replacing major parts of *dehesa* landscapes with large single-species plantations.
- Over the last 30 years, Cinque Terre (Liguria, Italy) is dramatically losing its traditional landscape character: approximately 85% of the terraces built and maintained over 1,000 years have fallen into disrepair and been abandoned (Stovel 2002).

over time (including the education system), spurred by economic development, led to the decline of many traditional belief systems in many parts of the world. This had a large impact on the exploitation of natural resources and the way ecosystems have been managed. The impact of culture-linked change in natural ecosystems is expressed through the rapid changes seen in the perception of societies toward culturally valued ecosystems and landscapes, notably "sacred groves." Destruction of these sacred ecosystems

BOX 17.5

Spiritual Traditions Linked to Nature and Natural Resources

- Pre-Columbian societies in the Americas held the widespread view that Earth and all her creatures are sacred and that therefore permission had to be sought before the resources could be used, or else the spirits of those resources would seek revenge (Hughes 1998).
- For the enlightened sages of the eastern tradition, the forest is a world of wisdom, peace, and spirituality. The term "Aaranya," in the Sanskrit language of antiquity, comes from Aa for "no" and Ranya for "war," meaning a place of nonviolence (Saraswati 1998).
- A strong feeling of human participation in the universal order pervades the Vedas, the ancient scriptures of the Hindu religion, which is an oral tradition of wisdom, at least 5,000 years old (Vannucci 1993).
- The concept of the Cosmic Tree (the Tree of Life) represents the center of the Universe in the eastern culture and is part of many traditional belief systems.
- The cosmologies of American Indians, Australian aboriginals, New Zealand Maori, and many others are intimately connected with the land (Carmichael 1994) and extend to cover all elements of nature such as mountains, rivers, plants, animal, fish, and even human beings (Matunga 1994; Wijesuriya 2001).

BOX 17.6

Sacred Landscapes and Groves around the World (Hughes and Chandran 1988)

- In Africa, possibly the original home of humankind, sacred groves still exist in the sub-Saharan region. For the Kikyus of East Africa, cutting trees, breaking branches, gathering firewood, burning grass, and hunting animals are prohibited from groves that have the sacred Mugumu tree. These are still common in Ghana, Nigeria, Zimbabwe, and South Africa, often under the control of the local tribal leader. In Egypt, it was an ancient practice to have a sacred grove along with a sacred lake. Egyptians conserved many sacred species such as Palm and Persea (*Mimusops laurifolius, M. shcimperi,* called ished in Egyptian).
- Siberians used the groves for the rites of Shamanism. The nomadic Ostyaks and Voguls of the Ob river basin protected them very strictly, considering even eagles alighting in a grove as sacred.
- Chinese, Japanese, and Koreans have many groves linked with Buddhist temples. Shifting agriculture-based hill people of the Yunnan province in China have designated sacred woodlands. Balinese in Indonesia have "monkey forests," which are fragments of the ancient rain forest dedicated to the Hindu monkey God, Hanuman.
- Australian aborigines have groves dedicated to ancestral spirits of the ancient "Dreamtime," when the landscape was shaped. Maoris of New Zealand call the sacred sites Waahi Tapu, which include trees and forests, among many other natural features.
- Europe had thousands of sacred groves in ancient times, such as Mt. Atlas in Greece, with its sacred forests, and the Celts, Slavs, and Germans all worshipped in groves and regarded the Oak as the most divine tree.
- The Maya people cultivated certain trees like Cacao (*Theobroma cacao*) for a valuable drink for Mayan priests and royalty, and its seeds were widely used as currency in Mesoamerica. Tribes such as the Ojibwas and Utes reserved certain sections of the forest where hunting was prohibited, except when in great need.

(for timber, for instance, or through warfare) started in the fifth century BC during the Persian invasion in Greece. And with the advent of Christianity, most of the sacred groves and sacred sites in Mediterranean Europe were eliminated, being considered "pagan" (Hughes and Chandran 1988). Similarly, in the northeastern hill area of India, only a few scattered sacred groves now remain where formerly each Khasi village had its own (Ramakrishnan 1992).

In more recent times, there has been a growing interest in protecting the value systems of indigenous communities through initiatives such as natural heritage and cultural heritage conservation, human rights, and so on—as in *Akwé: Kon Voluntary Guidelines for the Conduct of Cultural, Environmental and Social Impact Assessments Regarding Developments Proposed to Take Place on, or which are Likely to Impact on, Sacred Sites and on Lands and Waters Traditionally Occupied or Used by Indigenous and Local Communities* from the Secretariat of the Convention on Biological Diversity and in the IUCN working group on Cultural Values of Protected Areas. (See Box 17.8.)

17.2.3.3 Consequences of Change for Human Well-being

The world is passing through an "emerging systems" view of life, mind, and consciousness and human evolution, which could have profound consequences for our social and political structures (Capra 1982). On a spiritual dimension, slow gradual changes in value systems and cultural values have already started happening. The traditional wisdom, embedded in the concept of sacred species, ecosystems, and landscapes and its revival in the contemporary context of biodiversity conservation (such as World Heritage Sites) is worth noting. Rather than taking a merely mechanistic view of Earth processes, where humans are continually struggling for unlimited material progress through economic growth mediated by technological innovations, a greater appreciation of interconnections between ecological and social systems is emerging.

17.2.4 Inspirational Services

Natural and cultivated systems inspire an almost unlimited array of cultural and artistic expressions, including books, magazines, film, photography, paintings, sculptures, folklore, music and dance, national symbols, fashion, and even architecture and advertisement. Consciously or subconsciously, representations of natural (and cultivated) ecosystems in art, writings, and so on remind us of our ties with nature (and our cultural heritage) and shape our views and appreciation of the represented ecosystems and species.

17.2.4.1 Current Status and Dependence on Ecosystem Condition

Five main types of inspirational services are distinguished and briefly described here: verbal art and writings inspired by nature, the performing arts, fine arts, design and fashion, and the media in general.

Many literary and oratory works use nature as a source of inspiration. Poet-naturalist Henry David Thoreau spent a year living in a simple cabin at Walden Pond in Concord, Massachusetts, in 1845, which resulted in *Walden,* his eulogy on nature and its spiritual dimension—long considered a classic of the genre. Naturalist John Muir believed that "wilderness mirrors divinity, nourishes humanity, and vivifies the spirit," while Ralph Waldo Emerson, in his first essay "Nature," published in 1836, claimed that spirit is present behind and throughout nature (Enger and Smith 1995). Since then, many writers have had a strong inspirational impact, such as Aldo Leopold's *A Sand County Almanac*

BOX 17.7
Sacred Species (Ramakrishnan et al. 1998)

- The Bodhi (Pipal tree; *Bot. Ficus religiosa*) is sacred to Buddhists. The tree that provided shelter for the Buddha to attain enlightenment is in Bodhgaya in India (recently declared as a World Heritage Site). Its sapling was sent to Sri Lanka in the third century BC and is still surviving, thus qualifying as the oldest recorded tree. It is one of the most sacred places of the Buddhists in Sri Lanka, and the Na tree (National Tree) is sacred as it is extensively used for temple building and supports associated bird diversity.
- The Sacred Lotus (*Nelumbo nucifera Gaertn*), an icon of Buddhism (associated with Buddhist heaven) and Hinduism (also associated with the energy centre of the human body) and the national symbol of India, is revered for its sanctity, for its multipurpose medicinal properties, and for numerous uses of the whole plant, all over Asia.
- Prevalent in the Mediterranean region, the sacred value is attached to species like oak, olive, apple, and may even extend right up to the Central Himalayan region, where oaks (*Quercus spp*) are culturally valued keystone species in an ecological sense, acting as a trigger for ecosystem/landscape rehabilitation.
- *Ocimum sanctum* (locally known as Tulsi) is an important multipurpose medicinal plant, which is not only worshipped as a Goddess incarnate but also put on an elevated platform in the entrance to Hindu homes.

BOX 17.8
Global Concern for Protecting Biodiversity-linked Spiritual Values

The ILO Convention on Indigenous and Tribal Peoples, 1989, though signed by only 14 state parties, suggests the need to uphold indigenous and tribal peoples' right to recognition and retention of customary law and practices, with special reference to control over land and resources, with many more new initiatives.

The World Heritage Convention in 1972 recognized that culture and nature are complementary and started listing both natural and cultural products of "outstanding universal values" and developed the concept of the cultural landscape, thus recognizing the spiritual links maintained with nature by different cultures. Other conventions, declarations, and initiatives in this direction are the UNESCO Man and the Biosphere program, the International Decade of the World's Indigenous People, The World Conference on Science for the Twenty-First Century, the UNESCO Recommendation on the Safeguarding of Traditional Culture and Folklore, and Agenda 21. The most comprehensive document on this aspect is the United Nations Draft Declaration on the Rights of Indigenous Peoples, which was drafted for approval in 2004.

This trend of changing attitudes toward recognizing the culture-nature link is complemented in the area of cultural heritage conservation as well. Over the last three decades, increasing interest in indigenous cultures brought major changes in recognizing intangible values. The concept of cultural landscape now encompasses all items, both natural and human-created artifacts, such as historical and religious monuments, as items of intangible value (Wijesuriya 2001), with many national governments adopting legislation to protect interests of traditional societies—such as the Native American Graves Protection and Repatriation Act in the United States in 1990, the Archaeological Resources Protection Act in the United States in 1979, the Historical Place Trust Act of New Zealand, and the Burra Charter of Australia.

(1949) on land ethics, *Silent Spring* by Rachel Carson (1962), and the poem by Samuel Taylor Coleridge entitled "To Nature" (Farrel 1992).

The performing arts—dance, song, drama, theatre, and so on—have entertained and delighted people for thousands of years. For example, Indian classical art forms seek to uplift the human spirit to a higher level of awareness, an awareness that is both inward as well as outward. This is expressed by a verse from the Sanskrit work *Abhinaya Dharpana* that signals a student's initiation into the world's oldest existing dance forms, *Bharathanatyam,* a classical dance style predominant in South India. About 66% of the 500 hand gestures in Bharathanatyam relate to ecosystems. Wetlands and water have also inspired music, such as "Swan Lake" from Tchaikovsky and the "Water Music Suite" from Handel. (See also Figure 17.3.)

Dance can be a powerful medium to address environmental and development issues. For instance, dance was one of the prime movers that instilled nationalism among the masses during the freedom movement in India in the 1930s and 1940s. Dance and song through the media of film, photography, and records or CDs can be used to inspire the needed intergenerational movement for conservation of ecosystems. Examples include the "Dance for the Earth and its People" promoted by the IUCN/WCPA Task Force on Cultural and Spiritual Values of Protected Areas.

The fine arts, expressed through crafts, painting, and sculpture, have always made extensive use of ecosystems as a source of inspiration. For instance, Vietnamese stone-crafted turtles and lotus incense holders, block prints narrating the lotus plant's life-history, bamboo grove candle holders, and woven scenes of rice fields on fabric are inspired by the prevailing rice fields, the ponds and lakes, and the bamboo groves and forests of Viet Nam today. And the motifs of baby carrier baskets of a Borneo tribe include tigers, dragons, and human faces that serve to protect the baby and nourish his or her soul to attain the proper social and spiritual level (Heidi Munan of Borneo, personal communication). Examples from the industrial world include the work of the famous French Impressionist painters Claude Monet and Camille Corot in the 1800s, who used landscapes as their source of inspiration (for example, Monet's *Water Lilies* and Corot's *Souvenir de Mortefontaine*).

Designs and fashion have for generations captured the beauty of the natural world and reproduced them onto items of utilitarian use—from crockery to home furnishings and clothing, such as the china of Royal Doulton and Noritake, the daily-worn *molas* of the indigenous Kuna women of Panama, the fabrics of Laura Ashley, and the Kanchivaram saris of India. In the latter case, the artist who sees nature, the weaver who interprets it, and the woman who wears a sari all become one in their wonder of and homage to the beauty of nature. In the industrial world, many industrial and architectural designs and many national symbols—the bald eagle in the United States, for instance—also use nature as an example and source of inspiration.

Radio, films, videos, television, the Internet, photography, and advertising all use nature as a source of inspiration to make programs and sell products. The National Geographic, Discovery, and Animal Planet Channels on television in the United States are examples of this, as is the ARKIVE initiative in the United Kingdom, which attempts to maintain photographs, videos, and sound recordings of species so that they may remain available even if these species become extinct (see www.arkive.org). Over the past 50 years our emotional and economic dependence on this service has grown constantly and we are now "consuming"

Figure 17.3. Bavarian State Ballet Performance in Wetland

this inspirational service of nature through media, often without being aware of it.

17.2.4.2 Observed Changes, Causes of Change, and Future Trends

Urbanization and the increasing influence of the global market economy have strongly influenced the inspirational ties between humans and nature. The continued degradation of cultural landscapes and pristine ecosystems have led to changing perceptions regarding what is considered valuable in terms of providing inspiration to culture and art. Thus, even degraded ecosystems inspire the creation of songs, drama, dance, films, and photography, although they are not only used to show the beauty of, for example, eroded sand dunes but are often used as examples to warn of the dangers of the changes in our environment. The numbers of products of inspirational services depicting ecosystem degradation are potential indicators of the effect changes in these ecosystem services has on human welfare.

On the other hand, positive trends can be observed. For example, since about 2001, eco-textiles of banana and pineapple linen have started to appear in Southeast Asia (at the World Eco-Fiber and Textile Forum 2001 in Kuching, Malaysia, for instance), along with craft products such as handbags, rugs, and cushions made of jute, *mengkuang,* and *pandan* (traditional Malaysian and Southeast Asian natural fibers). And in Panama, there is a growing interest in the *molas* (stitched textile designs produced by the Kuna people).

Consumer and purchasing choices will change through the changed values placed on the various inspirational services, and it is expected that the early years of this century will see a marked increase in the use of natural dyes and cultivated fibers for indigenous crafts and functional items. In many parts of the world, women will play a vital role in the choice and purchase of consumer products, since they are the primary managers of their homes and the primary purchasers of a family's needs.

17.2.4.3 Consequences of Change for Human Well-being

The ability to experience and express inspiration from natural, semi-natural, and cultivated ecosystems is important for the well-being of many, if not all, people. As one writer once put it ''without nature, life would be very dull indeed'' (van Dieren and Wagenaar Hummelink 1979). Determining the consequences of the loss of inspirational services caused by a loss in quality and quantity of valued ecosystems is difficult, however. The gradual change from direct and participative experience of nature (through all senses) to its virtual representation through the media and the impact of this change on human well-being is hard to describe, let alone quantify.

Various measures of the dependence of human society on inspirational services have been suggested. These include the number of people engaged in various art activities, the number of people growing and harvesting the raw material used to create fashion and art, the quality and variety of natural resources used for art activities, the variety and numbers of art pieces created, and the price people are prepared to pay for products based on these services. In principle, these indicators could be used to measure the effect of changes in inspirational services on human health (physical and emotionally) and income caused by ecosystem change.

17.2.5 Aesthetic Services

Natural environments are an important source of aesthetic pleasure for people all over the world. The high aesthetic value of nature is reflected in many areas of human behavior, such as the use of plants and flowers as decorative elements in interiors, the use of computer screensavers depicting natural environments, and the demarcation of ''scenic routes.''

To most people, the fact that nature is beautiful is so obvious and self-evident that they rarely take time to think about it. Likewise, scientists have for a long time neglected this topic because there was no need to prove that nature is beautiful or to explain this phenomenon. Scientific interest in this topic was raised only when it became clear that aesthetic values of nature were being threatened by the ongoing human demand for expansion and that these deserved protection in their own right. In the United States, for example, the National Environmental Policy Act of 1969, which required federal agencies to take into consideration the impacts of large-scale interventions on the natural environment, constituted an important impetus for systematic scientific inquiry into the aesthetic quality of nature.

17.2.5.1 Current Status and Dependence on Ecosystem Condition

Three general findings about aesthetic services are worth noting: people's preference for natural over built environments, people's preference for park-like settings, and the existence of individual differences in preferences for wild versus cultivated landscapes. With a few exceptions (e.g., Chokor and Mene 1992; Yu 1995), nearly all studies have focused on industrial countries, which are the focus therefore of this section. However, as will be noted, one of the most remarkable findings of environmental perception research is the overwhelming similarity in aesthetic preferences between people from different subgroups and with different backgrounds (Kaplan and Kaplan 1989). Thus there is no indication that the assessment presented here would be highly different for developing countries.

A great number of studies in environmental aesthetics have shown that people display, in general, a strong preference for natural over built environments (see reviews by Ulrich 1983; Kaplan and Kaplan 1989; Hartig and Evans 1993). In samples of European and North American adults, for example, photographs of natural scenes consistently receive higher ratings for scenic beauty than photographs of urban scenes do (e.g., Stamps 1996). (See Figure 17.4.) In fact, this preference is so strong that even plain grassland is generally considered equally or more beautiful than any built environment, including pretty townscapes such as the monumental buildings along the river Seine in Paris (Ulrich 1983).

People's preference for natural over built environments can also be inferred from behavioral indicators, such as the higher prices paid for real estate surrounded by trees or adjacent to parks (e.g., Luttik 2000) and the higher number of recreational stays in natural areas. The latter observation is substantiated by the finding that aesthetic pleasure has consistently been found to be one of the most important motivations for outdoor recreation. (See the section on recreation and ecotourism.)

The preference for natural over built environments has been observed across all times and cultures. Even very early urban people apparently took aesthetic pleasure in nature, as is indicated by the gardens of the ancient Egyptian nobility, the walled gardens of Persian settlements in Mesopotamia, and the gardens of merchants in medieval Chinese cities (Ulrich 1993). Consequently, several researchers have proposed that people's preference for nature may be the result of an ancient evolutionary history (Ulrich 1983; Kaplan 1987). In particular, they have suggested that modern humans prefer nature because evolution has made contact with natural environments an innate source of restoration and well-being. The promise of restoration stimulates people to seek out contact with non-threatening natural environments that contain resources and opportunities that are necessary for survival.

In corroboration with this assumption, numerous studies have demonstrated that contact with nature may enhance restoration from stress and increase health and well-being (e.g., Hartig et al. 2003; Ulrich 1983; Ulrich et al. 1991; Van den Berg et al. 2003). For example, Ulrich (1984) has shown that patients who were recovering from gall bladder surgery had shorter postoperative hospital stays and required fewer injections of painkillers when they were given a room with a natural view than when they were in one looking out at a brick wall. Likewise, Hartig and colleagues (2003) have shown that fatigued individuals who walked through natural environments showed more positive changes in mood state, ability to concentrate, and physiological stress levels than fatigued individuals who walked through built environments.

Aesthetic preference for different types of natural environments is strongly dependent on the environment's ecological condition. In general, people prefer natural settings that are healthy, lush, and green. Verdant vegetation is preferred over arid landscapes (Abello and Bernaldez 1986), and forests with sick trees receive much lower preference ratings than healthy forests (Ulrich 1986). These findings are often interpreted as evidence that aesthetic quality is identical to ecological quality. However, it is necessary to distinguish aesthetic values and preferences associated with traditional knowledge systems from those from formal knowledge systems. Although there are some areas in which aesthetic quality and ecological quality may overlap, these two values may diverge strongly in other areas, and aesthetic (traditional knowledge) values need to be considered in their own right and must not be confounded with ecological (formal knowledge) values.

Although people prefer nearly all natural environments to urban environments, this does not mean that they find all natural environments equally beautiful. Certain natural environments are consistently judged as more beautiful than others. Kellert's (1993) review of the environmental perception literature states that European, North American, and Asian populations consistently prefer park-like settings. Most of these studies used rankings of photos or slides. Among the characteristics of park-like settings that people prefer are depth, (half-)openness, uniform grassy coverings, presence of water, absence of threat, and scattering of trees.

Like the general preference for natural over built environments, the preference for park-like natural landscapes has also been explained as a genetic disposition that impels modern humans to seek out the natural settings that, for early humans, were most likely to offer primary necessities of food, water, security, and exploration (Heerwagen and Orians 1993;). Thus it appears that our aesthetic judgments of natural settings are still to a large extent based on implicit assessments of their survival value, even though most of us are no longer directly dependent on nature for our primary supplies.

In addition to the general preference tendencies just described, there are important individual differences in aesthetic preferences for natural landscapes across different times and cul-

Figure 17.4. Preference for Natural over Built Environments. Numerous studies in environmental esthetics have shown that natural environments are generally considered more beautiful than urban environments. This "love for nature," or biophilia, has been explained as an adaptive genetic mechanism that stimulates people to seek out environments that are beneficial for their health. In line with this assumption, experimental studies have demonstrated that contact with natural environments is associated with greater health benefits than contact with urban environments, especially greater and more complete recovery from stress. (Photos from Van den Berg et al. 2003)

tures. For instance, historical analyses have revealed that the appreciation of wilderness in the western world has changed dramatically over the centuries. Until late in the seventeenth century, wild, uncultivated land was generally regarded with indifference and hostility (Nash 1973). But the Romantic Era artists and intellectualists of the eighteenth century began to describe wild places in terms of divinely endowed beauty and order (Thacker 1983), and public perceptions began to change. Since then, more and more people have adopted a positive attitude toward wilderness.

Negative perceptions of wilderness continue to exist in certain groups and cultures, however, even in modern times. Indeed, empirical investigations of modern people's landscape preferences indicate that differences between groups and cultures can nearly always be interpreted in terms of differences in the preferred degree of "wildness" in natural landscapes (Kaplan and Kaplan 1989; Van den Berg 1999). In particular, farmers and low-income groups have been found to prefer managed natural landscapes with a high degree of human influence, while urbanites and high-income groups have been found to prefer wild natural landscapes with a low degree of human influence.

17.2.5.2 Observed Changes, Causes of Change, and Future Trends

The general preference for natural over built environments appears to be relatively stable across different times and cultures. Yet there are reasons to believe that the strength of this preference may vary depending on the degree of stress and mental overload. In particular, Staats et al. (2003) have found that the preference for nature over the city was twice as strong in individuals who were asked to imagine that they suffered from stress and attentional fatigue. These findings suggest that nature becomes more important to people as their levels of stress and mental exhaustion increase.

Urbanization, industrialization, and globalization mean that life is becoming more stressful for people all over the world. Particularly in developing countries, rapid and uncontrolled urban expanse may lead to increased levels of stress and stress-related diseases. These higher levels of stress may result from environmental factors, such as noise and air pollution, but also from social factors, such as unemployment and poverty (World Resources Institute 1996). Thus, it can be expected that people's preference for natural over built environments will become stronger with increasing urbanization. Paradoxically, while the appreciation of nature can be expected to increase with increasing urbanization, the supply of nature and access to natural settings tend to decrease with urban expansion, thereby underlining the importance of green spaces in and near cities.

While the effects of urbanization on the appreciation of nature may apply to all types of nature, regardless of its aesthetic or ecological value, it can also be expected that urbanization will specifically affect the popularity of wilderness settings. As pointed out earlier, preference for wilderness tends to be higher among urban residents. These findings suggest that the popularity of wilderness environments may increase as more and more people start to live in urban areas. At the same time, a lack of recognition of the aesthetic value of wilderness can lead to less value being attributed to wilderness areas in parts of the world where people still live in or near the wilderness. Taken together, these developments may eventually lead to a situation in which the majority of the world population longs for a wilderness that no longer exists.

17.2.5.3 Consequences of Change for Human Well-being

Contact with nature has been related to a large number of health and economic benefits, including decreased levels of stress, mental fatigue, and aggression (restorative effects) (e.g., Hartig et al. 2003); decreased need for health care services and decreased levels of aggression and criminality due to restorative effects of contact with nature (Kuo and Sullivan 2001; Ulrich 1984); increased health due to increased levels of activity stimulated by the presence of attractive nature in the nearby work and living environment (Taylor et al. 1998); increased social integration due to the function of urban natural settings as social meeting places (Kweon et al. 1998); improved motoric development in children who regularly engage in outdoor activities (Fjortoft 1997); increased worker productivity and creativity in offices with plants or views of nature (Lohr et al. 1996); economic benefits for society due to enhanced employability, reduced criminal behavior, and lower substance abuse by disadvantaged youth who participate in wilderness programs (Russel et al. 1998); and increased value of real estate property in natural surroundings (Anderson and Cordell 1988; Luttik 2000).

Most of these benefits apply to all types of nature, including plants, green spaces, and agricultural areas, and are not necessarily dependent on the ecological value of an area. Contact with ecologically valuable nature, such as wilderness areas, may provide the individual with additional benefits, such as increased self-confidence and personal growth, which may be of crucial importance to certain groups, such as youth-at-risk (teenagers from disrupted families, for instance) (Fredrickson and Anderson 1999). However, contact with wilderness may also evoke fears and increase the risk of hazards and diseases (such as Lyme disease or accidents), in particular for people who are unfamiliar with wilderness environments and their potential threats and dangers (Bixler and Floyd 1997).

Based on the benefits just described, it can be expected that a decline in aesthetic services due to a reduction in the availability of and access to natural areas for urban residents may have important detrimental effects on public health, societal processes, and economics.

17.2.6 Recreation and Tourism

Many ecosystems have important value as a place where people can come for rest, relaxation, refreshment, and recreation. Through the aesthetic qualities and almost limitless variety of landscapes, natural and cultural environments provide many opportunities for nature-based recreational activities, such as walking, bird-watching, camping, fishing, swimming, and nature study. With increasing numbers of people, affluence, and leisure time, the demand for recreation in natural areas and cultivated landscapes will most likely continue to increase in the future.

17.2.6.1 Current Status and Dependence on Ecosystem Condition

Travel and tourism have been interrelated throughout human history via ancient roots related to play, ritual, and pilgrimages. Tourism has been referred to as both "a sacred journey and a profane vision quest" (Graburn 1976). Some anthropologists have even suggested that tourism is preeminently a "secular ritual," and that in many contemporary societies it fulfills some of the functions once met by sacred rituals (Graburn 1983). The driving agents of this host-visitor interaction can be recreation and enjoyment, the search for knowledge, religious pilgrimages, and so on. The World Tourism Organization, the most comprehensive collector of data on tourism, distinguishes several types of tourism, including cultural tourism, rural tourism (agri-tourism), and nature tourism (including ecotourism and adventure tourism) and, secondarily, "sun-and-beach tourism" and "fitness, wellness and health tourism."

Cultural tourism is a form of experiential tourism based on the search for and participation in new and deep cultural experiences of an aesthetic, intellectual, emotional, or psychological nature (Reisinger 1994). Cultural landscapes and heritage services are important attractions for people wanting to experience other cultures and religions. The Ganges River–based cultural and sacred landscape system in India, for example, is visited every year by millions of people, being sacred for close to a billion people of the Indian subcontinent. Similarly, the Demajong landscape of the Tibetan Buddhists in the Eastern Himalayan State of Sikkim, India, and the Koyasan landscape in Japan are equally important for Buddhists living in that part of the world. More than 1 million people visit Koyasan annually.

Rural tourism can be interpreted in a number of ways. Over the last decade, the concept has come to encompass more and more activities. For instance, Bramwell and Lane (1994) included activities and interests in farms, adventure, sport, health, education, arts and heritage, and even natural sites. Pedford (1996) added aspects of living history such as rural customs and folklore, local and family traditions, values, beliefs, and common heritage. And Turnock (1999) further broadened the view of rural tourism to embrace all aspects of leisure appropriate in the countryside (cultural landscapes). The growing overlap of cultural tourism and rural tourism led MacDonald and Jolliffe (2003) to integrate the two concepts into "cultural rural tourism."

The World Conservation Union (IUCN) defined ecotourism in 1996 as tourism that "is environmentally responsible travel and visitation to relatively undisturbed natural areas, in order to enjoy and appreciate nature (and any accompanying cultural features—both past and present) that promotes conservation, has low negative visitor impact and provides for beneficially active socio-economic involvement of local populations." It is estimated that in 1997 nature tourism, including ecotourism, accounted for approximately 20% of total international travel (WTO 1998) and that nature travel is increasing between 10% and 30% a year (WRI 1990).

17.2.6.2 Observed Changes, Causes of Change, and Future Trends

There is evidence of rapid growth of nature- or ecotourism (Skayannis 1999), demonstrated in the surging growth of international arrivals to the countries with high biodiversity. (See Table 17.3.) Travel and tourism was one of the few industries identified in *Agenda 21* as having the potential to make a positive contribution to healthier national economies as well as a healthier planet. Tourism is now the primary economic development strategy for many developing nations, as demonstrated in 1996 when all the presidents of Central America at a summit in Nicaragua declared their intentions to make tourism the primary revenue source for the region (UN 51/197 1996). Similar sentiments have been expressed throughout the world.

Research indicates that nature tourism has experienced a surge in demand that has far exceeded supply (Diamantis 1998). Tourism is a well-recognized agent of change, and the rapid expansion of recreation and tourism planning in recent years has led to the need for managing its impacts. Yet the cultural phenomenon of societies protecting special areas for visitors has been common for centuries. Indeed, in many cases it was the increasing arrivals of travelers to special sites that were the impetus for site designation and protection (Eagles et al. 2001).

Well-planned and well-managed tourism has proved to be one of the most effective tools for long-term conservation of biodiversity when the right conditions, such as market feasibility, social and physical carrying capacity, management capacity at local level, and clear and monitored links between tourism development and conservation, are present. For example, a study of nature-based tourism in southern Africa in 2000 estimated the aggregate value to be \$3.6 billion per year, which represented approximately half the total income from foreign travel in the region (the other half was contributed mostly by business travel and visits to family and friends) (MA *Multiscale Assessments,* South African Assessment). (See also Box 17.9.)

Sustainable tourism, in the context of development, has been defined as "all forms of tourism development, management and activity, which maintain the environmental, social and economic integrity and well being of natural, built and cultural resources in perpetuity" (FNNPE 1993). In the years since the concept of sustainable tourism was first defined, a consensus has formed on the basic objectives and targets. Sustainable tourism should contribute to the conservation of biodiversity and cultural diversity; should contribute to the well-being of local communities, enhancing social equity and respect for the rights and sovereignty of local communities and indigenous people; should include an interpretation/learning experience; should involve responsible action on the part of tourists and the tourism industry; should be appropriate in scale; should require the lowest possible consumption of nonrenewable resources; should respect physical and social carrying capacities; should involve minimal repatriation of earned revenue; and should be locally owned and operated (through local participation, ownership, and business opportunities, particularly for rural people).

Now more than ever, the protection of natural and cultural areas is intimately connected to the tourism industry. High growth and demand have greatly influenced the management trends of protected areas, with the interaction between humans and the environment as one of the main factors. These effects in the protected-area tourism management industry include linking sustainable use and conservation, increasing travel to protected areas, moving toward self-regulation in the tourism industry, acknowledging the important financial aspects of tourism to protected areas, and acknowledging the importance of the sociocultural aspects of sustainable tourism (Eagles et al. 2001).

17.2.6.3 Consequences of Change for Human Well-being

It is important to note that in countries without large mineral resources, tourism is often the major source of foreign income (WTTC 1999). (See also Box 17.10.) It is useful to compare income from nature-based tourism to that generated from the other main sectors based on ecosystem services: agriculture, forestry, fisheries, and the provision of water. Assuming that nature-based tourism is half of all tourism, and excluding the manufacturing sector knock-on effects of agriculture, forestry, and fisheries, the contribution by nature-based tourism is nearly equal to the other natural resource sectors combined (WTO 1998; WTTC 1999). It is important to note that these other sectors are growing slowly (1–3% a year) while tourism is growing rapidly (5–15% a year).

Thus, the balance of policy drivers in relation to natural resources is likely to shift over the next few decades, from being strongly influenced by the needs of agriculture, forestry, and fishing to being more influenced by considerations of conservation and aesthetics. The dominance of industries based on nonrenewable resources, such as mining and oil extraction, must in the long term decline, but it is likely to remain high over the next quarter-

Table 17.3. Examples of Hotspots of Countries with High Biodiversity and Tourism Growth of More than 200 Percent (Conservation International 2003, based on data from WTO)

Hotspot/Country	International Arrivals 1990	1995	2000	Growth 1990–2000 Number	Increase
	(thousand people)			(thousand people)	(percent)
Indo-Burma					
Laos	14	60	300	286	2,043

BOX 17.9

Inter-American Development Bank Lessons on Tourism Development with Conservation (Conservation International 2003)

The Brazilian state of Bahia harbors one of the most threatened conservation hotspots, the Atlantic rain forest. The $400-million PRODETUR I project, funded by the IDB from 1994 to 2001, improved and expanded eight international airports, built and improved over 800 kilometers of highways and access roads, provided water and sewage infrastructure, and attracted more than $4 billion in private tourism investment. Its negative impacts on the environment, though, became clear to IDB officers: uncontrolled settlement of people looking for jobs, private building in environmentally sensitive areas, encroachment on rain forests and mangroves, and impacts on coastal reefs and other coastal ecosystems.

Intense pressure from local and international NGOs and community groups, supported by bank officials, ultimately overcame the initial resistance from investor groups and development-oriented government officers to allocate funds for conservation. The result was the conservation of 22 historical heritage sites and the beginning of efforts to conserve over 70,000 hectares of coastal ecosystems and protected areas, including the creation of the new Serra do Conduru State Park. These lessons are being applied to new IDB projects in the region.

BOX 17.10

Economic Importance of Cultural and Nature-based Tourism

The economic importance of global travel and tourism is indicated by a few figures on the sector as a source of jobs and national income; about 30% of these revenues are related to cultural and ecotourism. Global travel and tourism:

- generates 11% of global GDP (WTTC), growing at 7.5% per year (Carsten Loose, personal communication);
- employs 200 million people or 7.6 % of total employment for the world (WTTC);
- transports nearly 700 million international travelers per year—a figure that is expected to double by 2020 (WTTC);
- accounts for 36% of trade in commercial services in industrial economies and 66% in developing economies (WTO);
- accounts for 36% of trade in commercial services in industrial economies and 66% in developing economies (WTO);
- constitutes 3–10% of GDP in advanced economies and up to 40% in developing economies (WTO);
- generated $464 billion in tourism receipts in 2001 (WTO); and
- is one of the top five exports for 83% of countries and the main source of foreign currency for at least 38% of countries (WTO).

century. A key trade-off is between the social benefits that such sectors offer now and the long-term benefits that may be afforded by nature-based tourism.

Management is frequently the weak link in the connection between tourism and the environment (Valentine 1992). Tourism provides both benefits and hazards, and the monitoring and controlling of impacts is necessary in order to mitigate the negative impacts from uncontrolled visitation, both ecologically and socioculturally (such as prostitution and the spread of diseases); to prepare for the expected rapid increase in visitor arrivals as well as rapid increase in the value of pristine lands; to move beyond past relationship failures between host ecosystems, visitors, local cultures, foreign developers, governments, indigenous groups, and scientists; and to allow crucial economic and natural science contributions to community and indigenous self-determination and resource conservation within rapidly changing environments.

Responsiveness to the relationships between cultures, biodiversity, and tourism is important to the objectives of the Convention on Biological Diversity—that is, the conservation of biological and cultural diversity and the sustainable use of the components of biodiversity—while intimately linked to issues of equity as well. The CBD Guidelines (Decision VII/14) on Biodiversity and Tourism Development are the most recent, comprehensive, and multilateral effort toward more sustainable tourism development. Its coordinating framework represents one of the best opportunities to improve global human well-being by strengthening protected area management systems (public, private, or indigenous); by increasing the value of sound ecosystems through generating income, jobs, and business opportunities in tourism and related business networks; by sharing information, capacity building, and public notification; and by allowing people to internalize the benefits of the biodiversity that has been a part of their historical, natural, and cultural heritage.

17.3 Drivers of Change in Cultural and Amenity Services

Changes in ecosystem characteristics are determined by direct and indirect drivers (see also Chapter 3), which in turn can affect sociocultural, spiritual, and recreational activities. The consensus now seems to be that complex interactions between the indirect and direct drivers—including market forces (both national and international), taxes and subsidies, consumption patterns, population migration and resettlement, land ownership, autonomic cultural rights, participation in decision-making, poverty, and the problem of invasive species (to mention but a few)—lead to land degradation and loss of ecosystem services (Lambin et al. 2001).

Issues such as population and poverty, which are often assumed to be ultimate drivers of ecosystem transformation, are now recognized as much more complex, even under diverse socioecological-economic-political situations as found in India, China, and the United States (Indian National Science Academy et al. 2001). For example, conversion of Mediterranean mixed cultivation systems, such as traditional olive cultivation combined with livestock grazing, into intensive cropping systems is the consequence of agricultural policies and subsidies, which in turn lead to increased mobility that causes, for example, landscape fragmentation. These changes may lead to both negative and positive effects in terms of the real or perceived availability and value of cultural and amenity services. In many parts of the world, for instance, so-called cultural landscapes are highly valued for aesthetic or historic reasons but from an ecological point of view are highly degraded (for instance, the heath landscapes in the Netherlands, a succession stage that is artificially maintained by preventing natural forest regrowth).

The problem of invasive species, an important global change phenomenon, is becoming a major issue in the maintenance of cultural and amenity services in different parts of the world. A global synthesis and a recent international initiative on invasive species (Drake et al. 1989), suggest that invasions by exotic species have a strong impact on land transformations and land degradation and affect traditional livelihoods. For the poorer sections of rural society, particularly in the developing tropics, the adverse impact of invasions can be critical because these communities depend on natural ecosystems for socioeconomic as well as cultural and spiritual well-being (Ramakrishnan 1991).

In spite of the disruptions caused to ecosystem characteristics, humans have both learned to appreciate changes in ecosystems (such as conversion of natural ecosystems into landscapes that, over time, have developed cultural-historic values) and intentionally transformed natural systems into landscapes with special cultural, spiritual, or amenity values (such as urban parks, sacred landscapes, and recreational sites). However, changes in value systems (a loss of religious beliefs, say, or cultural identity) have also led to the loss of previously valued sacred or historic landscapes.

17.4 Consequences for Human Well-being of Changes in Cultural and Amenity Services

The importance of a service to human well-being can be described by many different indicators, including environmental safety (low risk of natural disasters, provision of clean water, and so on), economic security (employment and income), health (physical and psychological), and social aspects (cultural identity, traditional knowledge, social networks, and so on). (See Chapter 5 for further details.)

As described in previous sections, natural and cultivated systems provide many cultural and amenity services that contribute significantly to the general well-being of humans. Inspirational, aesthetic, and recreational services of ecosystems are important not only for their therapeutic value (physically and mentally) and other human well-being aspects but also for their considerable economic value. Changes in ecosystem conditions will always change the availability of ecosystem services and hence affect human well-being (either positively or negatively). Part of these changes in well-being can be measured by economic valuation methods, including monetary data. (See Chapter 2 for methods and tools for economic valuation of ecosystem services.) It is beyond the scope of this chapter to substantially expand on this, but three types of impacts of changes in ecosystem-based cultural services on human well-being are briefly discussed.

17.4.1 Cultural Identity and Social Values

As described earlier, population growth and economic development in many parts of the world have led to changes in traditional land use, cultural values, and spiritual ties between human society and their surrounding ecosystems. In most cases, this has meant that economic gains, including increased use of amenity services (such as tourism) has led to the loss of cultural identity and heritage values. Recently, a reverse in the trend has become noticeable, where cultural identity and heritage values are being rediscovered and restored while simultaneously bringing economic benefits to the region. A good example of this is the long-standing and evolving interest of UNESCO, as part of its World Heritage Centre on culturally valued natural landscape systems (Rossler 2000; UNESCO 2003). Also, the emerging interest of

FAO on the Globally Important Ingenious Agricultural Heritage Systems is indicative of this growing interest in conserving and sustainably developing cultural landscapes with economic benefits to local communities and society at large (Ramakrishnan 2003).

17.4.2 Human Health

The loss of cultural ties between people and ecosystems often leads to a loss of cultural identity, causing increased social disruption and stress that in turn causes a whole array of mental and physical health effects. Similarly, a loss of opportunities to enjoy the inspirational, aesthetic, and recreational benefits of natural and cultural landscapes has negative mental and physical health effects. And the loss of traditional knowledge systems can have negative health effects, notably through plant medicine that could help humankind deal with pandemics like AIDS, cancer, and other health problems in a globalizing world.

17.4.3 Material Well-being

Many of the changes described in this chapter have considerable economic and financial consequences. On the one hand, more modern and large-scale land use systems, increased tourism, and so on bring higher financial revenues. On the other hand, social disruption and negative health effects lead to higher costs (to prevent and combat crime, diseases, environmental problems, and so on). The problem is that the higher revenues usually accrue to a small number of specific stakeholders (landowners, for instance, and tourist companies) while the costs in terms of loss of cultural identity and reduced health and income are felt by society as a whole (and usually the more vulnerable people), including future generations. The challenge is to find a balance between the maintenance of cultural and amenity services and values and the (sustainable) development of their full economic potential. ''Diversity in use'' seems to be the key here: scientific evidence is mounting that if all services and associated values are properly taken into account, multifunctional use of ecosystems is not only environmentally and socioculturally more sustainable but also economically more beneficial than single-function use (e.g., Balmford et al. 2002).

17.5 Lessons Learned

17.5.1 Landscape Management and Sustainability Issues: The Ecosystem Approach

Current international conservation initiatives are increasingly based on the ''ecosystem approach'' (see CBD Decisions V/6 and VII/11) and the ''eco-region'' approach of the World Wide Fund for Nature, although there have been both older and more recent attempts to take a more integrative socioecological system approach to managing natural resources. The cultural and amenity values of landscape are one important dimension in this integrated method.

The concept of Biosphere Reserves (in which humans are viewed as an integral part of the component ecosystems), the concept of UNESCO's ''cultural'' World Heritage Sites, and the recently initiated Globally Important Ingenious Agricultural Heritage Systems of FAO are indicative of the importance attached to the cultural and spiritual dimensions of the issues. Emphasis is also being directed toward conservation linked with sustainable use of these systems, viewing them not merely as ecosystems in a biophysical sense but more appropriately as constantly evolving ''socioecological systems.''

17.5.2 Cultural Basis for Landscape Management

Landscape planning and management needs to be based on a better understanding of the way in which societies manipulate ecosystems and to consider cultural, spiritual, and religious belief systems. Human societies understand and interact with landscapes through a cultural lens, and traditional knowledge has played an important role in mediating a sustainable relationship between biophysical and human systems. (See Box 17.11.) This is an area of evolving interest, with possible linkages between traditional and formal knowledge systems to create landscape management institutions and practices, though this still remains somewhat problematic.

Traditional beliefs, practices, and knowledge are often embedded in shared territory, common property rights, and lifestyles. In November 2002, the Convention on Wetlands (Ramsar 1971) adopted Resolution VIII.19 on 'Taking into account cultural values in the management of sites' and is now working in various parts of the world for its implementation. The purpose of this resolution is twofold: to reconnect people with nature, by strengthening traditional cultural links, and to promote an integrated perception of the natural and cultural heritage of wetland sites, which can attract visitors and provide benefits to local communities. As the examples in Box 17.12 illustrate, the motivations for conservation range from spiritual to utilitarian, and in many situations they could potentially play a significant role in fostering sustainability.

17.5.3 Traditional Technologies

The term ''technology'' is taken here to represent the composite of all protocols, processes, practices, and institutions that are applicable to the management of natural resources, documented or transmitted through oral tradition. As with TEK, there are many examples of such technologies underpinning the development of complex societies that have long-lasting relationships with landscapes.

For example, the development of plant cultivars as part of landscape organization by traditional societies in South America dates back to at least 10,000 BP (Pearsall 1992). Pre-Hispanic cul-

BOX 17.11

Some Examples of Landscape Management and Traditional Knowledge

Throughout Africa, natural resource management practices are traditionally linked to religious sanctions. The rules and regulations are implemented through living authorities, often with pragmatic objectives that are relevant to conservation issues too. In the Miombo woodlands in Southern Africa, for instance, it is prohibited to cut fruit trees or trees growing around ''sacred'' water springs. Sacred groves, often occurring on hills or in river valleys, are protected for ceremonial reasons, as an abode for departed souls, as a source for natural water springs, or as a source for medicinal plants and other non-timber forest products (Clarke et al. 1996), but they also perform critical ecological functions.

Buddhist monks are prohibited from doing any harm to trees and animals by the code of conduct known as *Vinaya* (the discipline). Locations related to Buddha, the place of birth, enlightenment, and death, are recognized and protected as places of worship. Sri Pada (or Adams Peak) in Sri Lanka, a landscape of rich diversity, is considered by the Buddhists, Christians, Hindus, and Muslims as a place of worship and is protected (Wijesuriya 2001).

tures managed complex ecosystems and conserved biodiversity, which through an extended historical process of cultural adaptation reached a surprising degree of stability. These included the grazing systems of native *Camelidae* in the Punas, complex lacustrine agricultural systems of the Mexican Chinapas, Zenu hydraulic society in the Caribbean lowlands of Colombia, and the shifting agricultural systems that permitted maintenance of diversity in the Amazonian and Mayan forests (Monasterio 1994). Similarly, *Miombo* savanna landscape management practices are typical of what is found in many parts of tropical Africa (Campbell 1996), with a long history of connectivity between people and the ecosystem, where the traditional bush-fallow rotational *Chitemane* system of agriculture is linked with livestock husbandry.

17.5.4 Adaptive Management Strategies

Adaptive management—an interactive process of ''learning by doing''—is founded on the premise that natural systems are dynamic and complex and that information on which to base decision-making is inevitably incomplete. Specific management strategies and actions are therefore approached as experiments that can be reviewed and adapted based on the information gained from monitoring systems on the strengths and weaknesses of these strategies (Holling 1978; Lee 1999; Borrini-Feyerabend et al. 2001). This has been promoted as the approach of choice by a number of international bodies (IUCN 1999). Tools that enable local perspectives and voices to be articulated in planning processes can help bridge this gap, notably methods such as Participatory Rural Appraisal, Participatory Learning and Action, and Participatory Assessment, Monitoring and Evaluation (Zanetell and Knuth 2002). An important proviso is that the application of such methods should not be mechanical or ultimately substitute for the development of collaborative relationships and ongoing communication that underpin real knowledge sharing between stakeholders (Poffenberger 2000).

The integration of social and cultural dimensions of resource management within an adaptive management framework requires an integrative approach by practitioners at the level of knowledge, worldview, and practice. The integration of traditional and formal knowledge systems through ''knowledge partnerships'' involves a creative blending of technical and local perspectives to achieve a balanced approach to managing landscapes. (Jiggins and Roling 2002; Zanetell and Knuth 2002). An example of successful co-management is the collaboration between the Inuvialuit and the government in the Northwest Territories of Canada (Harriet Kuhnlein, 2003, personal communication).

Combining the reductionistic, formal perspective of knowledge with a more ''traditional'' and more holistic perspective toward natural resource management is likely to yield better results, although the proportionality of these two elements will differ depending on the socioecological systems being dealt with (Ramakrishnan 2001). Cases where success has been realized by combining the two knowledge systems can act as ''field laboratories'' for scientific research and as reference points for monitoring environmental change brought about through appropriately designed technologies derived from an integration of formal and traditional knowledge systems.

Main Messages

All oceans are affected by humans to various degrees, with overfishing having the most widespread and the dominant direct impact on food provisioning services, which will affect future generations. Areas beyond the 50 meters depth are mainly affected directly by fishing and indirectly by pollution. Fish are also directly affected by coastal pollution and degradation when their life cycle takes them into coastal habitats. Recent studies have demonstrated that global fisheries landings peaked in the late 1980s and are now declining despite increasing fishing effort, with little evidence that this trend is reversing under current practices. Fishing pressure is so strong in some marine systems that the biomass of some targeted species, especially larger high-value fish and those caught incidentally (the "bycatch"), has been reduced to one tenth or less of the level that existed prior to the onset of industrial fishing. In addition, the average trophic level of global landings is declining, which implies that we are increasingly relying on fish that originate from the lower part of marine food webs.

Industrial fleets are fishing with greater efficiency, further offshore, and in deeper waters to meet the global demand for fish. Until a few decades ago, depth and distance from coasts protected much of the deep ocean fauna from the effect of fishing. However, recent large investments in fishing capacity and navigation aids have led to fleets that now cover the world's ocean, including polar and deep, low-productivity areas, where catches are affecting easily depleted populations of long-lived species. The biomass of large pelagic fish in these areas taken by longlines, purse seines, and drift nets has also plummeted. Studies on available data have shown that deep-sea fisheries that collapsed in the 1970s have not recovered.

Overfishing has negative impacts on marine biodiversity. The lowered biomasses and fragmented habitats resulting from the impacts of fishing have led to local extinctions, especially among large, long-lived, slow-growing species with narrow geographical ranges. In addition, the ability of the component ecosystems and their embedded species to withstand stresses resulting from climate change and other human impacts will be reduced, though direct demonstration of this effect may not be evident in many systems for some decades.

Destructive fishing practices have long-term impacts on marine habitats. Destructive practices such as trawling, dynamiting, and dredging change the structure of marine ecosystems, with consequential changes in their capacity to provide services, such as food provisioning and income generation. Long-term losses in species and habitats through destructive fishing ultimately reduce the biodiversity of these affected systems, resulting in a further loss of services such as coastal protection. Some systems may recover and improve the availability of some services and products fairly quickly; other more vulnerable systems, such as cold-water corals and seamounts, may take hundreds of years to recover.

The implementation of no-take marine reserves combined with other interventions, such as controls on fishing capacity, would be a more proactive response to fisheries management than current reactive approaches. Marine reserves can contribute to better fisheries management—helping to rebuild stocks through enhanced recruitment and spill-over effects, maintaining biodiversity, buffering marine systems from human disturbances, and maintaining the ecosystems that fisheries rely on.

Aquaculture is not a solution to the problem of declining wild-capture fisheries. Good governance and effective management of wild-capture fishing are likely to be more successful approaches. Farmed species such as salmon and tuna, which use fishmeal, may in fact contribute to the problem since much of the fishmeal and oil currently used in the aquaculture industry is derived from wild-caught small pelagic fish. In some countries, such as Chile, small pelagic fish that were once a source of cheap protein for people are now largely diverted for fishmeal.

The supply of wild marine fish as a cheap source of protein for many countries is declining. Per capita fish consumption in developing countries (excluding China) has declined from 9.4 kilograms per person in 1985 to 9.2 kilograms in 1997. In some areas, fish prices for consumers have increased faster than the cost of living. Fish products are heavily traded, and approximately 50% of fish exports are from developing countries. Exports from developing countries and the Southern Hemisphere presently offset much of the demand shortfall in European, North American, and East Asian markets.

The proposed future uses of marine systems pose significant policy challenges. Ocean ranching of marine organisms, bioprospecting, seabed mining, and carbon sequestration in deep ocean waters are foreseeable uses of marine systems. However, the potential impacts of these activities are not well known. In some cases no or only limited field studies have been conducted to test the theoretical basis for the activity. Policies will need to deal with the uncertainty of potential impacts and the limited understanding of marine biodiversity. National and regional ocean policies that incorporate zoning for various uses within an integrated ecosystem-based management framework are likely to be needed. Such policies might include marine protected areas that can contribute to the restoration of species and habitats and thus form part of a precautionary strategy for guarding against management errors.

18.1 Introduction

Most of Earth—70.8%, or 362 million square kilometers—is covered by oceans and major seas. Marine systems are highly dynamic and tightly connected through a network of surface and deep-water currents. The properties of the water generate different density layers, thermoclines, and gradients of light penetration in marine systems, which result in productivity varying vertically. Tides, currents, and upwellings break this stratification and, by forcing the mixing of water layers, enhance primary production.

One widely accepted classification divides marine systems into four biomes (Longhurst et al. 1995; Longhurst 1998): the coastal boundary zone, trade-winds, westerlies, and polar. (See Figure 18.1.) These biomes are subdivided into a total of 57 biogeochemical provinces with distinct seasonal patterns of surface nutrient enrichment, which determine primary production levels and, ultimately, fisheries yield. The provinces of the coastal boundary zone biome largely overlap with the large marine ecosystems of K. Sherman and collaborators (see Watson et al. 2003), and hence those are implicitly included here. For practical reasons, we also refer to the U.N. Food and Agriculture Organization's classification that has been used to report on global fisheries statistics since 1950 and that divides the world's oceans up into 18 FAO statistical areas (FAO 1981).

The coastal boundary zone that surrounds the continents is the most productive part of the world ocean, yielding about 90% of marine fisheries catches. Overall, coastal and marine fisheries landings averaged 82.4 million tons per year during 1991–2000, with a declining trend now largely attributed to overfishing. The other three biomes are less productive, and their deep waters are exploited mainly for their large pelagic fish. The four biomes are described in detail in the next section.

In this assessment, the marine system is defined as the marine waters from the low-water mark to the high seas that support marine capture fisheries and deepwater (>50 meters) habitats.

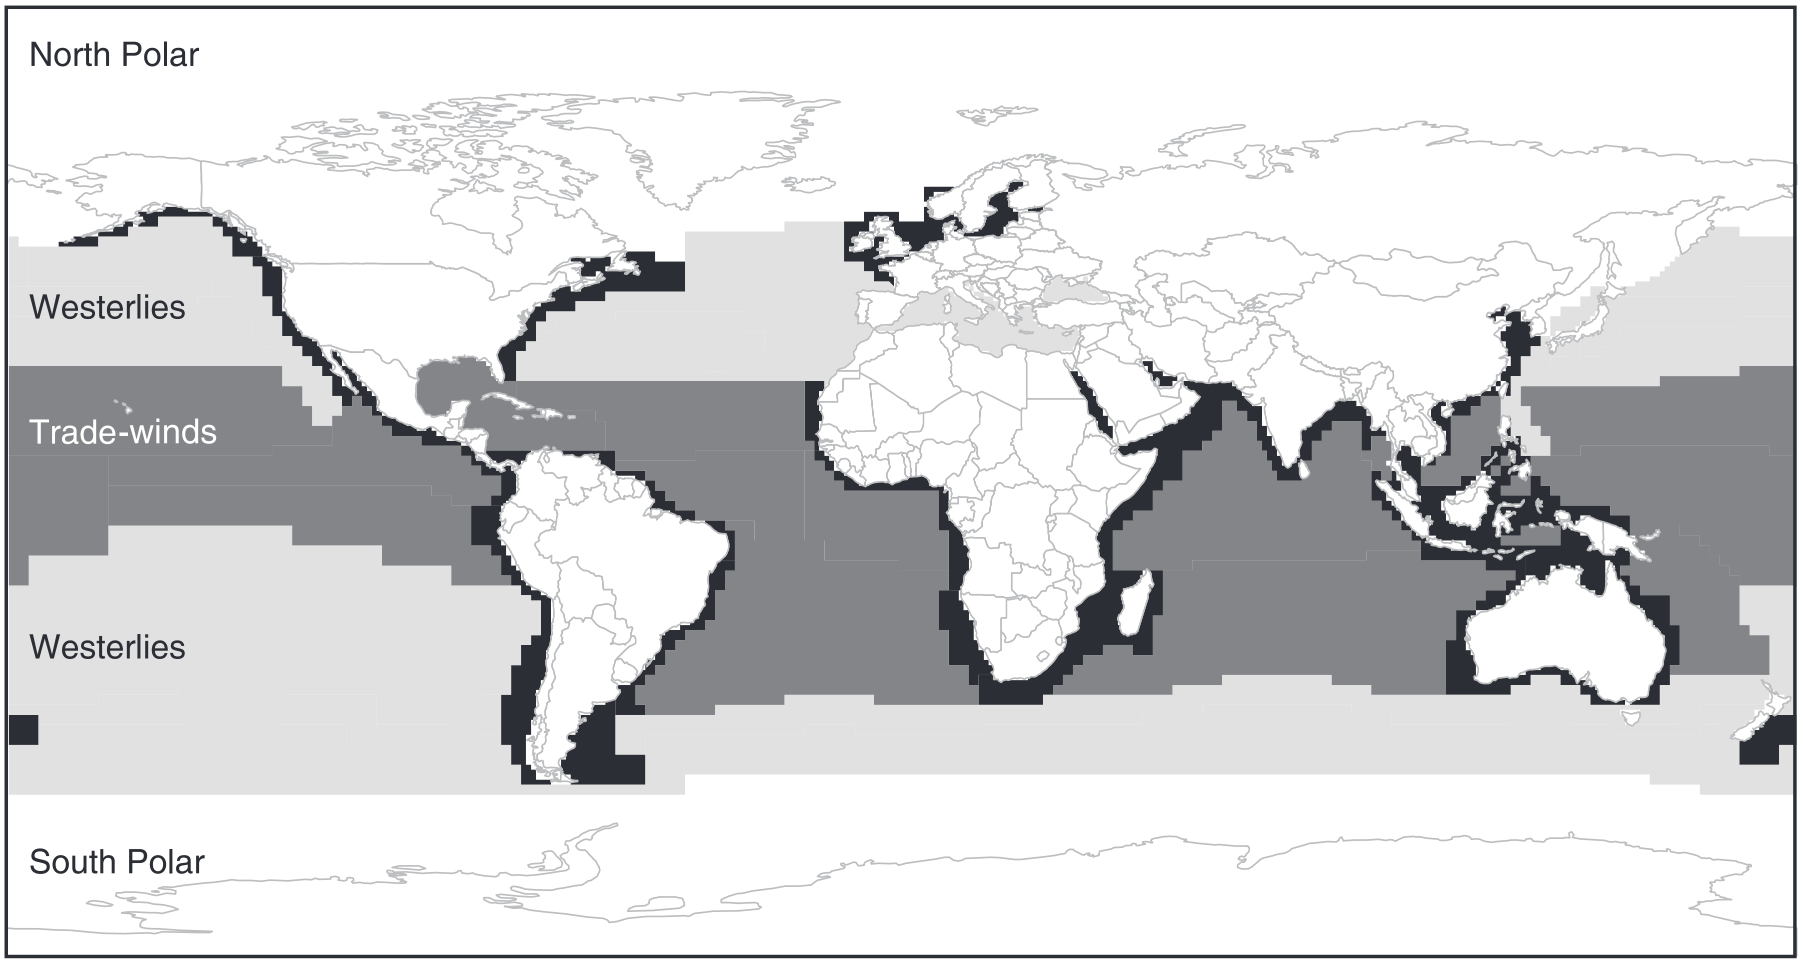

Figure 18.1. Classification of World's Oceans. Four "Biomes" were identified: Polar, Westerlies, Trade-winds, and Coastal Boundary (Longhurst et al. 1995; Longhurst 1998). The Coastal Boundary is indicated by a black border around each continent. Each of these Biomes is subdivided into Biogeochemical Provinces. The BGP of the Coastal Boundary Biome largely overlaps with LMEs identified by K. Sherman and coworkers (see Watson et al. 2003).

This definition spatially overlaps with coastal systems, which are bounded inland by land-based influences within 100 kilometers or 100-meters elevation (whichever is closer to the sea) and seaward by the 50-meter depth contour. Chapter 19 focuses on coastal habitats and coastal communities, however. It does not overlap conceptually with this chapter, which focuses on the condition and trends of fisheries resources in marine ecosystems for the following reasons:

- Living marine resources and their associated ecosystems outside of coastal areas (as defined by the MA), which maintain the food provisioning services of marine systems, have been affected over the last 50 years mostly by fishing.
- Our level of understanding of fisheries and the availability of information needed to assess the impact of fisheries are much better than for other human activities in marine systems. However, studies on biodiversity changes in marine systems are lagging behind our understanding of fisheries systems or terrestrial biodiversity changes. And overall, our understanding of long-term impacts and their interactions with other activities (current and future) is very limited.
- Chapter 19 describes the condition and trends of marine habitats and significant marine animals from the high-water mark to the 50-meter bathymetric line. Thus it discusses in detail the condition and trends of shallow inshore coastal habitats such as coral reefs, mangroves, and seagrasses, as well as important fauna such as seabirds, turtles, and marine mammals. Since most human uses of marine systems (tourism, gas and oil extractions, and so on) occur in the coast, they are discussed in detail there. On the other hand, the impact of human use, especially fishing, on deeper-water systems such as shelves, slopes, seamounts, and so on are discussed in this chapter.
- Chapter 4, on biodiversity, includes many non-fisheries aspects of marine biodiversity not covered here. Chapter 12, on nutrient cycling, discusses the cycling of carbon, nitrogen, and phosphorus and the changes in these cycles in marine systems. And Chapter 13, on air quality and climate, highlights possible changes, including acidification, carbon sequestration, and fluxes in marine systems, over the short term.

Nevertheless, this chapter touches on various aspects of marine ecosystems such as marine biodiversity as they relate to fisheries and deepwater habitats, and some activities such as tourism and transportation are also mentioned. But there is currently insufficient information available to assess which activities have relatively more impact than others in marine systems.

Marine ecosystems are diverse—some are highly productive, and all are important ecologically at the global scale and highly valuable to humankind. The major ecosystem services (as described in Chapter 1) derived from marine ecosystems are summarized in Table 18.1.

Marine systems play significant roles in climate regulation, the freshwater cycle, food provisioning, biodiversity maintenance, energy, and cultural services, including recreation and tourism. They are also an important source of economic benefits, with capture fisheries alone worth approximately $81 billion in 2000 (FAO 2002); aquaculture worth $57 billion in 2000 (FAO 2002); offshore gas and oil, $132 billion in 1995; marine tourism, much of it in the coast, $161 billion in 1995; and trade and shipping, $155 billion in 1995 (McGinn 1999). There are approximately 15 million fishers employed aboard decked and undecked fishing vessels in the marine capture fisheries sector. About 90% of these fishers work on vessels less than 24 meters in length (FAO n.d.).

More than a billion people rely on fish as their main or sole source of animal protein, especially in developing countries. (See Table 18.2.) Demand for food fish and various other products from the sea is driven by population growth, human migration

Table 18.1. Percentage of Animal Protein from Fish Products, 2000 (FAO 2003)

toward coastal areas, and rising incomes that increase demand for luxury seafood.

Detailed data on fisheries catches—that is, food provisioning, the major ecosystem service considered here—are available since 1950 for (groups of) species for all FAO areas and maritime countries of the world. (See www.fao.org for tabular statistics and www.seaaroundus.org for spatially disaggregated statistics.) These show that catches increased more rapidly than the human population through the 1950s and 1960s, leading to an increase in available seafood. (See Figure 18.2.) This period also saw the depletion of many local stocks, but this was masked by the global increase of landings. The first fisheries collapse with global impact on prices of fishmeal and its substitutes was the Peruvian anchoveta, in 1971/72, which fell from an official catch of 12 million tons annually in the 1972–73 season (in reality, probably 16 million tons annually; see Castillo and Mendo 1987) to 2 million tons in 1973 (Tsukayama and Palomares 1987), ushering in two decades of slow growth and then stagnation in global fish catches. (See Figure 18.3.)

18.2 Condition and Trends of Marine Fisheries Systems

18.2.1 Global Trends

The mid-twentieth century saw the rapid expansion of fishing fleets throughout the world and an increase in the volume of fish landed. These trends continued until the 1980s, when global marine landings reached slightly over 80 million tons per year; then they either stagnated (China included; FAO 2002) or began to slowly decline (Watson and Pauly 2001). However, regional landings peaked at different times throughout the world, which in part masked the decline of many fisheries.

Indeed, the world's demand for food and animal feed over the last 50 years has resulted in such strong fishing pressure that the biomass of some targeted species, such as the larger, higher-valued species and those caught incidentally (the "bycatch"), has been reduced over much of the world by a factor of 10 relative to levels prior to the onset of industrial fishing (Christensen et al. 2003;

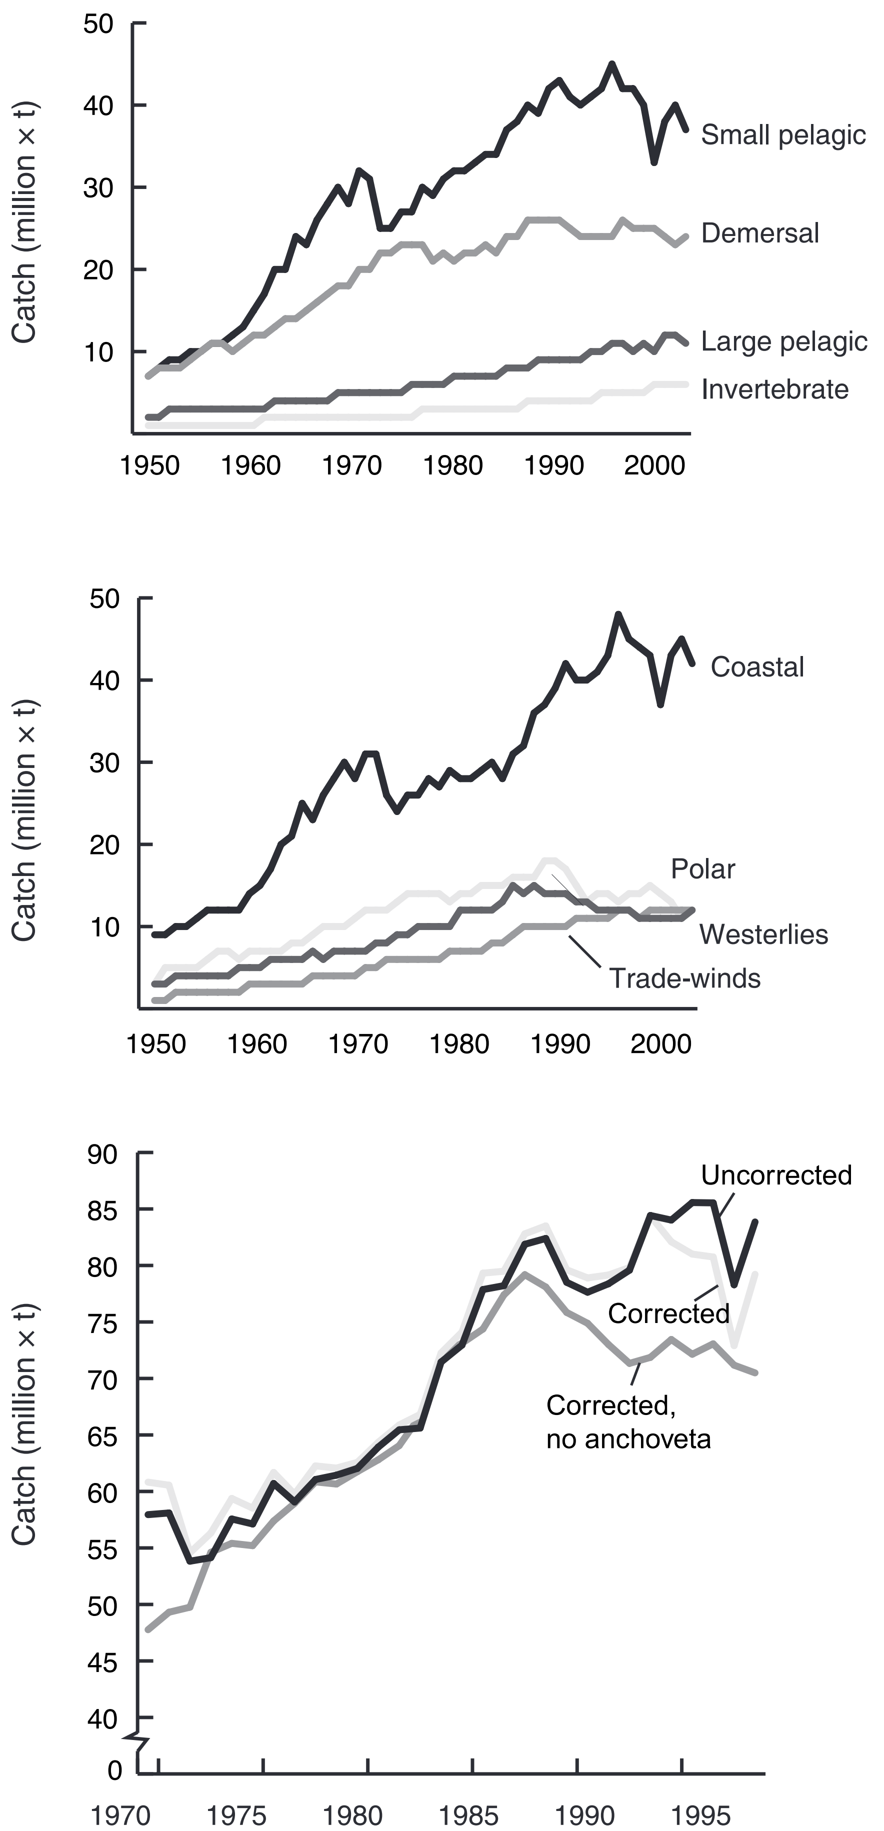

Figure 18.3. Estimated Global Fish Catches, 1950–2001, by Target Group and Biome, with Adjustment for Over-reporting from China. Note: bottom graph is the total landings, adjusted and not adjusted for China. (Watson and Pauly 2001)

Myers and Worm 2003). In addition, with fleets now targeting the more abundant fish at lower trophic levels (see Figure 18.4), it would be expected that global catches should be increasing rather than stagnating or decreasing, as is actually occurring. Indeed, this by itself indicates the extent that fishing has affected marine ecosystems.

Changes in trophic levels of global and regional catches are considered a better reflection of trends in fisheries than the proportion of fish stocks that are reported as depleted, overexploited, fully exploited, and moderately exploited (FAO 2002). The FAO analysis lists the status of commercially important stocks where there is sufficient information. While the information presented is simple and many people use it to reflect the state of fisheries globally, they have the potential to provide an overoptimistic estimate of the state of fisheries. First, the figures presented only consider stocks currently exploited and exclude those that were fished either to extinction or abandoned over the last 50–100 years. Second, the reporting is based on over 1,500 stocks, with an assessed ''stock'' actually representing species distributed over large areas—that is, the aggregate of many stocks that are at varying states of exploitation. Moreover, the ''stocks'' presented do not represent the thousands of stocks that are fished by small-scale fishers that are not assessed or included in official statistics. For example, there are thousands of coral reef fish stocks that are fished by small-scale fishers in areas such as Indonesia and the Philippines, which are severely overfished but not a part of the FAO global analysis.

Until a few decades ago, depth and distance from coasts protected much of the deep-ocean fauna from the effect of fishing (Figure 18.5). However, fleets now fish further offshore and in deeper water with greater precision and efficiency, compromising areas that acted as refuges for the spawning of many species of commercial interest to both industrial and artisanal fleets (Kulka et al. 1995; Pauly et al. 2003). (See Figure 18.6.) Investments in the development of fishing capacity have led to fleets that cover the entire world's oceans, including polar and deep-sea areas and the low-productivity central gyres of the oceans. Trawl catches particularly target easily depleted accumulations of long-lived species, and the biomass of large pelagic fish has also plummeted (Worm and Myers 2003).

Not only are once inaccessible areas of the ocean increasingly being fished, they are also increasingly exploited for other ecosystem services. The marine realm is seen by many as the next frontier for economic development, especially for gas and oil and other energy sources (wind, gas hydrates, and currents), seabed mining (such as polymetallic nodules), bioprospecting, ocean dumping, aquaculture, and carbon sequestration. Worm et al. (2003) have identified pelagic ''hotspots'' of biodiversity (see Figure 18.7 in Appendix A), while Bryant et al. (1998) identified key coral reef areas. These and other hotspots, which may play a key role in supporting ecosystem services such as biodiversity, will be negatively affected by these developments unless they are appropriately managed.

The gas and oil industry is worth more than $132 billion annually, and the potential for further development is considered high (McGinn 1999). Current levels of development in the deeper ocean environments are low, but future rises in the price of carbon-based fuels could make the extraction of crude oil and gas further offshore financially feasible.

Mining in shallow offshore coastal areas for gold, diamonds, and tin is already under way and there is little doubt that the technology can be developed for deeper mining for a range of minerals, including manganese nodules, cobalt, and polymetallic sulfides, given appropriate economic incentives (Wiltshire 2001). It is assumed that institutional constraints in the future may ensure that activities in these deep-sea environments are conducted in a sustainable way and with minimal impact. This raises a number of questions regarding the nature and scale of the impacts on the little-known deep-ocean habitats. Mineral extraction may include ship- or platform-based processing of the extracted product, which has the potential to pollute the adjacent ecosystems. While bioprospecting does not have the magnitude of physical impacts that oil and mineral extraction does, there is nevertheless the po-

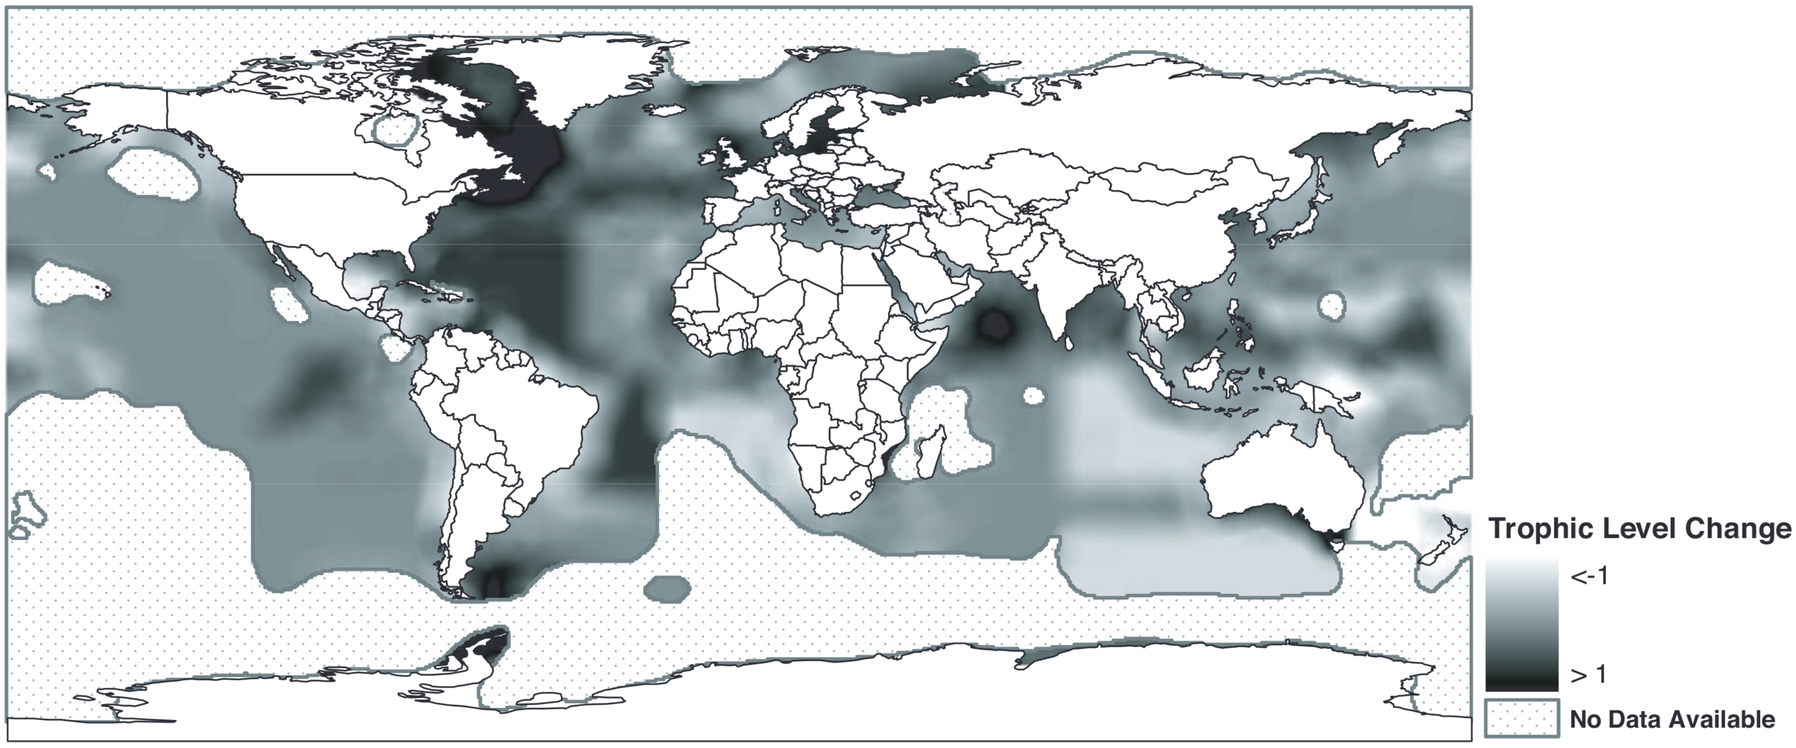

Figure 18.4. Trophic Level Change, 1950–2000

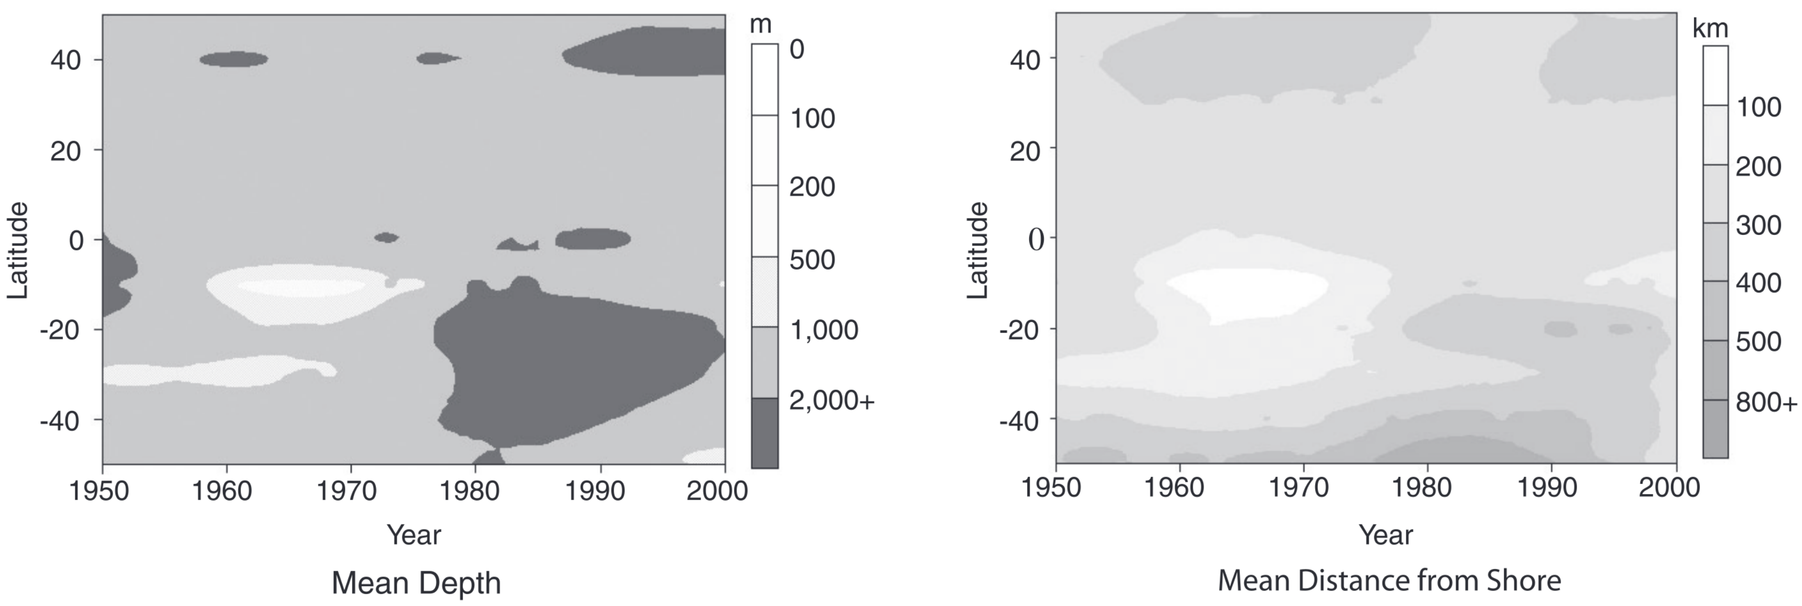

Figure 18.5. Mean Depth of Catch and Mean Distance of Catch from Shore since 1950. Both panels show that fisheries catches increasingly originate from deep, offshore areas, especially in the Southern Hemisphere.

tential for overexploitation (see Chapter 10), resulting in impacts similar to those described for overfishing.

Ocean biomes are also strongly affected by humans. While the coastal biome is heavily affected by coastal development and land-based pollution sources (see Chapter 19), the three other biomes have been affected by a variety of actions such as oil spills, over-hunting of marine mammals, seabird mortalities, and ocean dumping of waste. (See Tables 18.3 and 18.4.) For instance, the estimated 313,000 containers of low-intermediate emission radioactive waste dumped in the Atlantic and Pacific Oceans since the 1970s pose a significant threat to deep-sea ecosystems should the containers leak (Glover and Smith 2003), which seems likely over the long term. Other examples include seabird populations that have been seriously affected by fishing and oil pollution, such as the estimated 14,000 seabirds killed each year by the Alaskan longline groundfish fishery between 1993 and 1997 (Stehn et al. 2001) and the chronic pollution along the coast of Chubut (Argentina) that has significantly increased Magellanic penguin (*Spheniscus megellanicus*) mortality (Gandini et al. 1994).

Knowledge of the effects of persistent organic and inorganic pollutants on marine fauna, including reproductive effects, is limited, and we know even less about how these pollutants interact with fisheries impacts. Similarly, non-fishery factors and their impacts on habitats, primary productivity, and other ecosystem features are often described in the literature. However, their joint and cumulative effect on ecosystems is usually not assessed, limiting comparative analyses. Other human activities, as well as climate (due to natural variation and anthropogenic sources), influence marine systems, but their effects cannot usually be clearly separated from the impact of fishing. However, this should not detract from the urgent need to implement sustainable fisheries practices.

18.2.2 Coastal Boundary Zone Biome

The coastal boundary zone biome (10.5% of the world ocean) consists of the continental shelves (0–200 meters) and the adjacent slopes—this is, from the coastlines to the oceanographic front usually found along the shelf edges (Longhurst 1998). The 64 large marine ecosystems listed in Sherman and Duda (1999), which serves as a conceptual framework for an increasing number of multisectoral projects, largely match the biogeochemical prov-

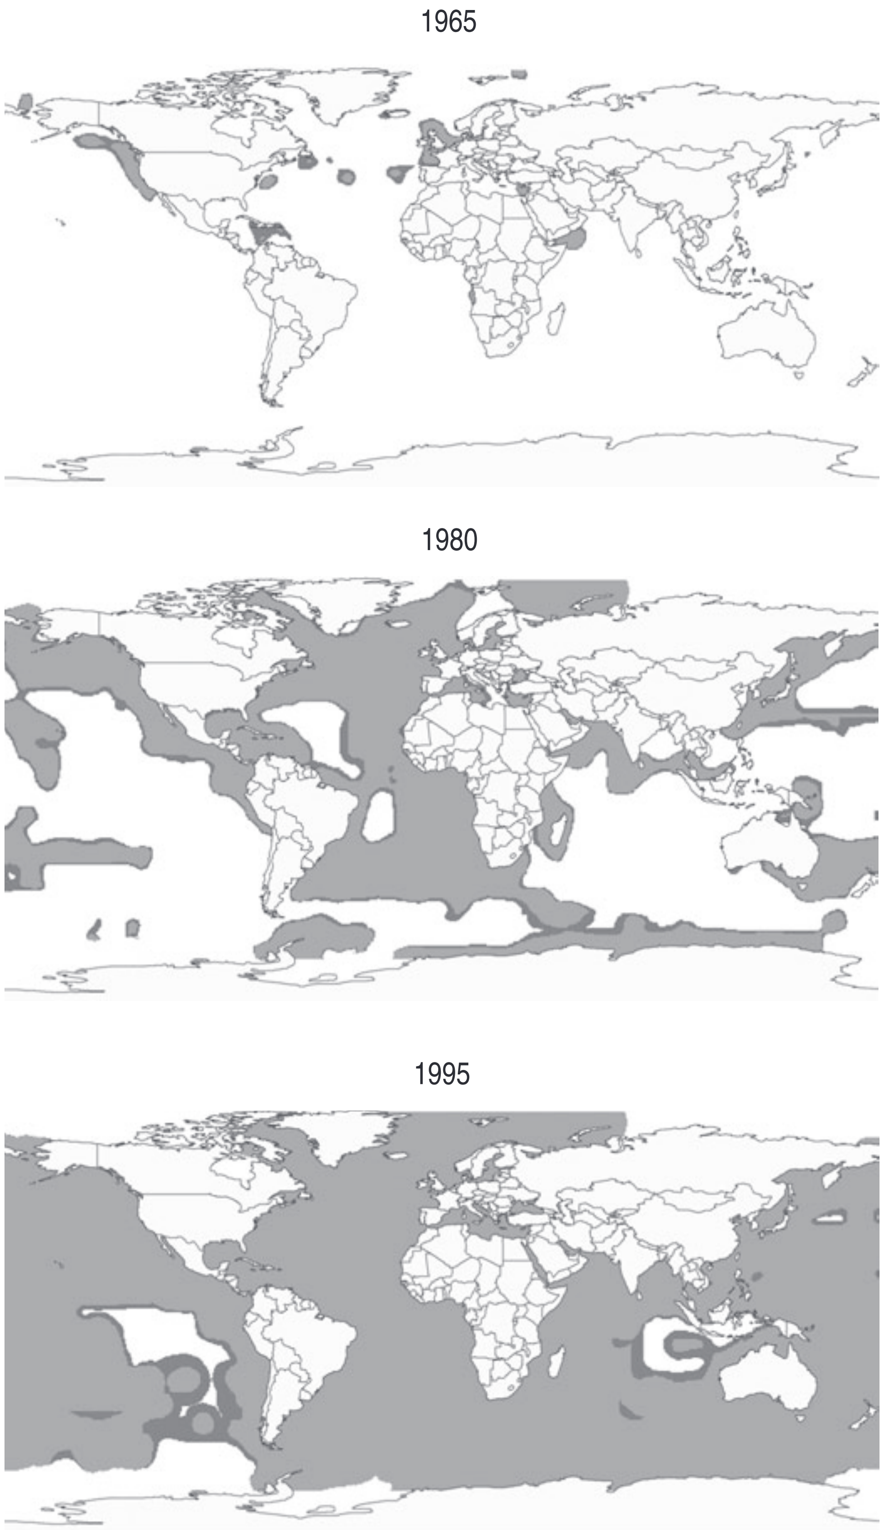

Figure 18.6. Year of Maximum Catch, 1965, 1980, and 1995. Solid lines indicate the current year and shading indicates that the maximum catch has already been reached. (SAUP 2005)

inces of Longhurst's coastal boundary biome and hence are implicitly considered here.

This biome fully includes the coastal systems (0–50 meters) covered in Chapter 19, the outer shelves (50–200 meters), and most of the continental slopes (200–1,000 meters). The coastal component of this biome is the first to have been accessed by fisheries, and it provides the bulk (53% in 2001; R. Watson, Sea Around Us Project, unpublished data) of the world's marine fisheries catches. The major processes that lead to ecosystem services such as food provisioning and biodiversity from this biome are described here.

Marine food webs are based largely on primary production by microscopic algae, the phytoplankton. This production occurs in the lighted, upper layers of the ocean, especially in the coastal zone, and is intensified by processes that lift nutrient-laden water from deeper layers. Most of this production is then either grazed by herbivorous zooplankton (mainly copepods) or falls to the sea bottom in form of detritus aggregates known as marine snow, which is formed of decomposed phytoplankton and zooplankton as well as the feces of the zooplankton attacked by bacteria while on the way down and consumed by benthic organisms upon reaching the sea floor. Little marine snow reaches the bottom of tropical seas due to, among other things, the higher metabolic rates of bacteria in warm waters. Hence, there is less benthos and fewer ground fish to catch in the deeper reaches of tropical seas than in otherwise comparable temperate or polar seas and upwelling systems. This creates a limit to the expansion of deep-sea benthic fisheries in tropical areas (Longhurst and Pauly 1987).

The coastal boundary biome is the most significant source of marine fish landed globally, and it also bears many of the impacts of fishing on ecosystems and of other human activities. Most depleted stocks are in this biome. In the North Atlantic, this has resulted in substantial marine biomass declines over the last 100 years (see Figure 18.8 in Appendix A) as well as the mean trophic level of the catch (see Figure 18.9) over the last 50 years. The majority of bottom-trawling fleets operate in this zone, affecting large areas of the seabed on a continual basis while catching both target and nontarget species. Holmes (1997) suggested that trawling destroyed seabed habitat and this contributed to fish declines in heavily trawled areas. A century of trawling in the North Sea has reshaped part of the seabed and changed the structure of the ecosystem (Malakoff 1998). Areas of the greatest decline in landings are in the coastal boundary biome.

Fishing pressure in this biome is not just attributed to excessively large industrial fleets but also to small-scale or recreational fishers, whose landings have a minor impact when viewed individually but who collectively can significantly deplete local resources, as described later. Coastal habitats such as coral reefs and similar biogenic bottom structures (for example, soft corals and sponge beds) are degraded where destructive fishing methods such as explosives, poisoning, and trawling are used by small-scale fishers (Cesar et al. 2003). Such fishing practices have particular impacts on coral reef habitats and the ability of damaged reefs to recover.

Coral reef fisheries are overexploited in many reef systems around the world (Christensen and Pauly 2001; Jameson et al. 1998). Although many fisheries have become unsustainable due to the scale of high-technology improvements to boats and fishing gear, even small changes of technology can shift the balance toward unsustainability. In Pacific Islands, for instance, spearfishers' catch of large humphead wrasse (*Cheilinus undulates*) used to be limited due to their reliance on snorkeling gear. However, scuba diving equipment has recently given fishers access to wider areas of reef and let them use other methods such as cyanide and dynamite both day and night, decimating humphead wrasse as well as populations of other large fish that are sold to the live fish market (Birkeland and Friedlander 2002).

The trading of fish sourced in the coastal boundary biome has undermined food security in coastal communities of the developing world. The demand for fish in local, regional, or international markets can, though increased prices, promote overfishing when demand from a luxury market largely exceeds the supply and fisheries management is ineffective. Eight of the top 40 food-deficient countries are also major fish producers and exporters (Kurien 1998). Much of the fish from the coastal boundary biome is exported to industrial countries, often to service the national debt of developing nations. The export of captured marine fish from developing countries has removed a cheap source of protein from their people in some cases. Senegal, for instance, which is a significant exporter of marine products, also has a protein deficit among its rural population because the growth of export-oriented

Table 18.3. Summary of Human Disturbances at the Deep-sea Floor, in Pelagic Waters, and on Continental Slopes (Deep-sea floor from Glover and Smith 2003)

Human Use	Temporal Scale	Knowledge of Impacts/Severity/Spatial Scale	Estimated Importance in 2025
Past impacts			
Deep-sea floor			
Dumping of oil/gas structures	isolated incidents (now banned)	good/low/regional	low
Radioactive waste disposal	1950s–90s	good/low/local	low
Lost nuclear reactors	1960s onwards	good/low/local	low
Dumping of munitions	1945–76 (now banned)	poor/low/local	low
Pelagic waters and continental slopes			
Dumping of wastes	until 1980s (now regulated)	low/low/low	moderate
Present impacts			
Deep-sea floor			
Deep-sea fisheries	1950s onward	good/high/regional	high (overfished)
Collateral damage by trawling	1950s onward	good/high/regional	high
Deep-sea oil and gas drilling	1990s onward	poor/moderate/basin	moderate
Dumping of bycatch causing food falls	1990s onward	poor/moderate/basin	moderate
Research and bioprospecting at vents	1960s onward	good/low/local	very low
Underwater noise	1960s onward	poor/low?/local	probably low for benthos
Pelagic waters and continental slopes			
Fishing	until 1950s very limited; steadily increasing, especially since 1960s	good/good/global	high (some unsustainable or highly variable)
Transportation — oil spills	increasing accidental oil spills until 1990s; decreasing	good/low/isolated	moderate
Transportation — other pollution (oil from bilges, litter, ballast)	despite regulations, still occurring	low/low/basin	moderate
Sewage discharge	1990s	good/good/local	high
Mining — minerals, gas and oil (slopes only)	1980s onward	good/good/local	high
Future impacts			
Deep-sea floor			
Polymetallic nodule mining	10–20 year time scale	poor/very high/regional-basin	high
CO_2 sequestration	10–30 year time scale	poor/very high/local-regional	high
Dumping of sewage sludge	5–10 year time scale	good/moderate/local-regional	moderate
Dumping of dredge spoil	5–10 year time scale	poor/low/local	moderate
Climate change	50–100 year time scale	poor/very high/basin-global	low
Manganese crust mining	unknown	poor/high/local	low
Polymetallic sulphide mining	unknown	poor/high/local	low
Methane hydrate extraction	unknown	poor/moderate/regional	low
Pelagic waters and continental slopes			
Dumping of dredge spoils	< 5 years	good/poor/local	high
Aquaculture	5–10 years	low/low/local	moderate-high
Tourism — mega cruise liners or offshore structures	unknown	low/low/low	low

fisheries disrupted domestic supplies of cheap, small pelagic fish (UNEP 2002a).

In contemporary literature on fisheries economics, it is accepted that once fisheries cease to be open access (by instituting some form of property rights), they can be managed sustainably to ensure the holder of quotas the maximum discounted economic rent, which is the highest present value of the sum of all future flows of resource rent from a given fishery (Hannesson 2000; Arnason and Gissurarson 1999). However, many authors have challenged this view because whether the stock is managed sustainably will also depend on a number of other factors, including the price-cost ratio of landing a unit weight of fish and the

Table 18.4. Summary of Specific Deep-sea Habitats (Based on Baker et al. 2001)

Deep-sea Habitat	Current Condition/Threats	Potential Threats
Hydrothermal vents	limited disturbances – currently due to limited research undertaken on vents; low number of species but high endemism and high abundance	high potential for biotechnology, mining, energy, and tourism
Seamounts	few of the more than 10,000 seamounts have been studied; high endemism on studied seamounts; some seamounts are heavily exploited for fisheries resources, trawling damages benthic habitats	mining of ferromanganese oxide and polymetallic sulfides
Deep-sea trenches	highly unique "hadal" fauna, much of it associated with soft sediments and holothurians; high endemism; supports diverse and abundant bacterial community; no known disturbances	research, biotechnology, and waste disposal
Deep-water corals	limited knowledge, speculation that they are more widespread than currently known; high diversity except for fish and mollusks compared with tropical reefs; colonies growing on gas and oil platforms; damaged by trawling but spatial extent unknown; gas and oil platforms can damage corals	biotechnology
Polymetallic nodules	primarily inhabited by hard substrate epifauna with foraminifera dominating by abundance and coverage; diverse fauna; limited disturbance resulting from current research and feasibility studies	high for mineral exploration including spoils disposal, especially if prices increase; mining also has potential to have an impact on pelagic communities
Cold seep and pockmarks	limited knowledge; high endemism; limited disturbances except for Gulf of Mexico (trawling and oil exploitation) or areas of research	biotechnology and mineral exploitation
Gas hydrates	limited knowledge and disturbance but scientific studies emerging in Gulf of Mexico, offshore India, and Japan; important bacterial diversity	source of methane gas for energy, but potential to exacerbate climate change
Submarine canyons	high diverse flora and fauna including commercially important species such as lobsters; important nursery areas for marine species; some areas affected by fishing and oil exploitation	gas and oil developments

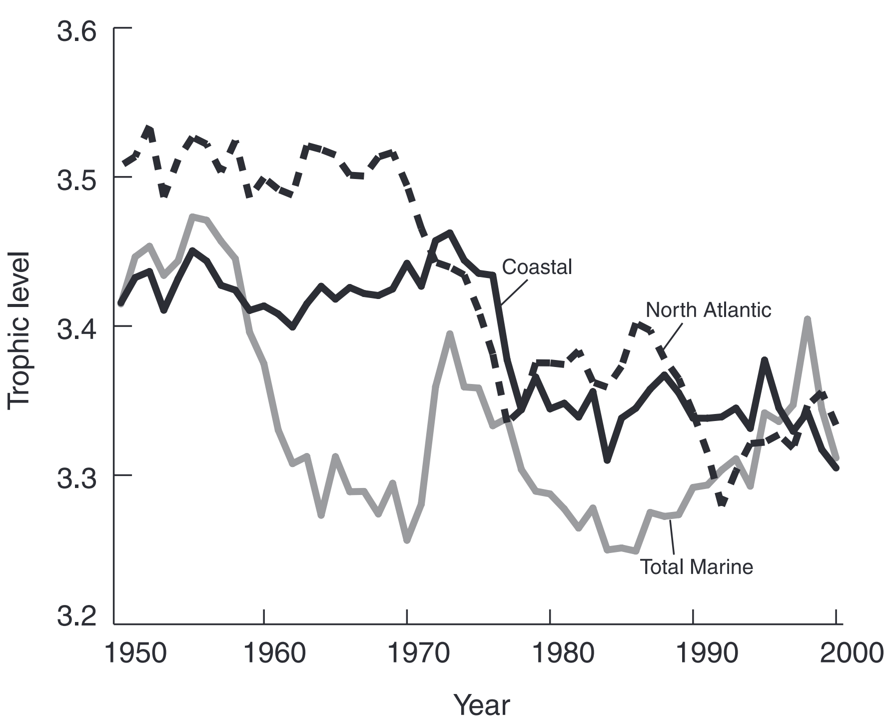

Figure 18.9. Changes in Trophic Level in North Atlantic and Coastal Areas at Less Than 200 Meters Depth, and Total Marine Landings, 1950–2000 (SAUP 2005)

discount rate applied to calculate the discounted rent. If both this ratio and the discount rate are very high, it may well be economically rational for the quota holder to deplete the fish stocks. In fact, it will be optimal in a strictly economic sense, as doing so may provide the maximum economic rent from a resource (Clark 1973; Heal 1998; Sumaila 2001; Sumaila and Walters 2004). Current economic models for fisheries, including those based on property rights, need to better accommodate underlying biological constraints.

18.2.3 Trade-winds Biome

The trade-winds biome (covering 38.5% of the world ocean) lies between the northern and southern sub-tropical convergences, where a strong water density gradient hinders nutrient recycling between deep layers and upper surface layers. The resulting low levels of new primary production make these zones the marine equivalent of deserts. Therefore, fisheries in this biome rely mainly on large pelagic fish, especially tunas, capable of migrating over the long distances that separate isolated food patches. In the eastern tropical Pacific, a major portion of the tuna purse-seine catch results from exploitation of a close association with pelagic dolphins, which suffered severe depletion in the 1970s due to incidental kills in the tuna purse seines (Gerrodette 2002). Between 1990 and 2000, 1.5 to 3.5 million Northeastern spotted dolphins (*Stenella attenuata*) were incidentally captured annually in tuna seine nets (Archer et al. 2002).

One exception to the general low productivity of the trade-winds biome is around islands and seamounts, where physical processes such as localized upwelling allow for localized enrichment of the surface layer. Above seamounts, these processes also lead to the retention of local production and the trapping of advected plankton, thus turning seamounts into oases characterized by endemism and, when pristine, high fish biomass.

Exploitation of the demersal resources of seamounts usually occurs in the form of intense trawling pulses, mainly by distant water fleets, which reduce biomass to extremely low levels, reduce diversity in the associated pelagic systems, and destroy biogenic bottom structures and their associated benthic diversity. Similar exploitation occurs along ocean ridges, such as in the North Atlantic and the Central Indian Ocean, where poorly documented bottom trawl fisheries developed in the 1990s outside of any regulatory regimes.

Overall, the trade-winds biome contributed 15% of the world's marine fisheries catch in 2001. Of this, 34% consisted of large pelagic fish and the rest were largely deep demersal species.

18.2.4 Westerlies Biome

In the westerlies biome (35.7% of the world's oceans), seasonal differences in the depth of the mixed layer result from seasonality in surface irradiation and wind stress, inducing strong seasonality of biological processes, including a spring bloom of phytoplankton. The fisheries of this biome, mainly targeting tuna and other large pelagic species, are similar to those of the trade-winds biome.

The westerlies and trade-winds biomes are also inhabited by an enormous number of small mesopelagic fish that aggregate during the day at depths of 500–1,000 meters, forming a dense layer of fish and invertebrates, especially squid, and that migrate upward every night to feed on zooplankton at the surface layer (vertical migration). Their aggregate biomass, almost 1 billion tons (Gjøsaeter and Kawaguchi 1984), has often been described as a potential resource enabling further fisheries development. However, mesopelagic fish rarely occur in fishable concentrations, and their bodies tend to contain large amounts of wax esthers, which render their flesh unpalatable to humans.

Overall, the westerlies biome contributed 15% of the world's marine fisheries catch in 2001. Of these, 9% were large pelagic fish with the rest consisting of small pelagic fish (40%), demersal fish (23%), and squid (11%). The marine environment in this biome is relatively unaffected by human use other than fishing. However, the large pelagic fish, such as tuna and shark, are strongly exploited.

18.2.5 Polar Biome

The polar biome covers only 15% of the world ocean and accounts for 15% of global marine fish landings. Its vertical density structure is determined by low-salinity waters from spring melting of ice. The bulk of annual primary production occurs in ice-free waters during a short intense summer burst. However, primary production under lighted ice occurs over longer periods, especially in Antarctica.

The Arctic fisheries along the north coast of Siberia, Alaska, and Canada (FAO Area 18) are poorly documented, and the few thousand tons of landings reported for this area by FAO are likely to be underestimates. The Arctic marine system is important for the well-being of indigenous people living in the area. For instance, marine mammals, such as whales and seals, are an important source of food and are of significant cultural value. However, high levels of persistent organic pollutants in their blubber pose a health concern. (See also Chapter 25.) Climate change has the potential to have a significant impact on the people of this area, since the ice forms a fundamental part of subsistence, shelter, travel, safety, and culture in the region. Oil and gas exploitation pose another set of issues for inhabitants of the Arctic (through social changes, for instance) and the ecosystem (through impacts on marine mammals, habitat damage or changes, oils spills and contamination).

The Antarctic krill, *Euphausia superba,* consumes the primary production from both open waters and under the ice and then serves as a food source for a vast number of predators, notably finfish, birds (including penguins), and marine mammals. As in the Arctic, the marine mammal populations of Antarctica were largely decimated before the middle of the twentieth Century. There is also a relatively small direct fishery for krill (about 150,000 tons per year) in Antarctica, which may expand if krill proves a suitable feed for salmon or other forms of farming.

The development of fisheries in the southern polar biome demonstrates the fragility of fish stocks, marine mammals, and seabirds in terms of the impacts of exploitation by humans in just over 30 years. The distant water fleet of the former Soviet Union began exploiting this biome in the mid-1960s when ships began to deplete stocks of Marbled notothenia (*Notothenia rossii*), Mackerel icefish (*Champsocephalus gunnari*), and Gray notothenia (*Lepidonotothen squamifrons*) in different areas of the South Indian, South Atlantic, and South Pacific Oceans. (See Figure 18.10.) In all these areas, the same catch trends emerged: within a few years of opening fisheries, catches would peak and then rapidly decline to a small fraction of their original biomass. This operating mode of distant water fleets, including those of Russia, Chile, Argentina, France, and the United Kingdom, continued until the beginning of the 1990s.

The formation of the Commission for the Conservation of Antarctic Marine Living Resources in 1982 brought the first conservation measures for stocks of Marbled notothenia (in 1985). Other stocks remained unmanaged until the 1990s, when dra-

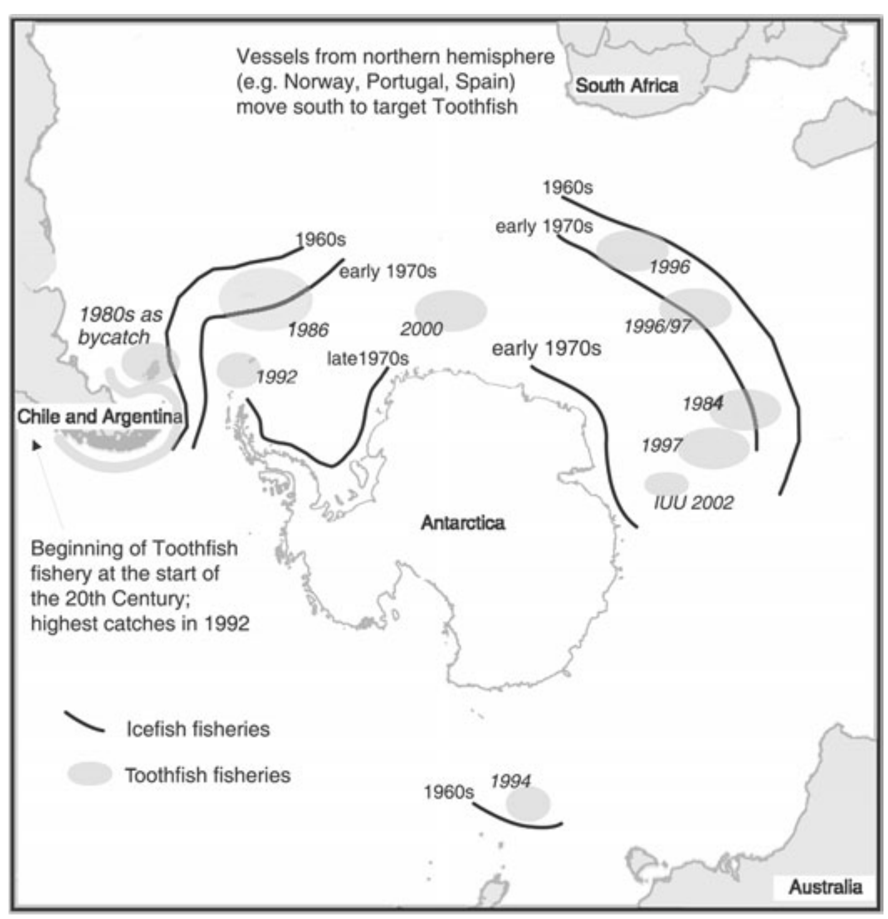

Figure 18.10. Growth of Fishing for Icefish and Toothfish in the Southern Polar Biome, 1900 to Present (Sabourenkov and Miller 2004; Kock 1991, 2001)

matic declines in stocks of Mackerel icefish at South Georgia and Kerguelen were recognized. Assessment, management, and control of the fisheries became much more stringent (Constable et al. 2000), and Mackerel icefish around South Georgia recovered sufficiently to allow limited commercial catches from the mid-1990s onward (CCAMLR 2002). However, Kerguelen stocks have remained at a very low level (Duhamel and Claudet 2002).

In the second half of the 1980s, the Soviet Union developed a longline fishery on Patagonian toothfish *Dissostichus eleginoides* (Kock 1991, 1992). The same declining catch trend for these long-lived, slow-growing species emerged for the stock around the Prince Edward Islands, which was reduced to very low levels within a few seasons. As a side effect, a large numbers of seabirds (such as albatrosses) became hooked on lines during the process of setting and hauling (Kock 2001). The situation became more aggravated when longline fishing was extended to virtually all grounds in the northern part of the southern polar biome from 1996/97 onward, and concern over the sustainability of stocks grew. Nevertheless, illegal, unregulated, and unreported fishing on the highly prized Patagonian toothfish increased dramatically from 1997 onward, and it is estimated that 80–90% of the current catch is taken illegally (CAMLR 2002).

While it was possible to reduce IUU fishing around South Georgia to low levels, fishing pressure by IUU vessels remained high on other fishing grounds, notably in the Southern ocean, in FAO Area 58, despite considerable efforts by France and Australia to improve surveillance around the territories under their control. Commission members are working in closer cooperation with countries to assist with the apprehension of IUU vessels (as, for example, in the *Viarsa* incident; see www.intrafish.com).

New fisheries are still being developed in the southern polar biome despite the lessons learned about the vulnerability of the local fish (including the Patagonian toothfish) to high levels of exploitation. Thus, New Zealand started an exploratory fishery on Antarctic toothfish (*Dissostichus mawsoni*) in the Ross Sea in the 1998/99 season (CCAMLR 2002) and has increased catches every year since.

18.2.6 Marine Biodiversity

18.2.6.1 Global Trends

This section provides a brief overview of marine biodiversity in the context of fishing. Chapter 4 gives a broader view of marine biodiversity trends.

Assessing the biodiversity of the oceans has not been completed, both in general terms and with respect to specific system types, such as rocky grounds on continental slopes (Carlton et al. 1999). The factors influencing species distributions and patterns of species richness are only just emerging for widespread habitats such as soft sediments (MacPherson 2002; Gray 2002). Similarly, methods for measuring diversity and its patterns are evolving rapidly, so that in the future, if such methods are put into practice and applied in research and monitoring activities, our understanding of the condition and trends of marine biodiversity will improve significantly (Price 2002; MacPherson 2002; Warwick and Clarke 2001; Warwick and Turk 2002).

Information on commercially important or threatened species required for management purposes is quite limited. New non-fish species are frequently discovered and described in association with fisheries surveys or, more recently, environmental impact assessments. However, recent initiatives, such as the Census of Marine Life, are increasing the rate at which new knowledge on marine life is becoming available, although understanding of most taxa other than fish is very limited and reflects a failure to seek any systematic understanding of fisheries systems. For some groups important in fisheries catches, notably finfish and cephalopods, online databases that provide information on all species described so far do exist (see www.fishbase.org and www.cephbase.org). Also, a fair understanding of the factors influencing the distribution (depth, temperature, and so on) and population dynamics of major commercial species is available.

It is widely assumed that marine fish and invertebrates are somewhat less susceptible to extinction than most other marine as well as terrestrial and freshwater organisms. However, recent advances in methodology allowed studies that have questioned this assumption (Dulvey et al. 2003; Hutchings 2000). Although few marine species are known to have become globally extinct in the last century, there are numerous instances of extirpations of marine fish species—for example, the European sturgeon (*Acipenser sturio*) in the North Sea and the Green wrasse (*Anampses viridis*) in Mauritius.

Recent analyses suggest that marine extinctions may have been underestimated because of low detection abilities and a generally poor understanding of the conservation status of species that live in the marine realm (Dulvey et al. 2003; Carlton et al. 1999). Moreover, given that a major cause of declines or local extinctions in marine populations is overexploitation and that exploitation is rapidly increasing in scope and volume, there is a real likelihood that extirpations will increase (Dulvey et al. 2003). Other factors such as environmental degradation and climate change, alone or in combination with exploitation, can also play a role in local extinctions. As the first step toward global extinction, extirpations (local extinctions) cannot be dismissed as unimportant or irrelevant to a species' status and have significant impacts on the provision of ecosystem services. (See Chapters 4 and 11.)

The now rapidly fading notion that marine fish and invertebrates are inherently more resilient to impacts on their populations than other wildlife was based on a number of unfounded assumptions about their biology, particularly in the case of species that release large numbers of eggs into the open water. The key assumption was that high fecundity combined with a seemingly high dispersal capacity of the eggs or larvae, high recruitment variability, and wide-ranging distributions minimizes the risk of extirpations or extinctions even under heavy fishery exploitation. However, scientific support for this assumption is lacking or poor. Indeed, there is now an emerging consensus that marine fish are no more resilient to extirpations or extinctions than any other wildlife species of similar size (Roberts and Hawkins 1999; Hutchings 2000; Sadovy 2001).

18.2.6.2 Ecosystem and Habitat Diversity

The number of species present and their relative abundance is an important aspect of biodiversity and is threatened in marine systems. Overfishing and destructive fishing methods have an impact on marine ecosystems by changing community structure and altering trophic and other interactions between ecosystem components and by directly modifying habitats, notably when trawlers erode biogenic bottom structures (Pandolfi et al. 2003). By removing important components of the ecosystem, such as algal feeding fish in coral reef systems, overfishing results in altered ecological states that may be impossible to restore to former conditions. (See Chapter 19.)

A number of generalities can be drawn from the literature on biodiversity. One is that biological production declines with increasing "trophic level" (the number of feeding levels that organisms are removed from phytoplankton and other primary producers; see Chapter 8 for an explanation of the trophic level concept). In fisheries, most catches occur at around trophic level 3, which consists of small fish (such as sardines and herrings) feeding on herbivorous zooplankton (zooplanktivorous fish), and around trophic level 4, which consists of fish that prey on the zooplanktivorous fish (such as cods and tunas). Many fish, however, have intermediate trophic levels, as they tend to feed on a wide range of food items, often feeding on zooplankton as juveniles and other fish when adults. (See www.fishbase.org for diet composition data and trophic level estimates on thousands of fish species and the corresponding references.)

Biomass energy is transferred up the food web, with transfer efficiencies between trophic levels ranging, in marine ecosystems, from about 5% to 20%, with 10% a widely accepted mean. Thus the productivity of the large, high trophic–level fish that are traditionally targeted will always be lower than that of lower trophic–level fish. This has led to suggestions that fisheries yields should be increased by deliberately ''fishing down the food chain'' (Sprague and Arnold 1972)—that is, by exploiting species located at lower trophic levels more intensively. But this is already occurring throughout the world's oceans as a result of the decline in catches of the large, slow-growing high trophic–level fish, which are gradually being replaced, in global landings, by smaller, shorter-lived fish, at lower trophic levels (Pauly et al. 1998). Unfortunately, fishing down marine food webs does not necessarily lead to increased catches (see earlier Figures 18.3 and 18.9). Indeed, globally both the landings and their mean trophic levels are currently falling under the pressure of fisheries (Pauly et al. 1998; Watson and Pauly 2001); what seems to be increasing worldwide is the abundance of jellyfish, which are increasingly exploited throughout the world and exported to East Asia.

The deep ocean bottom contains some of the least explored areas of the world, with only 0.0001% of the deep seabed subject to biological investigations thus far (WWF/IUCN, 2001; Gray 2002). Nevertheless, studies have revealed a wealth of diverse habitats in the deep sea, which include seamounts, cold-water coral reefs, hydrothermal vents, deep-sea trenches, submarine canyons, cold seeps and pockmarks, and gas hydrates and polymetallic nodules. Of those, seamount ecosystems and cold-water coral reef communities are particularly threatened by high-impact fishing methods, such as bottom trawling (Thiel and Koslow 2001; Freiwald et al. 2004).

Scientific exploration of seamounts is minimal, with only approximately 300 of them sampled biologically, out of what is believed to be tens of thousands worldwide (ICES, 2003; see also seamounts.sdsc.edu). As mentioned previously, seamounts increase the biological productivity of waters surrounding them. The tops and upper flanks of seamounts also tend to be biological hotspots, with potentially high species diversity and endemism. Marine mammals, sharks, tuna, and cephalopods all congregate over seamounts to feed, and even seabirds have been shown to be more abundant. Suspension feeders, such as corals, dominate seamount benthic fauna. Seamounts may also act as ''stepping stones'' for transoceanic species dispersal (WWF/IUCN, 2001).

Our knowledge of cold-water coral diversity is also limited, and new reefs are still being discovered. For example, the largest known cold-water reef—35 kilometers long and 3 kilometers wide—was discovered off the Norwegian coast in June 2002 (Freiwald et al. 2004). There are few quantitative studies of fauna associated with cold-water corals, but it is known that they provide habitat for high diversity of associated species. More than 800 species have been recorded in the *Lophelia pertusa* reefs in the northeast Atlantic, and 3,000 species of fish and mollusks have been identified on deepwater reefs in the Indo-West Pacific region (WWF/IUCN, 2001).

The biggest threat to deep-sea coral reefs comes from trawling activities. WWF (2002) suggest that 30–50% of the deep-water corals along the Norwegian coast have already been lost due to bottom trawling, marine pollution, and oil and gas exploration.

Inconsistent and opportunistic sampling in deep and isolated areas, where cold waters and deep-sea corals are located, hampers efforts to study these habitats, and it is likely that global assessments will underestimate the biodiversity of these areas. More is known about local habitats and local extinctions in warm waters, such as the loss of the sawfish (*Pristis pectinata*) in Mauritania (UNEP 2002b) and the Chinese bahaba (*Bahaba taipingensis*) in Hong Kong (Sadovy and Cheung 2003).

18.2.6.3 Species Diversity

The lowered biomass and fragmented habitats resulting from overexploitation of marine resources is likely to lead to numerous extinctions, especially among large, long-lived, late-maturing species (Sadovy and Cheung 2003; Sadovy et al. 2003a; Denney et al. 2002).

Fishing is thus one of the major direct anthropogenic forces that has an impact on the structure, function, and biodiversity of the oceans today. Climate change will also have impacts on biodiversity through changes in marine species distributions and abundances. In the coastal biome, other factors, including water quality, pollution, river and estuarine inputs, have large impacts on coastal and marine systems. (See Chapter 19.) Historical overfishing and other disturbances have caused dramatic decreases in the abundance of large predatory species, resulting in structural and functional changes in coastal and marine ecosystems and the collapse of many marine ecosystems (Jackson et al. 2001).

One well-documented example is that of the historic fishing grounds ranging from New England to Newfoundland and Labrador, which once supported immense cod fisheries but which have now been almost completely replaced by fisheries targeting invertebrates, the former prey of these fish (providing a classic example of fishing down marine food webs). The system that once supported cod has almost completely disappeared, fueling fears that this species will not rebuild its local populations, even though fishing pressure has been much reduced (Hutchings and Ferguson 2000; Hutchings 2004; Lilly et al. 2000). However, some collapsed stocks have been able to recover once fishing pressure is removed: the North Sea herring fishery collapsed due to overharvest in the late 1970s but recovered after a four-year closure (Bjørndal 1988). On a much smaller scale, but nevertheless widespread throughout the tropics, coral reef areas have been degraded by a combination of overfishing, pollution, and climate variability. (See Chapter 19.)

18.2.6.4 Genetic Diversity

An important component of biodiversity is genetic diversity (FSBI 2004). Even for those marine groups that are taxonomically well documented, relatively little is known about the subdivision of species into populations with distinct genetic (and sometimes morphological) features, which are of evolutionary importance and of potential human use. Lack of knowledge about appropriate conservation units can lead to inadvertent overexploitation of distinct populations and to their extirpations (Taylor 1997; Taylor and Dizon 1999); where recovery is possible, it may take decades or centuries, as in the case of some populations of large species of whale (Clapham et al. 1999). In some cases, genetic diversity may be irretrievably lost due to a ''bottleneck'' effect caused by overexploitation, as with the northern elephant seal (*Mirounga angustirostris*) population, which was nearly exterminated by early commercial sealing (Bonnell and Selander 1974; Stewart et al. 1994).

18.3 Drivers of Change in Marine Fisheries Systems

There are two direct drivers and several indirect drivers of changes in marine ecosystems. The climate, due to its natural variability and increasingly because of greenhouse gas emissions, drives a number of changes affecting marine ecosystems, while government policy primarily drives change through the effect on investment in fisheries, with direct drivers such as overfishing resulting from government subsidies. Economic factors, including an increase in demand reflected in an increase in price and food preferences, also affect fisheries, with population growth exacerbating most of these.

18.3.1 Climate Change

Climate change is a direct driver in marine systems (McLean et al. 2001) and its potential impacts are described later, in the section on choices and trade-offs. Changing wind patterns and sea temperatures have an impact on various oceanographic processes, including upwellings (for example, Benguela) and surface currents (as in the Gulf Stream) (McLean and Tsyban 2001). (See also Chapters 12 and 13.) These currents may slow down, shift spatially or disappear altogether, resulting in changes in population abundance and distribution for many marine species.

There may be local extirpations, but global extinctions in the oceans are unlikely to result from climate change alone. Recent results from monitoring sea temperatures in the North Atlantic suggest that the Gulf Stream may be slowing down and affecting abundance and seasonality of plankton that are food for larval fish (Richardson and Schoeman 2004). Declining larval fish populations and ultimately lower adult stocks of fish will affect the ability of overexploited stocks to recover (Beaugrand et al. 2003).

Climate-induced changes in their physical characteristics (such as currents and circulation patterns) and their chemical characteristics (such as nutrient availability) will affect marine ecosystems directly. These impacts include sea surface temperature–induced shifts in the spatial distribution of some species and compositional changes in biodiversity, particularly at high latitudes. A poleward shift of marine production due mainly to a longer growing season at high latitudes is anticipated. While a complete shutdown of the North Atlantic circulation is unlikely, it cannot be ruled out, even in the foreseeable future (IPCC 2003).

A poleward shift of marine production due mainly to a longer growing season at high latitudes is anticipated (IPCC 2003). Recent findings show that warming in the Northern Hemisphere will cause a northern shift of distribution limits for various species through improved growth and fecundity in the north and lower growth or even extinctions in the south of this range. Such shifts may seriously affect fishing activities in the North Sea (Portner et al. 2001) and other productive areas of the world's oceans. However, current knowledge of the impacts of climate change in marine ecosystems is still poor, and literature on the subject is scarce.

Current scenarios of global climate change include projections of increased upwelling and consequent cooling in temperate and sub-tropical upwelling zones. Such cooling could disrupt trophic relationships and favor less complex community structures in these areas (Aronson and Blake 2001; Barret 2003). Marine export production may be reduced (estimated at −6%), although regional changes may be either negative or positive (from −15% zonal average in the tropics to +10% in the southern polar biome) (Bopp et al. 2001).

18.3.2 Subsidies

There are two forms of subsidies: direct financial support in industrial countries (price supports, for instance) and indirect support, notably in the form of open access policies that allow resource rents to be spent on excess capacity. The latter happens when the surplus of funds from a fishery after all costs have been paid are spent on purchasing additional capacity.

Financial subsidies are considered to be one of the most significant drivers of overfishing and thus indirect drivers of change in marine ecosystems. In most cases, government subsidies have resulted in an initial increase of overall effort (number of fishers and size of fleet), which translates into increased fishing pressure and overexploitation of a number of species. While it appears that the number of fishing vessels (see Figure 18.11) and fishers stabilized in the late 1990s, other subsidies, e.g. cheap fuel subsidies, can keep fleets operating even when fish are scarce. Without such subsidies, many of these fisheries would cease to be economically viable (Munro and Sumaila 2002).

Subsidies also play a role in fisheries expansion. Globally, the provision of subsidies to the fisheries industry has been variously quantified at $20 billion to over $50 billion annually, the latter roughly equivalent to the landed value of the catch (Christy 1997). More conservative estimates are provided by Milazzo (1998) and by an OECD (2000) study, recently reanalyzed and scaled to the North Atlantic by Munro and Sumaila (2002). The latter suggested an annual subsidy of $2.5 billion for a part of the world ocean that contributes about one sixth of the world catch.

The subsidies given to fisheries vary between countries and range from unemployment benefits in Canada to tax exemption in the United States and payment of fees to gain access to foreign fishing grounds by the European Union (Kaczynski and Fluharty 2002). For instance, in 1997 Canada provided over $198 million in unemployment benefits to its fishing sector; the United States gave $66 million in tax exemptions, and the European Union provided subsidies of $155 million to obtain access to other countries fishing grounds. Each of these have the effect of either reducing the cost of fishing or increasing the net revenues fishers obtain, and hence they lead to more fishing than would have been the case without the subsidies.

Over half the subsidies in the North Atlantic have negative effects on fleet development (Munro and Sumaila 2002). This, perhaps surprisingly, includes decommissioning subsidies, which

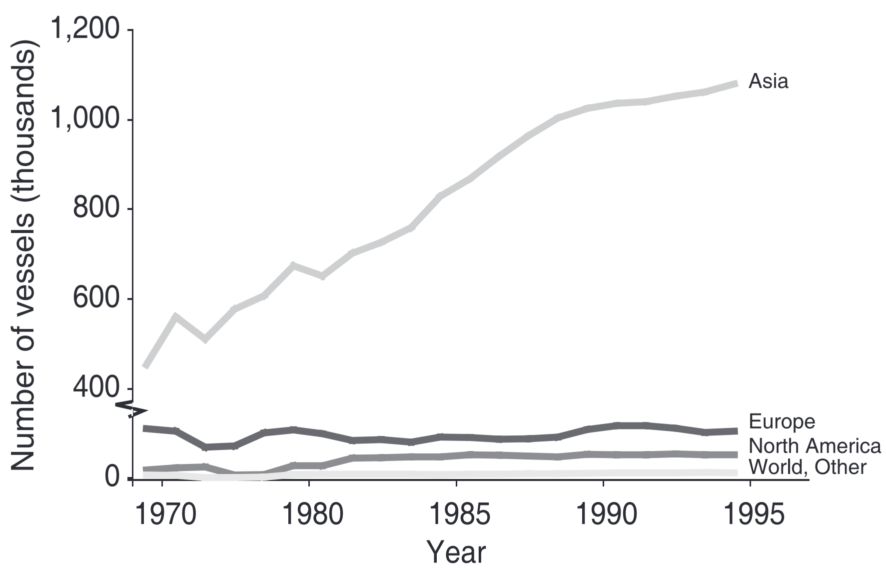

Figure 18.11. Trend in Fishing Vessels, 1976–2000 (FAO 2003)

have been shown under most circumstances to have the effect of helping to modernize fleets, thereby bringing about an increase in their catching powers.

18.3.3 Demand and Fish Prices

Overfishing drives ecosystem change, including changes in biodiversity, as described earlier. The growing demand and correspondingly increase in prices has contributed to overfishing. Marine products are in demand as a luxury food as well as for subsistence in many coastal communities, and as feed for aquaculture and livestock. It is the relatively high prices for these products combined with subsidies (plus the use of coastal systems as disposal sites for their waste products) that makes aquaculture a feasible industry.

It has been reported that bluefin tuna (*Thunnus thynnus*) have sold on the Tokyo market for as much as 20 million yen for a single fish (Japan Times 2001). Other fishery products such as eel larvae (*Anguilla* spp) and large prawns are also extremely high priced commodities. Such very high prices generate extreme pressures for overexploitation that are sometimes nearly impossible to counter through local management measures. As such items become increasingly scarce, they increasingly assume the status of luxury foods. The result is that increasing scarcity, rather than causing a relaxation of pressure on the remaining remnants of the resource populations, may act to increase the incentives to harvest the remaining individuals. For example, the Chinese bahaba (*Bahaba taipingensis*) is highly sought after for its swimbladders used in traditional medicine. Consequently, this fish—which fetches \$20,000–64,000 per kilogram (see Figure 18.12)—has been exploited to critically low levels (Sadovy Cheung 2003).

18.3.4 Shifting Food Preferences and Consumption

It could be argued that human population growth and the resulting need for inexpensive food have been driving fisheries expansion. However, human population growth did not drive excess fleet capacity from Northern Europe and Japan into the southern oceans. Human population growth did not stimulate people in countries not accustomed to eating fish to shift toward a heavy consumption of seafood, as seen in China where income growth and urbanization has fueled fish consumption (Delgado et al. 2003). In industrial countries, such as the United States, fish is no longer a cheap source of protein compared with other sources. The price of fish has increased in real terms while the price of red meat has lost half its value over the last 20 years (Delgado et al. 1999).

Factors driving overfishing other than human population growth are also at work. One of these is increase in incomes and

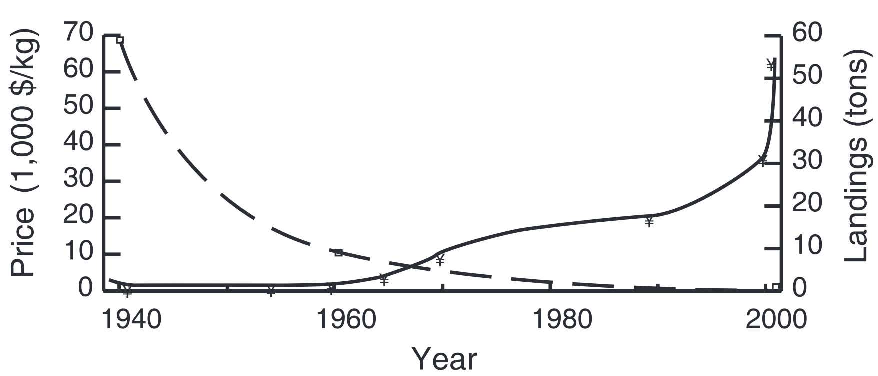

Figure 18.12. Estimated Annual Landings of *Bahaba Taipingensis* (Giant Yellow Croaker) and Swimbladder Market Price in Hong Kong, 1940–2000 (in constant 2000 US Dollars) (Sadovy and Cheung 2003)

therefore fish consumption in various countries that previously did not appear in international markets, such as China (Ahmed et al. 1999). Another factor is the consumption of fish promoted as part of a "healthy" diet and changing food preferences in many industrial countries.

18.3.5 Technological Change

Historically, the global expansion of fisheries has been driven by successive waves of technological innovation, much of it developed for naval warfare following the Industrial Revolution, two World Wars, and the cold war. These innovations included the invention of steam and diesel engines, the onboard manufacturing of ice, and blast freezing, all of which expanded the range of industrial fishing vessels. This expansion was followed by the incorporation of an enormous array of electronic devices facilitating fish detection, including radar and acoustic fish finders on fishing vessels, culminating in the introduction of GPS technology and detailed seabed mapping at the end of the cold war. These technologies, while improving the safety of people working at sea, also allowed fishers to aim for specific places with high fish abundances, places that once were protected by the depths and vastness of the oceans.

18.3.6 Illegal Fishing

The profits of fisheries that choose to operate outside of national and international laws and conventions can be very high. In some areas there is a lack of surveillance, enforcement, and monitoring due to high operational costs. In other areas corruption and cheating are tolerated due to the economic conditions or social obligations within a country. Managers recognize illegal, unreported, and unregulated fishing as a global problem, and recent initiatives, such as FAO's International Plan of Action, will help formulate strategies to deal with the problem. Regional fishery management organizations, such as the International Commission for the Conservation of Atlantic Tunas, are dealing with nonmembers and members who do not comply with management measures through the use of economic sanctions. "Name and shame" strategies are being used by NGOs to force companies and governments to comply with international management measures (for example, the Coalition of Legal Toothfish Operators, see www.colto.org/vessels.htm).

Large-scale cheating in some fisheries that were supposedly regulated internationally has led to extreme depletion of some living marine resources. An especially egregious example is the misreporting of Soviet whale catches to the International Whaling Commission (Brownell and Yablokov 2002). Between 1947 and 1972, some 90,000 more whales were taken in the Southern Hemisphere than was reported, including more than 3,000 endangered southern right whales that were supposedly fully protected at the time. Similar violations occurred in the North Pacific and Indian Oceans, and it was only with the introduction of international on-board observers that these practices ceased. It is now widely agreed that independent surveillance is an essential part of any fishery management and enforcement plan.

18.3.7 Globalization

Fish represent the fastest-growing food commodity entering international trade (Preston 1997). Accordingly, fish and fish products are an extremely valuable source of foreign exchange to many countries, in some cases providing as much as half of their total available foreign exchange income. For example, in Guinea-Bissau fishing agreements with the EU finance more than 45% of the government's annual fisheries operations budget, though this country only receives a very small fraction of the value (<10%) of the fish taken by European fleets (Kaczynski and Fluharty 2002).

Stocks of bluefin and other large tuna species around the world are being strained by fishing pressure driven by the extremely high prices such fish fetch in the Japanese luxury fish markets. Traditional local fish foods are, in many cases, no longer available to local consumers due to their inability to match the prices available by shipping the products elsewhere. An example is Senegal, where exports have disrupted local supplies of fish (UNEP 2002a). Consequently, highly nutritious fish foods produced in poorer regions of the world are increasingly being eaten by more economically advantaged populations in distant areas of North America, Europe, and East Asia. Of particular concern is the East and Southeast Asian market for shark fins that is threatening many shark species around the world, which are already under pressure from being a significant part of the bycatch of many pelagic fisheries.

One benefit of globalization is the improved quality of fish, because most importing countries demand that exporting facilities meet Hazard Analysis and Critical Control Point standards, which require exporting countries to follow safe food processing and handling standards. The associated benefits have been mainly to industrial countries, however. In developing countries, benefits have been limited to companies that can afford the required investment (Atta-Mills et al. 2004) or to the few local fishers able to participate in "boutique" fisheries for live fish, seahorses, and aquarium fish, which are low volume but a high-price export product (Erdmann and Pet-Soede 1996; Tomey 1997; Sadovy and Vincent 2002; Alder and Watson in press).

Export fisheries have also influenced the aquaculture industry, especially for salmon and shrimp, which are bred to meet the demand from industrial countries for luxury high-value seafood. For example, salmon (much of it farmed) was the leading fish export commodity of the EU in 1998 (Smith and Taal 2001). Countries such as Thailand that are the leading producers of shrimp (much of it from aquaculture) are often the leading exporters.

Increasing exports have contributed to the expansion of fishing fleets (facilitated by subsidies) leading to overcapacity and overexploitation as seen in the development of the pollock industry in the 1980s in Alaska (St Clair 1997). Depending on the fishery, this can lead to habitat destruction through trawling and biodiversity loss through, for example, turtles caught in shrimp trawls, albatross and sharks caught by longlines, and other bycatch in various fisheries (Hall et al. 2000).

Globalization clearly has the benefit of supplying foreign exchange to developing countries and potentially decreasing national debt. But this benefit has been at the cost of domestic supplies of fish resources, resulting in increasing domestic prices; in India, for example, the cost of fish has increased faster than the cost-of-living index and other meats (Kurien 1998) and has decreased food security.

18.3.8 Other Drivers

Habitat changes in coastal systems are a major driver of fisheries declines. (See Chapter 19.) Other factors of lesser apparent importance are invasive species, pollution, and disease. Human impacts, especially exploitation, are increasing. Moreover, persistent and widespread misconceptions about the ability of marine fish populations to withstand and recover from fishing continue to undermine initiatives to address the root causes of these problems (Roberts and Hawkins 1999; Hutchings 2004). Habitat loss or damage is caused by a range of fishing practices (from bottom trawling to the use of dynamite), by pollution, or possibly by global warming, as in the case of extensive bleaching of coral reefs. Even well-intended attempts to remediate declines in fisheries through stocking can be problematic as hatchery operations have an impact on the genetic structure of wild stocks.

Two additional processes have effects similar to subsidies. One is the rapid increase in the demand for fish, reflected in increased prices of fish products, which in the last 50 years have increased three to four times faster than the consumer price index (Delagado and Courbois 1999). The other is the low price of fuel, which keeps numerous, otherwise bankrupt fisheries afloat in many countries. Moreover, due to the decline in stock abundance, the catch and edible protein per amount of fuel burned has decreased over time (Tydemers 2004). Indeed, fisheries are probably the only sector of the economy that has decreasing fuel efficiency (compared with, say, trucking, aviation, or manufacturing). Obviously, this growing dependence of the fishing industry on cheap fuel makes it highly vulnerable to fuel price increases, as well as to implementation of the Kyoto protocol or similar agreements that would tax industries for their energy intensity (Pauly et al. 2003).

18.4 Choices, Trade-offs, and Synergies within the System

Marine systems are still considered a new frontier for development by some people (McNutt 2002), and therefore a number of choices and trade-offs over fisheries will need to be made in the future. History has shown that once humans exhaust resources on land they look to the sea for alternatives. In repeating history, coastal environments are becoming degraded (for loss of coral reefs, see Chapter 19) and biodiversity is declining, beginning with the loss of large predators at high trophic levels (Pauly et al. 1998; Myers and Worm 2003). Now areas deeper and further offshore are increasingly exploited for fisheries and other resources such as oil and gas.

Marine fish resources often have value and benefits beyond that of food security. Some species are of considerable cultural importance (salmon are an important part of aboriginal culture in the Northeast Pacific, for instance), while others generate substantial income from tourism (especially dive tourism) and recreation (Rudd and Tupper 2002). Yet others may be important keystone species within their community, with a loss even at local levels cascading throughout the ecosystem. (See Chapter 11.) These trade-offs need to be considered when allocating resource access. Nevertheless, there are some uses of marine systems that have minimal impacts and that can be developed in tandem with other uses such as tourism, well-managed recreational fisheries, and bioprospecting. (See Table 18.5.)

18.4.1 Environmental Impacts of Capture Fishing versus Other Uses

Contrary to the coastal systems, where many uses are mutually incompatible, few other economic activities in the marine realm directly preclude fishing. In fact, the major problem for fishers is other fishers. Thus, for example, by modifying habitats, trawlers affect the yield of other fishers who do not use such destructive gear.

Three different classes of multiple uses and synergies can be identified:

- relationships between fisheries and other sectors, such as aquaculture and coastal development;

Table 18.5. Trade-offs and Synergies in Marine Ecosystems

	Extraction			Conservation		Aquaculture		Other
	Fishing	Bioprospecting	Mining, Gas and Oil	Tourism	Biodiversity	Growout	Farm	Shipping
Fishing		minor trade-offs if the levels of bioprospecting not excessive and fishing sustainable—however, if aquaculture has genetic impact then the story changes; the need for biologically active products may force managers to improve the management of exploited fisheries	few trade-offs as seen except in the immediate vicinity; some gas and oil facilities have provided refuges for fish stocks and therefore a hedge against overexploitation	major trade-offs since people enjoy seeing wildlife, especially diving, and lobby for their protection (e.g., seahorses), but can have social consequences if not managed properly; may protect some species if they are valued by the tourism industry	major and varied trade-offs, if destructive fishing such as trawling takes place, then food provisioning is traded off against biodiversity, forgoing biodiversity over a range of ecosystems whereas longlining forgoes seabird biodiversity; few synergies but could provide a niche for new species that are bioactive or species to move into the niche	minor trade-offs since argument is that fish would have been caught anyway and therefore just ensures the economic value is realized, but this could affect fisheries since it takes away the potential for wild-capture fisheries; possibility to improve coastal communities economically since they do not have to spend so much time fishing	major trade-offs especially if genetic dilution takes place or diseases introduced; while it may provide more high-quality fish it does not necessarily provide same total fish tonnage; can reduce the price of wild capture fish, making fishing financially difficult; in developing countries, often export-oriented and therefore risks the food security of the country; possibility of maintaining some species that are at risk of overexploitation	few trade-offs or synergies
Bioprospecting			few trade-offs except in the immediate vicinity unless areas of mineral, gas, and oil exploitation also contain organisms of high bioactivity, then trade-offs are needed; may provide refuges, as noted above	few trade-offs if the bioprospecting is done with minimal impact or small footprint; strong synergism in that the bioprospecting could form the basis of ecotourism	few trade-offs (see tourism); strong synergism since maintaining biodiversity will maintain bioactivity	minor trade-offs unless aquaculture introduces diseases that threaten the populations of bioactive species; farms could be used to grow out biologically active species	major trade-offs if genetic dilution occurs as well as the introduction of diseases; if produced on large scale, could threaten the livelihood of small-scale collectors; provides the facilities for mass production	few trade-offs or synergies

(continues over)

- relationships between fisheries and top predators or charismatic fauna (marine mammals, seabirds, turtles); and
- competition within the fisheries sector.

Generally, fisheries do not appear to be affected to a large extent by other extractive activities, such as oil or seabed mining, at least relative to the wide impact of the fisheries themselves.

The issue of competition with humans does not arise with marine turtles, which along with marine mammals and seabirds are key indicator species for problems and changes in the marine environment. (See Chapter 19 for more on marine wildlife.)

It has been proposed that marine mammals directly or indirectly compete with fisheries (commercial and artisanal) for resources targeted by fisheries. This perceived competition has been used to justify annual sustainable harvests of marine mammals during the last decade (Lavigne 2002) and also to justify the resumption of whaling in many international fora (Holt 2004). Though competition may occur at small local scales, this issue warrants much further investigation. A recent analysis of global trophic overlap between marine mammals and fisheries indicated that there is limited competition in the Northern Hemisphere on a large scale, while competition between the two is low in most other areas of the world (Kaschner 2004; Kaschner and Pauly 2004). Moreover, the analysis suggested that, overall, fisheries are more likely to adversely affect marine mammal species, particularly those with restricted ranges, than vice versa (Kaschner 2004).

Examples of marine mammals adversely affecting humans do exist. However, such impacts are far less severe and mostly fisheries-related, such as when killer whales take fish from the catch of longline fisheries in Alaska. Reducing the competition between higher vertebrates and fisheries is likely to involve both technological changes in the way fishing gears are deployed and the creation of suitably large marine reserves (as described later).

The third group of interactions occurs between fishers and fleets. Essentially, these interactions are shaped by the fact that each fisher looks for exclusive access to the resource. In fact, the technological improvements that characterize modern fisheries, and that enable access to resources deeper and further offshore, are a response to competition between fishers. This competition, which drives the technological development of fisheries, has over time eliminated the refuges, such as depth and distance offshore, that naturally protected fisheries resources (Pauly et al. 2002).

The case study in Box 18.1 documents an example of how European Union subsidies for technological development and fleet improvements gave Mediterranean trawlers access to fish populations in previously out-of-reach areas of the deep sea.

A significant proportion of world fish stocks and catches is overexploited or depleted (Watson and Pauly 2001; FAO 2002) and the marine habitats that many of the world's fish stocks rely on at some stage of their life cycle are being degraded. (See Chapter 19.) The combination of overfishing and degradation or conversion of habitats, which contribute to the loss of biodiversity and food provisioning, occurs almost everywhere. In developing countries this is aggravated by export-driven fisheries that overexploit their resource base and that divert food away from the do-

Table 18.5. *continued*

	Extraction		Conservation		Aquaculture		Other
	Bioprospecting	Mining, Gas and Oil	Tourism	Biodiversity	Growout	Farm	Shipping
Mining, Gas and Oil			major trade-offs since most tourists seeking natural experience, not high infrastructure and possible pollution; onshore infrastructure could facilitate offshore tourism (e.g., NW of W. Australia)	major local impacts if spill takes place, minor if footprint small and pollution contained; platform provides a niche for new species or species to move into the area	major trade-offs—while the risk of spills on the farms is low, if it does happen, financial and ecological impacts extremely high, therefore generally they do not coexist; possibly onshore infrastructure synergies	see growout	few trade-offs or synergies
Tourism				minor trade-offs, tourism can have an impact on biodiversity at the local scale from overfishing, collecting, etc. (e.g., Red Sea overfishing to meet restaurant trade); tourism provides an incentive to maintain biodiversity since that is one of the attractions to the area	the offshore infrastructure and the concept of penned fish may not appeal to many tourists; the associated pollution with aquaculture facilities as well as with tourism facilities (e.g., human diseases in shellfish); limited	see growout	
Biodiversity						trade-off in terms of the introduction of diseases into wild populations; alterations to population structure; localized habitat changes; declining food supply for other species that consume small pelagics/krill; possibly maintenance of species at risk	genetic dilution; same as growout

mestic market. (See Figure 18.13.) As a result, the fishing sector has declined as a source of employment in many industrial countries.

18.4.1.1 Food and Protein

Overfishing affects human well-being through declining food availability in the long term, since fewer fish are available for consumption and the price of fish increases (Alder and Sumaila 2004). Due to declines in coastal habitats, fishers are forced to go further offshore and for longer periods of time, resulting in reduced food security (Alder and Christanty 1998). In Canada, the collapse of the cod fishery resulted in severe unemployment (see Figure 18.14), compounded by restrictions on subsistence fishing (Neis et al. 2000).

While fish is a healthy, luxury food in high demand by the industrial world, it is still a significant and cheap source of protein for many countries in the developing world. However, per capita consumption of fish in the latter is much lower than in the industrial world. (See Figure 18.15.) Therefore declines in the availability of cheap fish protein either through overfishing, habitat changes, or shifting trade practices contribute to reduced food security in countries such as Ghana, Senegal, and Chile (Atta-Mills et al. 2004; Alder and Sumaila 2004).

The developing world produces just over 50% of the value of fish that is traded globally, and much of the fish caught in the developing world is exported to industrial countries (FAO 2002). Fishing to meet export demands should, theoretically, provide funds to allow the import of cheaper fish and protein products, reduce the government debt, and supply cheap protein to the local population. However, the benefits to developing countries from trade in fish will not be realized if the funds generated are not reinvested in the economy. That this is not always the case may contribute to the fact that some of the major fish-exporting countries are also the least developed. (See Table 18.6.)

The industrial world, in particular the United States, the EU, and Japan, have been able to buffer against declines in fish availability and increases in prices because they have been able to purchase or otherwise get access to high-quality fish. Indeed, the per capita consumption of fish by industrial countries was 21.7 kilograms in 1997, compared with 9.2 kilograms in the developing world (excluding China, although if China is included, the per capita consumption for the developing world rises to 14 kilograms due to China's massive consumption of locally produced farmed freshwater fish) (Delgado et al 2003).

18.4.1.2 Livelihoods

Fisheries and fish products provide direct employment to nearly 27 million people (FAO 2002). Globally, the bulk of people employed in fisheries are poor, and many are without alternative

BOX 18.1

Subsidy-driven Removal of a Natural Reserve

The Mediterranean Sea has a long history of fisheries exploitation with a variety of gears. Yet the landings of many species, including highly valued demersals, have increased in the last decades (Anonymous 2002; Fiorentini et al. 1997). A large part of the landings consist of the juvenile of demersal species (Stergiou et al. 1997; Lleonart 1999; Lloret et al. 2001), such as hake, *Merluccius merluccius*—one of the six most important species, in terms of both landings and landed value, in the Mediterranean Sea (Fiorentini et al. 1997). Hake landings rose from about 5,000 tons in the late 1940s in the eastern and western Mediterranean to about 15,000 and 40,000 tons in the mid-1990s in two areas of the Mediterranean (Fiorentini et al. 1997).

The increase in landings is not only the result of increasing fishing mortality (that is, increasing effort and technological developments), but also due to recent development of new fisheries and expansion of fishing grounds (mainly by fishing in deep waters). Increasing landings are also related to the increase in phytoplankton production due to eutrophication of Mediterranean waters (e.g., Caddy et al. 1995; Fiorentini et al. 1997; Tserpes and Peristeraki 2002). For some demersal species, increasing landings might have been mitigated by the fact that a large part of the spawning population was not available to fishing gears because of:

- life history—with the onset of maturation, many demersal fish species (e.g., *M. merluccius* (Abello et al. 1997), *Pagrus pagrus* (Labropoulou et al. 1999), and *Pagellus erythrinus* (Somarakis and Machias 2002)) migrate to deep bottom areas that were not accessible to trawlers—and
- the geomorphology of the Mediterranean Sea deep areas provides natural refuges (low-take zones), allowing mature individuals to contribute to recruitment and stock size maintenance (Caddy 1990, 1993, 1998; Abella et al. 1997).

In the last several years, however, the modernization of trawlers and small-scale vessels, driven mainly by EU subsidies, allowed fishing to expand in deeper waters and to operate during harsh weather conditions. As a result, deepwater fisheries, practiced for instance with bottom or vertical longlines, were developed, heavily exploiting the large mature hake as well as of other species (e.g., *Pagellus bogaraveo*). Given the absence of appropriate management procedures (Lleonert 1999; Stergiou et al. 1997), this will lead to recruitment overfishing and the fisheries will eventually collapse, adding another data point to the records on the negative effect of subsidies.

sources of work and sustenance. In addition, fish and fishing are enormously important to the cultural life of many coastal communities, and often define the ''quality of life'' of people with a cultural tradition of harvesting the sea (Johannes 1981).

The global consequences of exploiting marine resources are numerous and significant. Overcapacity in the global fleet implies that both labor and physical capital are wasted (Mace 1997) and could be used more beneficially in other sectors of the economy, where they are most needed. The huge deficits detract from human well-being in sectors such as education and health care. The Common Fisheries Policy of the European Community, for example, allows for vessels to be decommissioned to reduce effort in some countries while simultaneously subsidizing others to increase their fishing capacity (Alder and Lugten 2003).

18.4.1.3 Habitats

Some coastal habitats have been converted to other uses, such as mangroves for coastal aquaculture ponds or cage culture of high-valued species such as penaeid shrimp, salmon, or tuna. This conversion can affect wild-capture fisheries, which use these coastal habitats for part of their life cycle. It also has sometimes caused displacement of fishers, loss of revenues, and social unrest. Coastal residents often no longer have access to cheap protein or sources of income. (See Figure 18.16) In addition growing juvenile fish taken from wild populations, in the case of tuna, in pens or cages can also be a significant source of pollution for the area in which they are located.

Area closures and the halt of destructive fishing have improved fisheries, especially in coral reefs (Roberts et al. 2002). Overall, however, overfishing and habitat destruction continue throughout the world (Jackson et al. 2001; Jennings et al. 2001).

Ultimately, overfishing has a significant impact on most marine systems. Habitat degradation due to pollution, infrastructure development, and so on contributes to the further degradation of the ecosystem and declining human well-being (mercury and PCBs in Baltic Sea fish, for example) or impedes recovery of the marine or coastal system (as when the conversion of mangroves affects important nursery habitat for some species of fish). Considering the serious nature of many non-fisheries impacts, attention should be given to addressing these impacts and within the context of integrated coastal management. (See Chapter 15 of the MA *Policy Responses* volume).

Offshore areas, especially the deep sea, vents, and seamounts, are at risk of being exploited beyond recovery. It is difficult to say how much direct impact the crossing of such thresholds will have on human well-being. Nevertheless, it will ultimately affect ecosystem services. The lack of good information on these systems, past experiences regarding the impact of fishing, and lack of good international management frameworks add to the uncertainty of the impacts on these systems.

Climate change, El Niño/Southern Oscillation, and hydrological conditions will have a significant impact on some marine habitats, especially coastal areas (Chapter 19) and in polar marine and coastal systems (Chapter 25) (Chavez et al. 1999). Climate change will affect marine systems but may not have as severe an impact on open-ocean and deep-water systems (McLean et al. 2001).

18.4.1.4 National Economies and Foreign Exchange

Many areas where overfishing is a concern are also low-income, food-deficit countries. For example, the exclusive economic zones of Mauritania, Senegal, Gambia, Guinea Bissau, and Sierra Leone in West Africa all accommodate large distant water fleets, which catch significant quantities of fish. (See Figure 18.17 in Appendix A.) Much of it is exported or shipped directly to Europe, while compensation for access is often low compared with the value of the product landed. These countries do not necessarily benefit through increased fish supplies or increased government revenue when foreign distant water fleets access their waters. In some countries, such as Côte d'Ivoire, the landings of distant water fleets can lower the price of fish, which affects local small-scale fishers.

Although Ecuador, China, India, Indonesia, and the Philippines, for example, do not provide access to large distant water fleets, these low-income, food-deficit countries are major exporters of high-value fish products such as shrimp and demersal fish. As shown in the West African example, several countries in the region export high-value fish, which should provide a significant

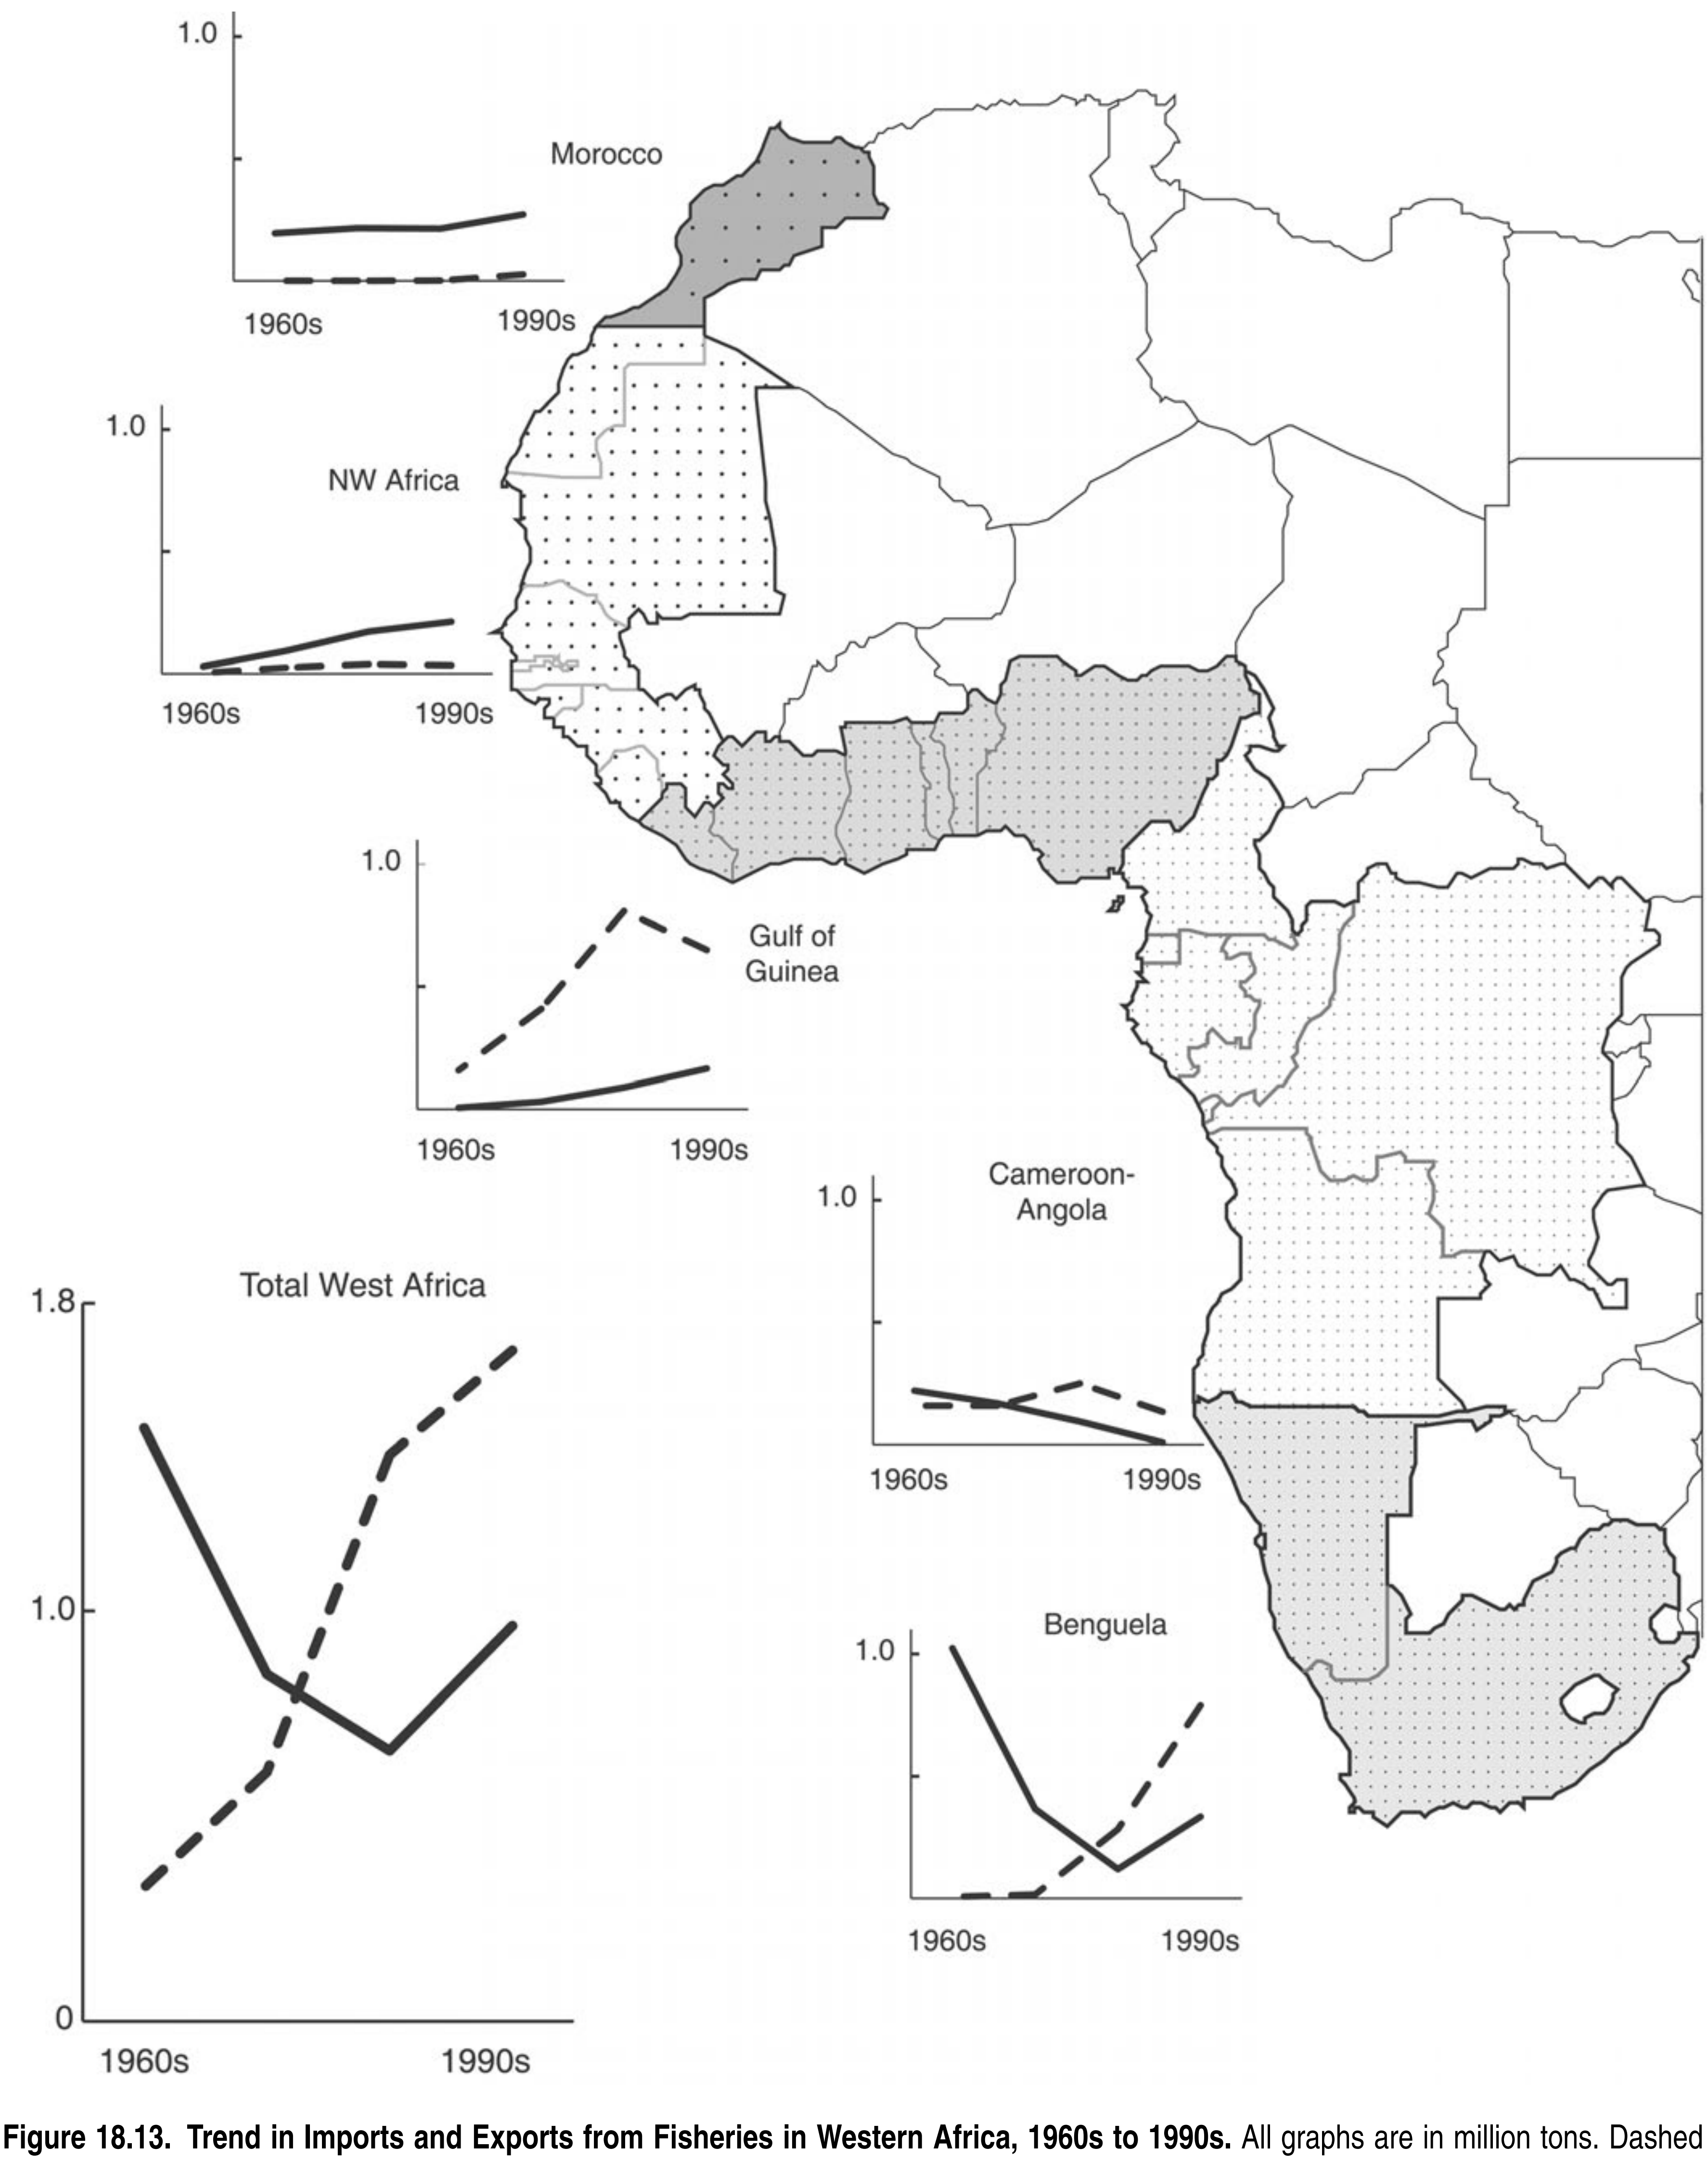

Figure 18.13. Trend in Imports and Exports from Fisheries in Western Africa, 1960s to 1990s. All graphs are in million tons. Dashed lines are imports and solid lines are exports. (Alder and Sumaila 2004)

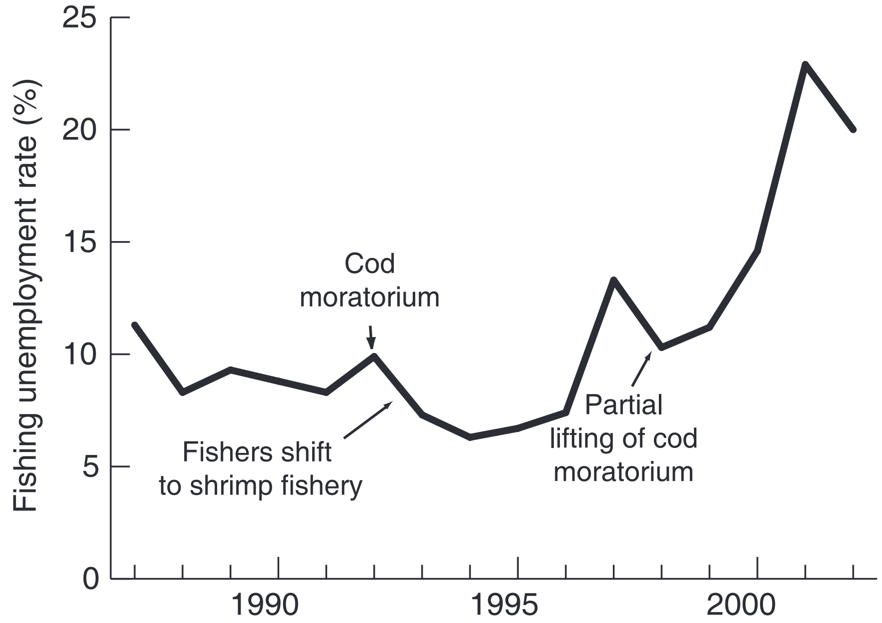

Figure 18.14. Unemployment in the Newfoundland Fishing Sector, 1987–2002 (Stats Canada 2003)

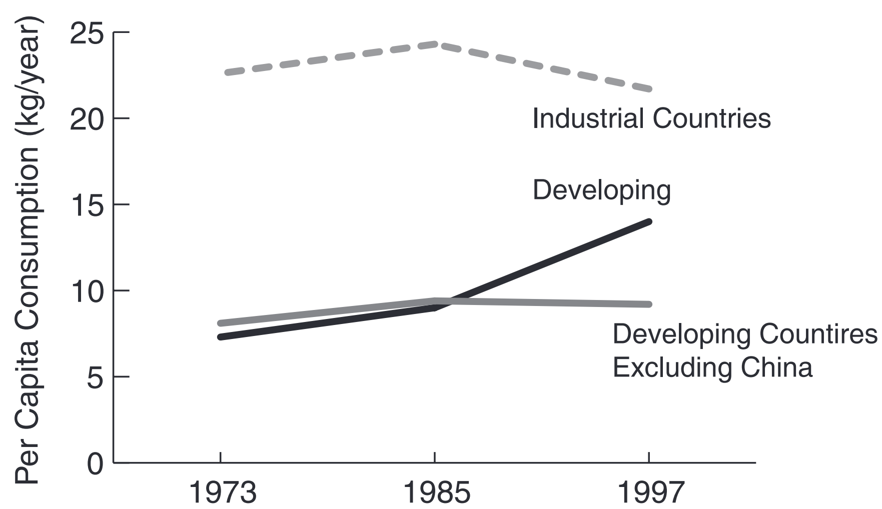

Figure 18.15. Trend in Per Capita Fish Consumption, 1973–97 (Delgado et al. 2003)

national economic gain so that cheaper forms of protein can be imported. In countries such as Ghana, however, the value of exports is often less than the value of imported fish, and the volume of imported fish does not meet the domestic demand for fish (Atta-Mills et al 2004).

Fish products are heavily traded, and exports from developing countries and the Southern Hemisphere presently offset much of the demand shortfall in European, North American, and Northeast Asian markets (Ahmed et al. 1999). Given the global extent of overfishing, however, it is likely that the global decline in marine fisheries landings, which already affects the poorer consumers in developing countries, will also catch up with consumers in industrial countries (Garcia and Newton 1997).

18.4.2 Unintentional Trade-offs

There are many unintended consequences of policies. However, it is worth noting that the economics of natural resources, including fisheries, usually only consider market forces and not the underlying biological constraints or environmental costs. For example, building an access road to a fishing village with the intention of connecting it to various cultural, social, and economic amenities (markets) has been shown in many cases to lead to massive increase in fishing effort and a collapse of local resources, the exploitation of which was previously regulated by the absorptive capacity of the local market.

Table 18.6. Major Exporters of Marine Products, 2000. Those shown in bold are lower-income food-deficit countries. (FAO 2003)

Country/Area	Export Value *(billion dollars)*	Country/Area	Export Value *(billion dollars)*
Thailand	**4.4**	Australia	1.0
China	**3.7**	**Morocco**	**1.0**
Norway	3.6	Japan	0.8
United States	3.1	Argentina	0.7
Canada	2.8	Mexico	0.7
Denmark	2.8	New Zealand	0.7
Chile	1.8	**Ecuador**	**0.6**
Taiwan	1.8	Sweden	0.5
Spain	1.6	Belgium	0.5
Indonesia	**1.6**	Singapore	0.5
South Korea	1.5	Faeroe Islands	0.4
Viet Nam	1.5	**Philippines**	**0.4**
India	**1.4**	Italy	0.4
Russian Federation	1.4	Ireland	0.3
Netherlands	1.4	**Bangladesh**	**0.3**
United Kingdom	1.3	Portugal	0.3
Iceland	1.2	South Africa	0.3
Peru	1.1	Panama	0.3
Germany	1.1	Greenland	0.3
France	1.1	Senegal	0.3

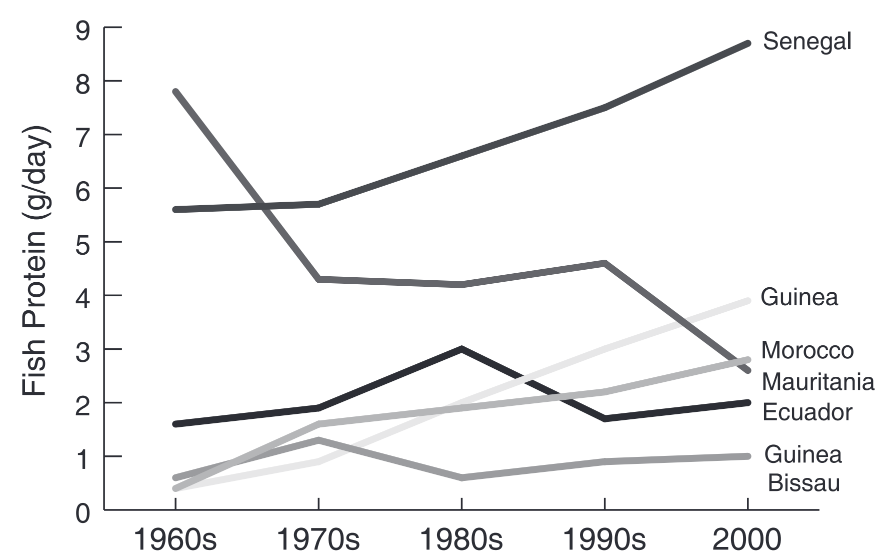

Figure 18.16. Available Fish-Based Protein of Selected Lesser-Income Food-Deficit Countries, by Decade since 1960 (FAO 2003)

Fish aggregating devices, which are large floating structures, are constructed and use materials so that fish, especially pelagic fish, are attracted to them. They were seen as a cost-effective means to increase fish catches without affecting other aspects of the marine ecosystem or juvenile tuna stocks. However, monitoring of catches by these devices has shown that juvenile tunas are also attracted, which may, by increasing the effort on tuna juveniles and other "by-catch" species, have an impact on tuna stocks. Indeed, the mean size of caught fish is diminishing in both yellowfin tuna (*T. albacares*) and bigeye tuna (*T. obesus*) (Bromhead et al. 2003).

Perverse incentives in fisheries are well studied by economists. They include size limits for landed fish, which encourage undersized bycatch to be discarded at sea, and decommissioning schemes that lead to fleet modernization and ''technology stuffing.'' Alder and Lugten (2002) discuss this in the context of the EU Common Fisheries Policy.

18.5 Choices, Trade-offs, and Synergies with Other Systems

The ocean is the ultimate receptacle for discharges from the land and coast. While land use has significant and frequently obvious impacts on terrestrial and coastal systems, impacts on deeper marine systems are not as evident. However, indirect impacts such as air pollution deposition and water pollution are being detected in marine systems (such as the POPs found in high Arctic marine mammals). Marine systems play an important role in climate regulation, the water cycle, and coastal processes, especially in the recycling of nutrients. El Niño events highlight the widespread geographic and ecosystem impact of perturbations of marine systems on pelagic fish stocks, coastal areas, and land systems.

18.5.1 Climate Change

Climate change is affecting the global distribution of heating and cooling of the ocean surface, which is a major factor in determining the large-scale patterns of ocean current flow and will have an impact on the marine ecosystem, including fisheries, in a number of ways (Mclean and Tsyban 2001).

Most marine fish and many other marine organisms have complex life cycles, featuring at least one planktonic early life stage. Consequently, reproductive habits and behaviors may be specifically adapted to current conditions, which will transport passively drifting larvae to appropriate nursery grounds. Bakun (1996) has shown that for the Brazilian sardine (*Sardinella brasiliensis*), enrichment of nearshore waters, the presence of a retention mechanism, and concentration of small fish in nearshore waters must all occur at the right place and time for successful recruitment. Climate change, acting through changes in sea temperature and especially wind patterns, will disturb and displace fisheries. Disruptions in current flow patterns in marine and estuarine systems, including changes to freshwater inputs as predicted under climate change, may cause great variations in reproductive success (Welch et al. 1998; Francis and Mantua 2003).

Research in the Northeast Pacific indicates that alternating climate ''regimes'' can affect marine ecosystem structure. Haigh et al. (2001) coupled a planktonic ecosystem model to a general ocean circulation model for the Pacific Ocean (18° S to the Bering Strait) to study the 1976 ''regime shift.'' The results showed clear geographical patterns in primary production and significant changes in the levels of primary production and standing stocks of phytoplankton and zooplankton before and after 1976. This implies that fish and other marine species will establish new geographic distributions as they seek new areas with the optimal temperature and food supplies. For example, it can be expected that North Pacific cold temperate species will move northward and will be replaced, along the coast of British Columbia, by warm temperate species (Welch et al. 1998). A similar set of replacements has been occurring in the last two decades in Europe, notably herring and pilchards in the Bay of Biscay, the English Channel, and the North Sea.

The capacity of fish species to adapt rapidly in reaction to such environmental changes is not clear at the present time. There are some hypothetical mechanisms available that might conceivably facilitate quite rapid adaptive adjustments (e.g., Bakun 2001). However, these adjustments imply high populations (biomass) capable of producing numerous and varied offspring, some of which will be adapted to the newly opened niches. Also, oceanographic conditions may be changing too rapidly. Given the low biomasses for most exploited stocks, the prospect of rapid environmental change is doubly problematic for marine fisheries and marine biodiversity preservation.

Finally, it should be noted that the changes in physical features predicted by various global and regional simulation models under likely CO_2 emission scenarios fall well outside the parameter range so far observed under natural marine regimes (IPCC 2003).

18.5.2 Interactions with Coastal Systems

One of the major interactions between marine fisheries and coastal systems is through the life history of the large number of marine species that use coastal areas, especially estuaries, mangroves, and seagrasses, as nurseries. (See Chapter 19.) Thus, coastal habitat modifications and coastal pollution, as well as inshore fishing, can adversely affect offshore fisheries by reducing the supply of recruits to the offshore adult stocks. The scale of this problem varies between continents, however. For example, a large fraction of the fish species occurring along the continental shelf of eastern North America produce juveniles that are dependent on estuarine habitats, while fish along the coasts of western Australia, northwestern Africa, or southwestern South America appear to depend less on coastal systems.

The presence of juveniles in coastal systems and of adults further offshore means that small-scale inshore and industrial offshore fisheries effectively compete for the same resources, even though they are apparently geographically separated.

18.5.3 Interactions with Island Systems

Small islands throughout the Pacific, Indian, and Atlantic Oceans have coastal and shelf areas whose physical and biological features differ from those typical of the biogeochemical province in which the islands are located. In many cases, these islands, whose nearshore fisheries have often reduced the limited coastal resources, are attempting to get access to pelagic offshore resources (see Chapter 23) (Petersen 2003). This has led to a new set of conflicts between island states and industrial countries with distant water fleets.

From the perspective of island states, the oceanic resource—even in its present depressed state—far exceeds the coastal fish population they initially relied on. The United Nations Convention on the Law of the Sea and various other treaties discussed later in this chapter have begun to provide mechanisms to address some of these issues of perception and equity.

18.6 User Rights and Protection Status of Marine Ecosystems

Marine systems are often described as ''commons'' (for everyone's use) and their overexploitation as a tragedy (Hardin 1976). While this may hold true for the open ocean, complex property rights exist in many coastal areas. The property rights in question can be traditional (aboriginal), historical or local, and commercial (that is, the government sells the right to gain access to resources). The boundaries between these rights are frequently unclear and in some cases generate conflicts.

Some of the major groups of fishers involved in exploiting marine resources are described briefly in this section, along with major issues, outlooks, and prospects.

The introduction of UNCLOS and other jurisdictional restrictions has had minimal impact on countries or companies that can afford to "buy" access to fishing grounds. Other countries find themselves having to fish further offshore or purchase cheap, low-quality fish. This situation is clearly demonstrated in West Africa, where Europe has extended its fishing grounds from Northwest Africa to the whole of the West coast. Countries such as Nigeria and Ghana have seen a reduction in their traditional fishing grounds, intensification of small-scale fishing in coastal waters since they can not afford to gain access to foreign EEZs, and increases in imports of cheap, low-quality fish (Atta-Mills et al. 2004).

The term "aboriginal" refers to the descendents of the original inhabitants of countries whose population now largely consists of recent immigrants (such as in the Americas, Australia, and New Zealand). Aboriginal peoples are often marginalized, especially with regard to access to natural resources. In some areas, their existence is not even legally recognized. Other areas recognize aboriginal rights based on the original occupancy of the territory. Such rights are now recognized in Canada's Constitution and Supreme Court decisions, for instance (Haggan and Brown 2002). Similar rights were granted to New Zealand Maoris, who now own one third of the country's fishing quotas. Examples of aboriginal groups with strong fishing traditions are the First Nations along the Pacific coast of Canada and the United States, the Maoris of New Zealand, and the Torres Strait Islanders of Northern Australia. In some situations, their rights can be a source of conflict with non-aboriginal fishers, whose behaviors and activities are governed by additional or different laws and regulations (Tomlinson 2003).

Aboriginal fishing methods tend to be used only in the coastal zone, but their impact can extend much farther, as the target species often have broad offshore distributions. Aboriginal fisheries are often subsistence fisheries, though not necessarily so. Indeed, the term "subsistence fisheries" is frequently a misnomer, since much of what is caught by subsistence fisheries is actually sold. True subsistence fisheries without subsequent sale of harvested products are now rare (an example is shellfish gathering in Kwazulu Natal, South Africa; see Branch et al. 2002).

Small-scale or artisanal fishers exist both in industrial and developing countries, and consequently their definition varies. However, competition between small-scale and large-scale fisheries is a common issue in all countries. Competition can be either direct (such as fixed gears versus trawlers targeting shrimps in tropical waters, as described in the next section) or indirect (such as coastal traps versus trawlers targeting different age classes of the same cod stock off Newfoundland). There is also competition for political and financial support as well as markets. The resulting conflicts, often couched as "equity" issues and aggravated by large-scale fleets, have tended to paralyze regulatory agencies in both industrial and developing countries. Community-based property rights may be one way of dealing with this issue, as seen in the Philippines, where local communities have jurisdiction over inshore waters within 15 kilometers of the coast (Rolden and Sievert 1993). However, synergies can also emerge with new markets, infrastructure improvements (processing and transport), and technology transfers occurring. Figure 18.18 illustrates the respective role and impacts of small-scale versus large-scale fisheries in one case study.

In most of the industrial world, such as the European Union and United States, the large-scale sector receives the bulk of government subsidies. Consequently, the economic efficiency of these fisheries is questionable. Another characteristic of large-scale fleets is that once local waters are depleted, they lead the expansion further abroad, often requesting subsidies to gain access to the resources of other countries, as with EU fleets off West Africa (Kaczynski and Fluharty 2002). However, the industrial fishing sector is declining as a source of employment in the industrial world. EU member countries and Japan, for example, are finding it difficult to recruit young workers into the industry and are turning to developing countries in Africa and Asia to crew their vessels (FAO 2002; Morales 1993).

Recreational fishing was considered relatively benign until recently, mainly because information about its impact has been limited. FAO's first estimate of global recreational catches was put at only 0.5 million tons (Coates 1995), but recent estimates of over 1 million tons are probably more accurate (Coleman et al. 2004). Indeed, recent studies in British Columbia have shown that for inshore fisheries, the catch from the recreational sector can exceed the commercial sector (Forrest 2002). Recreational fishing is an important economic activity in some countries; in the United States it is worth approximately $21 billion a year; in Canada, $5.2 billion a year (Department of Fisheries and Oceans 2003); and in Australia, $1.3 billion a year (Henry and Lyle 2003). Although recreational fisheries often promote catch and release practices, the mortality associated with these practices is not well known and may be high (Wilde and Pope 2003).

There are major conflicts between commercial fishers, especially small-scale or artisanal ones, and recreational rod-and-line and underwater spear fishers in many countries (in Portugal, for instance). Large numbers of so-called recreational fishers in fact fish for a living and are not licensed or regulated in any way. In southern Europe, there is evidence that spear fishing has had a significant impact on inshore fish communities (to depths of 30–40 meters), with a decrease in abundance and mean size of many species, such as groupers and large sea breams. In addition, pressure on fish populations may have contributed to the disappearance of some small-scale fishing gear (such as small-hook longlines) due to the decline in catch rates and profitability (K. Erzini, Universidade do Algarve, personal communication 2004).

Marine tourism is a growing industry, principally in the marine wildlife tours sector. Similarly, coral reef tourism has increased in visitation levels and value, with a current net present value estimated at $9 billion (Cesar et al. 2004). The Great Barrier Reef attracts 1.6 million visitors each year and generates over $1 billion annually in direct revenue (Harriott 2002).

18.6.1 Competition between User Groups—Equity and Access Rights

Given the involvement of a number of user groups, management of fisheries and marine natural resource allocation requires the consideration of rights and equity among stakeholders. There is a strong tendency among fisheries economists to view individual transferable quotas and another form of "rights-based fishing" as the solution to mismanagement of fisheries (Hannesson 2000; Arnason and Gissurarson 1999). Others argue that the citizens of each country in question are the implicit owners of coastal and shelf fishery resources and that exploiting these resources can only be granted as a privilege for which payment is due, for example, through annual auctions (Macinko and Bromley 2002). The solution to these access and equity issues lies within the sociopolitical situation of each country rather than within the realm of science.

Shallow waters of tropical continental-shelf ecosystems are characterized by relatively high fish densities and the presence of high-value species, such as penaeid shrimps (Longhurst and Pauly 1987). The incursion of trawlers, which target shrimps for export, into shallow shelf ecosystems (10–100 meters) where artisanal

FISHERY / BENEFITS	LARGE-SCALE	SMALL-SCALE
Number of fishers employed	about 2 million	over 12 million
Annual catch of marine fish for human consumption	about 29 million tons	about 24 million tons
Capital cost of each job on fishing vessels	$30,000 – $300,000	$25 – $2,500
Annual catch of marine fish for industrial reduction to meal and oil, etc.	about 22 million tons	Almost none
Annual fuel oil consumption	14–19 million tons	1–3 million tons
Fish caught per ton of fuel consumed	= 2–5 tons	= 10–20 tons
Fishers employed for each $1 million invested in fishing vessels	5–30	500–4,000
Fish and invertebrates discarded at sea	16–40 million tons	None

Figure 18.18. Comparison of Small-scale and Large-scale Sub-sectors in Norwegian Fisheries, 1998. Schematic illustration of the duality of fisheries prevailing in most countries of the world. This largely reflects the misplaced priorities of fisheries "development" but also offers opportunity for reducing fishing mortality on depleted resources while maintaining social benefits. The solution here is to reduce mainly the large-scale fisheries. (David Thompson in Alverson et al. 1994)

fisheries operate results in open competition between the two fisheries for the same resource (Pauly 1997).

Catching and discarding undersized fish is another source of conflict between the two fisheries. Shrimp trawl fisheries, particularly for tropical species, have been found to generate more discards than any other fishery type while accounting for small fraction of global marine fish landings (Kelleher 2004). Since many discarded species are of commercial value to small-scale fisheries, bitter conflicts between the two fisheries often ensue, leading to conflicts between fishers using different gear and political infighting over resource allocation and bycatch removal quotas (Alverson et al. 1994; Kelleher 2004; Pauly 1997).

Artisanal and industrial fisheries also experience conflicts in markets where they use the same inputs such as fuel and gear or they catch the same or similar species of fish (Panayotou 1982). Industrial fisheries may bid up the prices of fishing inputs or their massive landings may depress fish prices, making small-scale fishers increasingly uncompetitive. Industrial fisheries have access to low-interest institutional credit and loans and government subsidies, whereas small-scale fishers usually only have access to informal credit at interest rates many times higher than the institutional rates (Panayotou 1982).

Institutional support is often skewed in favor of the large-scale fishers because of their apparently higher efficiency and greater contribution to economic growth; their use of fewer landing areas, which allows economies of scale in the provision of infrastructure and the delivery of assistance programs; their political and economic power; and a general bias in favor of large-scale fisheries under an open-access regime. In contrast, small-scale fishers are geographically dispersed and lack political and economic power and hence do not generally benefit from institutional support (Bennett et al. 2001).

Several management interventions and conflict mitigation processes can minimize conflicts. These range from outright banning of certain gears—as occurred in western Indonesia in 1980, for example, when trawling was banned (Sardjono 1980)—to clarifying property rights and gear and area restrictions. In some cases, the role and recognition of traditional and local ecological knowledge are increasing as management responsibilities are transferred to local communities and stakeholders. For example, traditional and local knowledge is used to manage a bait fishery in the Solomon Islands (Johannes et al. 2000). Protection of the rights of small-scale fishers is also recognized explicitly in the Convention on Biological Diversity decision VII/5 and the FAO Code of Conduct for Responsible Fisheries.

18.6.2 Effectiveness of International Instruments in Managing Shared Stocks

While there are more than 100 fisheries access agreements (multilateral and bilateral) currently used to manage access to marine resources, few are monitored or evaluated for their effectiveness, equitable access, and sharing of economic benefits. The European Union has initiated a monitoring program for the EU's Common Fisheries Policy, and other regional fisheries bodies are considering monitoring programs, but none have been developed to date (FAO 2001a).

A recent study of international fisheries instruments for the North Atlantic suggested that global and regional treaties covering the area are of limited effectiveness; the treaties themselves are not found to be weak, but many governments appear unwilling to act on commitments made under them (Alder and Lugten 2002). The study showed that the 14 relevant instruments have a strong North-South gradient of decreasing implementation, as measured by adherence to reporting requirements, issuance of reports, and other formal requirements. On the other hand, there was no such gradient in the state of the stocks, and it could therefore be argued that these instruments are of limited effectiveness even when completely implemented. Consequently, reinforcing international agreements and ensuring they are implemented is likely to contribute significantly to solutions to the present problem of overfishing. This will require that these bodies free themselves from the influence (dominant participation) of the very industry they are intended to regulate, as documented in a detailed study of the U.S. Fisheries Management Councils (Okey 2003).

Various legal instruments, such as the Marine Mammal Protection Act in the United States, explicitly require protection of the food and habitat of charismatic marine fauna. International instruments such as the International Whaling Commission and the Convention on International Trade in Endangered Species of Wild Fauna and Flora restrict harvesting of species or limit bycatch.

A recent joint study between the CBD and the UNCLOS found that whereas the provisions of these two conventions are complementary and mutually supportive regarding the conservation and sustainable use of marine and coastal biodiversity, an important legal gap exists with respect to commercially oriented activities relating to marine genetic resources in areas beyond national jurisdiction. (Each country's national legislation could address the issues within its EEZ.) The gap is yet to be addressed by the international community, and it would seem particularly important given the increasing importance of genetic resources in these areas and the threat posed to them by various activities, such as bio-prospecting by multinational pharmaceutical companies, that may be carried out without due regard to conservation and equity principles.

The implementation of North Atlantic agreements is among the best funded and supported administratively, and yet fisheries in the North Atlantic continue to decline (Alder and Lugten 2002). The refusal of EU-member governments to set sustainable harvest levels or to take a precautionary approach to the Common Fisheries Policy is a clear example of a well-funded management system supported by sound science with overfished stocks. Agreements in the South Atlantic, and for the most part in the rest of the world, are largely similar in nature to North Atlantic legal instruments. However, there are substantially fewer agreements elsewhere, and the level of support for them is much less, although some of the instruments of the southern polar biome are exceptions in terms of support. Globally, there is potential for instruments to assist in finding solutions to fisheries sustainability problems, but the lack of political commitment to their use to effect change prevents significant progress toward such solutions.

18.6.3 Effectiveness of Marine Protected Areas

Marine protected areas with no-take reserves at their core can reestablish the natural structures that have enabled earlier fisheries to maintain themselves. (See also Chapter 4.) MPAs are not a recent concept. Historically, many fisheries were sustained because a portion of the target population was not accessible. Most targeted fisheries were offshore or in areas adjacent to lands with low human populations and therefore subject to relatively low threat. However, modern fishing technology for mapping the seabed and for finding and preserving fish (artificial ice and blast freezing) expanded the reach of fishing fleets.

A number of recent studies have demonstrated that MPAs can help in managing fisheries (Roberts et al. 2002). Most of these studies have covered spatially small areas and primarily in tropical shelf systems, although emerging studies from temperate areas, such as New Zealand and Chile, have also demonstrated MPA effectiveness. However, other studies have found that MPAs have not delivered the expected benefits of protecting species and their habitats (Hilborn et al. 2004; Edgar and Barrett 1999; Willis et al. 2003). In many cases failure was due to either not including MPAs as part of a broader coastal management system or a lack of management effectiveness, funding, or enforcement. In the Gulf of Mexico, for example, the establishment of MPAs merely shifted fishing effort to other areas and increased the vulnerability of other stocks and endangered species (Coleman et al. 2004). Knowledge on the size and location of MPAs that can act as effective buffers against the impacts of fishing requires further research.

It has been widely and repeatedly demonstrated that marine protected areas, particularly no-take marine reserves, are essential to maintain and restore biodiversity in coastal and marine areas (COMPASS and NCEAS 2001). Their wide-scale adoption is inhibited by the perception that biodiversity is unimportant relative to fishers' access to exploitable resources. Therefore, the proponents of marine reserves have been saddled with the additional task of demonstrating that setting up no-take reserves will increase fisheries yields in the surrounding areas, as well as determining the appropriate size and siting of marine reserves that are needed to at least sufficiently offset the loss of fishing grounds. This requirement, combined with initiatives by recreational fishers asserting rights to fish, has effectively blocked the creation of marine reserves in many parts of the world.

Thus while the cumulative area of marine protected areas is now about 1% of the world's oceans, only about one tenth of that—0.1% of the world's oceans—is effectively a no-take area. This gives an air of unreality to suggestions that 20% and an optimum of 30–50% of the world's ocean should be protected from fishing to prevent the loss of some species now threatened with extinction and to maintain and rebuild some currently depleted commercial stocks (National Research Council 2001; Roberts et al. 2002; Airame et al. 2003; Agardy et al. 2003). Even the more modest CBD target of 10% MPA coverage by 2012 will be hard to reach.

One approach to resolving this dilemma is to take an adaptive management approach so that the use of MPAs within a suite of fisheries management options can be assessed and modified as new information emerges and lessons learned are shared (Hilborn et al. 2004). This avoids unrealistic expectations on the improved performance of MPAs. Any approach to the use of MPAs in managing marine ecosystems would also benefit enormously from including performance monitoring and enforcement programs to address some of the management problems that have traditionally hindered effectiveness (Coleman et al. 2004).

If properly located and within a context of controlled fishing capacity, no-take marine reserves enhance conventional fisheries management outcomes. They may, in some cases, reduce catches in the short term, but they should contribute significantly to improving fishers' livelihoods as well as biodiversity over the mid to long term. Marine reserves generally perform this way in inshore shelf systems (such as reefs); many case studies, as shown in Saba Marine Park (Netherlands Antilles), Leigh Marine Reserve (New Zealand), and Sumilon Island Reserve (Philippines), are described in detail in Roberts and Hawkins (2000) to support this. However, understanding of the effectiveness of marine reserves in managing fisheries in deeper oceanic areas is more limited. Further, the protection and monitoring of these deep-sea areas and other undamaged areas may, in line with the precautionary principle, avoid the need for mitigation or restoration of the systems later, when costs are likely to be higher (and in some cases restoration may not be viable).

Already, the demand for fish resources has pushed fishing fleets into international waters, and as other resources become scarcer in national waters (such as gas, oil, minerals, and carbon sinks), conflicts over the best use of these common resources and spaces will increase. Hence the growing call for ocean zoning, including the creation of no-take zones that would reestablish the reserves that were once in place due to vessels lacking the technology to gain access to deeper, offshore areas, which in the past has protected exploited species.

18.6.4 Effectiveness of Fisher Mobilization

Recently, small-scale and artisanal fishers, with the assistance of organizations such as the International Collective in Support of Fishworkers, have established local groups to lobby government and industry. The mobilization of these groups is taking place globally in industrial and developing countries alike. In India (Mishra 1997), Chile (Phyne and Mansilla 2003), the Philippines, and Japan (Kurien 2004), for instance, fisher unions and collectives have used their numbers to lobby government and industry for improved resources access, better working conditions, and social benefits. In addition, these groups have provided mechanisms to enable women, who play a number of roles within the fishing sector (including sometimes also fish capture), to participate more in fisheries management. However, considerable resources and the legal basis to demand change are required, and in some countries mobilization of fishers is discouraged or hindered by governments or cultural norms (Alauddin and Hamid 1999).

18.7 Sustainability and Vulnerability of Marine Fisheries

Fishing has grown to become a much larger business than it was in the 1950s. Modern, highly capitalized fleets now range the oceans of the world, in some cases competing for a limited common resource with small-scale fishers and local communities. Overcapitalization of the global fishing industry is, in fact, an enormous problem. FAO estimated that on a global basis world fisheries operated at an annual deficit of up to $20 billion in the 1990s (Milazzo 1998). Thus, present-day commercial fisheries actually represent a large net burden on other economic sectors. This unfortunate situation is at least to some degree due to the lack of a sound scientific basis to correctly gauge the productivity of the resources and to effectively manage impacts in the face of large-amplitude variability in both physical and biological aspects of ocean ecosystems.

In ecological terms, many marine fish appear to be vulnerable to anything above low levels of fishing pressure because of their biological characteristics, including their late age of sexual maturation, association with specialized or limited habitats that might also be vulnerable or widely damaged by fishing activities (such as trawling), and vulnerable life-history strategies such as aggregation spawning (Ehrhardt and Deleveaux 2001). Distinct genetic units may be susceptible to irrecoverable declines if they are self-recruiting or exhibit Allee-type effects (effects of birth rate declines at low population densities), whereby they cannot recover below some lower threshold of population numbers or density (Stephens and Sutherland 1999).

18.7.1 Natural Population Variability and Sustainability

Analysis of multidecadal time series fishery data has shown that many important fish populations are highly variable (e.g., Csirke and Sharp 1984; Schwartzlose et al. 1999). This is often in response to changes in ocean climate and ecosystem structure. This variability greatly compounds the difficulties in properly managing fisheries exploitation (Bakun and Broad 2002). For example, a level of fishing pressure calculated to be sustainable may cause unexpected collapse of a population whose productivity has decreased naturally. Moreover, even when evidence of declining numbers is available, the fishing industry may cite natural variability to argue against the results and question the need for action and may continue with unsustainable levels of exploitation.

Sustainability in fisheries, as evidenced by long-term data series showing no downward trend in catches, is generally a matter of fishers lacking either the technical means to catch more fish or the outlets (the large markets) to sell more than a small fraction of the fished population (Pauly et al. 2002). Increasing demand relative to the productivity of local resources and the technology to gain access to the entire distributional range of a species will tend to deplete the resource.

In a number of case studies, responses to fisheries management problems have mitigated or reversed the impact of fisheries. For instance, the introduction of community-based management of reef areas in the Philippines has resulted in increased fish landings that ultimately improved the well-being of those communities (Russ and Alcala 1994). Also, more effective enforcement measures for Namibian fisheries and the nationalization of the fishery sector contributed to better socioeconomic conditions for many coastal communities (Erastus 2002). In general, relatively small and often single-species fisheries can be restored, as has occurred in the Peruvian hake (*Merluccius gayi peruanus*) fishery (Instituto de Mar del Peru 2004).

However, there are also a number of spectacular failures—cod (*Gadus morhua*) in Newfoundland and orange roughy (*Hoplostethus atlanticus*) in New Zealand are two often-cited examples. A combination of increasing fishing efficiency through technology, expansion by Canadian fishers into fishing grounds previously used by foreign fleets, and an apparent but misleading increase in stock density as the overall biomass collapsed in the 1980s partly account for the repeated underestimation of the problem facing cod (Walters and Maguire 1996). Similarly, early in the development of orange roughy fisheries, there were management failures as the stocks were harvested at much higher rates than considered sustainable (Francis et al. 1995 in Clark 2001). Also, responses or interventions that mitigate or reverse negative effects of the large-scale, multispecies fisheries, such as the demersal fisheries within EU waters, managed by the EU Common Fishery Policy have been implemented since the early 1970s. But these were ineffective due to lack of political will to decrease effort, poor data quality for specific fisheries and countries, and limited enforcement (Alder and Lugten 2002).

Some fisheries have been certified as sustainable by the Marine Stewardship Council and the Marine Aquarium Council. Only seven fisheries, including for Thames (U.K.) herring (*Clupea harengus*) and Western Australian rock lobster (*Panulirus cygnus*), have been MSC-certified since the program began in 1997, however, and most are small-scale with no impact at regional or global scales. Nevertheless, such schemes are important in communicating to consumers the need to manage fisheries sustainably and in educating them about the source and harvest techniques of the seafood products they purchase. Similarly, the Marine Aquarium Council's certification scheme has had a positive impact on the aquarium trade (GEF 2004).

Conventions that have been effective in sustainably managing fisheries, such as the Pacific Salmon Treaty and the North Pacific Anadromous Fish Convention, have had small-scale impacts since they are focused on a particular species or set of species. Broader bodies, such as the International Commission for the Conservation of Atlantic Tunas, face greater challenges in managing the fisheries in their charge sustainably. Some fisheries, such as those under the EU's Common Fisheries Policy and those in Canada and the United States (cod and Atlantic salmon (*Salmo salar*), for instance), have not been managed sustainably despite sound scientific evidence being available suggesting that reduced fishing effort would significantly assist the situation.

18.7.2 Thresholds

It has not so far been possible to predict the critical thresholds beyond which a fish stock will collapse, and the major stock collapses of the last few decades have been a surprise, even to those involved in monitoring and managing these stocks. One well-known example is Newfoundland's northern cod (*G. morhua*). Almost the same scenario was reenacted 10 years later, in 2001, in Iceland, which very nearly lost its cod stock (Marine Research Institute Reykjavik 2002), in spite of the Icelandic government's commitment to sound fisheries management. Because of the unpredictability of these thresholds, precautionary approaches such as those involving marine protected areas and reductions in fishing effort (and in fishing mortality) are likely to safeguard against such thresholds being reached.

18.7.3 Areas of Rapid Change

Within 10–15 years of their arrival at a new fishing ground, new industrial fisheries usually reduce the biomass of the resources they exploit by an order of magnitude, (Myers and Worm 2003). This is well illustrated by the Gulf of Thailand demersal fisheries (Eiamsa-Ard and Amornchairojkul 1997), by orange roughy fisheries around various seamounts around New Zealand (Koslow et al. 2000), by the Antarctic fisheries discussed in Chapter 25, by the live reef fish trade (Sadovy et al. 2003b), and by a multitude of others. This process is often accelerated by encouragement from governments to ''diversify'' fisheries, often resulting in fleet overcapacity and a drive to exploit new or ''unconventional'' species. This level of biomass reduction renders the species in question extremely vulnerable to subsequent exploitation and other perturbations, notably those likely to result from climate change.

Many areas of the coastal zone have undergone rapid changes directly due to coastal use and indirectly through upstream changes and land use. The consequences of this have been significant habitat loss, declining coastal environments, and reduced fish landings, as discussed in Chapter 19.

18.8 Management Interventions in Marine Systems

Any management initiative aiming to reduce the impacts of marine resource use or to strengthen sustainable use and conservation of biodiversity need to be addressed at different levels and by various means, and to involve local communities, including indigenous peoples. In the case of industrial fisheries, industry needs to be included as well. There are numerous examples from around the world of local involvement resulting in recovery of ecosystems and social benefits—the Philippines (Alcala and Russ 1994), Chile (Castilla 2000), and Brazil (Ferreira and Maida 2001), for example. There are also regional initiatives, as shown by the Regional Fishery Management Councils in the United States, that develop management plans to rebuild stocks. All sectors of society can be a part of the solution—governments by enforcing mandates and ensuring compliance with appropriate environmental codes, industry by operating responsibly, NGOs by providing capacity and training where needed, and consumers by demanding goods and services that are provided at minimal impact on marine ecosystems.

A number of international instruments can also be used to manage fishing and its impacts on the marine environment, domestically and internationally. Various fishing instruments have been discussed throughout this chapter. FAO's Code of Conduct for Responsible Fisheries includes approaches for avoiding or mitigating the impacts of fishing on other components of ecosystems and is one of the few fisheries-specific instruments that includes fishing impacts on other species.

Other instruments, such as the Convention on International Trade in Endangered Species of Wild Fauna and Flora, can be used indirectly to manage the impact of fishing on threatened species through the development of species management strategies. CITES is an international agreement among 167 countries to cooperatively manage international trade in species of conservation concern, to ensure that trade does not threaten their survival in the wild.

The recent listing of seahorses and two other species of shark on CITES Appendix II now requires countries to determine that proposed exports will not be detrimental to the survival of the species in the wild (known as a nondetriment finding) as a precondition to permitting export. From a practical perspective, this means that countries that are parties to CITES need to implement management strategies to ensure that the export of seahorses and listed shark species (and therefore catch levels and methods) does not threaten the sustainability of their fisheries and wild populations. The Convention on the Conservation of Migratory Species of Wild Animals (known as the Bonn Convention) and its Agreement on the Convention of Albatrosses and Petrels, as well as FAO's International Plan of Action for Seabirds, are other examples of international management interventions in marine systems.

The continuation of present fisheries trends, including the buildup of fishing capacities, suggests a serious risk of losing more fisheries. Interventions such as the halting of destructive fishing practices by developing alternative technologies or financial incentives, reducing fishing effort, and establishing MPAs are needed to reverse the current trends. There is likely to be no single most suitable intervention; rather, a mix of interventions is likely to be the most effective approach. The composition of that mix will require an adaptive approach to management of marine ecosystems.

18.8.1 Integrating Management of Sectors in Marine Areas

No global or regional framework for integrated management of the oceans exists. Internationally, some activities on or in the high seas are managed through a range of organizations. For example, the International Seabed Authority manages seabed mining through UNCLOS, and the International Maritime Organization and the conventions it administers (such as the International Convention for the Prevention of Pollution from Ships, known as MARPOL) manages marine transportation and pollution, including dumping of waste at sea. These organizations have worked with industry on measures to reduce the impact of hazardous and damaging activities. Such measures have included, for example, the introduction of double-hulled oil tankers to lower the risk of oil spills. However, there is no integrated approach to managing ocean use, which has resulted in concern over some issues, such as bioprospecting, high-seas MPAs, and the management of marine biodiversity. Not all issues can be addressed within UNCLOS and changes to the convention or the introduction of a new legislative framework (including zoning plans) may be needed to overcome current impediments to making and managing the needed trade-offs for equitable and sustainable use of ocean space and deep-sea resources.

National ocean policies based on sustainable development principles have been successful frameworks for integrating the management of the various marine sectors. Despite countries declaring their exclusive economic zones over the last 25 years, few countries have actually formulated or implemented comprehensive ocean policies. It is only in the last five years that we have seen the introduction of such policies in Australia, Canada, the United States, and the Netherlands (Alder and Ward 2001), along with, most recently, the Pacific Islands Regional Ocean Policy (South Pacific Regional Environment Program 2003).

UNEP has a comprehensive Regional Seas Programme that includes 13 regions and 140 countries with a focus on tackling the sources of degradation of marine and coastal systems. The program has a broad mandate and can integrate various sectors, including transportation and oil development, and initiatives at the regional scale to address pollution problems. It can also play a key role in establishing MPAs crossing multiple borders, as seen in the successful Mediterranean network of specially protected areas that conserve critical areas through MPAs, reserves, and refuges.

The European Community's marine strategy is an example of the challenges in managing marine ecosystems on a regional basis (EC 2002). Other regional programs, such as OSPAR for the North-East Atlantic and HELCOM for the Baltic, also integrate various marine sectors to address a range of marine issues.

18.8.2 Integrating Coastal Management and Ocean Policy

Oceanic and coastal ecosystems are tightly linked. While integrated coastal management is now well entrenched in many countries (see Chapter 19), the development of ocean policies lags behind. Where ocean policies are in place, there is recognition of the need to take an ecosystem-based approach and to ensure that coastal management plans and ocean policies are harmonized. Depending on the legislative basis and jurisdictional issues, coastal management may be embedded within ocean policy, as demonstrated in Canada's Oceans Act.

18.8.3 Marine Protected Areas

Attempting to maintain fisheries for depleted or collapsed fish populations (through subsidies, for example) is economically and ecologically damaging. As provided for in the 1982 Law of the Sea Convention, the 1995 UN Fish Stock Agreement, and the 1995 FAO Code of Conduct, declining populations must be rebuilt and marine ecosystem productivity must be restored as far as possible. No-take marine reserves can make an important contribution when they are part of an overall policy to maintain fisheries. No-take marine reserves are important for providing places where critical life stages, such as adult spawners and juveniles, can find refuge and for providing additional insurance to more conventional fisheries management while safeguarding against local extinctions.

Extinction is a gradual process, but many species of commercial fish species already have severely depleted populations. Avoiding the loss of threatened species must involve not only allowing their biomass to rebuild, but also rebuilding the ecosystems in which they live. MPAs may also contribute to reducing the impacts of global climate change by increasing biomass and widening age structure so that the population of fish stands a greater chance of withstanding wider fluctuations in the environment.

Moreover, the implementation of no-take marine reserves combined with other interventions, such as controls on fishing capacity, would be a more proactive response to fisheries management than current reactive approaches. Small reserves may be effective in protecting sedentary organisms, since they do not move or only move small distances. But marine reserves intended for the conservation or sustainable use of fish, marine mammals, seabirds, and large species need to be larger and particularly appropriately located to take into account the life characteristics of such species. Some species can spend various parts of their life cycle in different habitats (larval stages in estuaries, juvenile stages in coastal seagrass meadows, and adult stages in the open ocean, for instance), and marine reserves need to be strategically located to account for these differences. In areas left open for fishing, however, explicit consideration needs to be given to the food required to maintain recovered populations, and the scientific tools (such as ecosystem models) exist to perform the required accounting for biomass. Populations of small fish and invertebrates presently not exploited should not be viewed as a latent resource that should be developed. They are the remaining food basis for marine mammals, seabirds, and large fish that need to be sustained and rebuilt (as described in the next section).

The immediate and urgent need to manage risks to the marine biodiversity of seamounts and cold-water coral reefs through measures such as the elimination of destructive fishing practices, such as bottom trawling, has been highlighted in a number of recent international fora. These include the fourth meeting of the United Nations Open-ended Informal Consultative Process on Oceans and the Law of the Sea (2003), the 2003 World Parks Congress (recommendation 5.2.3 and the Congress document on emerging issues), the Eighth Meeting of the Convention on Biological Diversity Subsidiary Body on Scientific, Technical and Technological Advice (SBSTTA recommendation VII/5) (2003), the 2003 Defying Ocean's End conference, the 10th Deep-Sea Biology Symposium (2003), and the 2nd International Symposium on Deep-Sea Corals (2003). These meetings have resulted in initiatives to protect cold-water reefs, as through a marine protected area established by Norway to conserve the Tisler Reef along the Norwegian-Swedish border.

18.8.4 Iron Enrichment of Ocean Waters for Carbon Sequestration and Increased Fish Yields

There is growing interest in experiments wherein large areas of low productivity oceanic waters are fertilized using micronutrients, principally iron (Boyd et al. 2000). One major reason for these experiments is to investigate the potential for sequestration of atmospheric carbon, whereby carbon is taken up by the cells of primary producers (the growth of marine phytoplankton populations is often limited by the availability of iron in the water), which would then sink to the bottom as marine snow (Cole 2001). The net effect of this process on carbon sequestration is not clear, however, because localized algal outbursts can also lead to anoxia and the production of methane, a powerful greenhouse gas.

It has been suggested that the enhanced primary production resulting from fertilization could also lead to increased fish yields and could even help alleviate dietary iron deficiencies in some parts of the world (Jones 2001). However, the success of such schemes is extremely doubtful, given the wide range of evolved adaptations that are required for planktivorous species such as anchovies to thrive in a highly productive variable environment, such as the Peruvian upwelling system (Bakun 1996).

18.8.5 Selected Examples of Human Responses to the Sustainability Challenge

While the problem of overfishing has been globally identified at high policy level as a key fisheries issue since the mid-1940s, the broad-scale recognition that it is also an important component of the global environment issue only emerged in the early 1990s in the wake of the U.N. Conference on Environment and Development (Garcia 1992). Even though the word "overfishing" was in common usage long before then (applying to "isolated" instances), there was still a general belief that the oceans had a an enormous capacity to provide fish and invertebrates for direct human consumption and for reduction products such as fishmeal and fish oils used in intensive food production systems (see, e.g., Idyll 1978; Pike and Spilhaus 1962).

In theory, the 1982 United Nations Convention on the Law of the Sea should have been an international instrument for wise use of the oceans: it espouses the right and need for coastal nations to monitor and manage their fish stocks. In retrospect, however, UNCLOS exacerbated overfishing problems in at least two important ways. First, as it gave coastal nations the ability to declare a 200-mile EEZ, many national governments saw this as an opportunity to greatly augment their fishing industries as sources of more secure employment and export earnings. While a few industrial countries managed to achieve some of the expected benefits by testing and adopting new management measures (such as limited entry and fishing rights), most others simply failed to realize them because of uncontrolled, anarchic, and subsidized development of chronic overcapacity (FAO 1993).

The subsidies injected into the industry in the 1980s and 1990s resulted in immense global overcapacity of fishing fleets, perhaps the most important problem—and apparently the hardest one to resolve—faced today in marine resource management (Mace 1997). For example, the EU's subsidies for the construction of fishing vessels in the late 1980s and early 1990s resulted in overcapacity, and until recently attempts to reduce this capacity were not very effective (Alder and Lugten 2002). Subsidies in the form of employment insurance to Newfoundland fishers were one of the factors that contributed to overcapacity in the industry and the ultimate collapse of the cod fishery (Brubaker 2000).

Second, the UNCLOS requirement that coastal nations without sufficient fishing capacity to exploit the resources within their respective EEZs should make these resources available to other nations has ultimately proved detrimental to many developing nations. Although these countries do receive some form of reimbursement from other nations acquiring access, this has frequently resulted in payments that are significantly less than the value of the resource (particularly the long-term value; see Kaczynski and Fluharty 2002), in underreporting of foreign catches, in depletion of developing nations' deep-sea resources, and in depletion of the coastal resources that supported local fishing communities.

The change in the perception that there was considerable potential to increase the exploitation levels of marine resources, including fisheries, which began in the early 1990s, was influenced by several factors: the globalization of information (making it more rapidly and more widely available), the awareness-raising work of the World Commission on Environment and Development and UNCED, and the active mobilization of the media by the NGO environmental movement. Fishing capacity was widely perceived to be getting out of hand. Opportunities for further expansion of fisheries were diminishing as an increasing portion of the globe was being surveyed and assessed, albeit yielding few new areas for fishing or new fisheries. Deepwater species were mostly found to have very low productivity. Many environmental organizations such as the World Wide Fund for Nature that had previously focused mainly activities on terrestrial systems and marine mammals began to expand into fisheries. Legislation was tightened in many nations, and work began on several binding and nonbinding international instruments, some related to ecosystems in general and others specifically on marine systems and fisheries.

Subsequently, there has been a marked increase in national and international instruments that are gradually changing people's perceptions of the sustainability of current practices. For marine systems, the most important such instruments range from the 1992 Rio Declarations formulated at UNCED to several FAO International Plans of Action, including the International Plan of Action for the Management of Fishing Capacity (FAO 2001b) and the International Plan of Action to Deter, Prevent and Eliminate Illegal, Unreported and Unregulated Fishing (FAO 2001b). (See also MA, *Policy Responses,* Chapter 6.) All of these embody some facet of the ''precautionary approach,'' which has been instrumental in shifting attention to the benefits of conservative harvest strategies rather than risk-prone management (Mace 2001).

Concerted efforts to implement these agreements have been launched in many regions, with results ranging from unanticipated levels of success, to moderate success, and to failure. In terms of successes, the most notable accomplishments appear to have been those where national legislations have been modified to better accomplish the spirit and intent of the international instruments.

For example, the most recent amendment to the Magnuson-Stevens Fisheries Conservation and Management Act in the United States (popularly known as the Sustainable Fisheries Act) embodied the precautionary approach (without mentioning it by name) as exemplified in Annex 2 on the implementation of UNCLOS (UN 1995), in which the fishing mortality associated with maximum sustainable yield is suggested as a limit reference point to be avoided rather than a target that is routinely exceeded. This has resulted in considerable reductions in fishing mortality for some previously overfished U.S. fisheries, and several have rebuilt to levels not recorded in three or more decades.

One of the most dramatic examples is the density of Georges Bank scallops, which increased eighteenfold in the seven years following exceptional recruitment and implementation of management measures for bottom fishing that resulted in substantial reductions in fishing mortality during the fishing closure. Other U.S. examples include mid-Atlantic scallops (*Haliotis* spp), Georges Bank haddock (*Melanogrammus aeglefinus*), Georges Bank yellowtail flounder (*Limanda ferruginea*), Atlantic stripped bass (*Morone saxatilis),* Atlantic Acadian redfish (*Sebastes fascicatus*), Pacific chub mackerel (*Scomber japonicus*), and Pacific sardine (*Sardinops sagax*) (Murawski et al. 2000; NEFSC 2002). Yet while these and many other stocks in the United States and elsewhere are slowly but steadily rebuilding (NMFS 2004), the biomass of most of them is generally still well below historic levels. Closures of seamount fisheries on the Chatam Rise in New Zealand have also resulted in the slow rebuilding of orange roughy biomass (Clark 2001). Globally, however, these success stories represent a small proportion of the many overfished stocks.

Other examples of successful national initiatives include Australia's implementation of the Environment Protection and Biodiversity Act in 1999, which requires several fisheries to be assessed for their ecological sustainability. Regionally, the ICCAT has been able to work toward compliance of management measures for nonmember countries through tuna import and export restrictions by member countries.

Notable failures in fisheries management are exemplified by attempts to reduce harvest overcapacity while maintaining that exploitation of natural resources is a human right. This ''birthright'' is hard to dispute: all humans ought to have the ''right'' to a healthy life with adequate nutrition. And for some people, fish are one of the few available sources of protein. Solutions to this dilemma lie in assistance that improves the health, education, and non-fisheries-related employment opportunities of coastal communities as well as empowering coastal communities to manage resources sustainably.

Even relatively rich industrial nations that routinely pay their farmers not to produce crops seem unable to resolve the fish harvesting overcapacity problem, however. The European Union, for example, appears to have been largely unsuccessful with the capacity reduction plan in its Common Fisheries Policy, which has been in place for more than 15 years. With a few exceptions, substantial overcapacity reductions have been recorded in cases where individual transferable quotas, which allocated a quota of the catch to license holders as well as allowing those individuals to sell part or all of their quota, have been implemented (for instance, ITQs in New Zealand, Iceland, and some U.S. fisheries, such as Atlantic surf clams (*Spisula solidissima*) and ocean quahogs (*Arctica islandica*), South Atlantic wreckfish (*Polyprion americanus*), and Pacific halibut (*Hippoglossus stenolepis*) and sablefish (*Anoplopoma fimbria*)).

Although the emphasis in recent years has been on unsustainable fishing practices, fisheries represent only one of many human influences on marine ecosystems. In coastal marine systems in particular, coastal development—with concomitant problems of local pollution and habitat destruction—is very important. (See Chapter 19.) Non-fisheries human influences such as marine debris and oil slicks are also important on the high seas. As a result, as described earlier, several nations are attempting to develop legislation and policies to facilitate integrated management of marine systems—that is, coordinated management of all alternative uses of the ocean. Such uses include harvesting marine species for food and other purposes, aquaculture, research, oil and gas exploration, ocean mining, dredging, ocean dumping, energy generation, ecotourism, marine transportation, and defense. To date, it has proved difficult to integrate the management of all these activities because the authorities regulating these activities are usually independent of one another (Sissenwine and Mace 2003).

In Australia, the Environment Protection and Biodiversity Act requires management agencies to demonstrate that the fishery or fisheries are ecologically sustainable, with defined benchmarks to quantitatively assess sustainability. Since the introduction of this Act in 1999, more than 35 fisheries have been assessed (www.ea.gov.au/coasts/fisheries/assessment/index.html). The private sector has responded similarly to the introduction of the Marine Stewardship Council's accreditation scheme for fisheries, which is supported by major fish buyers, such as Unilever, and conservation organizations, such as WWF.

With increased public awareness of the limits of marine systems, binding and nonbinding international instruments in place, tightened national legislations, and a few success stories that emphasize the positive benefits of conservation, the future of the oceans may appear brighter than it did a decade ago. However, this is not the time for complacency, particularly considering the likely increase in pressure on natural resources that will result from the world's growing human population and rising incomes.

Main Messages

Coastal ecosystems—coastal lands, areas where fresh water and salt water mix, and nearshore marine areas—are among the most productive yet highly threatened systems in the world. These ecosystems produce disproportionately more services relating to human well-being than most other systems, even those covering larger total areas. At the same time, these ecosystems are experiencing some of the most rapid environmental change: approximately 35% of mangrove area has been lost or converted (in those countries for which sufficient data exist, which encompass about half of the area of mangroves) and approximately 20% of coral reefs have been destroyed globally in the last few decades, with more than a further 20% being degraded. Coastal wetland loss in some places has reached 20% annually (*high certainty*).

Coastal systems are experiencing growing population and exploitation pressures; nearly 40% of the people in the world live within 100 kilometers of the coast. Demographic trends suggest coastal populations are increasing rapidly, mostly through migration, increased fertility, and tourist visitation to these areas (*high certainty*). Population densities on the coasts are nearly three times that of inland areas. Communities and industries increasingly exploit fisheries, timber, fuelwood, construction materials, oil, natural gas, sand and strategic minerals, and genetic resources. In addition, demand on coastal areas for shipping, waste disposal, military and security uses, recreation, aquaculture, and even habitation are increasing.

Coastal communities aggregate near the types of coastal systems that provide the most ecosystem services; these coastal subtypes are also the most vulnerable. Within the coastal population, 71% live within 50 kilometers of estuaries; in tropical regions, settlements are concentrated near mangroves and coral reefs. These habitats provide protein to a large proportion of the human coastal populations in some countries; coastal capture fisheries yields are estimated to be worth a minimum of $34 billion annually. However, many of these habitats are unprotected or marginally protected; as a result, ecosystems services in many areas are at risk (*medium certainty*).

Human pressures on coastal resources are compromising many of the ecosystem services crucial to the well-being of coastal economies and peoples. Coastal fisheries have depleted stocks of finfish, crustaceans, and mollusks in all regions (*high certainty*). Illegal and destructive fisheries often cause habitat damage as well as overexploitation. Large-scale coastal fisheries deprive coastal communities of subsistence and are causing increasing conflicts, especially in Asia and Africa. Demands for coastal aquaculture have been on the rise, partly in response to declining capture fisheries, but the doubling of aquaculture production in the last 10 years has also driven habitat loss, overexploitation of fisheries for fishmeal and fish oil, and pollution. Overexploitation of other resources such as mangroves for fuelwood, sand for construction material, seaweeds for consumption, and so on also often undermine the ecological functioning of these systems.

The greatest threat to coastal systems is development-related loss of habitats and services. Many areas of the coast are degraded or altered, such that humans are facing increasing coastal erosion and flooding, declining water quality, and increasing health risks. Port development, urbanization, resort development, aquaculture, and industrialization often involve destruction of coastal forests, wetlands, coral reefs, and other habitats. Historic settlement patterns have resulted in centers of urbanization near ecologically important coastal habitats: 58% of the world's major reefs occur within 50 kilometers of major urban centers of 100,000 people or more, while 64% of all mangrove forests and 62% of all major estuaries occur near such centers. Dredging, reclamation, engineering works (beach armoring, causeways, bridges, and so on) and some fishing practices also account for widespread, usually irreversible, destruction of coastal habitats (*medium certainty*).

Degradation is also a severe problem, because pressures within coastal zones are growing and because such zones are the downstream recipients of negative impacts of land use. Worldwide, human activities have increased sediment flows in rivers by about 20%, but reservoirs and water diversions prevent about 30% of sediments from reaching the oceans, resulting in a net reduction of sediment delivery to coasts of roughly 10% (*high certainty*). The global average for nitrogen loading has doubled within the last century, making coastal areas the most highly chemically altered ecosystems in the world, with resulting eutrophication that drives coral reef regime shifts and other irreversible changes to coastal ecosystems. Nearly half the people living along coasts have no access to sanitation and thus face decreasing ecosystem services and increasing risks of disease. Mining and other industries cause heavy metal and other toxic pollution. Harmful algal blooms and other pathogens, which affect the health of both humans and marine organisms, are on the rise, in part because of decreased water quality. Invasions of alien species have already altered marine and coastal ecosystems, threatening ecosystem services.

The health of coastal systems and their ability to provide highly valued services is intimately linked to that of adjacent marine, freshwater, and terrestrial systems, and vice versa. Land-based sources of pollutants are delivered by rivers, from runoff, and through atmospheric deposition, and these indirect sources account for the large majority (77%) of pollutants (*high certainty*). In some areas, especially drylands, pollution in coastal zones contaminates groundwater. Another linkage occurs between expanding desertification and pollution of coral reef ecosystems caused by airborne dust. Destruction of coastal wetlands has similarly been implicated in crop failures due to decreased coastal buffering leading to freezing in inland areas (*medium certainty*).

Sub-national sociological data suggest that people living in coastal areas experience higher well-being than those living in inland areas, but the acute vulnerability of coastal ecosystems to degradation puts coastal inhabitants at greater relative risk. The world's wealthiest populations occur primarily in coastal areas (per capita income being four times higher in coastal areas than inland), and life expectancy is thought to be higher in coastal regions, while infant mortality is thought to be lower (*medium certainty*). However, many coastal communities are politically and economically marginalized and do not derive the economic benefits from coastal areas. Wealth disparity has denied many coastal communities access to resources. Access issues have in turn led to increased conflict, such as between small-scale artisanal fishers and large-scale commercial fishing enterprises. Regime shifts and habitat loss have led to irreversible changes in many coastal ecosystems and losses in some ecosystem services. Finally, given the fact that many degraded coastal systems are near thresholds for healthy functioning (*medium certainty*), and that coastal systems are simultaneously vulnerable to major impacts from sea level rise, erosion, and storm events, coastal populations are at risk of having their relatively high levels of human well-being severely compromised.

Trade-offs occur not only within coastal ecosystems, but also between the different uses of coastal systems and inland areas. In general, the choice to exploit coastal resources results in a reduction of other services; in some cases, overexploitation leads to loss of most other services (*medium certainty*). Within the coastal system, choices that result in irreversible changes, such as conversion of coastal habitat for industrial use, urbanization, or other coastal development, often bring short-term economic benefits but exact longer-term costs, as regulating and provisioning services are permanently lost. Choices made outside coastal areas, such as the decision to divert water for agriculture and thus reduce the flow of fresh water to estuaries, are cause for particular concern because virtually none of the benefits accrue to the coastal sector. Estuaries and coral reefs are the most threatened of all coastal ecosystems, precisely because impacts are both direct (originating from activity within the ecosystem), and indirect (originating in watersheds and inland areas).

Management of coastal systems to maximize the supply of services has been inadequate, but some negative trends are slowing and degradation can be halted with policy reform and by scaling up small successes to broader-scale initiatives. Effective coastal area management requires the integration of management across many sectors that have traditionally been separated. Because coastal systems are strongly affected by activities both in and outside of coastal regions, watershed management is a necessary element of effective coastal management. Integrated coastal management, marine protected area networks that effectively protect the most ecologically important habitats, and comprehensive ocean zoning all hold great promise. Restoration of some coastal habitats such as marshlands and mangrove is being undertaken. Other success stories do exist, but such successes have generally been small-scale, and scaling up has proved difficult. Business as usual will not avert continued degradation, associated loss of services, and declining human well-being in certain portions of society, such as coastal communities in developing countries and much of the low- to middle-income populace of industrial countries (*high certainty*).

19.1 Introduction

Coastal and marine ecosystems are among the most productive, yet threatened, ecosystems in the world; included in this category are terrestrial ecosystems, areas where fresh water and salt water mix, and nearshore coastal areas and open ocean marine areas. For the purpose of this assessment, the ocean and coastal realm has been divided into two major sets of systems: ''coastal systems'' inshore and ''marine fisheries systems.''

Coastal systems are places where people live and where a spate of human activity affects the delivery of ecosystem services derived from marine habitats; marine fisheries systems are places that humans relate to and affect mainly through fisheries extraction. Continental shelf areas or large marine ecosystems span both coastal and marine systems and provide many key ecosystem services: shelves account for at least 25% of global primary productivity, 90–95% of the world's marine fish catch, 80% of global carbonate production, 50% of global denitrification, and 90% of global sedimentary mineralization (UNEP 1992).

These shelf areas contain many different types of coastal systems, including freshwater and brackish water wetlands, mangrove forests, estuaries, marshes, lagoons and salt ponds, rocky or muddy intertidal areas, beaches and dunes, coral reef systems, seagrass meadows, kelp forests, nearshore islands, semi-enclosed seas, and nearshore coastal waters of the continental shelves. Many of these coastal systems are highly productive; Table 19.1 illustrates the relative productivity of some of these coastal ecosystems compared with selected terrestrial ecosystems.

In this assessment, the inland extent of coastal ecosystems is defined as the line where land-based influences dominate up to a maximum of 100 kilometers from the coastline or 50-meter elevation (whichever is closer to the sea, as per Small and Nicholls 2003) and with the outward extent as the 50-meter depth contour. Marine ecosystems begin at the low water mark and encompass the high seas and deepwater habitats. (See Figure 19.1.)

The resulting definition of coastal systems is geographically constrained and departs from many earlier assessments. The narrower band of coastal zone is a terrestrial area dominated by ocean influences of tides and marine aerosols, and a marine area where light penetrates throughout. This narrow definition was chosen for two reasons, relating to inshore and offshore boundaries: first, it focuses on areas that truly rely on and affect coastal ecosystems and it omits areas that may be near the coast but have little connection to those ecosystems (such as areas in valleys behind coastal mountain ranges); second, the ''watery'' portion of the coastal zone to 50 meters depth captures shallow water ecosystem like coral reefs but avoids deeper portions of the continental shelves in which fisheries impacts are paramount above all others (which are treated extensively in Chapter 18).

Table 19.1. Relative Productivity Estimates for Select Coastal and Terrestrial Ecosystems (based on Odum and Barrett in press)

Ecosystem Type	Mean Net Primary Productivity	Mean Biomass per Unit Area
	(kilograms per sq. meter per year)	(kilograms per sq. meter)
Swamp and marsh	2.0	15
Continental shelf	0.36	0.01
Coral reefs and kelp	2.5	2
Estuaries	1.5	1
Tropical rain forest	2.2	45

The heterogeneous ecosystems embodied in these coastal systems are dynamic, and in many cases are now undergoing more rapid change than at any time in their history, despite the fact that nearshore marine areas have been transformed throughout the last few centuries (Vitousek et al. 1997). These transformations have been physical, as in the dredging of waterways, infilling of wetlands, and construction of ports, resorts, and housing developments, and they have been biological, as has occurred with declines in abundances of marine organisms such as sea turtles, marine mammals, seabirds, fish, and marine invertebrates (Jackson et al. 2001; Myers and Worm 2003). The dynamics of sediment transport and erosion deposition have been altered by land and freshwater use in watersheds; the resulting changes in hydrology have greatly altered coastal dynamics. These impacts, together with chronic degradation resulting from land-based and marine pollution, have caused significant ecological changes and an overall decline in many ecosystem services. (Known rates of change and degradation in coastal subtypes are described later in this chapter.)

Dependence on coastal zones is increasing around the world, even as costs of rehabilitation and restoration of degraded coastal ecosystems is on the rise. In part, this is because population growth overall is coupled with increased degradation of terrestrial areas (fallow agricultural lands, reduced availability of fresh water, desertification, and armed conflict all contributing to decreased suitability of inland areas for human use). Resident populations of humans in coastal areas are rising, but so are immigrant and tourist populations (Burke et al. 2001). At the same time, wealth inequities that result in part from the tourism industry decrease access to coastal regions and resources for a growing number of people (Creel 2003). Nonetheless, local communities and industries continue to exploit coastal resources of all kinds, including fisheries resources; timber, fuelwood, and construction materials; oil, natural gas, strategic minerals, sand, and other nonliving natural resources; and genetic resources. In addition, people increasingly

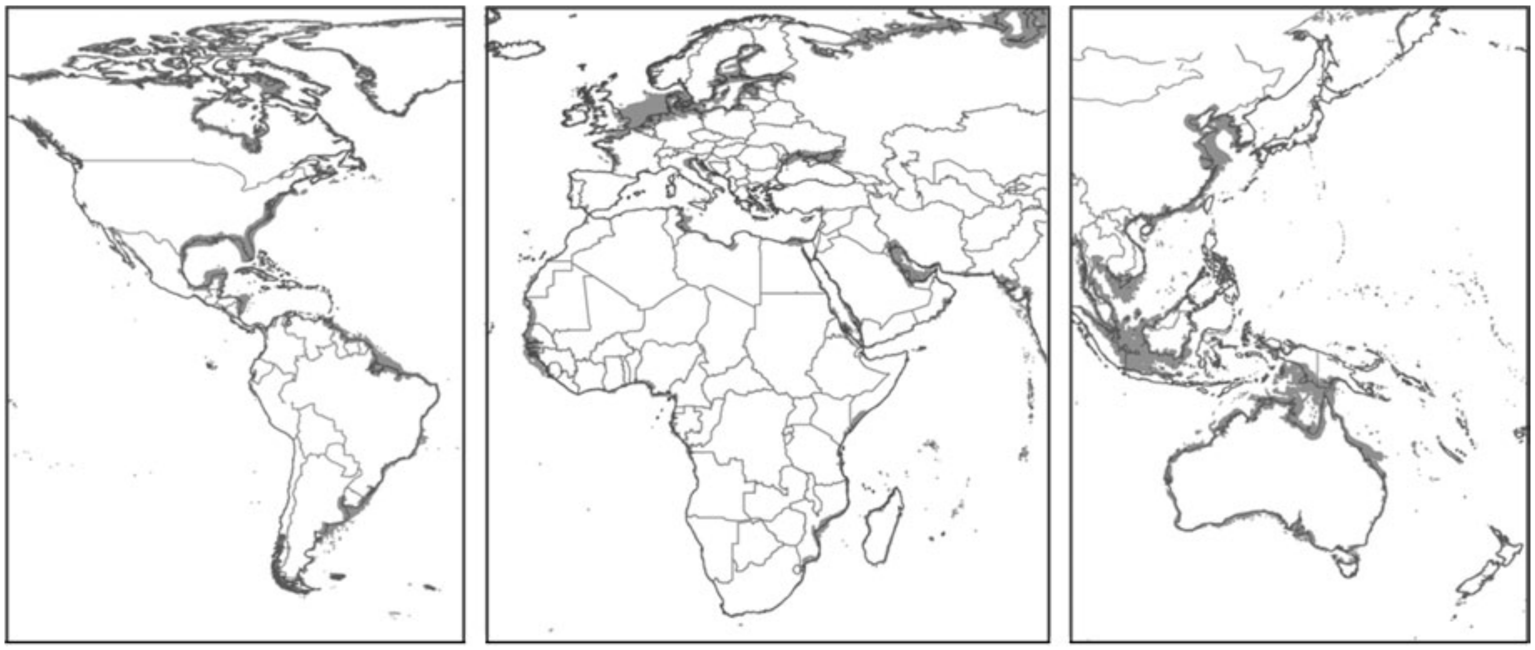

Figure 19.1. Coastal and Marine Systems Delimitation

use ocean areas for shipping, security zones, recreation, aquaculture, and even habitation. Coastal zones provide far-reaching and diverse job opportunities, and income generation and human well-being are currently higher on the coasts than inland.

Despite their value to humans, coastal systems and the services they provide are becoming increasingly vulnerable (*high certainty*). Coastal systems are experiencing growing population and exploitation pressures in most parts of the world. Though the thin strip of coastal land at the continental margins and within islands accounts for less than 5% of Earth's land area, 17% of the global population lives within the coastal systems as defined in this chapter, and 39% of global population lives within the full land area that is within 100 kilometers of a coast (CIESIN 2000). Population density in coastal areas is close to 100 people per square kilometer compared with inland densities of 38 people per square kilometer in 2000. Though many earlier estimates of coastal populations have presented higher figures (in some cases, near 70% of the world population was cited as living within the coastal zone), previous estimates used much more generous geographic definitions of the coastal area and may be misleading (Cohen 1995; Tibbetts 2002). That we have used a narrower definition and refined the coastal population numbers downwards in no way implies that coastal systems have lesser importance to humans—on the contrary, this assessment underlines the central extent to which human well-being is linked to the health and productivity of coastal systems.

Human pressures on coastal resources compromise the delivery of many ecosystem services crucial to the well-being of coastal peoples and national economies. Coastal fisheries, like many more offshore fisheries, have severely depleted stocks. (See Chapter 18.) These depletions not only cause scarcity in resource availability, they also change the viability of coastal and marine food webs, affecting the delivery of other services such as coastal protection (Dayton et al. 1995, 2002).

Biological transformations are also coupled to physical transformations of the coastal zone. Habitat alteration is pervasive in the coastal zone, and degradation of habitats both inside and outside these systems contributes to impaired functioning. Similarly, human activities far inland, such as agriculture and forestry, affect coastal ecosystems when fresh water is diverted from estuaries or when land-based pollutants enter coastal waters (nearly 80% of the pollutant load reaching the oceans comes from terrestrial sources). These chemical transformations affect the functioning of coastal systems and their ability to deliver services. Thus, changes to ecosystems and services occur as a function of land use, freshwater use, and activities at sea, even though these land-freshwater-marine linkages are often overlooked.

Larger forces are also at play. Coastal areas are physically vulnerable: many areas are now experiencing increasing flooding, accelerated erosion, and seawater intrusion into fresh water; these changes are expected to be exacerbated by climate change in the future (IPCC 2003). Such vulnerabilities are currently acute in low-lying mid-latitude areas, but both low-latitude areas and polar coastlines are increasingly vulnerable to climate change impacts. Coral reefs and atolls, salt marshes, mangrove forests, and seagrasses will continue to be affected by future sea level rise, warming oceans, and changes in storm frequency and intensity (*high certainty*) (IPCC 2003). The ecosystems at greatest risk also support large numbers of people; thus human well-being is at risk from degradation of coastal systems.

In general, management of coastal resources and human impacts on these areas is insufficient or ineffective, leading to conflict, decreases in services, and decreased resilience of natural systems to changing environmental conditions. Inadequate fisheries management persists, often because decision-makers are unaware of marine resource management being ineffective, while coastal zone management rarely addresses problems of land-based sources of pollution and degradation (Agardy 1999; Kay and Alder in press). Funds are rarely available to support management interventions over the long term.

At the same time, the incidence of disease and emergence of new pathogens is on the rise, and in many cases coastal degradation has human health consequences as well (NRC 2000; Rose et al. 2001). Episodes of harmful algal blooms are increasing in frequency and intensity, affecting both the resource base and people living in coastal areas more directly (Burke et al. 2001; Epstein and Jenkinson 1993).

Effective measures to address declines in the condition of coastal systems remain few and far between and are often too little, too late. Restoration of coastal habitats, although practiced, is generally so expensive that it remains a possibility only on the small scale or in the most industrialized countries. Education about these issues is lacking. The assessment in this chapter aims to contribute to a better understanding of the condition of coastal ecosystems and the consequence of changes in them, and thereby to help decision-makers develop more appropriate responses for the coastal environment.

19.2 Coastal Systems and Subtypes, Marine Wildlife, and Interlinkages

Total global coastlines exceed 1.6 million kilometers and coastal ecosystems occur in 123 countries around the world (Burke et al. 2001). The MA coastal system includes almost 5% of the terrestrial surface area of Earth. Coastal systems are a complex patchwork of habitats—aquatic and terrestrial. Figure 19.2 illustrates the heterogeneity of the habitats, human communities, and interconnected systems commonly referred to as the coastal zone. The diversity of habitat types and biological communities is significant, and the linkages between habitats are extremely strong (IOC 1993).

Scaling is a very important consideration in deciding how to treat the varied set of habitats in coastal systems, since investigations at fine scales will not reveal the global situation, and investigations at coarse scales will inevitably exclude important detail (O'Neill 1988; Woodmansee 1988). Thus, for the purposes of this discussion, the coastal system is divided into eight subtypes, relying in part on former classification systems (e.g., Allee et al. 2000) and in part on the model set forth in other chapters of the MA. Each subtype is described separately, including discussions of the services each provides, and is then assessed in terms of current condition and trends in the short-term future. In subsequent sections in which we discuss drivers of change, trade-offs, management interventions, and implications for human well-being, the coastal system is treated as a single unit.

19.2.1 Coastal Subtypes: Condition and Trends, Services and Value

19.2.1.1 Estuaries, Marshes, Salt Ponds, and Lagoons

Estuaries—areas where the fresh water of rivers meets the salt water of oceans—are highly productive, dynamic, ecologically critical to other marine systems, and valuable to people. Worldwide, some 1,200 major estuaries have been identified and mapped, yielding a total digitized area of approximately 500,000 square kilometers. (See Figure 19.3.)

There are various definitions of an estuary. One commonly accepted one is "a partially enclosed coastal body of water which is either permanently or periodically open to the sea and within which there is a measurable variation of salinity due to the mixture of sea water with freshwater derived from land drainage" (Hobbie 2000). Other definitions accommodate the fact that the

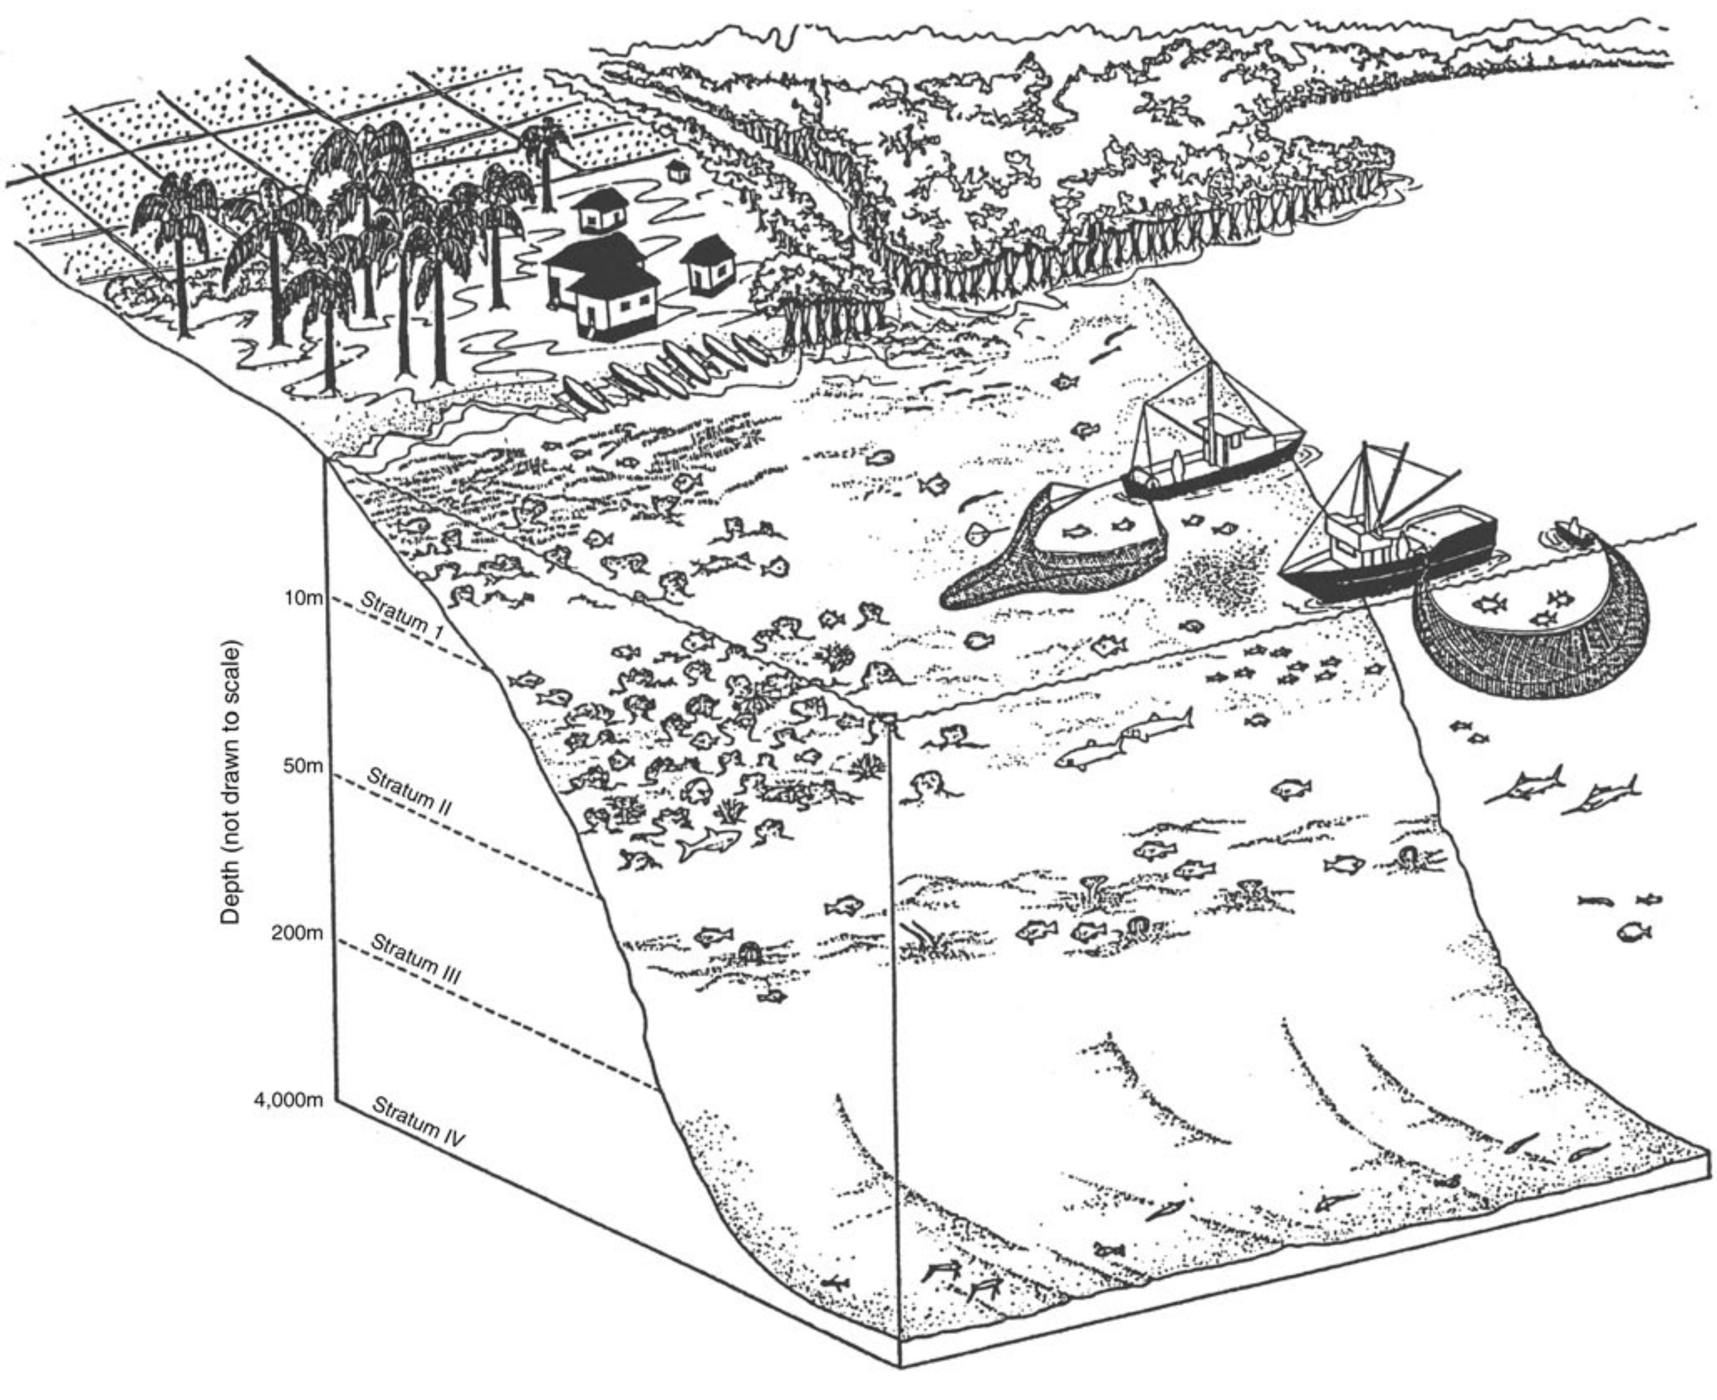

Figure 19.2. Schematic of Coastal System (Pauly et al. 1998)

Figure 19.3. Distribution of World's Major Estuaries (UNEP-WCMC 2003b)

range of estuarine organisms is often larger than suggested by a "biophysical" definition. Coastal marshes and lagoons are essentially extensions of true estuaries and are included in estuarine analysis and assessment. Mangroves are also often found in estuaries, but their importance to coastal communities warrants a separate detailed discussion, which is given in the next section.

Regardless of location or latitude, estuaries, marshes, and lagoons play a key role in maintaining hydrological balance, filtering water of pollutants, and providing habitat for birds, fish, mollusks, crustaceans, and other kinds of ecologically and commercially important organisms (*high certainty*) (Beck et al. 2001; Levin et al. 2001). The 1,200 largest estuaries, including lagoons and fiords, account for approximately 80% of the world's freshwater discharge (Alder 2003).

Of all coastal subtypes, estuaries and marshes support the widest range of services and may be the most important areas for ecosystems services. One of the most important processes is the mixing of nutrients from upstream as well as from tidal sources, making estuaries one of the most fertile coastal environments (Simenstad et al. 2000). There are many more estuarine-dependent species than estuarine-resident species, and estuaries provide a range of habitats to sustain diverse flora and fauna (Dayton 2003). Estuaries are particularly important as nursery areas for fisheries and other species, and form one of the strongest linkages between coastal, marine, and freshwater systems and the ecosystem services they provide (Beck et al. 2001).

Freshwater wetlands close to the coast form a salinity gradient and play a key role in maintaining freshwater flows. These areas are also under pressure for conversion to other uses, as well as for fish production. Many of these freshwater wetlands have been lost, and those that remain are under threat from coastal development, with pollution exacerbating threats. The European Union Habitats Directive has declared the conservation of coastal freshwater wetlands a priority (Ledoux et al. 2003).

An array of anthropogenic impacts has degraded, altered, or eliminated these ecosystems in many areas. The main threats include the loss or destruction of large areas of an estuary's watershed; eutrophication; effects of non-nutrient pollutants such as pesticides, herbicides, and bacteria; overfishing; invasions of exotic species; and, most important, habitat conversion within estuaries themselves. There has been a substantial loss of estuaries and associated wetlands globally (Levin et al. 2001). In California, for example, less than 10% of natural coastal wetlands remain, while in the United States more generally, over half of original estuarine and wetland areas have been substantially altered (Dayton 2003). In Australia, 50% of estuaries remain undamaged, although these are away from current population centers (Dayton 2003). Of the world's major estuaries, 62% occur within 25 kilometers of urban centers having 100,000 or more people.

Estuaries, especially those in proximity to urban centers, are often subjected directly and indirectly to trade-offs between development and conservation. Alterations such as infilling, dredging, channeling, installation of harbor works including seawalls and groins affect estuaries directly. Altering soft bottom habitat to hard bottom in the process often affects estuaries indirectly by creating conditions for new assemblages of species, and facilitating range expansions of invasive species (Ruiz and Crooks 2001). The resulting ecosystems may have losses in some ecosystem services and biodiversity. In New Zealand, invasive species have displaced commercially important mussel beds, causing significant economic losses for many mussel farmers (NOAA News Online 2003).

Figure 19.4 shows the interplay among urbanization, port development, and estuary loss worldwide. (See also Box 19.1.) Changes to freshwater flows through river impoundment and diversion are indirect trade-offs—worldwide, human activities have increased sediment flows in rivers by about 20% but reservoirs and water diversions prevent about 30% of sediments from reaching the oceans, resulting in a net reduction of sediment delivery to coasts of roughly 10% (*high certainty*) (Syvitski et al. 2005; Vörösmarty et al. 2003). Delivery of ecologically important nutrients is also impeded by freshwater diversion in watersheds, affecting not only coastal ecology but also marine fisheries yields. In the Nile Delta region of the Mediterranean, fish yields dropped significantly following the construction of the Aswan Dam (Nixon 2003). Although biomass levels rebounded from increasing nutrient input through human sewage, species composition was altered, and fish caught from the polluted waters of the Nile estuary continue to have human health impacts.

Poor management of watersheds often leads to degradation of estuaries. Agricultural and grazing practices that destroy natural riparian habitats have resulted in floods and burial of the natural estuarine habitats under silt and enriched sediment (Teal and Teal 1969). Urbanization of watersheds interrupts natural flows of both fresh water and nutrients, and it increases pollution. Agricultural inputs often result in excessive nutrient loading, which in turn causes large coastal areas to become eutrophied, hypoxic, or even anoxic (Boesch et al. 2001; D'Avanzo et al. 1996). An extreme example is the massive dead zone (up to 15,000 square kilometers) in the Gulf of Mexico (Turner and Rabalais 1994). Eutrophication is pervasive close to most of the world's large estuaries and all centers of human population, and the resulting ecosystem

Figure 19.4. Distribution of Major Ports and Estuaries (UNEP-WCMC 2003b; GDAIS 2004)

BOX 19.1

Case Study of the Paracas National Reserve

The Paracas National Reserve (335,000 hectares) is located along the Peruvian Pacific Coast, 250 kilometers south of the capital city, Lima. The reserve represents the best example of Pacific sub-tropical coastal desert on the South American continent (Rodriguez 1996). It includes relicts of the coastal desert plant communities (*lomas*). Paracas is one of the most biologically productive marine areas in the world, serving as a home for nearly 300 fish species, over 200 migratory bird species (60 of which migrate between Peru and the United States), and marine mammals and reptiles. The reserve also provides food for human populations in local communities and numerous coastal cities, providing about 60% of the seafood consumed by the people of Lima, which is home to 8 million people.

Historically, the arid coasts near Paracas gave rise to numerous pre-Colombian cultures, including the Paracas culture, and their villages built up "a life of unexpected richness in the arid dunes" (Stone-Miller 1995). The allochthonous subsidies from the sea may explain the apparent contrast between the aridity of the habitat (Paracas is a Quechuan word meaning "sand falling like rain") and the richness of the Paracas culture. Today the industrial effluents from fish meal and fish oil factories reaching the Paracas Bay cause massive deaths of fish and marine invertebrates. Overfishing and overcollecting of invertebrates has reduced the food source of numerous seabirds and marine mammals, whose populations have been declining continuously since the middle of the last century. Currently, a fractionation plant to process natural gas is being built in the buffer zone of the protected area within the Paracas Bay, adding another source of environmental risk to an already vulnerable and degraded marine ecosystem.

The Paracas National Reserve is an important source of income for local fishers. Overfishing and overcollecting might have serious social and economic consequences in the town bordering the reserve, where most of the economy is centered on sea products. An economic valuation of Independencia Bay (Cuadros Dulanto 2001), a 25-by-9 kilometer bay in the southern part of the reserve, calculated its direct use value as $17.42 million. Fish and seafood accounted for 98% of this, whereas guano accounted for 1.4% and algae 0.4%. The value of indirect use, calculated through a model accounting for carbon sequestration by phytoplankton, was of $181,124 per year. Potential, existence, and biodiversity values were estimated to be $9.5 million, $2.7 million, and $29.8 million, respectively.

changes are difficult (though perhaps not impossible) to reverse once algae take over benthic habitats or cause shifts in trophic structure.

Estuarine systems are among the most invaded ecosystems in the world, with exotic introduced species causing major ecological changes (Carlton 1989 and 1996). Often introduced organisms change the structure of coastal habitat by physically displacing native vegetation (Grosholz 2002; Harris and Tyrrell 2001; Murray et al. 2004). For example, San Francisco Bay in California has over 210 invasive species, with one new species established every 14 weeks between 1961 and 1995 (Cohen and Carlton 1995, 1998). Most of these bioinvaders were bought in by ballast water of large ships or occur as a result of fishing activities (Carlton 2001). The ecological consequences of the invasions include habitat loss and alteration, altered water flow and food webs, the creation of novel and unnatural habitats subsequently colonized by other exotic species, abnormally effective filtration of the water column, hybridization with native species, highly destructive predators, and introductions of pathogens and disease (Bax et al. 2003; Ruiz et al. 1997).

Salt ponds and salinas are formed when evaporation causes constrained marine waters to become hypersaline. Some are naturally formed and others are artificial, such as salt pans and shrimp ponds. In effect, these subtypes are the biophysical opposites of estuaries, yet these coastal features provide key feeding areas for coastal birds and have their own unique biological communities. In the Red Sea region, these salt flats contribute nitrogen to adjacent mangroves (Potts 1980; Saifullah 1997b). Many of these features are seasonal or ephemeral and provide certain services only during certain times of year. Salt ponds and salt flats are often converted for other uses.

Salt marshes and coastal peat swamps (see Chapter 20) have also undergone massive change and destruction, whether they are within estuarine systems or along the coast. Salt marsh subsidence has occurred in part due to restricted sediment delivery from watersheds. Peat swamps in Southeast Asia have declined from 46–100% in countries monitoring changes (MacKinnon 1997). Coastal birds using estuaries and salt marshes both are indicators of ecosystem condition and provide many of the aesthetic ecological services of coastal systems (Benoit and Askins 2002); shorebird diversity and abundance has declined dramatically in the last few decades (International Wader Study Group 2003). Changes in relative sea level have affected and continue to affect salt marsh productivity and functioning, especially the ability of marshes to accumulate and retain sediments (Adam 2002). Relative sea level is a function of absolute sea level, changes in land level due to plate tectonics, and sediment delivery levels. Since sea level is rising due to climate change and land subsidence, and since freshwater diversion impedes delivery of sediments to estuarine systems (Vörösmarty and Meyback 1999), salt marshes will continue to be degraded and lost (Cahoon et al. 1999). The greatest threat may be to salt marshes in the tropics, which are relatively poorly studied (Adam 2002).

In many parts of the world, freshwater wetlands occur inland along the gradient of coastal ecosystems that begins offshore and moves inland through estuaries and salt marshes. Such coastal freshwater wetlands include herbaceous wetlands (marshes) and arboreal wetlands (swamps). Freshwater wetlands are discussed in detail elsewhere in this volume (Chapters 7 and 20), but it should be noted that the provision of ecosystem services by coastal systems can be highly dependent on the condition of these freshwater wetlands, and many have been and continue to be degraded by coastal development, changes to hydrology, and pollution.

19.2.1.2 Mangroves

Mangroves are trees and shrubs found in intertidal zones and estuarine margins that have adapted to living in saline water, either continually or during high tides (Duke 1992). Mangrove forests are found in both tropical and sub-tropical areas (see Figure 19.5 in Appendix A), and global mangrove forest cover currently is estimated as between 16 million and 18 million hectares (Valiela et al. 2001; Spalding et al. 1997). The majority of mangroves are found in Asia.

Mangroves grow under a wide amplitude of salinities, from almost fresh water to 2.5 times seawater strength; they may be classified into three major zones (Ewel et al. 1998) based on dominant physical processes and geomorphological characters: tide-dominated fringing mangroves, river-dominated riverine mangroves, and interior basin mangroves. The importance and quality of the various goods and services provided by mangroves varies among these zones (Ewel et al. 1998). Fringe forests provide protection from typhoons, flooding, and soil erosion; organic matter export; animal habitat; and a nursery function. Riverine mangroves also provide protection from flooding and erosion, as well as sediment trapping, a nursery function, animal habitat, and the harvest of plant products (due to highest productivity). Basin forests provide a nutrient sink, improve water quality, and allow the harvest of plant products (due to accessibility).

These forests thus provide many ecosystem services, playing a key role in stabilizing land in the face of changing sea level by trapping sediments, cycling nutrients, processing pollutants, supporting nursery habitats for marine organisms, and providing fuelwood, timber, fisheries resources. They also buffer land from storms and provide safe havens for humans in the 118 coastal countries in which they occur (Spalding et al. 1997). Mangroves have a great capacity to absorb and adsorb heavy metals and other toxic substances in effluents (Lacerda and Abrao 1984). They can also exhibit high species diversity. Those in Southeast Asia, South Asia, and Africa are particularly species-rich, and those in association with coral reefs provide food and temporary living space to a large number of reef species. In some places mangroves provide not only nursery areas for reef organisms but also a necessary nursery ground linking seagrass beds with associated coral reefs (Mumby et al. 2004). Removal of mangrove can thus interrupt these linkages and cause biodiversity loss and lower productivity in reef and seagrass biomes.

Mangroves are highly valued by coastal communities, which use them for shelter, securing food and fuelwood, and even as sites for agricultural production, especially rice production. Due to their function as nurseries for many species, fisheries in waters adjacent to mangroves tend to have high yields; annual net values of $600 per hectare per year for this fishery benefit have been suggested (Giesen et al. 1991). In addition, an annual net benefit of $15 per hectare was calculated for medicinal plants coming from mangrove forests, and up to $61 per hectare for medicinal values (Bann 1997). Similarly large economic benefits are calculated for shoreline stabilization and erosion control functions of mangroves (Ruitenbeek 1992).

Many mangrove areas have become degraded worldwide, and habitat conversion of mangrove is widespread (Farnsworth and Ellison 1997). Much of the coastal population of the tropics and sub-tropics resides near mangroves; 64% of all the world's mangroves are currently within 25 kilometers of major urban centers having 100,000 people or more. Mangroves have been converted to allow for aquaculture and for agriculture, including grazing and stall feeding of cattle and camels (which in Pakistan, for instance, is the second most serious threat to mangrove ecosystems (Saifullah 1997a)). Mangrove forests are also affected by removal of trees for fuelwood and construction material, removal of invertebrates for use as bait, changes to hydrology in both catchment basins or nearshore coastal areas, excessive pollution, and rising relative sea levels (Semesi 1992, 1998).

Along with conversion to agriculture, salt pans, and urban and industrial development, an important cause of loss is the aquaculture industry, typically through conversion of mangrove wetlands to shrimp or prawn farms. This destruction is particularly wasteful and costly in the long term, since shrimp ponds created out of mangrove forest lose their productivity over time and tend to become fallow in 2–10 years (Stevenson 1997). Historically, abandoned shrimp ponds are rarely restored, but new policy directives and a shift in the aquaculture industry is helping to make aquaculture less destructive and more prone to supporting restoration or regrowth in some parts of the world.

Estimates of the loss of mangroves from countries with available multiyear data (representing 54% of total mangrove area at present) show that 35% of mangrove forests have disappeared in the last two decades—at the rate of 2.1%, or 2,834 square kilometers, per year (Valiela et al. 2001). In some countries, more than 80% of original mangrove cover has been lost due to deforestation (Spalding et al. 1997). In summary, the current extent of mangroves has been dramatically reduced from the original extent in nearly every country in which data on mangrove distribution have been compiled (Burke et al. 2001). The leading human activities that contribute to mangrove loss are 52% aquaculture (38% shrimp plus 14% fish), 26% forest use, and 11% freshwater diversion (Valiela et al. 2001). Restoration has been successfully attempted in some places, but this has not kept pace with wholesale destruction in most areas.

19.2.1.3 Intertidal Habitats, Deltas, Beaches, and Dunes

Rocky intertidal, nearshore mudflats, deltas, beaches, and dunes also provide ecosystem services such as food, shoreline stabilization, maintenance of biodiversity (especially for migratory birds), and recreation.

Rocky intertidal habitats display interesting patterns of biological regulation and have been the location of much of the research that provided the foundation for our knowledge of predator-prey interactions, keystone species, and other biological regulation (Foster et al. 1988; Paine 2002; Sebens 1986). (See Chapter 11 for more on biological regulation in coastal systems.) The rocky intertidal habitats of temperate areas are highly productive and, in some cases, an important source of food for humans (Murray et al. 1999b). Food and bait collection (including mollusks and seaweeds) and human trampling have substantially depleted many of the organisms in these habitats. In the United States, the rocky intertidal zone has undergone major transformation in the last few decades: the California mussel *Mytelus californianus* has become very rare, the seastar *Pisaster* sp. is now almost never seen, and the once abundant black abalone (*Haliotis cracherodii*) can no longer be found in southern California (Dayton 2003). In addition, dozens of formally abundant nudibranch species are now rare (Tegner and Dayton 2000). Similar trends have been observed elsewhere in the world (Dayton 2003). Along the Yellow Sea coast, China has lost around 37% of habitat in intertidal areas since 1950, and South Korea has lost ~43% since 1918 (Birdlife International 2004a).

Intertidal mudflats and other soft-bottom coastal habitats play pivotal roles in ocean ecology, even though research and public interest have not historically focused on these habitats. Soft-bottom coastal habitats are highly productive and can be extraordinarily diverse (Levin et al. 2001), with a species diversity that may rival that of tropical forests (Gray 1997). Mudflats are critical habitat for migrating shorebirds and many marine organisms, including commercially important species like the horseshoe crab (*Limulus polyphemus)* and a variety of clam species. Unfortunately, mudflats are commonly destroyed during port development or maintenance dredging (Rogers et al. 1998), and coastal muds in many areas are highly contaminated by heavy metals, PCBs, and other persistent organic pollutants, leading to mortality and morbidity in marine species and to human health impacts.

Coastal deltas are extremely important microcosms where many dynamic processes and human activity converge. The IPCC has identified ''deltas, estuaries, and small islands'' as the coastal systems most vulnerable to climate change and sea level rise (IPCC 2003). Deltas are high population and human land use areas and are dynamic and highly vulnerable. They are also experiencing significant global changes as a class in themselves, aside from their overlap with the categories of mangrove, marshes, and wetlands (discussions of which do not capture all the dynamic influences in deltas).

Beaches and sandy shores also provide ecological services and are being altered worldwide. Sandy shores have undergone massive alteration due to coastal development, pollution, erosion, storms, alteration to freshwater hydrology, sand mining, groundwater use, and harvesting of organisms (Brown and McLachlan 2002). Disruptions to the sand balance in many locations is causing the total disappearance of beaches and with it the loss of ecological services, such as the provision of food to migratory birds, provision of nesting habitat, delivery of land-based nutrients to the nearshore coastal system, and provision of both food and recreational space to humans. Removal of beach wrack (seaweeds cast up on beaches) near urban centers and tourism resorts also alters habitat and services.

Dune systems occur inland of the intertidal zone but are commonly found in conjunction with beaches and sandy shores. These habitats are often highly dynamic and mobile, changing their form in both the short and long term. Although dune systems are not as productive exporters of nutrients as many other coastal systems, they act as sediment reserves, stabilize coastlines, provide areas for recreation, and provide breeding and feeding sites for seabirds and other coastal species. Dunes support high species diversity in certain taxonomic groups, including endangered bird, plant, and invertebrate species. Encroachment in dune areas often results in shoreline destabilization, resulting in expensive and ongoing public works projects such as the building of breakwaters or seawalls and sand renourishment. In the United States alone, coastal erosion of dunes and beaches costs $500 million in property losses annually (The Heinz Center 2000). Not only are such projects costly, they also have cascading impacts throughout the coast and nearshore areas.

19.2.1.4 Coral Reefs and Atolls

Coral reefs exhibit high species diversity and endemism and are valued for their provisioning, regulating, and cultural services (McKinney 1998). Reef-building corals occur in tropical coastal areas with suitable light conditions and high salinity and are particularly abundant where sediment loading and freshwater input is minimal. The distribution of the world's major coral reef ecosystems is shown in Figure 19.6 (in Appendix A). Reef formations occur as barrier reefs, atolls, fringing reefs, or patch reefs, and many islands in the Pacific Ocean, Indian Ocean, and Caribbean Sea have extensive reef systems occurring in a combination of these types. Coral reefs occur mainly in relatively nutrient-poor waters of the tropics, yet because nutrient cycling is very efficient on reefs and complex predator-prey interactions maintain diversity, productivity is high. However, with a high number of trophic levels the amount of primary productivity converted to higher levels is relatively low, and reef organisms are prone to overexploitation.

Reefs provide many of the services that other coastal ecosystems do, as well as additional services: they are a major source of fisheries products for coastal residents, tourists, and export markets; they support high diversity that in turn supports a thriving and valuable dive tourism industry; they contribute to the formation of beaches; they buffer land from waves and storms and prevent beach erosion; they provide pharmaceutical compounds and opportunities for bioprospecting; they provide curios and ornamentals for the aquarium trade; and they provide coastal communities with materials for construction and so on (Ahmed et al. 2004).

The fine-tuned, complex nature of reefs makes them highly vulnerable to negative impacts from overuse and habitat degradation—when particular elements of this interconnected ecosystem are removed, negative feedbacks and cascading effects occur (Nystrom et al. 2000). Birkeland (2004) describes ecological ratcheting effects through which coral reefs are transformed from productive, diverse biological communities into depauperate ones, along with similar cascading effects caused by technological, economic, and cultural phenomena. Coral reefs are one of the few marine environments displaying disturbance-induced phase shifts: a phenomenon in which diverse reef ecosystems dominated by stony corals dramatically turn into biologically impoverished wastelands overgrown with algae (Bellwood et al. 2004).

Most tropical reefs occur in developing countries, and this is where the most intensive degradation is occurring (Burke et al. 2002). Of all the world's known tropical reef systems, 58% occur within 25 kilometers of major urban centers having populations of 100,000 or more. Coral reefs are at high risk from many kinds of human activity, including coastal construction that causes loss of habitat as well as changes in coastal processes that maintain reef life; coastal constructions that change physical processes; destructive fishing and collecting for the marine ornamental trade; overfishing for both local consumption and export (Chapter 18); inadequate sanitation and poor control of run-off leading to eutrophication; dumping of debris and toxic waste; land use practices leading to siltation; oil spills; and degradation of linked habitats such as seagrass, mangrove, and other coastal ecosystems (Wilkinson 2000, 2002). In 1999, it was estimated that approximately 27% of the world's known reefs had been badly degraded or destroyed in the last few decades (Wilkinson 2000), although the latest estimates are of 20% of reefs destroyed (Wilkinson 2004) and more than a further 20% badly degraded or under imminent risk of collapse.

Of all the world's ecosystems, coral reefs may be the most vulnerable to the effects of climate change (Hughes et al. 2003). Although the mechanisms are not clear, warming seawater triggers coral bleaching, which sometimes causes coral mortality. Corals bleach when the symbiotic zooxanthellae that live in the tissue of the coral polyps and catalyze the reactions that lead to calcium carbonate deposition are changed or expelled. Bleaching does not automatically kill corals, but successive bleaching events in close proximity, or prolonged bleaching events, often do lead to mass mortality (Pandolfi et al. 2003). However, it has been estimated that approximately 40% of the reefs that were seriously damaged in the 1998 coral bleaching events are either recovering well or have fully recovered (Wilkinson 2004).

Climate change also has other detrimental impacts on coral. For example, rising carbon dioxide levels change the pH of water, reducing calcium carbonate deposition (reef-building) by corals. Climate change also facilitates the spread of pathogens leading to the spread of coral diseases. It has been suggested that climate change will reduce the world's major coral reefs in exceedingly short time frames—one estimate suggests that all current coral reefs will disappear by 2040 due to warming sea temperatures (Hughes et al. 2003), and it is not known whether the reefs that take their place will be able to provide the same level of services to humans and the biosphere.

Coral reefs are highly degraded throughout the world, and there are likely to be no pristine reefs remaining (Hughes et al. 2003; Pandolfi et al. 2003; Gardner et al. 2003). Historical analysis of conditions suggests that reef degradation, involving the decline of large animals, then smaller animals and reef-building species, precedes the emergence of bleaching and disease (Pandolfi et al. 2003). This suggests that overfishing, combined with pollution from land-based sources, predisposes reefs to be less resilient to disease and the effects of climate change. Such pollution includes increases in turbidity resulting from sediments washing into nearshore waters or from release during dredging, which results in significantly lower light levels reach corals, disrupting photosynthesis in algal symbionts and reducing calcification rates (Yentsch 2002). The coral reefs of the Caribbean Sea and portions of Southeast Asia have suffered the greatest rates of degradation and are expected to continue to be the most threatened (Gardner et al. 2003).

19.2.1.5 Seagrass Beds or Meadows

Seagrass is a generic term for the flowering plants that usually colonize soft-bottom areas of the oceans from the tropics to the temperate zones (some seagrass can be found on hard-bottom areas but the ones occupied are usually small). In estuarine and other nearshore areas of the higher latitudes, eelgrass (*Zostera* spp.) forms dense meadows (Deegan et al. 2001). Further toward the tropics, manatee and turtle grass (*Thalassia testudinum* and *Syringodium filiforme*) cover wide areas. Along with mangroves, seagrass is thought to be a particularly important in providing nursery areas in the tropics, where it provides crucial habitat for coral reef fishes and invertebrates (Gray et al. 1996; Heck et al. 1997). Seagrass is highly productive and an important source of food for many species of coastal and marine organisms in both tropical and temperate regions (Gray et al. 1996). It also plays a notable role in trapping sediments and stabilizing shorelines.

Seagrass continues to play an important ecological role even once the blades of grass are cut and carried by the water column. Drift beds, composed of mats of seagrass floating at or near the surface, provide important food and shelter for young fishes (Kulczycki et al. 1981), and the deposit of seagrass castings and macroalgae remnants on beaches is thought to be a key pathway for nutrient provisioning to many coastal invertebrates, shorebirds, and other organisms. For instance, nearly 20% of the annual production of nearby seagrass (over 6 million kilograms dry weight of beach cast) is deposited each year on the 9.5-kilometer beach of Mombasa Marine Park in Kenya, supporting a wide variety of infauna and shorebirds (Ochieng and Erftemeijer 2003).

Tropical seagrass beds or meadows occur both in association with coral reefs and removed from them, particularly in shallow, protected coastal areas such as Florida Bay in the United States, Shark Bay and the Gulf of Carpentaria in Australia, and other geomorphologically similar locations. Seagrass is also pervasive (and ecologically important) in temperate coastal areas such as the Baltic Seas (Fonseca et al. 1992; Green and Short 2003; Isakkson et al. 1994). The distribution of these major seagrass beds is shown in Figure 19.7 (in Appendix A).

Human impacts, including dredging and anchoring in seagrass meadows, coastal development, eutrophication, hypersalinization resulting from changes to inflows, siltation, habitat conversion for the purposes of algae farming, and climate change, are all causing widespread damage to seagrasses globally (Duarte 2002). Increased nutrient inflows into shallow water coastal areas with limited flushing (prime areas for seagrass growth) can cause algal and epifaunal encrustation of seagrass blades (Duarte 1995), limiting their ability to photosynthesize and in extreme cases smothering the meadows altogether (Deegan et al. 2001; Short and Wyllie-Echeverria 1996). Major losses of seagrass habitat have been reported from the Mediterranean, Florida Bay, and Australia (Duarte 2002). Present losses are expected to accelerate, especially in Southeast Asia and the Caribbean (Burke et al. 2001; Duarte 2002), as eutrophication increases, algal grazers are overfished, and coastal development increases.

19.2.1.6 Kelp Forests

The productivity of kelp forests rivals that of the most productive land systems (Dayton 2003). These temperate ecosystems have a complex biological structure organized around large brown algae, supporting a high diversity of species and species interactions. Kelp support fisheries of a variety of invertebrate and finfish, and the kelp itself is harvested for food and additives. Kelp forests are remarkably resilient to natural disturbances such as wave impacts, storm surges, and other extreme oceanographic events (Dayton 2003).

Kelp forests and other macroalgae provide specialized nursery habitats for some species. For instance, the upper layers of kelp provide nursery habitat for young rockfish and other organisms. Kelp communities consist of several distinct canopy types supporting many herbivores. Most important among these are sea urchins, which are capable of destroying nearly all fleshy algae in most kelp systems, and the spines of the red sea urchin (*Strongylocentrotus franciscanus*) provide crucial nursery habitat for other sea urchin species (Tegner and Dayton 1977). Factors affecting the abundance of sea urchins are thus important to the integrity of kelp ecosystems (Dayton 2003).

Unfortunately, the biological communities of many kelp forests have been so destabilized by fishing that they retain only a fraction of their former diversity (Tegner and Dayton 2000). It is likely that no kelp systems exist in their natural condition (Dayton

2003), and there have been enormous system responses to human impact. Fishing impacts (see Chapter 18) can cause cascading effects, reducing diverse kelp forests to much simplified sea urchin–dominated barren grounds. Such ''urchin barrens'' are exactly as the name implies: devoid of many normal forms of life and dominated by urchins. Urchin barrens are or were prevalent in the northwest Atlantic (Labrador to Massachusetts), the Aleutian Islands, southern California, the Chilean coast, Japan, New Zealand, and Australia.

Removal of predators plays a key role in these regime shifts, some of which regularly oscillate between states, while others remain in the barren state for long periods of time. For example, in the Atlantic Ocean large fish such as halibut (*Hippoglossus hippoglossus*), wolfish (*Anarichus latifrons*), and cod (*Gadus spp*.), which are the key predators of sea urchins, have been largely removed from the system, causing sea urchin populations to explode (Tegner and Dayton 1977; Dayton et al. 1998). Following this, directed exploitation and disease led to a collapse of the urchin populations, but kelp forests have not fully recovered and continue to be vulnerable to waves of exotic species (Dayton 2003).

In other places, kelp communities are tied to sea otter populations. When sea otters were decimated in the Aleutian Islands through hunting, kelp forests were destroyed by booming populations of sea urchins. Following protection of sea otters, the kelp forests temporarily recovered, but the barrens returned in the 1990s when the otters began declining again (Estes et al. 1998). The health of kelp forests is thus strongly related to the health of the predator populations.

19.2.1.7 Other Benthic Communities: Rock and Shell Reefs, Mud Flats, Coastal Seamounts, and Rises

Although public interest in coastal biodiversity has tended to focus on coral reefs, many other coastal systems harbor vast amounts of species (Gray 1997; Gray et al. 1997). Within estuaries, for instance, oyster reefs are considered important nursery areas, not just for oysters but also for a wide range of fish species, other mollusks, crabs, and other fauna. Rock reefs, for example, provide rich nursery habitat for fisheries, such as those that occur in the extensive banks inshore from the upwelling areas of the northern Gulf of Guinea in West Africa (Binet and Marchal 1993), as well as in temperate areas such as in the Mediterranean Sea. Mud flats in the intertidal area and on banks are also productive habitats that exhibit surprising species diversity.

Hard-bottom habitats below the photic zone tend to be dominated by sponges, corals, bryozoans, and compound ascidians. Most of these temperate, non-reef-building corals are found in deeper waters beyond the coastal limit, although their ecosystem dynamics and the threats facing them are similar to many coastal systems. Human-induced disturbances can cause major ecological damage and compromise biodiversity, regardless of whether these communities occur more inshore or offshore. Bottom trawling and other fishing methods that rake the benthos have destroyed many of these communities already (Dayton 2003; Jennings and Kaiser 1998). These impacts on biodiversity sometimes result in permanent losses when endemic or restricted species are wiped out. (See the section on biodiversity in Chapter 18.)

About 70% of Earth's seafloor, including that located within the MA coastal system, is composed of soft sediment (Dayton 2003). Although soft-sediment habitats do not always appear as highly structured as some terrestrial or marine reef habitats, they are characterized by extremely high species diversity. There is now strong evidence of fishing effects on seafloor communities that have important ramifications for ecosystem function and resilience (Dayton 2003; Rogers et al. 1998). Given the magnitude of disturbance by trawling and dredging and the extension of fishing effort into more vulnerable benthic communities (Chapter 18), this type of human disturbance is one of the most significant threats to marine biodiversity (Dayton 2003). Sponge gardens in soft substrates face particular threat from bottom trawling, since the soft substrate is easily raked by heavy trawling gear.

In places, the ocean floor's soft sediment is interrupted by highly structured seamounts with highly diverse communities of organisms (Dayton 1994). These underwater mountains or volcanoes are usually found far offshore and are thought to be crucial for many pelagic fish species, not just as sites for breeding and spawning, but also as safe havens for juvenile fishes seeking refuge from open ocean predators (Johannes et al. 1999). Since the vast majority of large seamounts occur in deeper marine waters, they are discussed in detail in Chapter 18. However, smaller seamounts occur in conjunction with coral reefs and elsewhere in the coastal zone, and they contribute significantly to coastal fisheries production and biodiversity maintenance. Because their high species diversity is concentrated into a relatively small, localized area, and because of their occasionally high endemism, seamounts are extremely vulnerable to fishing impacts. (See Chapter 18.)

Other benthic habitats that might be expected to fall into this subtype are not discussed in this assessment, such as the fjords of Norway and non-kelp-dominated rocky slopes and banks. Cold water corals of the temperate deeper waters are discussed in Chapter 18. Some of these habitats provide ecosystem services important to humankind, and some are also being degraded, but these habitats are either so specialized as to make generalizations impossible, or assessment information is lacking at the global scale.

19.2.1.8 Semi-enclosed Seas

A semi-enclosed sea is legally defined as ''a gulf, basin or sea surrounded by two or more States and connected to another sea or the ocean by a narrow outlet or consisting entirely or primarily of the territorial seas and exclusive economic zones of two or more coastal States'' (Convention on Law of the Sea, Article 122). Although this is a geopolitical, not an ecological, definition, and despite the fact that large portions of semi-enclosed seas thus defined fall outside the MA category of ''coastal,'' these areas are described here as another coastal subtype. (Chapter 18 mentions these systems in regard to fisheries as well.)

Notable examples of semi-enclosed seas include the Mediterranean, Black, Baltic, and Red Seas and the Gulf of Aden. Semi-enclosed seas can be intercontinental (such as the Mediterranean Sea), intracontinental (such as the Black and Baltic Seas), or marginal (such as the North and Bering Seas). Gulfs with restricted openings such as the Gulf of California in Mexico and the Gulf of Thailand could also be considered ''semi-enclosed.'' These systems all share similar attributes: they tend to be highly productive (primarily due to exogenous inputs from lands nearby), often have high species diversity and endemism, are heavily used by the countries and communities that border them, and are often at high risk from pollution.

Perhaps more than open ocean systems, semi-enclosed seas are directly linked to human well-being. Many of the world's great civilizations sprung up along the shorelines of semi-enclosed seas, which have historically provided food, trade routes, and waste processing services to burgeoning human populations. Today most semi-enclosed seas of the world are highly valued as tourism and recreational venues, adding to their value in continuing to provide food and other services (Sheppard 2000). Yet they are becoming highly degraded due to demands placed on them and their physical configuration.

Freshwater inflows to semi-enclosed seas have been severely curtailed in most areas, robbing them of recharging waters and nutrients. A particularly acute case of this degradation has occurred in the Gulf of California, which now receives only a trickle of water through the now dry, but once very fertile, delta of the Colorado River (GIWA 2003). At the same time, water reaching these basins is often of poor water quality due to land-based sources of pollution such as agricultural and industrial waste (GESAMP 2001). Such degradation is highly prevalent in semi-enclosed seas with major river drainages, such as the Black Sea (Bakan and Büyükgüngör 2000), Baltic Sea (Falandysz et al. 2000; Kautsky and Kautsky 2000), and even large parts of the Mediterranean Sea (Cognetti et al. 2000). The limited flushing and long recharge times in semi-enclosed seas means that pollutants are not as quickly diluted as in the open sea, and eutrophication and toxics loading are often the result.

Virtually all semi-enclosed seas have undergone dramatic transformation as the consequence of coastal development, ever-increasing fishing pressures, declines in freshwater input, and pollutant loading. The pollution that enters semi-enclosed seas from drainage basins is a significant source of degradation in these physically constrained coastal areas, especially in regions with major river basins and high rainfalls (for instance, see Cognetti et al. 2000 on the Adriatic Sea and Bakan and Büyükgüngör 2000 on the Black Sea). In the Bosporus region of Turkey, sewage pollution has been implicated in the decline of many fish species. However, land-based sources of pollution can also be a problem in arid and semiarid regions, as evidenced by the extensive local degradation of coral reefs in the Red Sea caused by seepage and runoff of untreated sewage into nearshore waters (Sheppard 2000).

Negative synergies often act together to bring about cataclysmic change in ecosystem condition in relatively short amounts of time. The Black Sea, which once supplied much of Europe with fisheries products, has undergone a slow but chronic environmental degradation in the last century as industrial pollution from major rivers, including the Danube, Dniester, and Dnieper, as well as more coastally based pollution, contaminated the waters. Overfishing and wetlands destruction occurred during roughly the same period, but intensified even as the health of the sea began to falter. When an Atlantic ctenophore, *Mnemiopsis leidyi,* was introduced through ship ballast water sometime in the 1980s, the voracious predator eagerly preyed on the struggling biota, causing the loss of over two dozen major fisheries (Zaitsev and Mamaev 1997). In recent years, the anoxic layer of this basin has expanded and moved upwards, making restoration of the sea to its once-vibrant state difficult.

19.2.2 Marine Wildlife

The world's oceans and coasts are home to many hundreds of species of marine mammals, turtles, crocodiles, and seabirds—some common, others rare; some with global distributions, others with narrow coastal distributions. Those with wide-ranging distributions demonstrate the connectivity of ecosystems and the need for holistic approaches to management of coastal and marine systems. Several species are threatened, either because they have not recovered from earlier exploitation (such as the Northern right whale, *Eubalaena glacialis*) or because they continue to suffer excessive mortality, mainly through incidental catches or as bycatch of fishing (such as the vaquita, *Phocoena sinus,* a dolphin endemic to the northern Gulf of California (D'Agrosa et al. 2000) and albatrosses (Stehn et al. 2001)).

Other human activities also threaten marine wildlife. Recent studies have found strong correlations between mass strandings of some marine mammals, such as beaked whales (family Ziphiidae), and military low frequency sonar exercises (Piantadosi and Thalmann 2004). More widespread is the threat of incidental catch in fisheries. Bycatch is currently recognized as a significant threat to conservation of small cetaceans (Dawson et al. 1998) and seabirds (Tasker et al. 2000).

19.2.2.1 Turtles and Crocodiles

None of the 23 known crocodile species have gone extinct despite local extirpations and multiple threats to their habitats as well as interactions with humans (Webb 1999). Although some species of crocodile are still threatened with extinction, others have increased in number and through appropriate management plans are being harvested sustainably (Ross 1998).

Marine turtles, along with marine mammals and seabirds, are key indicator species for problems and changes in the marine environment. The overall situation of the seven marine turtle species found worldwide is no better than that of most marine mammals. Human-related impacts—particularly habitat destruction, direct harvest of adults and eggs, international trade, bycatch, and pollution—are seriously threatening the survival of marine turtles. All seven species of turtles are listed under the Convention on International Trade in Endangered Species of Wild Fauna and Flora Appendix I, thereby restricting international trade in turtles or turtle-derived products between parties to the convention. According to the *IUCN Red List,* three of the seven species are critically endangered with extinction, three are endangered, and the status of the Australian flatback (*Chelonia depressa*) remains unknown due to insufficient information.

Although survival of marine turtles is threatened on a global scale, at the regional scale different turtle subpopulations show different growth trajectories. However, this may be a reflection of data availability. For example, information about turtle populations in Africa has been lacking until recently (Fretey 2001) and is still largely incomplete.

Green turtle (*C. mydas*) populations are particularly at risk in the Indo-Pacific, primarily due to high levels of directed take of adults, juveniles, and eggs. Leatherback turtle populations (*Dermochelys coriacea*) are especially at risk in the Eastern Pacific. It has been estimated that the number of leatherback turtles in that region has decreased from just under 100,000 adult females in 1980 to fewer than 3,000 adult females in 2000 (Spotila et al. 2000). Conservative estimates are that longline and gill-net fisheries were responsible for the mortality of at least 1,500 female leatherbacks per year in the Pacific during the 1990s (Spotila et al. 1996).

Similarly, leatherbacks and loggerhead turtles (*Caretta caretta*) at sea suffer from high rates of mortality due to unsustainable levels of bycatch in various fisheries (notably longline fisheries). Should these levels be sustained, Eastern Pacific leatherback turtles are anticipated to become extinct in the next few decades (Crowder 2000). In many parts of the world, however, direct harvest (as occurs for the hawksbill, *Eretmochelys imbricata*) and incidental capture of marine turtles in inshore fisheries represent a greater source of mortality than bycatch in longline fisheries (Seminoff 2002; Kaplan 2001).

In addition to mortalities experienced at sea, habitat loss and destruction of nesting beaches and important foraging grounds have contributed to marine turtle population declines (WWF 2003). Turtle products, such as jewelry made from hawksbill shells, also threaten marine turtles. Thousands of turtles die from eating or becoming entangled in nondegradable debris each year. Trash, particularly plastic bags, causes mortality for species like the leatherback, which cannot distinguish between floating bags and jellyfish prey. Pollution has also been linked to increased incidence of fibropapilloma disease, which kills hundreds of turtles annually (Herbst et al. 2004). However, the greatest recent historical losses in turtle populations occurred as a result of early European colonization of the Americas, when trade in turtle products helped finance further exploration and settlement, as occurred in the Caribbean (Carr 1979; Jackson et al. 2001).

19.2.2.2 Marine Mammals

Marine mammals are affected and frequently threatened by fisheries and other human activities (Northridge 2002). In the past, the main threats were large-scale whaling and sealing operations focused initially on the waters of northern Europe and Asia. Operations soon extended to Antarctica and reduced populations to small fractions of their former abundances (Perry et al. 1999) or extirpated them completely, as with the now extinct Atlantic grey whale (Mitchell and Mead 1977) or the Caribbean monk seal (Kenyon 1977; Gilmartin and Forcada 2002). While many of the pinniped (seals, sea lions, and walrus) species appear to have recovered quite successfully from former exploitation levels, recovery of some of the heavily depleted whale species has been slow, making them more susceptible to other emerging threats, such as bycatch in commercial fisheries or climate change (Clapham et al. 1999).

In recent decades, incidental entanglement in fishing gear, chemical and acoustical pollution, habitat degradation, climate change, and ship strikes are regarded as the most serious human-related threats for marine mammals, although impacts of these are highly variable for different species.

Small cetaceans such as dolphins are probably most threatened by bycatch (Northridge 2002; Kaschner 2003)—in some cases, to the verge of extinction, such as the vaquita (D'Agrosa et al. 2000). And worldwide estimated mortalities across all species add up to several hundred thousands every year (Read et al. 2003). Although entanglement in fishing gear is generally not fatal for the larger baleen whales, it may seriously affect the ability of an animal to feed and may potentially result in starvation (Clapham et al. 1999).

Increasing levels of chemical pollution and marine debris in the marine environment are likely having impacts on most marine mammal species through ingestion of pollution and floating plastic debris or entanglement (Merrick et al. 1987). Various health problems in marine mammals have been associated with high levels of accumulated pollutants that have been found in many species of predatory marine mammals (Aguilar and Borrell 1994).

Pinniped species combined represent the most abundant group of marine mammals in terms of population size. However, a high proportion of pinniped species are restricted to polar waters, and this group is most likely to be negatively affected by climate change (Harwood 2001). Currently, almost a quarter of all pinniped species are listed as endangered or vulnerable in the *IUCN Red List*.

19.2.2.3 Waterbirds

Many waterbirds are dependent on coastal systems (see Chapter 20 for a more detailed assessment of waterbird status and trends), and waterbirds themselves are important in the delivery of a number of coastal ecosystem services, including nutrient cycling, recreation, food provisioning, and cultural values. Coastal systems are vital for both shorebirds and seabirds, which use coastal areas for breeding, foraging and resting. There are 336 species of seabirds (Schreiber and Burger 2002). Some species, notably gulls, have increased because of widespread discarding of bycatch. Others have strongly declined in recent decades, both due to the reduction of their food base by fisheries and because they are caught as bycatch of pelagic fisheries.

Shorebirds are declining worldwide: of populations with a known trend, 48% are declining in contrast to just 16% increasing (International Wader Study Group 2003). For shorebirds in Africa and Western Eurasia, three times as many populations are decreasing as are increasing, although the trend status of the majority of populations seems not to have changed significantly over the last 10–20 years. Overall, 45 (34%) of African-Eurasian migratory shorebird populations are regarded as of conservation concern due to their decreasing or small populations (Stroud et al. 2004). Similarly, 54% of shorebird populations occurring in North America are in a significant or persistent decline, with only 3% increasing significantly and as many as 80% of populations in this region showing evidence of declines (Morrison et al. 2001). However, shorebird trend status in other regions is poorly known and has not been reassessed since the 1980s.

Information on trends in shorebirds and seabirds is highly variable geographically. For shorebird (wader) flyways in Africa-Eurasia, trend information is available for 93% of populations using the coastal East Atlantic flyway and 76% using the Black Sea/Mediterranean flyway. Only 35% of populations on the West Asia/East Africa flyway have good trend information, and the status of resident African populations is particularly poorly known (only 30%) (Stroud et al. 2004). While fewer seabirds than inland waters species have become extinct, a much larger proportion (41.8%) of extant seabirds are globally threatened. (See Chapter 20.) The decline in seabirds is occurring in all parts of the world and across major habitat types. The most threatened families are albatrosses (90.5% of species globally threatened), penguins (58.8%), petrels and shearwaters (42.9%), and frigate birds (40%).

Land use change and habitat loss and degradation seem to continue to be drivers of shorebird declines. For example, the decline of certain long-distance East Atlantic flyway populations (while other populations on the same flyway are stable or increasing) has been attributed to their high dependency on deteriorating critically important spring staging areas, notably the international Wadden Sea, that are being affected by commercial shellfisheries. Similar situations are reported from other flyways and key spring staging areas such as Delaware Bay in the United States and the Yellow Sea coast. Maintaining the ecological character of such staging areas is increasingly recognized as vital for the survival of Arctic-breeding species, yet many remain under threat (Baker et al. 2004; Davidson 2003).

For seabirds, direct drivers of declines are likely to be different from those of coastal and freshwater waterbirds. For example, for albatrosses—the seabirds showing the most dramatic current population declines—it is highly certain that the main driver is adult mortality caused by pelagic (longline) fisheries in southern oceans (BirdLife International 2004b).

For sea- and shorebirds, climate change is considered to be additional to the drivers of land use change and habitat loss and degradation. For example, changes in the non-breeding distribution of coastal wintering shorebirds in western Europe have been attributed to rising mid-winter temperatures (Austin et al. 2000), and seabird breeding failures in the North Sea in 2004 have been linked to a northward shift in plankton distribution driven by rising sea temperatures (Edwards and Richardson 2004).

Any effects of climate change on waterbirds are generally considered to be additive to the impacts of direct drivers such as habitat degradation. However, it is predicted that reduction in areas of Arctic tundra breeding habitat will contribute to population declines in high-Arctic breeding species (*medium certainty*). Similar shifts in distribution in several other parts of the world are well known and occur in relation to El Niño events (*medium certainty*).

19.2.3 Summary and Linkages with Other Systems

Coastal ecosystems are diverse, highly productive, ecologically important on the global scale, and highly valuable for the services they supply. (See Table 19.2.) Dividing the coastal system into separate subtypes and discussing each one independently obscures the fact that these habitats and the ecological processes within them are highly linked, with water mediating many of these linkages. While it is true that all habitats are ultimately connected in the marine environment, some habitats are more intimately connected than others.

Coral reefs provide a good example of this interconnectedness (Hatcher et al. 1989). The internal interconnectedness of coral reefs has historically been emphasized, giving the impression of self-contained entities: very productive ecosystems with nutrients essentially locked up in the complex biological community of the reef itself. Many of the most ecologically crucial habitats for reef organisms are actually not on the coral reef itself, however, but rather in seagrass beds, mangrove forests, and seamounts sometimes far from the reef (Birkeland and Frielander 2002; Mumby et al. 2004). Thus the coral reef ecosystem depends on these essential linked habitats as well. Currents and the mobile organisms themselves provide the linkages among the reefs, nursery habitats, and places where organisms move to feed or breed.

One of the strongest links between coastal subsystems is that between areas that act as nursery grounds for fish species. The majority of the world's marine fishery species are caught or reared in continental shelf waters, and many of these species spend at least some part of their life histories in the nearshore coastal habitats (Sherman 1993, cited in Burke et al. 2001). When nursery areas are lost due to habitat conversion, freshwater diversion from estuaries, or degradation, fisheries even outside the nursery area can be significantly affected (Deegan and Buchsbaum 2001; Lenanton and Potter 1987). Loss of nursery areas has been implicated in the collapse of some fisheries in North America, North Africa, and elsewhere (Chambers 1992; Deegan 1993).

Nursery areas and other habitats crucial for fisheries production can also be ecologically "lost" when degraded by seemingly natural (or, in any case, biotic) events. Harmful algal blooms, for instance, can be devastating to eggs and larvae of fish and can thus cause loss of nursery services. Often the population growth of such harmful algae is spurred by eutrophic conditions—the result of agricultural, sewage, aquacultural, or fish processing wastes overcoming the assimilative capacity of the coastal environment.

The ocean and coastal habitats are not only connected to each other, they are also inextricably linked to land. (See Table 19.3.) Fresh water is one specific mediator here: rivers and streams bring nutrients as well as pollutants to the ocean, groundwater flows to coastal systems, and the ocean gives some of these materials back to land via the atmosphere, tides and seiches, and other pathways, such as the deposition of anadromous fish (salmon carcasses, for instance) after spawning. The salinization of aquifers from marine intrusion, usually due to excessive freshwater extraction) is another factor. Seawater to freshwater linkages also occur; in experimental settings, polluted coastal water has been shown to contaminate freshwater aquifers (Jones 2003). But the atmosphere also provides a linkage, and land-sea-air interactions sometimes create complex feedback mechanisms between impacts on one habitat type and consequent impacts on another. For example, in

Table 19.3. Fluxes from Land to Sea and from Sea to Land, Differentiating between Natural and Anthropogenic Factors (Modified from Kjerfve et al. 2002)

Factor	Land to Sea	Sea to Land
Natural	river discharge groundwater sediment nutrients and minerals humics and organics storm debris earthquake debris volcanic debris	energy and debris from hurricanes cold water and nutrients from upwelling wave action salt and salt aerosols sand nutrients through carcasses, guano
Anthropogenic	sediment (increase from land use and decrease from dams) nutrients and organic matter from agriculture and sewage coliform bacteria herbicides and pesticides heavy metals oil and chemicals	oil and chemical spills chronic input of oil and chemicals sewage from ships ballast water with exotic organisms debris from ships brackish infiltrations of groundwater reservoirs by water extraction pharmaceuticals

Florida in the United States, the loss of coastal wetlands and their buffering capability may have caused severe freezes affecting inland agricultural lands in recent winters, costing millions of dollars in failed crops (Marshall et al. 2003).

Coastal systems serve as a major sink for sediments and are major sites of nutrient-sediment biogeochemical processes. Water quality in river systems plays a crucial role in the sustainability of coastal aquatic habitats, food webs, and commercial fisheries that serve as a major protein source for humans (Burke et al. 2001). The transport of sediment and biotically active materials (nutrients and toxic substances) to the coastal zone through long-distance river transport ultimately links the continental landmass to the oceans (Vörösmarty and Meybeck 1999). (See Box 19.2.) Thus coastal issues need to be addressed from a system perspective involving the whole catchment scale and the coupling of human and natural systems.

The cross-habitat movement of nutrients, detritus, prey, and consumers exerts major effects on populations and food webs in practically all habitats and can sustain communities of abundant consumers even in places with little or no primary productivity (Polis et al. 1997). This relationship is particularly strong in the coastal system, especially where highly productive oceanic waters meet relatively unproductive, dryland habitats (Polis and Hurd 1996).

The Pacific coast of Peru is one of the best examples of this, where high- and low-productivity systems are juxtaposed: highly productive marine waters associated with upwelling of the Humboldt current are next to one of the world's most arid areas, the Atacama desert. The system of the Humboldt current has a primary productivity rate that makes it one the world's richest marine areas (Arntz and Fahrbach 1996), whereas the desert it faces receives less than 5 millimeters of rainfall a year. Other examples are the Namib Desert facing the Benguela upwelling system, the Banc d'Arguin region of Mauritania, and the coasts and islands of the Gulf of California in Mexico.

The movement of nutrients from the ocean to land can occur in two different pathways. The first is the guano pathway, which includes the accumulation of seabird excrement. This pathway is likely to be significant only for islands and rocky shores where sea birds congregate in large numbers. The second is the detritus/scavenger pathway, with a significant amount of biomass entering the terrestrial system through algal or seagrass mats and through animal carcasses washing ashore. Fish or mammals may also become vectors of marine-derived energy and nutrients by migrating over large distances. River otters and sea lions have been shown to enrich terrestrial vegetation with marine-derived nitrogen in coastal environments.

Perhaps the best-known example is anadromous Pacific salmon (*Oncorhynchus kisutch, O tshawytscha, O. nerka*), the carcasses of which fertilize forests (Helfield and Naiman 2003) and provide a valuable source of nutrients for scavengers in the sites where they congregate to spawn (Ben-David et al. 1998b). In regions these salmon carcasses seem to be a keystone nutrient resource for scavengers, populations of such scavengers are greatly affected by reductions in anadromous fish stocks (Willson and Halupka 1995).

The idea that marine resources are also a key resource to human populations is verified archeologically. Moseley (1975) proposed a "marine hypothesis" to demonstrate that the paradigm of agricultural economy as being the foundation of civilizations does not hold for ancient populations in coastal Peru. He proposed instead that the enormous productivity of the upwelling system caused the rise of Andean civilizations. Numerous archeologists have challenged this hypothesis, noting that other sources of food had to be available for populations exposed to high variability in marine productivity. However, there is no doubt that marine productivity accounted for a large part of the diet in several major coastal civilizations.

In the Atlantic, for example, cod was said to fuel the immigration and growth of New England and Canadian maritime population centers, and in Europe herring is thought to have underpinned the mercantile expansion. The declining availability of marine resources has affected large portions of these populations even today. More recently, it has been surmised that declining availability of coastal and freshwater fish for subsistence fishers in West Africa has driven the increase in the illegal bush meat trade. This trade, in turn, has imperiled many endangered species in the region and is thought to contribute to outbreaks of primate-borne and other viruses in human populations (Brashares et al. 2004).

Ocean climate in one region may affect land and coastal systems in another, and in complex ways. For instance, it is now surmised that the warming of the Indian Ocean has caused the recent droughts of the Sahel, directly affecting millions of people through increased crop failure and decreased health (Giannini 2003), while the increased desertification of the Sahel region may have caused mortality of corals half a world away through the transport and subsequent deposition of Saharan dust. (See MA Caribbean Sub-global Assessment.)

Thus, negative impacts on coastal ecosystems, whether on land, in areas of fresh or brackish water, or in the sea itself, have enormous ramifications for the health and productivity of other terrestrial and marine systems, in addition to affecting coastal systems and their provisioning of ecosystem services. As human population pressures continue to grow, these declines in coastal ecosystem services will increase the strain on coastal communities and have negative impacts on human well-being in coastal systems.

BOX 19.2

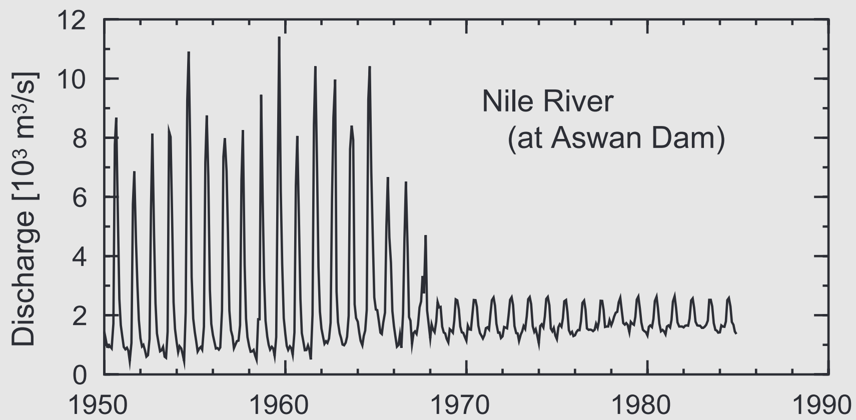
Trends in Sediment Loads into Coastal Zones

Fluvial systems evolve along with the landscape, and the sediment load observed today is influenced by the geologic history of these paleo-systems. Therefore it remains difficult to determine the sediment flux of unaffected rivers, given the natural variability within fluvial systems. While there is no accepted estimation for the paleo-flux of sediment to the coastal zones (Syvitski 2001, 2003), Milliman and Syvitski (1992) argued that the modern 20 gigatons a year global flux value may have been 50% smaller about 2,000 years ago, before human impact was great.

A recent study of the annual sediment load records for the world's rivers shows many examples of nonstationary behavior (Walling and Fang 2003). Simple trend analysis of this database indicates that about 50% of the sediment load records showed evidence of statistically significant upward or downward trends, with the majority evidencing declining loads. In about 50% of rivers, the sediment load records showed no evidence of significant trends. In some rivers, loads are declining as a result of dam construction and the implementation of soil and water conservation and sediment control programs. In other systems, loads are increasing due to land clearance and land use change and intensification, along with other forms of catchment disturbance and increased runoff as a result of increased precipitation and runoff. The results suggest that the dominant trends in sediment flux to the global coastal zone are either stability or a decrease. This analysis has not included rivers from other areas of the world, such as Africa, Southeast Asia, and South America.

Under this picture of the world's decreasing sediment load, less river sediment discharge alters the sedimentation-erosion equilibrium within the coastal zone. Coarse-grained bed load is normally taken to represent 10% or less of the total sediment discharge delivered to the coast. Hence, it has been assumed that a decrease of approximately 5% of the total sediment flux represents the critical threshold, beyond which the coastal system is likely to show evidence of significant deterioration (such as coastal erosion). This level of change results in mangrove siltation and severe erosion of coastal ecosystems and beaches (Lacerda et al. 2002). Thus river sediment flux plays an important role in the sediment budget of the coast.

Dramatic and virtually instantaneous changes are recorded in water fluxes measured at river discharge monitoring stations before and after impoundment. The Nile River has experienced, as many river systems worldwide, reduced flows and distortion of runoff due to water use for irrigation (Nixon 2003). (See Figure.)



Compared with the past five decades, both river discharge and sediment load will probably decrease for some large fluvial systems 30–40% in the next 50 years (Vörösmarty et al. 1997; Vörösmarty and Meybeck 1999) and decrease to 50% in the next 100 years as a result of human activities and dam construction (Yang et al. 1998). Thus general erosion in the coastal zone, including estuaries, deltas, and associated beach systems, seems to be inevitable.

The future discharge of sediment to the coastal oceans will continue to be controlled by humans and climate change. Determining the balance between increasing sediment loads (from land use, engineering, climate change, and climate variability) and decreasing sediment loads from reservoirs, engineering, climate change, and climate variability is of utmost importance for sound coastal zone and resource management (Syvitski 2003).

19.3 Coastal Systems and Human Communities

19.3.1 Humans in the Coastal System: Demographics and Use of Services

Humans are a natural element within coastal systems and have been so for thousands of years. However, the balance of nature in these systems has become altered. While human dependence on coastal systems has greatly increased in the last centuries, the impacts on the ecology of these habitats have become so severe that their productivity and functioning have been altered, mostly in the last few decades. It is increasingly difficult for coastal systems to accommodate the increased collective demands of growing populations and markets.
