Coastal populations are not spread evenly throughout the coastal zone. Using night light analysis, Small and Nicholls (2003) graphically demonstrated the concentration of habitation on the world's coasts. Quantitative analysis of newer population data has shown that there has been a decrease in the rate at which interior populations are increasing relative to coastal populations. Coastal population densities are nearly three times that of inland areas: in 2000, population density in coastal areas was 99.6 people per square kilometer, while in inland areas density was 37.9 people per square kilometer (Kay and Alder in press). At the turn of the millennium, half of the world's major cities (those with more than 500,000 people) were found within 50 kilometers of a coast. Growth in these cities since 1960 was significantly higher than in inland cities of the same size (Kjerfve et al. 2002).

Not only are population pressures high relative to those in many other ecosystems worldwide, but the bulk of those pressures stress many of the most ecologically important and valuable ecosystems within coastal zones. Some 71% of the world's coastal people live within 50 kilometers of an estuary, 31% live within 50 kilometers of a coral reef system, 45% live within 50 kilometers of mangrove wetlands, and 49% live within 50 kilometers of seagrass ecosystems (See Table 19.4.) This is not accidental, of course—these habitats and the ecosystem services they provide present many of the ''pull'' factors that resulted in initial settlement along a coast as well as subsequent migration to it. Historically, settlements first inhabited the sheltered areas near estuarine bays (many with associated mangrove and seagrass) and reef-protected coasts and only later expanded to other coastal areas.

Conversely, 58% of the world's major coral reef systems occur within 25 kilometers of urban centers with more than 100,000 people; 62% of major estuaries occur near such urban centers, and 64% of major mangrove forests are found near major centers. This

Table 19.4. Share of World and Coastal Populations Living within 50 Kilometers of Estuaries, Coral Reefs, Mangroves, and Seagrass. Based on spatially referenced population data; due to overlap of some habitat types, figures do not add up to 100 percent. (CIESN 1995)

Subtypes	Population	Share of World Population	Share of Coastal Population
	(million)	*(percent)*	
Estuaries	1,599	27	71
Coral Reefs	711	12	31
Mangroves	1,030	18	45
Seagrass	1,146	19	49
Total	**5,596**		

means that pressures from urbanization, including habitat conversion as cities and their areas of influence grow, are affecting the majority of these key coastal habitats. In fact, analysis of areas of recent rapid land cover change shows that all but three of the world's cities showing greatest rates of change and highest population occur in coastal areas, in both the tropics as well as higher latitudes. (See Chapter 28 for more on this work.)

By all commonly used measures, the human well-being of coastal inhabitants is on average much higher than that of people in inland communities. Of the world's total GNP of approximately $44 trillion, 61% comes from coastal areas within 100 kilometers of a coastline. Whereas per capita GNP in 1999 averaged only $4,018 across all inland areas, in the 100-kilometer coastal area it was nearly four times as much—at $16,035. Figure 19.8 shows that the concentration of global wealth as measured by GNP occurs primarily in coastal regions, although concentrations of wealth also occur in some inland areas (especially in the United States and Europe). Infant mortality and life expectancy indices are also thought to be relatively better in coastal areas. This situation partly explains why rates of population increase are highest in coastal areas.

Nonetheless, many coastal communities are at risk. There are considerable physical risks associated with living in some coastal areas; low-lying atolls, for example, are at risk of catastrophic events such as hurricanes, cyclones, tsunamis, and storm surge

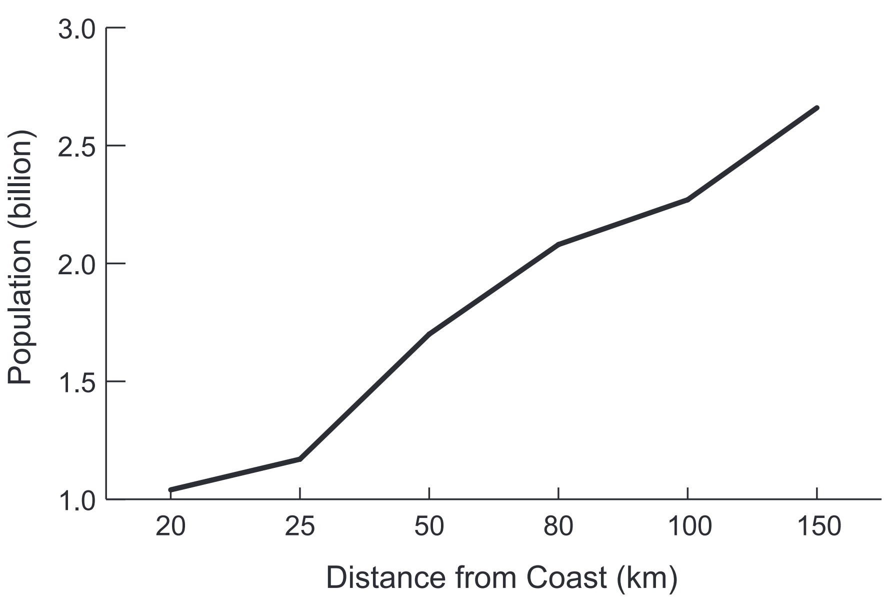

Figure 19.8. Population Density by Distance from Coast (CIESIN 2003)

flooding, as well as losses incurred from both sudden and chronic shoreline erosion. Figure 19.9 illustrates potential global vulnerability to erosion by highlighting areas where soil types and slope make shorelines prone to erosion and inundation from storm events. Many of these risks are increasing with climate change–driven changes to meteorology. And some countries, such as the United Kingdom, are developing contingency plans to cope with such changes (see www.foresight.gov.uk/fed.html). Some areas are prone to flooding because of relative changes in sea level—the average global sea level rise is projected at 1–2 millimeters per year over the next century (Church et al. 2001). This is an especially acute problem in small island nations, atoll communities, and low-lying flood-prone areas like much of Bangladesh.

Coastal communities are also at risk because the coastal ecosystems they exploit and rely on are stressed—and many are nearing ecological breaking point or thresholds (Birkeland 2004; Dayton 2003). Technological advances that allow greater access to resources, including boat design, navigation, fishing gear, and oil exploration methods and equipment, have pushed the use of many coastal resources beyond sustainable limits. Such advances have also increased the conflicts between large-scale industries and small-scale local users, such as subsistence fishers (Curran and Agardy 2002). Poorly planned or executed development has already compromised the ability of many coastal ecosystems to provide regulating services such as maintenance of hydrological balance, nutrient fluxes, and shoreline stabilization (Kay and Alder in press). Thus the relatively high levels of human well-being experienced by many coastal communities are at risk of declining as ecosystems continue to be degraded, lost, or rendered unproductive.

Human communities are also at risk from the health implications of these degraded ecosystems. Cholera and other waterborne diseases are on the rise in coastal countries (Anderson et al. 2001) and may be related to eutrophication-driven algal blooms (Colwell and Spira 1992; Islam et al. 1990). Cholera affects human well-being directly by increasing human morbidity and mortality rates, but it also has severe economic impacts in coastal countries (Rose et al. 2001). For instance, tuna coming from countries having incidences of cholera must be quarantined; this restriction affects many of the major tuna-producing and -exporting countries.

Algal blooms (including red tides) have caused neurological damage and death in humans through consumption of affected seafood (Rose et al. 2001). There are significant health impacts from swimming and bathing in water contaminated by fecal coliform and other pathogens; approximately half the people living in coastal areas have no access to sanitation, and even where sewage treatment exists it is often inadequate, with the result that coastal areas become polluted (UNEP 2002). In a particularly severe outbreak in Italy in 1989, harmful algal blooms cost the coastal aquaculture industry $10 million and the Italian tourism industry $11.4 million (UNEP 1992). Ciguatera, a tropical fish disease causing severe illness and sometimes mortality in humans who consume affected fish, is on the rise, both in terms of the number of cases and number of affected areas.

Human health effects are also caused by pollution of nearshore waters, whereby humans eat fish or other marine products that contain heavy metals, PCBs, and other toxins that have bioaccumulated in the food chain (Verlaan 1997). UNEP and the Water Supply and Sanitation Council estimate the global economic costs related to pollution of coastal waters is $16 billion annually (www.wsscc.org), much of which is due to human health impacts.

Changes in coastal systems also affect the well-being of those living there and elsewhere in more subtle ways. The destruction

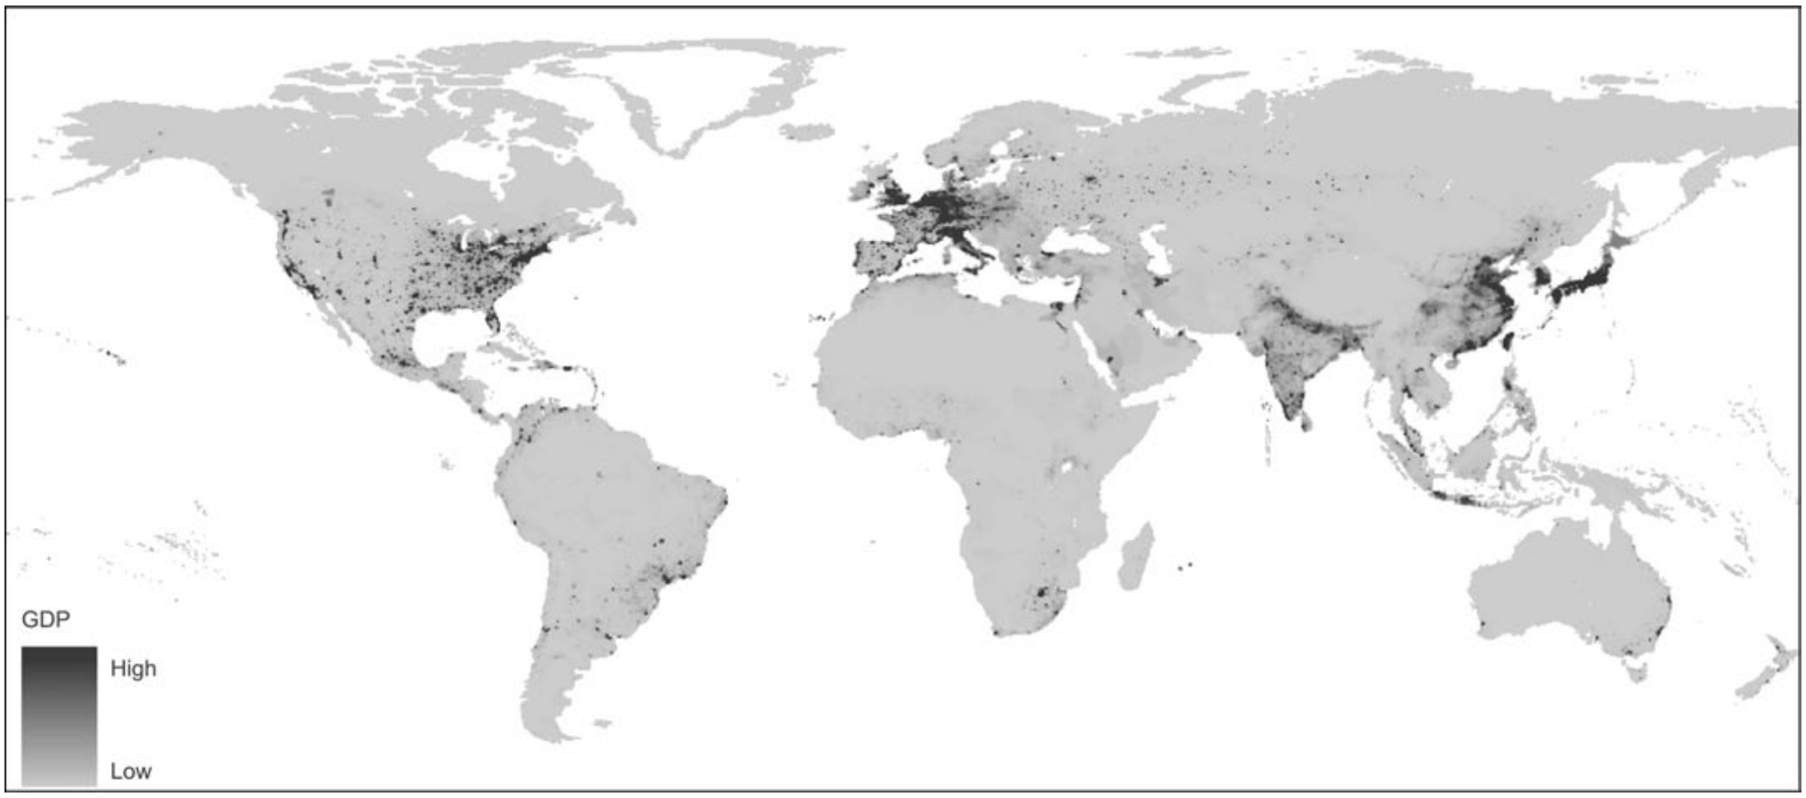

Figure 19.9. Relative Levels of GDP (CIESIN 2003; World Bank 2004)

of places that create opportunities for recreation, that are spiritually or culturally important, or that could potentially increase our knowledge and respect for the natural world entail costs that are more difficult to quantify. Surveys everywhere show that humans maintain strong spiritual connections to the sea and care about its condition, even if they live far inland with no direct reliance on coastal areas for obtaining food or employment, for example.

19.3.2 The Value of Coastal System Services

Coastal ecosystems provide a wide range of services to human beings (Wilson et al. 2004). These include regulation and supporting services such as shoreline stabilization, nutrient regulation, carbon sequestration, detoxification of polluted waters, and waste disposal; provisioning services such as supply of food, fuelwood, energy resources, and natural products; and amenity services such as tourism and recreation. These services are of high value not only to local communities living in a coastal zone (especially in developing countries), but also to national economies and global trade (Peterson and Lubchenco 1997).

In addition to the production of marketable goods and services, such as commercial fisheries and tourism, coastal systems provide services such as nutrient recycling, support for terrestrial and estuarine ecosystems, habitat for plant and animal life, and the satisfaction people derive from simply knowing that a beach or coral reef exists (Wilson et al. 2004). While estimating exchange-based values of marketed services in this case is relatively straightforward, as observable trades exist from which to measure value (Freeman 1993), estimating the economic value of coastal services not traded in the marketplace is more difficult (Freeman 1993; Bingham et al. 1995). However, such analysis often reveals social costs or benefits associated with coastal ecosystem services that otherwise would remain hidden or unappreciated. Market values and nonmarket values are discussed separately in this section.

Studies of specific regions and biomes give us some idea of the enormous economic value of coastal habitats (Balmford et al. 2002). The Wadden Sea in northern Europe, for instance, has provided up to one quarter of the North Sea catch of plaice, sole, shrimp, dab, and herring (De Groot 1992). Coral reef–based fisheries are also valuable: those in Southeast Asia generate $2.4 billion per year (Burke et al. 2001). Although it is widely cited that coral reefs contribute about one quarter of the annual total fish catch in developing countries, providing food to about 1 billion people in Asia alone, the empirical evidence to support such statements is not strong. However, the value of reef fisheries in this region is undeniably significant: Cesar et al. (2003) estimated net benefit streams of reef-dependent fisheries in Asia at over $2 billion.

In principle, a global picture of the potential economic value associated with the coastal zone can be built up via the aggregation of a number of existing valuation studies. For example, in a preliminary estimate of the total economic value of ecosystem services provided by global systems, Costanza et al. (1997) showed that while the coastal zone covers only 8% of the world's surface, the goods and services provided by it are responsible for approximately 43% of the estimated total value of global ecosystem services: $12.6 trillion (in 1997 dollars). While controversial (Pimm 1997; Pearce 1998), this preliminary study made it abundantly clear that coastal ecosystem services do make significant contributions to human well-being at a global scale. Furthermore, it demonstrated the need for additional research and indicated that coastal areas are among the ecosystems most in need of additional study (Costanza 2000).

19.3.2.1 Market Coastal Values

Coastal ecosystems are among the most productive in the world today, rivaling even tropical rainforests in terms of their overall productivity of raw materials and goods used by humans (Primavera 1991; Spurgeon 1992; Barbier 1993). As the following examples show, many coastal regions are valued through market activities that directly support humans—such as fishing, hunting, fuelwood and woodchip extraction, harvesting ornamental materials, and the extraction of medical resources.

Coastal systems generate a variety of seafood products such as fish, mussels, crustaceans, sea cucumbers, and seaweeds (Moberg and Folke 1999; Ronnback 1999). Many commercially important marine species, like salmon, shad, grouper, snapper, bluefish, striped bass, and invertebrates (such as shrimp, lobster, crabs, oysters, clams, mussels), use coastal nursery habitats. Capture fisheries in coastal waters alone account for $34 billion in yields annually. (See Chapter 18.) Given this level of economic productivity, it is perhaps not surprising that overfishing and intensive aquaculture have caused serious ecological and social problems in coastal regions throughout the world (Primavera 1991; Primavera 1997; Jackson et al. 2001).

Valuation studies of food directly or indirectly supplied by coastal systems have predominantly focused on the economic value of fishery products (Batie and Wilson 1978; Lynne et al. 1981; Farber and Costanza 1987; Buerger and Kahn 1989; Rivas and Cendrero 1991; Bennett and Reynolds 1993; Ruitenbeek 1994; Kaoru et al. 1995; Deb 1998; Gilbert and Janssen 1998; Ronnback 1999; Barbier 2000; Sathirathai and Barbier 2001). Most often, the market price of seafood products is used as a proxy when calculating the value of ecosystem goods provided by coastal systems. For example, the annual market value of seafood supported by mangroves has been calculated to range from $750 to $16,750 (in 1999 dollars) per hectare (Ronnback 1999). High-value species are harvested from coral reefs to meet live fish demand in restaurants, mainly in Asia. (See Chapter 18.)

Coastal areas also provide the foundation for the mariculture (marine aquaculture) industry, which uses coastal space or relies on wild stock to produce valuable fisheries products, from tiger prawns to bluefin tuna. Human reliance on farmed fish and shellfish is significant and growing. Global annual per capita consumption of seafood averages 16 kilograms, and one third of that supply currently comes from aquaculture (Lubchenco 2003). Globally, aquaculture is the fastest-growing food-producing sector, with production rates doubling in weight and value from 1989 to 1998 (Goldburg et al. 2001). Much of that growth has occurred in the shrimp and salmon farming industries.

Besides food and raw materials, at least three other types of marketable goods are provided by coastal systems: genetic, medical, and ornamental resources. For example, coral reefs have been shown to be an exceptional reservoir of natural bioactive products, many of which exhibit structural features not found in terrestrial natural products (Carte 1996). The pharmaceutical industry has discovered several potentially useful substances among the seaweeds, sponges, mollusks, corals, sea cucumbers, and sea anemones of reefs (Carte 1996; Moberg and Folke 1999). (See Chapter 10 for more on bioprospecting in coastal systems.) Furthermore, many coastal products are collected not only as food but also to sell as jewelry and souvenirs. Mother-of-pearl shells, giant clams, and red coral are collected and distributed as part of a worldwide curio trade (Craik et al. 1990). The marine aquarium market is now a multimillion-dollar industry trading in live reef-dwelling fishes that are collected and shipped live from coral reef communities (Moberg and Folke 1999; Wabnitz et al. 2003).

19.3.2.2 Nonmarket Coastal Values

In addition to marketable goods and products, landscape features and ecological processes within the coastal zone also provide critical natural services that contribute to human well-being and have significant economic value (Farber and Costanza 1987). As the data just cited suggest, much of what people value in the coastal zone—natural amenities (open spaces, attractive views), good beaches for recreation, high levels of water quality, protection from storm surges, and waste assimilation/nutrient cycling—is provided by key habitats within coastal systems. In Thailand, the conversion of mangroves to shrimp aquaculture ponds reduced the total economic value of the intact mangroves by 70% in less than a decade (Balmford et al. 2002).

Open space, proximity to clean water, and scenic vistas are often cited as a primary attractor of residents who own property and live within the coastal fringe (Beach 2002). Hedonic pricing techniques have been used to show that the price of coastal housing units varies with respect to characteristics such as ambient environmental quality (proximity to shoreline, for example, or water quality) (Johnston et al. 2001). For example, Leggett and Bockstael (2000) use hedonic techniques to show that water quality has a significant effect on property values along the Chesapeake Bay in the United States. They use a measure of water quality—fecal coliform bacteria counts—that has serious human health implications and for which detailed, spatially explicit information from monitoring is available. The data used in this analysis consist of sales of waterfront property on the western shore of the Chesapeake Bay between 1993 and 1997 (Leggett and Bockstael 2000). The authors consider the effect of a hypothetical localized improvement in observed fecal coliform counts on a set of 41 properties. The projected increase in property values due to the hypothetical reduction in coliform bacteria totaled approximately $230,000. Extending the analysis to calculate an upper limit benefit for 494 properties, it is estimated that the benefits of improving water quality at all sites would be around $12.145 million (Leggett and Bockstael 2000).

Stretches of beach, rocky cliffs, estuarine and coastal marine waterways, and coral reefs provide numerous recreational and scenic opportunities. Boating, fishing, swimming, walking, beachcombing, scuba diving, and sunbathing are among the leisure activities that people enjoy worldwide and thus represent significant economic value (Farber 1988; King 1995; Kawabe and Oka 1996; Ofiara and Brown 1999; Morgan and Owens 2001). Both travel cost and contingent valuation methods are commonly used to estimate this value. (See Chapter 2 for more on these valuation techniques.) For example, the Chesapeake Bay estuary has also been the focus of considerable research on nonmarket recreational values associated with coastal systems. When attempting to estimate the monetary worth of water quality improvements in Chesapeake Bay, Bockstael et al. (1989) focused on recreational benefits because it was assumed that most of the increase in well-being associated with such improvements would accrue to recreational users. The authors estimated the average increases in economic value for beach use, boating, swimming, and fishing with a 20% reduction in total nitrogen and phosphorus being introduced into the estuary. Using a combination of the two valuation methods, the annual aggregate willingness to pay for a moderate improvement in the Chesapeake Bay's water quality was estimated to be in the range of $10–100 million (in 1984 dollars) (Bockstael et al. 1989).

Global tourism has been deemed the world's most profitable industry, and coastal tourism is one of its fastest-growing sectors. Much of this tourism centers on aesthetically pleasing landscapes and seascapes, intact healthy coastal ecosystems with good air and water quality, opportunities to see diverse wildlife, and so on. For instance, much of the economic values of coral reefs—with net benefits estimated at nearly $30 billion each year—is generated from nature-based and dive tourism (Cesar et al. 2003). The demand for biologically rich sites to visit increases the value of intrinsically linked habitats such as mangroves and seagrass beds. Temperate bays and estuaries can similarly generate tourism revenues of similar orders of magnitude.

The link between tourist visits and the revenues from and condition of the coastal system has not been analyzed at the global level, but local case studies point to a strong correlation between value and condition. In the United States alone, reef ecosystems with their nursery habitats support millions of jobs and billions of dollars in tourism each year. For example, reef-based tourism generated over $1.2 billion in the Florida Keys alone, while in Hawaii, reefs generate some $360 million per year, with annual gross revenues generated from just one half-square-mile coral reef reserve exceeding $8.6 million (Birkeland 2004).

As these reefs decline in biodiversity and ecosystem health, these nature-based tourism industries stand at risk (Cesar and Chong 2004). In Jamaica and Barbados, for instance, destruction of coral reefs resulted in dramatic declines in visitation; loss of revenue streams subsequently led to social unrest and even further tourism declines (MA Sub-global Assessment on Caribbean Sea). Similarly, "willingness to pay" studies in the Indian Ocean suggest that the health of coral reefs is an important factor for tourists: they were willing to pay, on average, $59–98 extra per holiday to experience high-quality reefs (Linden et al. 2002). And in Florida, reef degradation is rapidly changing the structure of the tourism market, from high-value, low-volume tourism toward larger numbers of budget travelers (Agardy 2004).

Recreational fishing is also a major industry in many parts of the world, and it primarily targets marine or anadromous fishes in coastal ecosystems. The estimated revenue generated by coral reef–based recreational fisheries reaches several hundred million dollars annually (Cesar et al. 2003). The coastal zone also supplies nonmarket values associated with both recreational and commercial fisheries by providing some of the most productive habitat refugia in the world (Gosselink et al. 1974; Turner et al. 1996). Eelgrass, salt marsh, and intertidal mud flats all provide a variety of services associated with their nursery functions (Gosselink et al. 1974; Turner et al. 1996).

As already noted, improvements in the condition of these habitats may ultimately lead to measurable increases in the production of market goods such as fish, birds, and wood products. In other cases, however, ecological productivity itself can represent a unique class of values not captured by traditional market-based valuation methods. (See Box 19.3.) Instead, these values represent an increase in the production of higher trophic levels brought about by the increased availability of habitat, though analysis must be careful not to risk double counting some aspects of value or measuring the same benefits in different ways.

The seas and coasts are also of great spiritual importance to many people around the world, and such values are difficult to quantify. While the depth and breadth of these values are as diverse as the cultures that are found worldwide, there is the common theme of a cultural or spiritual connection. For example, the Baju peoples of Indonesia (Sather 1997) and the aboriginal people of the Torres Strait in Australia have a culture intimately connected to oceans, while many of the native peoples of North America have similar strong ties to coastal systems. Even systems on which we place low economic value today may be of importance and value tomorrow because they support species that may turn out to have pharmaceutical value or because they support species or habitat types that may become rare and endangered in the future. This gives them high option value associated with an individual's willingness to pay to safeguard the option to use a natural resource in the future, when such use is not currently planned. Non-use values are representative of the value that humans bestow upon an environmental resource, despite the fact they may never use or even see it.

In summary, ecosystem services are critical to the functioning of coastal systems and also contribute significantly to human well-being, representing a significant portion of the total economic value of the coastal environment. The best available market and nonmarket data suggest that substantial positive economic values can be attached to many of the marketed and nonmarketed services provided by coastal systems.

BOX 19.3

Examples of Productivity Analyses

In an example of coastal wetland productivity analysis, Johnston et al. (2002) used a simulation model based on biological functions that contribute to the overall productivity of the food web in the Peconic Estuary System in Suffolk County, New York, in the United States. Based on habitat values for fin and shellfish, birds, and waterfowl, an average annual abundance per unit area of wetland habitat in the estuary system was estimated by summing all relevant food web values and habitat values for a year (Johnston et al. 2002). The value of fish and shellfish was based on commercial harvest values. The marginal value of bird species usage of the habitat was based on the benefits human receive from viewing or hunting waterfowl. Using these values as input data, the simulation model resulted in annual marginal asset values for three wetland types: eelgrass ($1,065 per acre per year); salt marsh ($338 per acre per year); and intertidal mud flat ($67 per acre per year).

Farber and Costanza (1987) estimated the marginal productivity of a coastal system in Terrebonne Parrish, Louisiana, in the United States by attributing commercial values for several species to the net biomass, habitat, and waste treatment of the wetland ecosystem. Arguing that the annual harvest from an ecosystem is a function of the level of environmental quality, the authors chose to focus on the commercial harvest data for five different native species—shrimp, blue crab, oyster, menhaden, and muskrat—to estimate the marginal productivity of wetlands. The annual economic value (marginal product) of each species was estimated (in 1983 dollars) as shrimp, $10.86 per acre; blue crab, $0.67 per acre; oyster, $8.04 per acre; menhaden, $5.80 per acre; and muskrat pelts, $12.09 per acre. Taken together, the total value of marginal productivity of wetlands in Terrebonne Parrish was estimated at $37.46 per acre.

19.4 Projections of Trends, Areas of Rapid Change, and Drivers of Change

19.4.1 Projections of Trends and Areas of Rapid Change

Coastal habitat loss is likely to continue and possibly accelerate as increasing and sometimes conflicting demands for coastal space and resources rise (*high certainty*). Coastal systems and the habitats within them are rapidly becoming degraded around the globe; many have been lost altogether. Sometimes the changes are natural (such as hurricanes and naturally occurring climate variation), but more often than not the impacts are human-induced. These anthropogenic impacts are direct, such as the filling in of wetlands, or indirect, such as the diversion of fresh water from estuaries or land-based sources of pollution. Habitat is lost, usually permanently, when coastal development and marine resource use is destructive or unsustainable.

The greatest factor leading to loss of coastal habitats is conversion of wetlands, including marshes, seagrass beds, mangrove forests, beaches, and even mudflats to make way for coastal development. In the Philippines, for instance, 210,500 hectares of mangrove—40% of the country's total mangrove cover—were lost to aquaculture from 1918 to 1988 (UNESCO 1993). By

1993, only 123,000 hectares of mangroves were left—equivalent to a loss of 70% in roughly 70 years (Nickerson 1999; Primavera 2000). Transportation infrastructure claims much coastal land and will continue to do so as roads are widened, ports and airports are expanded, and so on. Climate change–induced sea level rise will likely exacerbate rates of habitat loss due to development, especially in vulnerable areas such as atolls, deltas, and floodplains (Nicholls 2004). Habitat conversion and loss is thus expected to continue, at least until all available natural habitat is used up or until policy reform stems the tide of habitat loss.

Exploitation beyond sustainable levels is likely to continue and even increase in rate for many resources (*high certainty*). Coastal ecosystems will likely continue to be used for both commercial and artisanal fisheries, and if current trends continue many of these stocks will be depleted to commercial and ecological extinction. The drivers behind coastal resource overexploitation may be direct, such as consumption, or they may be indirect, such as marginalization, perverse subsidization, political corruption, and socioeconomic condition (Myers and Kent 2001). (See Chapter 18.)

Some members of the biological community in coastal habitats have special roles to play in maintaining ecological interactions; the removal of keystone species, for example, can cause large-scale ecological havoc (Kaufman and Dayton 1997). The removal of fish and invertebrates that graze algae living on seagrasses can destroy seagrass beds when heavy algal mats subsume the seagrass meadows. Human activities also affect coastal ecology indirectly by causing the alteration and degradation of distant habitat and by causing mortality of species within the habitat (Keough and Quinn 1998). This threat is often unseen, noticed only once the cumulative effects of degradation has altered or destroyed these ecosystems.

One of the most severe anthropogenic impacts on coastal areas in the near future will likely be through continued interference with hydrology and water flows to the coast (Pringle 2000) (*medium certainty*). Diversion of fresh water from estuaries and riparian-zone conversion of land for agriculture, human use, and hydroelectric generation causes the hypersalinization of estuarine areas and renders them unable to fulfill these important ecological functions and services (Diop et al. 1985; Weinstein and Kreeger 2000). Reduced water delivery to coasts also lowers sediment delivery and greatly accelerates rates of deltaic loss and coastal erosion. For instance, the damming of the Nile caused severe erosion and exacted high costs due to the need for shoreline protection, as well as loss of fertility of agricultural lands in the floodplain. Fisheries in the Nile Delta region of the Mediterranean have also been altered and yields decreased, at least in part due to silicate depletion and changes in phytoplankton communities away from diatoms.

Although there are many specific, often quantified benefits derived from the use and diversion of water in river basins, such hydrological changes are expected to cause rapid change to many estuaries, deltas, and semi-enclosed seas worldwide in coming years, with largely unknown consequences. (See Box 19.4.)

The next few decades will see large increases in rates of eutrophication and prevalence of hypoxic or dead zones as levels of nutrient inputs and wastes rise and as ocean waters warm (*high certainty*). Some 77% of the pollutant load reaching the coastal ecosystems currently originates on land, and 44% of this comes from improperly treated wastes and runoff (Cicin-Sain et al. 2002). These figures are expected to rise if population growth continues to outpace proper sanitation and if agricultural and other runoff remains unregulated. The result will be increased rates of eutrophication through the addition of large quantities of fertilizers, sewage, and other non-natural nutrients, which will change the processes occurring in these ecosystems (NRC 2000). Eutrophied conditions are evident in virtually all coastal waters near areas of human habitation, being especially acute in areas where coastal wetlands and their filtering function have been destroyed. High nutrient concentrations are expected to have particularly large impacts on the ecology of semi-enclosed and other seas in arid areas (Beman et al 2005).

Since nutrient production through agricultural waste and human sewage are expected to increase in the future, and since wetland loss will likely occur at current or higher rates, eutrophication will undoubtedly increase worldwide (*medium certainty*). Numerous river basin and coastal zone studies (in the Baltic region, for instance, the Mississippi River and Gulf of Mexico, the North Sea, the Northern Adriatic, and the Black Sea) have shown that elevated levels of nutrients, coastal eutrophication, toxic phytoplankton blooms, and bottom-water hypoxia are a consequence of human settlement and industrialization. It has been estimated that fluvial fluxes of inorganic N and P to the world oceans have increased severalfold over the last 150–200 years. In certain regions, such as in Western Europe, N and P levels are ten- to twentyfold over pre-industrial levels (Meybeck and Ragu 1997; Vörösmarty and Meybeck 1999).

With *high certainty,* pollutant levels are expected to increase in the near future, despite effective controls on some substances in some areas. River loadings of biotically active elements, metals, hormones, antibiotics, and pesticides are known to have increased severalfold since the beginning of the industrial era, and levels of these toxins are expected to continue to increase. Pollutants not only affect water quality, and with it many provisioning and amenity services, but are also implicated in large-scale failures of fish farming operations. These failures are extremely costly (white spot syndrome in shrimp cost India $200 million over three years, and it nearly caused the collapse of the shrimp farming industry in Ecuador in 1999), and they can affect both ecosystem health at the farming site and human health where the product is consumed. Human health effects from all forms of pollutants have not been comprehensively quantified, but coastal pollutant–related human mortality and morbidity are undoubtedly on the rise (Verlaan 1997).

The geographically largest impacts to coastal systems will be caused by global climate change, and since rates of warming are generally expected to increase in the near future, projected climate change–related impacts are also expected to rise (IPCC 2003). Warming of the world's seas degrades coastal ecosystems and affects species in many ways: by changing relative sea level faster than most biomes can adapt; by stressing temperature-sensitive organisms such as corals and causing their death or morbidity (in corals, this is most often evidenced by coral bleaching); by changing current patterns and thus interfering with important physiobiotic processes; and by causing increased incidence of pathogen transmission. Coral reefs may be the most vulnerable, having already evidenced rapid change, and some projections predict the loss of all reef ecosystems during this century (Hughes et al. 2003). Climate change also alters the temperature and salinity of estuary and nearshore habitats, making them inhospitable to species with narrow temperature tolerances. Warming can also exacerbate the problem of eutrophication, leading to algal overgrowth, fish kills, and dead zones (WRI 2000). (See Figure 19.10 for the location of major hypoxic areas in coastal systems.) Finally, warming is expected to further increase the transmission rates of pathogens and hasten the spread of many forms of human and nonhuman disease.

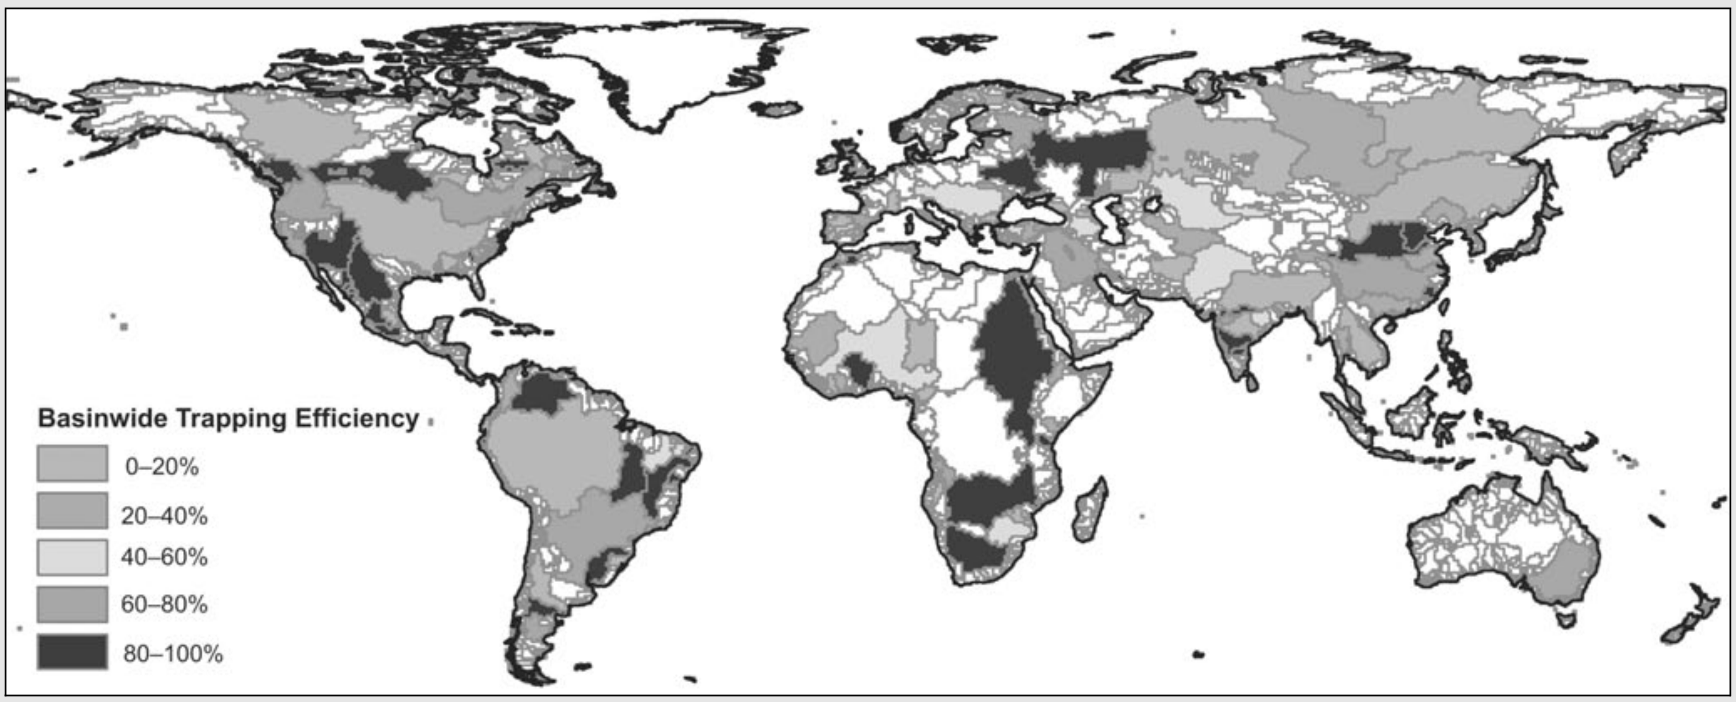
BOX 19.4

Water Diversion in Watersheds versus Water and Sediment Delivery to Coasts

The degree to which river water and sediment reach the coastal zone depends on other human activities, such as the construction of structures for water diversion, flood control, power generation, and recreation. Reservoirs and irrigation channels can retain a large proportion of the fluvial sediment discharge (Farnsworth and Milliman 2003). According to Vörösmarty et al. (1997, 2003), the 663 dams with large reservoirs (greater than 0.5 cubic kilometers maximum storage capacity) globally store about 5,000 cubic kilometers of water (approximately 15% of the global river water discharge). Also, global large reservoirs intercept more than 40% of global water discharge, and approximately 70% of this discharge maintains a sediment trapping efficiency of more than 50%.

Further analysis of the recent history of anthropogenic sediment retention by large dams (Vörösmarty et al. 2003) indicates that between 1950 and 1968, there was an increase from 5% to 15% in global sediment trapping, another increasing trend to 30% by 1985, and stabilization thereafter. As much as 25% of the current sediment load from the land to the coastal zones is trapped behind reservoirs. The trapping effect of fresh water discharge and suspended sediment by 45,000 dams analyzed in this study has dramatic impacts on water and sediment destined for the global coastal zone and inland seas. (See Figure.) Assuming that the global natural sediment discharge is between 18 and 20 gigatons per year, then the combined impact of all large dams will be on the order of 4–5 gigatons per year. Therefore, modern dam construction reduces the global sediment flux to the world's coastal zones by 25–30%.

According to Syvitski (2003), by decreasing sediment loads to the river through damming, coastal erosion is increased, and coastal marine ecosystems frequently deteriorate. Many dramatic examples of river control and utilization and their impacts on coastal systems have been recognized. After the Aswan Dam was completed in 1964, for example, the productive fishery collapsed and was reduced by 95%, and the delta subsided rapidly. The fishery remained unproductive for 15 years. It began a dramatic recovery during the 1980s, coincident with increasing fertilizer use and thus a flux of nutrients, expanded agricultural drainage, and increasing human population and sewage collection systems (see Nixon 2003). Similarly, after the Colorado River in the United States was dammed, sediment and nutrient discharge decreased dramatically and the shrimp catch in Baja California collapsed. After completion of the Kotri Barrage on the Indus River in Pakistan in 1956, fish catch decreased by a factor of three. And in China's Sea of Bohai, when the sediment discharge of the Yellow River was reduced the shrimp fishery decreased by 85% and the percentage of high-quality fish dropped by an order of magnitude.



Climate change–related sea level rise will cause continued inundation of low-lying areas, especially where natural buffers have been removed (Church et al. 2001). Sea level rise is due to thermal expansion of ocean waters and melting of land based–ice, and both expansion and ice melts are expected to increase (IPCC 2003). In most if not all cases, global climate change impacts act in negative synergy with other threats to marine organisms and can be the factor sending ecosystems over the threshold levels of stability and productivity. In limited cases, new habitats may be created. Changes in weather patterns modeled in some extreme scenarios of climate change—including increased precipitation in some areas, abrupt warming at the poles, and increased frequency and intensity of storm events—would affect oceanic circulation (perhaps even leading to the collapse of thermohaline circulation) and currents as well as the ability of organisms to live or reproduce.

Different coastal subtypes, habitats, and even taxonomic groups will be affected by these direct and indirect impacts to greater or lesser degrees. Coral reefs may be the most vulnerable of all coastal subtypes (*medium certainty*), since multiple threats affect systems and since tolerances for corals and related reef species are generally of a narrow range. Estuaries are also vulnerable because these systems are directly subject to impacts from land (Gosselink et al. 1974; Turner et al. 1996) and water. Semi-enclosed seas are more vulnerable to degradation than open ocean basins—and because more isolated coastal waters have higher endemism, biodiversity is at greater risk in these areas.

Looking ahead 10–50 years suggests that some geographic areas of the world are expected to show particularly high rates of change and loss of certain ecosystem services. Southeast Asia, with its burgeoning population growth, limited land area, and largely ineffective controls on fisheries, pollution, and coastal development, is expected to continue to be an area of extremely rapid coastal change with losses in food provisioning, biodiversity, nutrient cycling, and storm protection services (*high certainty*). Small islands will continue to suffer dramatic alterations to their coastal

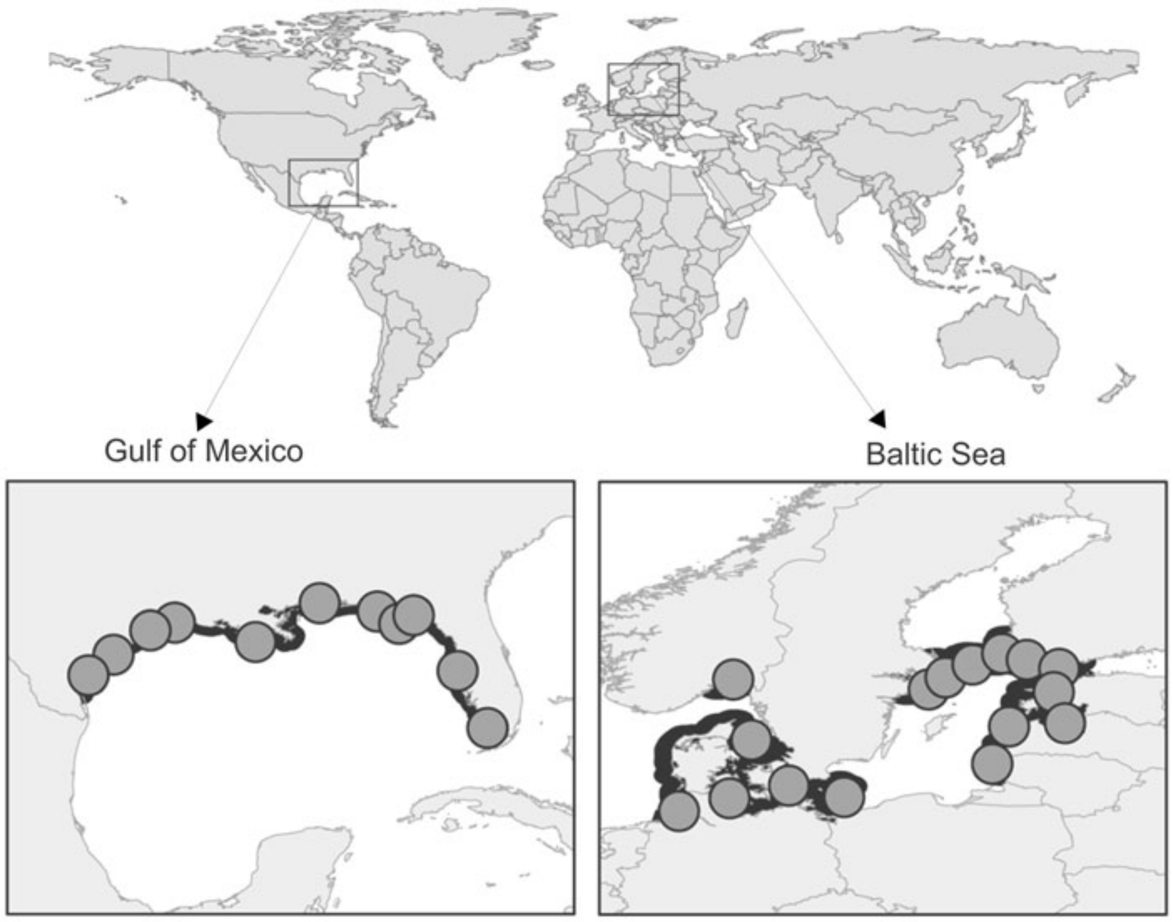


Figure 19.10. Hypoxic Zones in Gulf of Mexico and Baltic Sea (UNEP 2004)

environments, especially in the Pacific Ocean, Indian Ocean, and Caribbean Sea, where archipelagos of small islands support large numbers of residents and tourists but where monitoring and enforcement of regulations is difficult due to the distances between islands and limited resources. The areas of greatest change in land use that are situated in the coastal zone, such as those in the Middle East region, will also suffer rapid coastal change in the coming years.

The continued degradation of coastal ecosystems is paradoxical. Despite the value of coastal areas in supporting the tourism industry, for instance, coastal tourism development often uses habitats such as estuaries, mangroves, marshes, and atoll lagoons for waste disposal, degrading these areas and reducing their capacity to provide ecosystem services such as waste processing and coastal protection. Tourism development also results in conversion of habitat to accommodate infrastructure, resulting in loss of dune systems, wetlands, and even coral reefs. Damming damages estuaries and reduces fisheries yields, even if there are benefits of freshwater diversion for increasing food supply in terrestrial systems.

The costs of such trade-offs are significant, especially since the economic value of coastal developments that are put at risk by loss of protective and regulating services are high. A relatively new and rapidly growing form of coastal development that severely affects coastal ecosystems is uncontrolled building of shrimp ponds and other aquaculture sites (Lubchenco 2003). Dredging of waterways, as well as sand and coral mining, also cause habitat loss. Urbanization has enormous impact on the coasts, both in developing countries where displaced landless people often take up residence in urban shanties and in industrial countries where urban and suburban sprawl threaten natural habitats and ecosystem services. Finally, humans increasingly cause the loss of coastal habitats through destructive fishing practices such as blast fishing (the use of underwater explosives) and trawling (dragging of weighted nets along the sea floor).

For some degraded coastal habitats, such as mangroves, marshes, and areas of seagrass, it may be possible to regain ecosystem services through restoration, but the prohibitively high costs prevent restoration being an effective policy for other habitat types. Some ecosystems under the right conditions may recover or regenerate without intervention, but in most ecosystems active and expensive restoration may be necessary. Toxin loadings, pathogens, and alien species invasions will further stress coastal ecosystems and may impede natural recovery and managed restoration; human well-being will suffer as a consequence unless significant improvements to coastal management are systematically made across wide regions of the globe (*high certainty*).

19.4.2 Drivers of Change in the Coastal System

As noted previously, population growth is highest in coastal countries, and population densities within the coastal system are high. Urban areas are often concentrated on the coast: half of all major cities (with populations above 500,000 inhabitants) are located in coastal systems. Population doubling rates are highest in coastal areas.

However, the link between sheer population number and environmental quality is not clear-cut. Some authors argue that a direct link exists between the number of people and the quality of the environment or loss of diversity, regardless of consumption patterns (McKee et al. 2004). Others argue that the number of households is better correlated to the environmental impact or ecological footprint left by humans (Liu et al. 2003). In the coastal zone, however, neither population numbers nor household numbers tell the full story. Patterns of consumption and other human behaviors greatly influence the ecological footprint left by communities, and migration and its effects often spell the difference between sustainable and unsustainable use (Creel 2003; Curran and Agardy 2002). Local resource use and migration patterns are also affected by local and international markets.

In many industrial countries, urban sprawl is a major driver behind coastal ecosystem impacts and habitat loss. In the United

States, for example, it is the pattern of growth, which includes runaway land consumption, dysfunctional suburban development patterns, and exponential growth in automobile use, rather than population growth itself in the coastal zone that has affected ecosystems and their services (Beach 2002).

National and local economies influence the ability of countries to manage resource use and lessen impacts on ecosystem services. Industrial countries with strong economies have the ability to put resource management programs in place, undertake pollution mitigation and ecological restoration, and support surveillance and enforcement. However, wealthy countries also tend to be proportionately greater consumers, and their large-scale industries often threaten the environment (Creel 2003). Agribusiness and other large-scale industries often have a disproportionately large voice in democratic governments, since they can underwrite extensive lobbying on their behalf (Speth 2004), and subsidization can also steer such industries away from sustainability (Myers and Kent 2001).

Even individual wealth can have a negative impact on the environment. Expensive chemicals are generally available only to industry or the wealthy (such as tributyltin, used to prevent fouling of ship hulls, which has harmed marine species and caused changes in sex in exposed organisms), while in the industrial world, improved access to drugs threatens coastal systems, since antibiotics and hormones (especially ethinyloestradiol, a synthetic estrogen used in birth control pills) find their way into streams and rivers and eventually into coastal systems (Colburn et al. 1996). Since the magnitude of the impact of these chemicals on coastal ecology and on human health is not fully understood, there has been little impetus to implement mitigation measures to prevent pollutants from entering streams, rivers, sewers, and estuaries.

Foreign markets and globalization have been major drivers behind degradation of coastal ecosystems and diminishing services. Globalization causes greater mobilization of fishers and other users, greater flow of information and access to resources, increased fishery or other trade-related pollution and habitat loss, and loss of rights and representation of local peoples, leading to marginalization (Alder and Watson 2004). Access to markets and growing consumer demand (for both legal and illegal goods) increase pressures on resources and can lead to overexploitation and habitat loss.

For instance, conversion of habitat for aquaculture drives much of the loss of habitat and services in coastal South America and Southeast Asia. Although in Latin America, habitat conversion is undertaken primarily by large international corporations, in Thailand and Viet Nam there is a more balanced mixture of small- and large-scale farms. Production is geared completely toward export markets. The growth in this industry has little or nothing to do with population growth or local demands for sources of food. In Ecuador, more than 50,000 hectares of mangrove forest has been cleared to make shrimp ponds since 1969, representing a 27% decline in mangrove cover. During the same period, shrimp ponds have gone from zero to over 175,000 hectares. While there has been some recent reforestation in Ecuador (representing approximately 1% increase in a four-year period), this may be more to do with increasing market competition with Southeast Asian producers.

In Thailand, both primary conversion of mangroves and wetlands and secondary conversion of rice, rubber, and other agricultural crops to shrimp farms has occurred. Ten years of observations of shrimp farm production in Thailand (Lebel et al. 2002) suggests that once shrimp farms are established, the resulting sedimentation, salinization, and changed tidal influences may seriously impede natural or planned regeneration of coastal forests or tidal basin species and may alter animal communities in waterways and wetlands. An analysis of shrimp farm production also demonstrates the multitude of linkages via the vital flow of water between human-based, land-based, coast-based, and marine-based systems. (See Box 19.5.)

The aquaculture-driven conversion of coastal habitat in Asia presents lessons about understanding drivers of ecosystem change in all coastal habitats. While it is necessary to separate threats to ecosystems in order to assess their impact, it is equally important to note that most coastal areas are facing multiple threats simultaneously, and many have experienced chronic impacts over long periods of time. Table 19.5 presents a typology of drivers of change in coastal systems and ecosystem services.

In a set of systems as complex and diverse as coastal systems, however, it is more germane to discuss drivers behind certain classes of impacts separately, rather than speaking of coastal ecosystem degradation more generally. Arguably, the greatest impacts on coastal systems worldwide are caused by the conversion of habitat for the purposes of coastal development (wetlands infilling, dredging of bays and harbors for port development, and so on) and through certain kinds of resource use (mangrove harvest, destructive fishing, and the like). These changes cause major if not total losses in ecosystem services and are largely irreversible.

For this reason, much attention has been paid to population growth in the coastal zone and the ways in which population drives habitat loss. Certainly this is true in poorly developed areas, where mangrove remains an important source of fuelwood and competition for increasingly scarce fisheries forces fishers to use unsustainable techniques. However, population is not the only driver behind habitat loss, and a confluence of chronic negative impacts may eventually lead to as debilitating a loss of ecosystem services as the more visible loss of habitat caused by growing populations.

19.5 Trade-offs, Synergies, and Management Interventions

19.5.1 Trade-offs, Choices, and Synergies

A central concern in coastal management is one of making trade-offs between ecosystem services in allocating increasingly scarce resources among society's members. Decision-makers face questions such as, Should this shoreline be cleared and stabilized to provide new land for development, or should it be maintained in its current state to serve as wildlife habitat? Should that wetland be drained and converted to agriculture, or should more wetland area be created to provide nutrient filtration services? Should this coral reef be mined for building materials and the production of lime, mortar, and cement, or should it be sustained to provide renewable seafood products and recreational opportunities?

To choose from among competing options, it is often necessary to compare the value that various groups in society receive from any improvement in a given coastal ecosystem with the value these groups give up to degrade the same system. Given this, a key question comes down to, What gets counted and how? Unfortunately, there are usually very few (if any) studies that can provide decision-makers with information on the full range of values provided by coastal ecosystem services, which is needed to evaluate specific trade-offs.

The wide variety of habitats, resources, and ecosystem services provided by coastal systems, and the strong interlinkages between these various components and processes suggest that complicated choices and difficult trade-offs exist whenever any form of coastal

BOX 19.5

Four Pathways to Coastal Ecosystem Degradation and Poverty through Shrimp Production in Thailand (Lebel et al. 2002 and references therein)

Shrimp production and sales are one of the fastest-growing food commodity markets in the world. Farmed shrimp production in the world market went from 815,250 tons in 1999 to 1.6 million tons in 2002. The industry has been growing at the rate of 10–20% a year over the last five years. The increase in production results from the spread of shrimp farm production along coastal ecosystems and tidal plains around the world. The area farmed for shrimp is approximately 1.2 million hectares. This number does not include the estimated 250,000 hectares of abandoned shrimp farms around the globe.

In 2000, the vast majority of shrimp farms were located in Pacific rim countries, along the coasts of South, East, and Southeast Asia. Approximately 89% of shrimp farmland is located in Asia. Thailand is the leading exporter of shrimp, with 25% of the world market, and the growth in Thai shrimp farms has been dramatic. In 1995, there were 19,700 farms covering about 65,000 hectares; by 2003 there were 35,000 farms encompassing 80,000 hectares.

Shrimp farm production has garnered attention from environmentalists because the building of shrimp farms is often linked to mangrove forest clearing. But extensive work by Lebel and colleagues in Thailand over the last decade suggests that the relationship between shrimp farm production and coastal ecosystem degradation is much more complex than popular science would predict. Lebel describes four pathways through which shrimp farm production there degrades coastal ecosystems and affects coastal communities' livelihoods. The complex interaction between shrimp farm production for global markets, coastal ecosystems, farmer/fisher livelihoods, and unsustainable and short-lived capacity of individual shrimp ponds spurred both a dramatic deterioration of coastal ecosystems over the last decade and recent, aggressive exploration of inland freshwater systems as a substitute.

The first pathway is sedimentation. Artificial shrimp ponds must be dredged and cleaned regularly. Typically, farmers empty the sludge into nearby coastal creeks or river basins. The resulting sedimentation has several effects. The filling of creeks and river tidal basins deters small fisher navigation through the creeks and tidal basins, disrupts nesting and breeding grounds of coastal dependent marine and shore species, and diminishes coastal fisheries. The buildup of sediment also diminishes the flushing and nutrient cycling role of tidal surges, further depleting the quality of coastal creeks and tidal basins. Sedimentation results from the building of fish ponds, which are usually bulldozed, the regular dredging of the ponds, and the more frequent pumping of pond water into coastal creeks. Although regulations stipulate that all larger farms must operate post-production water treatment ponds, many do not.

Salinization, the second pathway, is the result of three processes. First, the standing water in ponds and the resulting evaporation yields a buildup of salt in the pond water. Second, because tidal surges are minimized, the salt buildup is not naturally flushed out to sea. Third, in some locations saline water is pumped or trucked inland because local water sources are too fresh. The impacts appear to be most serious in areas without immediate access to coastal inlets or the ocean. Here, wastewater effluent from ponds is dumped into canals and waterways previously for irrigation of rice, orchards, and rice-sugar palms systems. Productivity declines and some tree species die, making it hard for non-shrimp farming land uses to persist in an area. These "off-site" or landscape effects have often been a source of sharp conflict between shrimp farmers and other farmers. Over the past couple of years, techniques for rearing shrimp under freshwater conditions have greatly improved and spread.

Although the building of shrimp farms typically takes place on private land, the residual creeks, wetlands, and shoreline are frequently understood to be public lands, so public accessibility can be the third pathway of degradation. Because of the value of shrimp, however, shrimp farm producers limit access to once-public natural resources that are near ponds. Guards actively dissuade local fishers, farmers, and hunters from using these public goods. Those who need access to these public resources are those in most need of the livelihood income generated from gathering freshwater clams, plants and greens, and small fish.

Impoverization is the fourth pathway identified by Lebel et al. The establishment of shrimp farms improves wage-based employment opportunities for many local residents, and the presence of shrimp farms in an area provides opportunities for short-term work in sorting, pond cleaning, equipment maintenance, and reselling of inputs. Where factories are present, there can also be substantial wage-earning opportunities, primarily for young women. As a result, the poorest members of coastal villages, who used to define their livelihoods as coastal fishers, now work as low-wage earners in shrimp farm production. In addition, during the early to middle years of the growth in shrimp production, many small fishers and farmers established their own farms, despite the high cost of entry. Many of these smaller producers quickly lost their ponds, however, as the economies of scale, the high incidence of disease outbreaks, and the fluctuation in prices precluded success for those with few assets in reserve. Currently many owners of coastal land rent their property to large corporate shrimp farm producers. Rental contracts typically include clauses that abrogate a renter's responsibility for payment if the shrimp harvest fails.

In both cases, coastal residents—whether low-wage workers on shrimp farms or owners of land rented to shrimp farm producers—are increasingly vulnerable to global market price fluctuations that affect the profitability of local shrimp ponds, as well as the rapidly deteriorating quality of the coastal ecosystem. The latter not only increases the likelihood of disease outbreaks and shrimp pond abandonment, it also precludes possible alternative coastal-based resource livelihoods once the shrimp farm economy collapses or moves elsewhere. Recently, as a result of the deterioration of coastal sites and limited new sites for expansion along the coast, corporate research and development has focused on shifting shrimp production into freshwater systems.

development or protection takes place. For example, the choice to cut down mangrove forest to build a seaside resort will not only involve opportunity costs in reducing mangrove availability to local people, it will also have an impact on other uses of the coastal zone, such as fishing, and will dramatically reduce ecological services such as storm buffering, maintaining water and sediment balances, water purification, nutrient delivery, biodiversity maintenance, and provisioning of nursery areas for coastal fishery species. Similarly, the decision to protect a key habitat via establishment of a marine protected area will mean that access to resources will be restricted, and it may incur additional costs such as overexploitation of resources outside the protected area, as well as the costs of protected area management. Thus decisions over the management of coastal systems need to consider the various trade-offs inherent in alternative management practices (Brown et al. 2001).

Often the trade-offs are related to who has access to resources or who benefits from coastal development (Creel 2003). For ex-

Table 19.5. Drivers of Change in Coastal Ecosystems

Direct Drivers	Indirect Drivers
Habitat Loss or Conversion	
Coastal development (ports, urbanization, tourism-related development, industrial sites)	population growth, poor siting due to undervaluation, poorly developed industrial policy, tourism demand, environmental refugees and internal migration
Destructive fisheries (dynamite, cyanide, bottom trawling)	shift to market economies, demand for aquaria fish and live food fish, increasing competition in light of diminishing resources
Coastal deforestation (especially mangrove deforestation)	lack of alternative materials, increased competition, poor national policies
Mining (coral, sand, minerals, dredging)	lack of alternative materials, global commons perceptions
Civil engineering works	transport and energy demands, poor public policy, lack of knowledge about impacts and their costs
Environmental change brought about by war and conflict	increased competition for scarce resources, political instability, inequality in wealth distribution
Aquaculture-related habitat conversion	international demand for luxury items (including new markets), regional demand for food, demand for fishmeal in aquaculture and agriculture, decline in wild stocks or decreased access to fisheries (or inability to compete with larger-scale fisheries)
Habitat Degradation	
Eutrophication from land-based sources (agricultural waste, sewage, fertilizers)	urbanization, lack of sewage treatment or use of combined storm and sewer systems, unregulated agricultural development, loss of wetlands and other natural controls
Pollution: toxics and pathogens from land-based sources	lack of awareness, increasing pesticide and fertilizer use (especially as soil quality diminishes), unregulated industry
Pollution: dumping and dredge spoils	lack of alternative disposal methods, increased enforcement and stiffer penalties for land disposal, belief in unlimited assimilative capacities, waste as a commodity
Pollution: shipping-related	substandard shipping regulations, no investment in safety, policies promoting flags of convenience, increases in ship-based trade
Salinization of estuaries due to decreased freshwater inflow	demand for electricity and water, territorial disputes
Alien species invasions	lack of regulations on ballast discharge, increased aquaculture-related escapes, lack of international agreements on deliberate introductions
Climate change and sea level rise	insufficient controls on emissions, poorly planned development (vulnerable development), stressed ecosystems less able to cope
Overexploitation	
Directed take of low-value species at high volumes exceeding sustainable levels	population growth, demand for subsistence and market goods (food and medicinal), industrialization of fisheries, improved fish-finding technology, poor regional agreements, lack of enforcement, breakdown of traditional regulation systems, subsidies
Directed take for luxury markets (high value, low volume) exceeding sustainable levels	demand for specialty foods and medicines, aquarium fish, and curios; lack of awareness or concern about impacts; technological advances; commodification
Incidental take or bycatch	subsidies, bycatch has no cost
Directed take at commercial scales decreasing availability of resources for subsistence and artisanal use	marginalization of local peoples, breakdown of traditional social institutions

ample, conflicts frequently occur between large-scale commercial fisheries and small-scale (local) artisanal or subsistence fishing (see Chapter 18), or between tourism resort development and local communities who frequently receive little if any of the derived profits (nor even national economies in some instances). Zoning areas can reduce trade-offs and allow a suite of benefits to be derived from the same ecosystem, whether this occurs through smaller-scale marine protected areas (Brown et al. 2001; Villa et al. 2001) or through other coastal planning efforts such as those being installed throughout the Great Barrier Reef in Australia (Day 2002). Ocean zoning is also slowly becoming accepted as a problem-solving tool in much the same way that land use zoning evolved slowly (and simultaneously) in many regions of the world decades ago. Zoning plans and permitting procedures for development that is potentially environmentally harmful are most effective when taking into account the costs of losing the ecosystem processes and services that these areas provide (U.S. Oceans Commission 2004).

Environmental impact studies that take into account the full value of the most important coastal areas where ecological processes are concentrated help decision-makers understand and quantify the trade-offs to be made when coastal development, environmental degradation through waste discharge, or exploitation of coastal areas occurs (Bocksteal et al. 1989; Brown et al. 2001). However, such studies require the kind of detailed assessment information that is lacking in many coastal areas and countries.

Some choices, when made in concert with others, will have an exponentially larger impact on ecosystem services than merely the additive effect of individual choices (a synergetic effect). For instance, if a management authority authorizes the development of coastal hotels that do not have sewage treatment facilities and at the same time authorizes fisheries on reefs nearby, the combined effect of increased nutrient pollution and decreased abundances of grazing fishes leads to algal overgrowth of the reefs and, in extreme cases, a regime shift from coral reefs to algal reefs (Birkeland 2004; McManus et al. 2000). Recovery from such alternate states is very difficult to achieve—and since the alternate state (algal reef) may not be as attractive to tourists, the resort business may well falter (Moberg and Ronnback 2003). Thus decision-makers who weigh not only the immediate costs and benefits from development but also the longer-term ones make better and often economically more viable choices.

Long time frames are extremely important to keep in mind. Many of the impacts humans have on coastal systems are small-scale, but when these become chronic, the cumulative impact may be quite large. In coastal systems that are downstream of recipients of terrestrial environmental degradation and sites of more immediate and direct degradation, threats to ecosystem health are multiple and especially cumulative. In these cases, decisions about resource and space utilization that are viewed holistically, with the long term in mind, are likely to have better outcomes for society.

19.5.2 Management Interventions

The story of human impacts on coastal ecosystems is a complex one involving not only a large number of diverse drivers acting simultaneously but also cumulative effects over time. Unfortunately, effective responses to such impacts on natural systems have typically only emerged after changes have taken effect, and management of coastal areas remains largely reactive.

Complex problems require comprehensive solutions. Integrated management of watersheds, land use planning, and impact assessment are key to protecting coastal ecosystems (Sorenson 1997). For this reason, tackling the issues of loss and degradation of coastal areas by addressing single threats to these environments has not proved effective in the past. The holistic approach—looking at how human activities affect coastal ecosystems, identification of key threats, and implementation of management that is integrated across all sectors—is a relatively new focus and is likely to produce much more effective decision-making. Effective management of these crucial areas means coordinated pollution controls, development restrictions, fisheries management, and scientific research.

Resource use that is managed in a way that considers the impacts that resource removal has on all linked ecosystems and human well-being has proved to be more effective than sectoral or single-species management (Kay and Alder 2004). Fisheries management agencies and conservationists are promoting ecosystem-based fisheries management—management that looks at multispecies interactions and the entire chain of habitats these linked organisms need in order to survive and reproduce (Agardy 2002). Due to the linkages between marine fisheries production and coastal ecosystem condition, the protection of coastal habitats figures very prominently in ecosystem-based fisheries management (Pauly et al. 2002). However, truly holistic integrated management of coastal areas also requires complementary watershed management and land use planning to ensure that negative impacts do not reach coastal areas from outside the coastal realm.

Significant strides have been made in coastal management in the last few decades, in both the industrial and the developing world. Many of the world's 123 coastal countries have coastal management plans and legislation, and new governance arrangements and regulations are being developed every year (Burke et al. 2001). In 1993, it was estimated that there were 142 coastal management initiatives outside the United States and 20 international initiatives (Sorensen 1993). By 2000, there were a total of 447 initiatives globally, including 41 at the global level (Hildebrand and Sorensen 2001). This dramatic increase in activity was attributed both to initiatives that had started since 1993 and to the improved ability to find information on coastal management initiatives though the use of the Internet (Kay and Alder in press). The latest survey estimates that there are 698 coastal management initiatives operating in 145 nations or semi-sovereign states, including 76 at the international level (Sorensen 2002).

Yet even countries with well-developed coastal zone plans that have been in place for decades struggle with overexploitation of resources, user conflicts, habitat loss, and indirect degradation of ecosystems from activities occurring sometimes hundreds of kilometers away from the coastal zone itself. Management has not kept pace with degradation, as the number of management interventions worldwide has only increased two- or threefold over the last decade, while degradation of many habitats like coral reefs and mangroves has increased significantly more in the same time (Kay and Alder in press).

Some key coastal habitats such as mangrove forests, marshes, and seagrass meadows can be, and are being, restored once degraded. The science of mangrove restoration is relatively advanced, especially in the new world where natural species diversity is low and where replanting a few species can restore the ecosystems and most services quickly (Kaly and Jones 1998). Marshlands are also easily restored, as long as major alterations to hydrology have not taken place. Such restoration initiatives are risky, however, since it has yet to be shown that the full range of ecosystem services can be supported by artificially reconstructed wetlands (Moberg and Ronnback 2003; NRC 1992). Coral reef transplantation, though technologically possible, can only be practiced at a small scale and has had limited success (Moberg and Ronnback 2003). Furthermore, the costs of such restoration can be enormous, as the \$7.8-billion price tag for the restoration of the Everglades cord grass system in Florida in the United States attests. In fact, most full-scale restoration (habitat reconstruction) is practiced in highly industrialized countries that are able to finance the high costs over the long time frames needed.

Management interventions to deal with pollution in coastal areas have largely failed. One method of mitigation is to conserve, reconstruct, or construct new wetlands that act as filters of these pollutants before the compounds enter the coastal environment. Another is to encourage land use practices such as buffer strips in agriculture and forestry to prevent the runoff of fertilizers, sediments, and so on. Municipal waste and storm runoff is sometimes controlled to limit hydrocarbons and other toxic inputs, and regulations regarding dredging operations help control the release of pollutants deposited into coastal sediments. However, no country has succeeded in comprehensively limiting pollution of the near-shore environment, despite the large number of initiatives and regulations in place.

One reason for these failures is that neither the status of coastal habitats nor the full values of coastal systems are known in many parts of the world. Effective management of coastal systems and the evaluation of trade-offs and choices requires both information and awareness. Education plays a key role in supplying both, and although education about ecology has generally improved in recent decades, education on marine systems is underfunded and underdeveloped (Kay and Alder in press). Further applied multidisciplinary research on ecosystem function, sustainable yields, and economic valuation of coastal ecosystems is also needed (Lubchenco 1998). Research focused on fundamental questions about ecosystem function, impacts, and efficacy of management measures will aid decision-makers in mitigating loss and degradation of these habitats. Fully protected areas help in this regard because they provide crucial control sites to test management interventions and allow for baseline monitoring. Better economic valuations—particularly quantitative estimates of marginal benefits—are also required to understand fully the importance of coastal systems.

Individual sites are sometimes recognized for their valuable services, and management interventions are put in place to conserve these habitats and the species within them through marine protected areas (NRC 2001). These may be small fisheries reserves in which resource extraction is prohibited, or they may occur in the context of larger multiple-use areas. Increasingly, marine protected areas are being established in networks in order to safeguard key areas of the coastal and marine environment over a geographically large area (Agardy 1999; Murray et al. 1999a; Pauly et al. 2002). A prime example of this is the network of reserves encompassed by the newly rezoned Great Barrier Reef Marine Park in Australia (Day 2002).

In order for marine protected areas to succeed in meeting the objectives of conserving habitats and protecting fisheries and biodiversity, their management seeks to address all the direct threats to marine and coastal areas. In most habitats, these threats are multiple and cumulative over time. Thus protected areas that address only one of these threats will usually fail to conserve the ecosystem or habitats and the services they provide (Agardy 1997).

Marine and coastal protected areas already dot coasts around the world, and the number of protected areas continues to increase. The last official count of coastal and marine protected areas, in 2003, yielded 4,116 (Spalding et al. 2003), a marked increase over the 1,308 listed in 1995 (Kelleher et al. 1995), though this is a significant underestimate because unconventional protected areas that do not fit the IUCN categories for protected areas are typically not counted.

By far the bulk of these protected areas occur in coastal zones, and many include both terrestrial and aquatic components. However, even with the large number of individual sites, coverage accounts for less than 1% of the world's oceans. Many marine protected areas occur in relatively close proximity to human settlements—in fact, nearly 10% of the world lives within 50 kilometers of a marine protected area, and over 25% of the worldwide coastal population lives within 50 kilometers of one. (See Table 19.6.)

Management effectiveness of most marine protected areas remains questionable, and many of these areas have no operational management or enforced legislation at all. It is *well established* that marine protected area tools are not being used to their fullest potential anywhere in the world (Agardy et al. 2003). Nonetheless, there are good examples of effective marine management, such as the Great Barrier Reef Marine Park. And examples such as this highlight how even a protected area that begins with relatively modest protection measures can be strengthened over time (Lawrence et al. 2002).

Table 19.6. Share of World and Coastal Populations Living Close to a Coastal Marine Protected Area

Category	Within 50 Kilometers of MPA	Within 100 Kilometers of MPA	Within 150 Kilometers of MPA
		(percent)	
World population	9	19	26
Coastal population	25	51	70

Tenure of marine areas and some forms of traditional use can also be effective coastal conservation interventions, even when these patterns of sustainable use of marine and coastal resources occur outside of conventional protected areas (Curran and Agardy 2002; Young 2004). Common property and common property management regimes have evolved in many coastal communities and have in some cases been shown to be much more effective than conventional, top-down methods in keeping resource use to sustainable limits (Agardy 1997; Curran and Agardy 2002). Legitimizing such traditional uses remains an issue in many coastal countries, and recently nongovernmental organizations have begun to liaise with governments to help codify use rights for local communities.

An analysis of the efficacy of coastal and marine protected areas, sustainable traditional use regimes, and common property management regimes highlights the fact that all such local action must be supplemented by effective management at much larger scales (Agardy 1999). Indeed, the interlinkages between terrestrial environments, fresh water, coastal systems, and the marine realm prevent local interventions from succeeding unless the larger context is addressed. Coastal zone management at the provincial, state, or national level can help scale up management efforts, as can zoning initiatives (Norse in press). Coastal management is a particularly important facet of national policy-making, as most coastal zones exist wholly within the exclusive economic zones of individual nations (Sorenson 1997).

A relatively recent movement in this direction is the coupling of coastal zone management with catchment basin or watershed management, as has occurred under the European Water Framework Directive and projects undertaken under the LOICZ (Land–Sea Interactions in the Coastal Zone) initiative. Such freshwater–marine system coupling has resulted in lower pollutant loads and improved conditions in estuaries. However, due to the fluid nature of the marine system and the large-scale interconnectivities, even larger-scale integrated management initiatives are required for effective management of coastal and marine systems over the long term.

Several international instruments provide a framework for such larger-scale regional cooperation, including the United Nations Convention on the Law of the Sea (UNCLOS 1982), U.N. Regional Seas Conventions and Action Plans, the Global Programme of Action for the Protection of the Marine Environment from Land-based Activities (GPA 1995), the Jakarta Mandate on the Conservation and Sustainable Use of Marine and Coastal Biological Diversity (CBD 1995), the RAMSAR Convention, Chapter 17 of *Agenda 21* (UNCED 1992), and Paragraph 29 of the Implementation Plan of the World Summit on Sustainable Development (WSSD 2002). While some of these international agreements pertain more directly to marine systems (as discussed in Chapter 18), all carry obligations or give guidance to parties on management of coastal areas. Yet while many international agreements and policies promote the idea of ecosystem-based management, the practical application of the concept is still being developed.

Global treaties and multilateral agreements can bridge some of the gaps that occur between small-scale interventions on the ground and large-scale coastal problems, but most of these international instruments have not been effective in reversing environmental degradation (Speth 2004). For shared coastal and marine resources, it may well be that regional agreements will prove more effective, especially when such agreements capitalize on better understandings of costs and benefits accruing from shared responsibilities in conserving the marine environment.

Large marine ecosystems have been put forward as a logical way to frame such agreements (Duda and Sherman 2002; Kimball 2001). Each of the world's 64 LMEs averages 200,000 square kilometers and is characterized by distinct bathymetry, hydrology, productivity, and trophically dependent populations (Sherman 1993). The LME concept was originally applied in the fisheries context under CCAMLR to take into account predator/prey relationships and environmental factors affecting target stocks; thus Antarctica was the site of the first truly ecosystem-based approach to fisheries management (Griffis and Kimball 1996). Several recent international instruments refer to LMEs, and the geographic units serve as the basis for some global assessments, such as GIWA (UNEP's Global International Waters Assessment). In many parts of the world, however, the political constituency for nations to cooperate to conserve large-scale ecosystems is lacking, though this situation may well be improving (Wang 2004).

Coastal ecosystems are crucial elements of the global environment, supporting not only marine food webs but also providing key services for humankind. To stave off the dramatic losses in coastal habitats that are now occurring worldwide, valuing these habitats and communicating their value to the public is crucial. And because in many parts of the world migration dramatically undermines regulation of coastal resource use, migration patterns and the drivers behind them merit investigation to provide the foundation for migration policies. Coastal systems are so complex, and the impacts humans have on them so varied, that coastal ecosystem services will only be successfully protected when the entire spectrum of threats and integrated responses to them are addressed. As human dependence on coastal services grows, management will continue to be challenged to manage the coastal environment more effectively.

19.6 Coastal Systems and Human Well-being

The coastal systems of the world are crucially important to humankind and are under ever-increasing threat from activities within and outside the coastal zone. Provisioning, regulating, supporting and cultural services have all been affected by human use and indirect impacts on coastal habitats, and some habitat types are close to being degraded to the point that important services will be lost altogether. Diminishing services caused by poor choices threaten the well-being of not only coastal communities, but coastal nations and the global community as well.

Many of these impacts affect rural communities in developing nations, especially where livelihoods are closely tied to availability of coastal resources. However, coastal degradation affects people in industrial countries as well, and has an impact on suburban and urban human well-being. For instance, according to a new study by the European Commission, a fifth of the coastline of the newly enlarged European Union is eroding away from human-induced causes, in a few cases as much as 15 meters (49 feet) shoreline erosion inland a year (European Commission 2004). Such erosion threatens homes, roads, and urban infrastructure and the safety of individuals, as well as affecting biodiversity.

Resource overexploitation and coastal degradation undermine subsistence use of coastal ecosystems. Small rural populations are not the only ones to suffer from overexploitation and mismanagement, however—national economies are affected as well. For instance, potential net benefit streams from coral reefs include fisheries, coastal protection, tourism, and biodiversity values are estimated to total $29.8 billion annually (Cesar et al. 2003). Much of these revenues are at risk from ever-accelerating rates of coastal degradation. When the negative impacts from overfishing are coupled with inadequate environmental management that allows increases in pollutant levels and stresses coral reef health, the consequences can be a full-fledged ecosystem collapse or regime shifts to alternate (and less desirable) states (Birkeland 1997).

Many coastal communities, especially in poorer developing countries, are trapped in what has been called "a vicious cycle of poverty, resource depletion and further impoverishment" (Cesar et al. 2003). As in many other coastal and marine ecosystems, marginalization of fishers is largely responsible for "Malthusian" or exponentially increasing rates of overfishing (Pauly 1997). This phenomenon is not unique to coral reefs, of course, but once coral reefs are destroyed, restoration is extremely difficult, and the costs brought about by loss of services such as coastal protection continue to be incurred for long periods thereafter (Moberg and Ronnback 2003).

Pollution puts coastal inhabitants at great risk—directly, by affecting human health, and indirectly, by degrading the resource base on which many of them depend. Poor sanitation affects not only slum dwellers. For instance, South Asian waters are highly polluted throughout the region, partly as a result of 825 million people who live without basic sanitation services (UN System-Wide Earthwatch, cited in Creel 2003). Pathogens are spread more quickly and reach greater numbers of people in coastal ecosystems that have become degraded. Chronic exposure to heavy metals and other bioaccumulating pollutants may not cause death in large numbers of people, but their cumulative effect can lead to reproductive failure and significantly decreased well-being. Food security is also greatly compromised in degraded coastal ecosystems.

Yet even when people are made aware of the importance of coastal ecosystems, they still may not be able to stop the kinds of activities that destroy or degrade these areas unless alternative resources or livelihoods are made available to them. For instance, boat-builders of the coastal and island communities of East Africa have little choice but to harvest mangrove for boat construction from key nursery habitats, which support the very fisheries on which their boat-building industry is based (Agardy 1997). Few alternative materials for boat building exist, except when conservation projects have expressly built in alternatives and training on how to use them. In areas in which resource extraction is moving beyond ecologically sustainable limits or the removal of the resource causes major physical changes to the habitat, the search for alternatives is particularly crucial.

A "business as usual" approach is projected to lead to continued loss of habitats and species, with attendant changes to ecosystem services and negative impacts on many coastal-dependent industries and coastal communities. Degradation will result in future choices of either accepting loss of ecosystem services or investing in costly restoration programs that are not guaranteed to reinstate the full range of services. Connectivity of systems and the large spatial scale of impacts will mean that local-scale or site-specific conservation and management investments will be increasingly at risk as overall coastal and marine conditions deteriorate. Changes in species distribution and abundance in response to climate change, resource use, and pollution may render many protected areas ineffective.

Yet enough is known to change the current approach and begin to systematically develop strategic plans for more effective protection and more sustainable use of coastal ecosystems (Kay and Alder, in press). Coastal areas could be zoned to allow appropriate uses in various areas, reduce user conflicts, and limit the impacts of detrimental trade-offs. Marine protected areas could well serve as starting points for such zoning measures, as well as acting as small-scale models for integrating coastal and marine management across all sectors (Agardy 2002).

In all parts of the world, it will be crucial to find ways to involve local communities in planning management interventions and zoning schemes in order to better safeguard resources, coastal areas, and human well-being. At the same time, ecological linkages between systems must be maintained in order to continue the delivery of services. Effective management for sustainable use of coastal systems will best be achieved by applying an ecosystem-based, whole-catchment approach that addresses land use upstream and the use of marine resources far out to sea. Multilateral, regional initiatives and agreements could help foster an integrated and comprehensive approach and may well lessen the costs of management through economies of scale. Regional cooperation schemes would facilitate a scaling up of management interventions that have to date been on too small a scale, and thereby help abate declines in coastal services and related human well-being.

Main Messages

Inland water habitats and species are in worse condition than those of forest, grassland, or coastal systems (*medium certainty*). It is *speculated* that 50% of inland water habitats were lost during the twentieth century. It is *well established* that for many ecosystem services, the capacity of inland water systems to produce these services is in decline and is as bad as or worse than that of other systems. More than 50% of inland waters (excluding lakes and rivers) have been lost in parts of North America, Europe, and Australia, but on a global scale there is insufficient information on the extent of specific inland water habitats, especially those of a seasonal or intermittent nature, to substantiate the extent of habitat loss.

In addition to the loss of inland water systems, degradation is widespread. As with habitat loss, it has not, on the whole, been possible to quantify this with great confidence at a continental scale, although many site-specific instances have been well documented. The species biodiversity of inland waters is among the most threatened of all ecosystems, and in many parts of the world it is in continuing and accelerating decline. Global climate change is expected to exacerbate the loss and degradation of many inland water systems and the loss or decline of their species; however, projections about the extent of such loss and degradation or decline are not yet well established.

The loss and degradation of inland water systems have been driven directly by many pressures, acting individually and synergistically or cumulatively. The direct drivers of loss and degradation of inland waters are well known and documented and include changes in land use or cover due to vegetation clearance, drainage, and infilling, especially connected to expansion of agriculture; the spread of infrastructure, whether for urban, tourism and recreation, aquaculture, agriculture, or industrial purposes; the introduction and spread of invasive species; hydrologic modification; overharvesting, particularly through fishing and hunting; pollution, salinization, and eutrophication; and global climate change, which is expected (*high certainty*) to lead to even further degradation and to exacerbate existing pressures. While it is known that cumulative and synergistic effects between multiple pressures occur, there is insufficient quantitative analysis to readily tease out the relative individual and combined effects and their importance.

Agricultural development has historically been the principal cause of the loss of inland water systems worldwide (*high certainty*). It is estimated that by 1985, 56–65% of suitable inland water systems had been drained for intensive agriculture in Europe and North America, 27% in Asia, and 6% in South America. The construction of dams and other structures along rivers has resulted in fragmentation and flow regulation of almost 60% of the large river systems in the world. In many countries, the construction of large dams is still a controversial issue. Water pollution and eutrophication are widespread and in many countries have led to the degradation of many inland water systems. In addition to direct adverse effects on biodiversity, pollution has reduced the capacity of inland waters to filter and assimilate waste. Threats of water quality degradation are most severe in areas where water is scarce (dryland systems). Toxic substances and artificial chemicals are increasingly being released into waterways, with uncertainty about their long-term effects on ecosystems and humans. In recent years the devastation caused by invasive species has been increasingly recognized worldwide.

The decline of inland water systems has placed the ecosystem services derived from these systems and human well-being at increasing risk. Provisioning services from inland waters, such as fish, are essential for human well-being, with estimates of more than 50 million people involved directly in inland fisheries. At present almost 50% of the world depends on rice as a staple food item; this is expected to increase, and by 2020 some 4 billion people will depend on rice. Supporting and regulating services are critical to sustaining vital ecosystem functions.

Flow regulation within and between inland waters and links between surface and groundwater are critical ecosystem services that have been degraded on a global scale. The disruption of natural flooding regimes has devastated many riverine habitats and led to decreased sediment transport and a loss of flood buffering and nutrient retention. Flooding can cause severe hardship to humans, with the 1998 floods in China causing an estimated $20 billion worth of damage, but it is also essential for maintaining sediment-based fertility of floodplains and supporting fish stocks in large rivers.

In addition, inland waters have significant aesthetic, artistic, educational, cultural, and spiritual values, and they provide invaluable opportunities for recreation by many communities and, increasingly, for tourism. The economic value of these services is known for many local habitats but not necessarily well quantified economically nor recognized by policy-makers and given priority within resource development and conservation agencies in most countries.

Trade-offs between services from inland waters have been considerable, yet poorly considered. Alteration of rivers through infrastructure has improved transportation, provided flood control and hydropower, and boosted agricultural output by making more land and irrigation water available. At the same time, rivers have been disconnected from their floodplains and other inland water habitats, water velocity in riverine systems has decreased, in some places rivers have been converted to a chain of connected reservoirs, and groundwater recharge has been reduced. In other places, infrastructure has increased the likelihood of flooding by diverting water and increasing flows. These changes have, in turn, affected the migratory patterns of fish species and the composition of riparian habitat, opened up paths for exotic species, changed coastal ecosystems, and contributed to an overall loss of freshwater biodiversity and inland fishery resources. Irrigation has led to increased food production in drylands but in many cases is unsustainable without extensive public capital investment as waterlogging and pollution (especially eutrophication and salinization) degrade the system and other services and encourage the introduction or spread of human disease vectors.

The assessment of the extent and change of inland water systems at a continental level is compromised by the inconsistency and unreliability of data (*high certainty*). Estimates of the extent of inland water systems vary from 530 million to 1,280 million hectares. The extent and distribution of inland waters is unevenly or even poorly known at the global and regional scales, partly due to confusion over definitions as well as difficulties in delineating and mapping habitats with variable boundaries as a result of fluctuations in water levels. Larger wetlands, lakes, and inland seas have been mapped along with major rivers; there are some 10,000 lakes that are over 1 square kilometer, and peatlands are estimated to cover more than 400 million hectares. Smaller habitats that are critical for many communities are not well mapped or delineated.

On the whole, available information focuses on the broader regional or global scales. This introduces uncertainty into many assessments and necessitates caution when attempting to make comparisons between data sets, especially when collected at different spatial scales. Innovative tools for effective assessment of the status and trends of inland water systems and their species, especially in those parts of the world where data are lacking, inadequate, or in need of updating, are required.

20.1 Introduction

Inland water systems encompass habitats such as lakes and rivers, marshes, swamps and floodplains, small streams, ponds, and cave waters. These have a variety of biological, physical, and chemical characteristics. As coastal wetlands (such as estuaries, mangroves, mudflats, and reefs) are considered in Chapter 19, the broad definition of wetland adopted by the Convention on Wetlands in 1971, which includes inland, coastal, and marine habitats, is not used in this chapter. All inland aquatic habitats, however—whether fresh, brackish, or saline—as well as inland seas are considered.

As there is no clear boundary between inland and coastal ecosystems, this delineation is indicative only and is not strictly applied where there are strong interactions between the biodiversity, services, and pressures that affect inter-connected habitats. Rice fields, aquaculture ponds, and reservoirs are included in this chapter's analysis. The supply of fresh water and its regulation, both in terms of water quality and flow, are considered in Chapters 7, 15, and 16. Groundwater as a system is addressed here, recognizing that important links occur with many surface-water habitats.

This chapter provides a brief description of the services provided by inland waters, together with the condition and trends of their habitats and species. More detailed information on the specific services derived from inland waters (such as water supply and waste processing) is found in other Chapters. Where information is available, the drivers of change in the condition of these habitats and their species are related to the condition of the services and any subsequent effects on human well-being. Trade-offs and responses to changes in the habitats and species are also presented (with further information being provided in the MA *Policy Responses* volume).

Inland water systems have a temporal dimension—varying from perennial to ephemeral—and a dynamic dimension, including flowing systems (rivers), standing waters (lakes and ponds), and systems with at times large seasonal fluctuations in water depth—with some being waterlogged and others flooded permanently, seasonally, intermittently, or even episodically. The term wetland is often used to define all inland aquatic systems, such as lakes, rivers, or lagoons. At other times it is used to describe a narrower group of habitats that represent a variety of shallow, vegetated systems, such as bogs, marshes, swamps, and floodplains. Extensive information on wetland definition and delineation is available (e.g. Finlayson and van der Valk 1995; Mitsch et al. 1994), but the failure to consider fully the different dimensions and definitions that have been used around the world has resulted in confusion and inaccurate analyses on the extent and condition of these systems (Finlayson and Spiers 1999). In this chapter, the terms ''inland water systems'' or ''inland waters'' are used wherever possible unless specific habitat types are unambiguously referred to in the source material.

The extent and distribution of inland waters is poorly and unevenly known at the global and regional scales due to differences in definitions as well as difficulties in delineating and mapping habitats with variable boundaries due to fluctuations in water levels (Finlayson et al. 1999). In many cases, comprehensive documentation at the regional or national levels also does not exist. The larger habitats, such as lakes and inland seas, have been mapped along with the major rivers, but for many parts of the world smaller wetlands are not well mapped or delineated. As a consequence, assessment of the extent of and change in inland water habitats at the continental level is compromised by the inconsistency and unreliability of the data. The most recent attempt to ascertain the extent and distribution of inland water systems (Lehner and Döll 2004) is shown in Figure 20.1 (in Appendix A). As with previous estimates, these data contain many inaccuracies and gaps. For example, intermittently inundated habitats are not included, and there are many inaccuracies because of problems of scale and resolution.

20.2 Services Derived from Inland Water Systems

With the exception of the provision of fresh water, comprehensive global analyses of services provided by inland waters have not been undertaken, nor has the link between the condition and trend of the biodiversity, including habitats, and the provision of ecosystem services been strongly made at this scale. As such, the knowledge base of the true value of inland water systems is poorly known (see, e.g., Finlayson et al. 1999; Tockner and Stanford 2002; Malmqyist and Rundle 2002). Assessments of inland waters have not always considered inland saline waters, which are particularly widespread and important in many arid regions of the world.

A generalized list of services provided by or derived from inland waters has been compiled from a number of sources. (See Table 20.1.) The value of these services has been estimated at

Table 20.1. Ecosystem Services Provided by or Derived from Inland Water Systems

Services	Comments and Examples
Provisioning	
Food	production of fish, wild game, fruits, grains, etc.
Freshwater[a]	storage and retention of water for domestic, industrial, and agricultural use
Fiber and fuel	production of logs, fuelwood, peat, fodder
Biochemical	extraction of materials from biota
Genetic materials	medicine, genes for resistance to plant pathogens, ornamental species, etc.
Biodiversity	species and gene pool
Regulating	
Climate regulation	greenhouse gases, temperature, precipitation, and other climatic processes; chemical composition of the atmosphere
Hydrological flows	groundwater recharge and discharge; storage of water for agriculture or industry
Pollution control and detoxification	retention, recovery, and removal of excess nutrients and pollutants
Erosion	retention of soils
Natural hazards	flood control, storm protection
Cultural	
Spiritual and inspirational	personal feelings and well-being
Recreational	opportunities for recreational activities
Aesthetic	appreciation of natural features
Educational	opportunities for formal and informal education and training
Supporting	
Soil formation	sediment retention and accumulation of organic matter
Nutrient cycling	storage, recycling, processing, and acquisition of nutrients
Pollination	support for pollinators

[a] See also Chapter 7 for commentary on how this is variously considered a provisioning or regulating service.

$2–5 trillion annually (Costanza et al. 1997; Postel and Carpenter 1997). This wide range represents major differences in methods, reliability, and accuracy of the economic data and differences in the definition and area of habitats being assessed. Despite ongoing discussion about methods and data quality, it is *well established* that these systems are highly valued and extremely important for people in many parts of the world. It is *speculated,* but not well documented globally, that the loss and degradation of inland water systems has resulted in an immense loss of services.

As Chapter 7 deals solely with the critical service of the provision of fresh water, this service is not considered further here. Other chapters that contain information on services provided by or derived from inland water systems include those on food (Chapter 8), nutrient cycling (Chapter 12), waste processing and detoxification (Chapter 15), regulation of natural hazards (Chapter 16), cultural and amenity services (Chapter 17), and cultivated systems (Chapter 26).

Table 20.2 contains a summary of estimates for the global average value of services derived from or provided by inland and coastal water systems (referred to generically as wetlands in the source documents). The figures presented are average global values based on sustainable use levels and taken from two synthesis studies—Schuyt and Brander (2004), calibrated for the year 2000, and Costanza et al. (1997), calibrated for 1994—that together cover more than 200 case studies. Most of the data are derived from Schuyt and Brander (2004), except for the aesthetic information service and climate regulation. The total economic value of 63 million hectares of wetland around the world would, according to this data, amount to about $200 billion a year (which is a conservative estimate, since for many services no economic data were available). Costanza et al. (1997) arrived at a figure of $940 billion, mainly due to higher estimates for several services (flood control at $4,539 per hectare per year, for example, water treatment at $4,177 per hectare, and water supply at $3,800 per hectare).

Table 20.2. Total Economic Value of Ecosystem Services Provided by Wetlands (Costanza et al. 1997; Schuyt and Brander 2004)

	Average Value *(dollars per hectare per year)*
Provisioning services *(products obtained from wetlands)*	**601**
Fishing	374
Hunting	123
Water supply	45
Raw materials (thatch, timber, fodder, fertilizer, etc.)	45
Fuelwood	14
Other (genetic, medicinal, and ornamental resources)	?
Cultural services *(nonmaterial benefits obtained from wetlands)*	**1,373**
Aesthetic information	881
Recreation and tourism	492
Other (e.g., artistic, spiritual, historic, or scientific information)	?
Regulating services *(benefits obtained from ecosystem processes)*	**1,086**
Flood control/water regulation	464
Water treatment	288
Nursery function	201
Climate regulation	133
Other (e.g., sediment control, biological control)	?
Supporting services *(ecosystem functions necessary to maintain all other services)*	**214**
Habitat/refugia for biodiversity	214
Other (e.g., primary products, soil formation, nutrient/biogeochemical cycling)	?
Total value	**3,274**

Despite such figures becoming available, the importance of services derived from inland waters (such as fresh water, fish, and groundwater recharge) is often taken for granted or treated as a common good, with the real value only being recognized after the services have been degraded or lost. This is demonstrated particularly well in semiarid and arid regions, with Lake Chad in western Africa being very illustrative, as it has a multiplicity of valuable services (see Table 20.3), which are mostly in decline. This situation is common globally, particularly where population pressures are high and services have been overexploited or inland water systems have been inappropriately managed.

In addition, while the value of particular services may be low in terms of global economic analyses, it can be extremely high locally. This is evident in the preliminary analyses undertaken in 10 inland water systems in the Zambezi in southern Africa, where multiple services—including subsistence agricultural crops, fish production, natural products, and livestock grazing—were estimated to be worth $123 million per year (Seyam et al. 2001). Such analyses (other examples in Lupi et al. 2002; Emerton et al. 1998) are fraught with assumptions, but they do illustrate the relative worth of the main services to local populations.

An analysis of global ecosystems has established with some confidence that for a standardized set of services, the capacity of inland water habitats (referred to as freshwater habitats in the source material) to produce these services is in decline and is as bad as or worse than the other systems considered (Revenga et al. 2000; WRI et al. 2000). (See Figure 20.2 in Appendix A.) This conclusion has been supported by global analyses of the condition of inland water systems, such as those undertaken for large lakes and inland seas (Beeton 2002), flowing waters (Malmqvist and Rundle 2002), floodplains (Tockner and Stanford 2002), temperate freshwater wetlands (Brinson and Ines Malvarez 2002), tropical wetlands (Junk 2002), and salt lakes (Williams 2002).

20.2.1 Hydrological Regulation

It is well recognized that some inland waters serve as important storage sites, accumulating water during wet periods and providing a reserve of water during dry periods by maintaining base flow in adjacent rivers (e.g., Revenga et al. 2000; Malmqvist and Rundle 2002). Similarly, it is increasingly known that some inland waters, such as lakes and marshes, attenuate floods by retaining water or storing it in the soil and therefore reducing the need for engineered flood control infrastructure (Abramovitz 1996). While it has been known for many years that aquatic vegetation attenuates surface flows, the considerable value of this service is not often widely and accurately assessed in economic terms. (See Chapter 16.) In contrast, figures on the cost of flood damage are readily available after this function has been lost or seriously eroded by unsustainable development; for example, the 1998 flash floods in China caused an estimated economic loss of $20 billion (Qu 1999).

While the damage caused by floods is often discussed, it must also be recognized that natural floods provide an essential service

Table 20.3. Change in Ecosystem Services Derived from Lake Chad (White et al. 2004)

Ecosystem Service	Services in Lake Chad	Change in Services	Trend
Provisioning services			
Food – plant crops	rice, maize, cowpeas, wheat, cotton, millet, groundnuts, cassava	increase in production of food crops	up
Food – aquatic plants	spirulina for commercial production	loss of commercial plant production	down
Food – fish	harvesting for local diet and for trade	less fish for food and for trade	down
Food – milk	milk from livestock	decrease in milk available from Kuri population	down
Food – meat	meat from cattle	decrease in meat available from Kuri population	down
Fuel – wood	timber and fuelwood from floodplain forests	recession of floodplain and drying out of habitat for floodplain forests	down
Genetic resources	laboratory for genetic studies on endemic livestock breeds	decrease in availability of genetic material	down
Biochemicals	mineral resources used as salt and in preparation of soap and medicines	less deposition of mineral-contributing production of trade goods	down
Fresh water – surface water	water for domestic and agricultural use	decrease in volume and surface area	down
Fresh water – groundwater	groundwater recharge provides water supply	decrease in groundwater recharge	down
Regulating services			
Climate regulation	precipitation and temperature control	decrease in precipitation	down
Water regulation	seasonal fluctuations replenish farmland and feeding areas for fish	less replenishing of farmland for crops and fish feeding areas	down
Erosion control	aquatic vegetation holds sediment	less erosion control	down
Water purification	suspended solids reduced as water spreads across floodplain	increase in deposition of suspended solids	down
Storm protection	holds storm water, provides flood control	less flood protection	down
Cultural services			
Cultural diversity	permanent residents and seasonal herders	loss of cultural diversity	down
Spiritual/religious values	locally grown spirulina used as a treatment to ward off sorcerers	less growth of algae used in traditional treatment	down
Knowledge systems	traditional village-based systems of fisheries management	breakdown of village systems without fish resource base	down
Cultural heritage values	historical cultural landmarks of ancient Sao people	possibly no change	stable
Recreation	habitat for game species, local hunting reserve	fewer game species	down
Supporting services			
Soil formation	retains sediment, adding to islands, banks, polders	less soil formation and island/bank-building	down
Nutrient formation	fertile soil from alluvial deposits	less nutrient cycling with seasonal water fluctuations	down
Primary production	abundant aquatic vegetation for wildlife	less aquatic vegetation; more grazing habitat for domestic livestock	mixed
Habitat	habitat for endemic cattle, rich avifauna, endemic fish, diverse mammals	less habitat for domestic and wild aquatic species	down

to millions of people. For example, the livelihoods of many people depend on floods to replenish the soil and nutrients of the floodplains used in flood-recession agriculture and for grazing and to clean and renew streams and sandbanks to permit fish passage for migration and the enhancement of fish production, as on the Pongolo floodplain in southern Africa (Heeg and Breen 1982). Floods also replenish sediment in coastal areas. Despite a lack of reliable quantitative evaluations, the importance of hydrological regulation by inland water systems is widely recognized around the world (Mitsch and Gosselink 2000).

20.2.2 Sediment Retention and Water Purification

Over the past few decades the valuable role that plants and substrates play in many inland waters by trapping sediments, nutrients, and pollutants has been *well established* (see Chapter 15) and is illustrated in many analyses (see reviews of the condition of inland water systems cited earlier). Wide-scale vegetation clearing has caused erosion to increase, filling many shallow water bodies with sediment and disrupting the transport of sediment to coastal areas. Excessive amounts of sedimentation due to land disturbance are a global problem and have severely degraded many coastal-marine habitats, especially coral reefs close to shore. (See Chapter 19.) It is speculated that soil retention in inland waters would have ameliorated the impacts of excess sedimentation on coastal systems.

In addition to retaining sediments, the vegetation in some inland water systems, such as lakes and swamps, can remove high levels of nutrients, especially phosphorus and nitrogen, commonly associated with agricultural runoff, which could otherwise result in eutrophication of receiving ground, surface, and coastal waters. (See Chapter 12.) For example, cypress swamps in Florida in the United States can remove 98% of the nitrogen and 97% of the phosphorus that would otherwise have entered the groundwater (Brown 1981), and vegetation along the edge of Lake Victoria, East Africa, was found to have a phosphorus retention of 60–92% (Arcadis Euroconsult 2001). Inland water systems can also export nutrients, and although the general conditions under which these systems retain or export nutrients are known (e.g., Richardson and Vepraskas 2001; Mitsch and Gosselink 2000), they are often not investigated sufficiently on a site-specific basis.

The capacity of many wetland plants to remove pollutants derived from chemical or industrial discharges and mining activities is *well established* and increasingly used as a passive treatment process. (See Chapters 10 and 15.) The floating water hyacinth (*Eichhornia crassipes*) and large emergent species (such as some *Typha* and *Phragmites* species), for example, have been used to treat effluents from mining areas that contain high concentrations of heavy metals such as cadmium, zinc, mercury, nickel, copper, and vanadium. In West Bengal, India, water hyacinth is used to remove heavy metals, while other aquatic plants remove grease and oil, enabling members of a fishing cooperative to harvest one ton of fish a day from ponds that receive 23 million liters of polluted water daily from both industrial and domestic sources (Pye-Smith 1995). In another example, the Nakivubo papyrus swamp in Uganda receives semi-treated effluent from the Kampala sewage works and highly polluted storm water from the city and its suburbs. It has been established that during the passage of the effluent through the swamp, sewage is absorbed and the concentrations of pollutants are considerably reduced, at an estimated value of $2,220–3,800 per hectare per year (Emerton et al. 1998). These examples are indicative of the extremely important role that these habitats can play in removing pollutants from wastewater effluents.

It is also *well established* that not all inland water systems can assimilate all types and amounts of waste. Excessive loads of domestic sewage or industrial effluent can degrade inland water systems, with a consequent loss of biota and services. (See Chapter 15.) The environmental problems associated with waste from mining operations are a good example of the limited waste-processing capacity of these ecosystems. Recent examples of this problem include the failures of engineered waste containment structures, as occurred in 1999 in southern Spain, where more than 5 million cubic meters of heavy metal-laden sludge flowed into the Guadiamar River and part of the Coto Doñana wetlands (Bartolome and Vega 2002), and the discharge in 2000 of 100,000 cubic meters of cyanide and heavy metal-contaminated wastewater from the Baia Mare mine in Romania, which affected the Tisza, Szamos, and Danube Rivers (WWF 2002). In both these cases, species and ecosystem services from wetlands were severely affected by the excessive and toxic waste loads (Bartolome and Vega 2002; WWF 2002).

20.2.3 Recharge/Discharge of Groundwater

The issues of groundwater supply, use, and quality have received far less attention around the world than surface waters, even in industrial countries. Our understanding of groundwater resources is more limited as sufficient data, such as covering groundwater discharge/recharge and aquifer properties, for global applications are only beginning to be synthesized (Foster and Chilton 2003; UNESCO-IHP 2004). While many wetlands exist because they overlie impermeable soils or rocks and there is, therefore, little or no interaction with groundwater, numerous wetlands are fed largely by groundwater, and recharge of the aquifer occurs during flooding periods. It is well known though that many groundwater resources are vulnerable to a variety of threats, including overuse and contamination. (See Chapter 7.)

The importance of groundwater for human well-being is *well established*; between 1.5 billion (UNEP 1996) and 3 billion people (UN/WWAP 2003) depend on groundwater supplies for drinking. It also serves as the source water for 40% of industrial use and 20% of irrigation (UN/WWAP 2003). Many people in rural areas depend entirely on groundwater.

Because of unsustainable withdrawals, parts of India, China, West Asia, the former Soviet Union, the western United States, and the Arabian Peninsula, among other regions, are experiencing declining water tables, limiting the amount of water that can be used and raising the costs of getting access to it (Postel 1997; UNEP 1999). Overpumping of groundwater can lead to land subsidence, as has been recorded in megacities such as Mexico City, Manila, Bangkok, and Beijing (Foster et al. 1998). In coastal areas, lowering water tables can cause the underground intrusion of saline water, rendering these freshwater sources unusable for human consumption. In 9 of 11 European countries, for example, especially along the Mediterranean coast, where groundwater over-exploitation is reported, saltwater intrusion has become a serious problem. The main cause is groundwater overabstraction for public water supply (EEA 2003).

A common outcome of groundwater overabstraction is dryland salinization, which renders the soil unusable for cropping (see Chapter 22), often exacerbated by irrigation practices, such as those that have affected about 40% of the dryland area in West Asia (Harahsheh and Tateishi 2000). Salinity and waterlogging have affected 8.5 million hectares or 64% of the total arable land in Iraq, while 20–30% of irrigated land has been abandoned due to salinization (Abul-Gasim and Babiker 1998). In Azerbaijan, some 1.2 million hectares (about a third of total irrigated area) has been affected by salinization, and much of it has been abandoned (State Committee on Ecology and Control of Natural Resources Utilization 1998).

The ability of inland waters to recharge groundwater has been *well established*. For example, in monetary terms a 223,000-hectare swamp in Florida has been valued at $25 million per year for its role in storing water and recharging the underlying aquifer (Reuman and Chiras 2003). And the Hadejia-Nguru wetlands in northern Nigeria, in addition to supporting fishing, agriculture, and forestry, play a major role in recharging aquifers that are used by local people for domestic water supplies—a service estimated as being worth $4.8 million per year (Hollis et al. 1993).

20.2.4 Climate Change Mitigation

Inland water systems play two critical but contrasting roles in mitigating the effects of climate change: the regulation of greenhouse gases (especially carbon dioxide) and the physical buffering of climate change impacts. Inland water systems have been identified as significant storehouses (sinks) of carbon as well as sources of carbon dioxide (such as boreal peatlands), as net sequesters of organic carbon in sediments, and as transporters of carbon to the sea. Although covering an estimated 3–4% of the world's land area, peatlands are estimated to hold 540 gigatons of carbon (Immirizy and Maltby 1992), representing about 1.5% of the total estimated global carbon storage and about 25–30% of that contained in terrestrial vegetation and soils (Joosten and Clarke 2002; Lévêque 2003). Many wetlands also sequester carbon from the atmosphere through photosynthesis and act as traps for carbon-rich sediments from watershed sources. It is likely that one of the most important roles of wetlands may be in the regulation of global climate change through sequestering and releasing a major proportion of fixed carbon in the biosphere (Mitsch and Wu 1995).

Inland waters also contribute to the regulation of local climates. Possibly the most widely publicized example is that of the Aral Sea, where a combination of desiccation and pollution have altered the local climate, with dire effects on human health (as described later in the chapter). Similarly, the burning and degradation of peatland in Southeast Asia have degraded the atmosphere and affected the health of a large but possibly indeterminate number of people if the long-term effects on livelihoods as a consequence of the land degradation are considered. Getting accurate measurements of such effects and the number of people actually affected by changes in local climates is likely to prove difficult in some instances due to an absence of data and the dispersed nature of some effects or the population affected.

20.2.5 Products from Inland Water Systems

Inland water systems are a major source of products that can be exploited for human use, including fruit, fish, shellfish, deer, crocodile and other meats, resins, timber for building, fuelwood, peat, reeds for thatching and weaving, and fodder for animals. Many of these products are exploited at subsistence, cottage industry, or the larger commercial scale in most parts of the world.

Arguably the most important product derived from inland waters in terms of human well-being on a global scale is fish and fishery products. An estimated 2 million tons of fish and other aquatic animals are consumed annually in the lower Mekong Basin alone, with 1.5 million tons originating from natural wetlands and 240,000 tons from reservoirs. The total value of the catch is about $1.2 billion (Sverdrup-Jensen 2002). In recent years, the production of fish from inland waters has become dominated by aquaculture operations, mainly carp in China for domestic consumption and salmon, tilapia, and perch mainly for export to other countries (Kura et al. 2004). (See Chapters 8, 19, and 26.) In fact, since 1970 aquaculture has become the fastest-growing food production sector in the world, increasing at an average rate of 9.2% per year—an outstanding rate compared to the 2.8% rate for land-based farmed meat products (FAO 2004). In parallel, consumption of freshwater fish has shown the greatest increase over recent years, especially in China, where per capita consumption of fish increased nearly tenfold between 1981 and 1997 (Delgado et al. 2003; Kura et al. 2004).

Inland fisheries are of particular importance in developing countries, as fish is often the only source of animal protein to which rural communities have access (Kura et al. 2004). A large proportion of the recorded inland fisheries catch comes from developing countries, and the actual catch is thought to be several times the official 2001 figure of 8.7 million tons, as much of the inland catch is undereported (FAO 1999; Kura et al. 2004). Indeed, FAO considers its data on freshwater harvests so uncertain that it declined to give a comprehensive analysis of inland trends in its latest report on the state of world fisheries and aquaculture (FAO 2004).

Most of the above-mentioned increase in freshwater fish consumption has occurred in Asia, Africa, and more moderately in South America. In 1999, China accounted for 25% of the annual catch, India 11%, and Bangladesh 8% (Fishstat 2003). In North America, Europe, and the former Soviet Union, landings of fish have declined, whereas in Oceania they have remained stable (FAO 1999). Despite this increase in landings, maintained in many regions by fishery enhancements, such as stocking and fish introductions, the greatest overall threat for the long-term sustainability of inland fishery resources is the loss of fishery habitat and the degradation of the terrestrial and aquatic environments (FAO 1999). Historical trends in commercial fisheries data for well-studied rivers show dramatic declines over the twentieth century, mainly from habitat degradation, invasive species, and overharvesting (Revenga et al. 2000).

The Great Lakes of North America, shared by the United States and Canada, illustrate the value of inland fishery in these countries. These lakes have supported one of the world's largest freshwater fisheries for more than 100 years, with the commercial and sport fishery now collectively valued at more than $4 billion annually (Great Lakes Information Network 2004). The fishery consists of a mix of native and introduced species, some of which are regularly restocked. The fishery declined due to the combined effects of overfishing, pollution, and the introduction of invasive species. Recent years have seen a major resurgence in Lake Erie's fish production as some populations have recovered, and in Lake Ontario as a new fishery has been developed. However, this has only occurred in response to considerable expenditure in support of fish stocking and administration, including facilitating cooperation between governmental agencies; the real overall cost of recovering the fishery may not be accurately known (Dochoda 1988).

Another critical product derived from wetlands is rice—the staple food for nearly 50% of the world's peoples, mainly in Asia (FAO 2003). The world per capita rice consumption in 1990 was 58 kilograms per year of milled rice. This represents 23% of the average world per capita caloric intake and 16% of the protein intake (International Rice Research Institute 1995). In Asia alone, more than 2 billion people obtain 60–70% of their calories from rice and its derived products (FAO 2003). Rice is also the most rapidly growing source of food in Africa and is of significant importance to food security in an increasing number of low-income food-deficit countries. It is estimated that by 2020, 4 billion people—more than half the world's population—will depend on rice as a staple of their diet (International Rice Research Institute 1999).

Peatlands in particular, as a diverse group of habitats, provide many useful products. Peat soil has been mined extensively for domestic and industrial fuel, particularly in Western Europe but also in South America, and peat mining for use in the horticulture industry is a multimillion-dollar industry in Europe (Finlayson and Moser 1991; Maltby et al. 1996; Joosten and Clarke 2002). Whereas peat mining can be destructive in terms of the biodiversity values of the affected areas, there is an increased emphasis on sustainable practices through improved planning, water regulation, and post-mining restoration (Joosten and Clarke 2002). Peatlands also provide foods in the form of berries and mushrooms, and sometimes timber, all of which can be locally important. The tropical peat swamp forests of Southeast Asia, for example, have been an important source of tropical hardwood and are also a source of products that contribute significantly to the economy of local communities, including fish, fruit, latex, and tannins (Rieley et al. 1996). In all regions of the world there are indigenous people whose livelihoods and cultures are sustained by peatlands.

20.2.6 Recreation and Tourism

It is extremely apparent that the aesthetics as well as the diversity of the animal and plant life of many inland water systems has attracted tourism. Many inland water sites are protected as National Parks, World Heritage Sites, or wetlands of international importance (that is, Ramsar sites) and are able to generate considerable income from tourist and recreational uses. In some locations tourism plays a major part in supporting rural economies, although there are often great disparities between access to and involvement in such activities. The negative effects of recreation and tourism are particularly noticeable when they introduce inequities and do not support and develop local economies, especially where the resources that support the recreation and tourism, such as wetlands, are degraded.

The income generated by recreation and tourism can be a significant component of local and national economies. Recreational fishing can generate considerable income: some 35–45 million people take part in recreational (both inland and marine) fishing in the United States, spending $24–37 billion each year on their hobby (Thomsen 1999; Ducks Unlimited 2002). In 2001, freshwater fishing (including the Great Lakes) alone generated more than $29 billion from retail sales and more than $82.1 billion in total economic output (including contributions to household income and taxation revenues) (American Sportfishing Association 2001). The total economic value of such activities extends far beyond the direct expenditure and includes, for example, contributions to local property markets and taxation revenues.

The value of recreation and tourism from inland water systems is widely recognized in many other parts of the world, but not necessarily as well quantified (Finlayson and Moser 1991). There are many inland waters with significant recreational value for which a monetary value cannot easily be given because visitors use the area without direct payment. Employing economic valuation techniques, such as willingness to pay and other methods (see Chapter 2), to investigate the value that users ascribe to a wetland is becoming the topic of increased research and documentation. The recreational value of the Norfolk Broads wetlands in the United Kingdom, for instance, was estimated at $57.3 million per year for people living relatively close to the Broads and $12.9 million per year for those living further away (Barbier et al. 1997).

In considering such analyses, the cost of repairing any degradation or providing facilities for visitors must also be taken into account. It is well known, for example, that overuse of popular fishing or camping spots around lakes or along rivers can lead to severe degradation and result in the demise of such activities and the loss of income-generation opportunities.

Although not strictly speaking a ''recreational'' function, the educational value of wetlands is closely related: there are many wetland education centers and programs around the world that involve the general public and schoolchildren in practical activities in their local wetland environments; these activities span the border between education and recreation. Approximately 160,000 people a year visit a 40-hectare wetland complex in the heart of London; created from a series of reservoirs, it offers 30 lakes and marshes, boardwalks, hides, and pathways as well as an exhibition center that educates visitors on the functions and values of inland water ecosystems, biodiversity issues, and other environmental matters in an essentially recreational setting (Peberdy 1999).

20.2.7 Cultural Value

Inland waters are closely associated with the development of human culture—notably, for example, in the Indus, Nile, and Tigris-Euphrates valleys (Finlayson and Moser 1991)—and many major cities are built near rivers. In some cultures inland waters may have deep religious significance for local people. In Tibet, for example, pre-Buddhist belief identified various lakes as sacred, making them objects of worship as well as ensuring their protection from pollution and other harm. As Buddhism took over, these beliefs remained, albeit in a modified form, and certain lakes in Tibet are still sacred to the people, with strict regulations on their exploitation (Dowman 1997).

Cranes have a near-sacred place in the earliest legends of the world and have featured prominently in art and folklore for millennia. For example, the Brolga (*Grus rubicunda*) figures prominently in some indigenous Australian folklore and culture, and in Northeast Asia cranes are revered as symbols of longevity and peace (Wetlands International 1999). At anything but a local scale, however, cultural values are a relatively poorly documented service of inland waters, despite the many instances where wetlands have significant religious, historical, archaeological, or other cultural values for local communities. (See Chapter 17.)

20.3 Condition of Inland Water Systems

The information base for assessing the condition of inland water systems globally is widely documented and summarized in many reports (e.g., Finlayson et al. 1992; Finlayson and Moser 1991; Moser et al. 1993, 1996; Whigham et al. 1993; Mitsch 1994; McComb and Davis 1998). But it is as widely documented that at a global or continental scale there are large gaps in information (Finlayson and Spiers 1999; Darras et al. 1999; Revenga et al. 2000; Brinson and Ines Malvare 2002; Junk 2002; Malmqvist and Rundle 2002; Williams 2002). The information in this section on the biodiversity of inland water systems is largely based on analyses undertaken by Revenga and Kura (2003), which made use of global and regional-scale datasets while identifying the inadequacy of many information sources and the difficulties of gaining access to others.

20.3.1 Extent and Change of Inland Water Systems

Estimates of the extent of wetlands at a global level vary from 530 million to 1,280 million hectares, but it is *well established* that this is a clear underestimate (Spiers 1999; Finlayson et al. 1999). Estimates of the global extent of wetlands are highly dependent on the definitions for wetlands used in each inventory, the type of source material available, the methodology used, and the objectives of the investigation. The 1999 *Global Review of Wetland Resources and Priorities for Wetland Inventory* estimated wetlands extent from national inventories as approximately 1,280 million hectares (Finlayson et al. 1999), which is considerably higher than previous estimates derived from remotely sensed information.

Nevertheless, the GRoWI figure is considered an underestimate, especially for the Neotropics. For example, Ellison (2004) contends that in central America the savannas should be classed as seasonal wetlands rather than grasslands; it is not known if this is the case in other savanna landscapes. Analyses of wetland inventory in Mexico (CNA-INUBAN 1999) and Brazil (Maltchik 2003) similarly illustrated the poor state of knowledge covering wetland classification and inventory. Another limitation of the data used in GRoWI is that for certain wetland types (such as intermittently flooded inland wetlands, peatlands, artificial wetlands, seagrasses, and coastal flats), data were incomplete or not readily accessible (Finlayson et al. 1999).

Even so, the data collated by Finlayson et al. (1999) suggest that the largest area of wetlands is in the Neotropics (32%), with large areas also in Europe and North America. But note that figures provided by Lehner and Döll (2004) (see Table 20.4) suggest that Asia may contain a greater and Europe a lesser area of wetlands. Table 20.4 presents the two best available estimates from

Table 20.4. Estimates of Inland (Non-marine) Wetland Area (Finlayson et al. 1999; Lehner and Döll 2004)

Region	1999 Global Review of Wetland Resources	2004 Global Lakes and Wetlands Database
	(million hectares)	
Africa	121–125	131
Asia	204	286
Europe	258	26
Neotropics	415	159
North America	242	287
Oceania	36	28
Total area	**~ 1,280**	**~ 917**

Note: Not all wetland types are equally represented in the underlying national inventory data. Some countries lack information on some types of wetlands.

wetlands extent: the GRoWI assessment (Finlayson et al. 1999) and the WWF/Kassel University Global Lakes and Wetlands Database (GLWD) (Lehner and Döll 2004).

Mapping exercises have been undertaken for inland waters, but the level of detail varies from region to region. The most recent global map, with a 1-minute resolution, was produced by combining various digital maps and data sources (Lehner and Döll 2004), but it still suffers from the problems of definition and scale outlined by Finlayson et al. (1999). Problems with the scale and resolution of data sources for inventory have been shown for northern Australia, where estimates of the area of inland water systems from 10 data sources varied from 0 to 98,700 square kilometers (Lowry and Finlayson 2004).

Inventories of major river systems, including data on drainage area, length, and flow volume are available, but there is considerable variability between estimates, based on the method and definitions used. Information on river flow volume and discharge, for example, varies considerably depending on the water balance model applied and the different time periods or locations for the measurement of discharge (see Revenga and Kura 2003).

Information on the estimated 5–15 million lakes across the globe is also highly variable and dispersed (WWDR 2003). Large lakes have been mapped reasonably well, but issues of scale also occur with smaller lakes being more difficult to map. Nevertheless, there is no single repository of comprehensive lake information, which makes assessment of these water bodies difficult and time-consuming. A high proportion of large lakes—those with a surface area over 500 square kilometers—are found in Russia and in North America, especially Canada, where glacial scouring created many depressions in which lakes have formed. Tectonic belts, such as the Rift Valley in East Africa and the Lake Baikal region in Siberia, are the sites of some of the largest and most "ancient" lakes, all of which have highly diverse species assemblages. Some of the largest lakes are saline, with the largest by far being the Caspian Sea (422,000 square kilometers). There are many saline lakes occurring on all continents and many islands; given the impermanence of many, it is difficult to derive accurate values for their number worldwide.

Reservoirs are also widespread; the number of dams in the world has increased from 5,000 in 1950 to more than 45,000 at present (WCD 2000). These reservoirs provide water for 30–40% of irrigated agriculture land and generate 19% of global electricity supplies (WCD 2000).

Peatlands are known to occur in at least 173 countries throughout most parts of the world, from Arctic systems through temperate to tropical regions (Joosten 1992). Their total area has been estimated as approximately 400 million hectare, of which the vast majority are in Canada (37%) and Russia (30%), which together with the United States account for over 80% of the global peatland resource. The largest area of tropical peatland is in Indonesia (6–7% of the global area). Peatlands are estimated to store 30% of Earth's surface soil carbon (Joosten and Clarke 2002). The global area of paddies has been estimated as 1.3 million square kilometers (130 million hectares) (Aselmann and Crutzen 1989), of which almost 90% is in Asia, but it is likely that this figure is now out of date. Information on other human-made wetlands is variable and even lacking for some countries.

Groundwater systems have received slightly increased attention in recent years. These systems vary in size, from the small-scale alluvial sediment along rivers to extensive aquifers such as the 1.2 million square kilometers of the Guarani aquifer located across parts of Argentina, Brazil, Paraguay, and Uruguay (Danielopol et al. 2003). Groundwater systems have many connections and interactions with surface waters, although many of these are not well understood. Some aquifers are better known for their biodiversity values, such as the karst systems of Slovenia that cover some 8,800 square kilometers and are increasingly known for their high species biodiversity (see Box 20.1), while others are not known at all.

The loss and degradation of inland waters have been reported in many parts of the world (Finlayson et al. 1992; Mitsch 1998; Moser et al. 1996), but there are few reliable estimates of the actual extent of this loss. Dugan (1993) speculated that on a global scale the loss of wetlands was about 50%, but he did not provide supporting evidence, and as reliable estimates of the extent of wetlands (and particularly of intermittently inundated wetlands in semiarid lands) are lacking, it is not possible to ascertain the extent of wetland loss reliably.

The information available on the distribution of inland waters is on the whole better for North America than for many other parts of the world. The overall area of wetlands in North America includes 2.72 million hectares in Mexico (CNA-IBUNAM 1999), 127–168 million hectares in Canada (Wiken et al. 1996; Moore and Wiken 1998; National Wetlands Working Group 1988; Warner and Rubec 1997), and 43 million hectares in the conterminous United States (Dahl 2000).

As with the information on the distribution of wetlands, data on their conditions and trends are on the whole better for the United States than that for many other parts of the world. The United States is one of the few countries that systematically monitors change in wetlands extent. From the mid-1970s to mid-1980s, wetland losses (excluding lakes and rivers) in that country amounted to about 116,000 hectares per year (Dahl and Johnson 1991). This rate of loss decreased by 80% to a loss of approximately 23,700 hectares a year from 1986 to 1997, with 98% of these losses being from forested and freshwater wetlands, mostly from conversion or drainage for urban development and agricultural purposes (Dahl 2000). As of 1997, an estimated 42.7 million hectares remains out of the 89 million hectares of wetlands present in the United States at the time of European colonization (Dahl 2000).

The overall decline in the rate of loss observed in the United States is attributed primarily to wetland policies and programs that promote restoration, creation, and enhancement of wetlands, as well as incentives that deter the draining of wetlands. Between

BOX 20.1

Biodiversity of Karsts in Slovenia (Information supplied by G. Beltram from multiple sources)

Approximately 8,800 square kilometers or 44% of the surface area of Slovenia is carbonate bed-rock, known as karst. It is very permeable and supports many caves and fissures. Over many centuries the karst areas have been greatly modified by humans, with eventual replacement of the deciduous forests by dry, rocky pastures and meadows, small arable fields, dry stone walls, and karst pools. Logging, grazing, forest fires, and strong winds have further degraded the karsts through soil erosion and exposed a stark and bare-stone landscape. In the last 50 years or so, further change has occurred as local people abandoned the agricultural land and as shrubs and trees invaded meadows and arable fields—changing the vegetation structure and cultural significance of these areas (Beltram and Skoberne 1998). Pollution and habitat destruction are also problematic.

The subterranean caves and fissures within the karst are important for biodiversity as well as human use. The subterranean fauna, particularly aquatic stygobiontic species, is very rich and includes about 800 endemic fauna taxa. Many species also have extremely small distributions. The fauna in the caves is varied, with many species not found elsewhere—for example, the cave vertebrate (*Proteus anguinus*), tubeworm (*Marifugia cavatica*), mollusk (*Kerkia kusceri*), cnidarian (*Velkovrhia enigmatica*), and water fleas (*Alona sketi* and *A. stochi*), as well as a number of stygobiontic snails (*Gastropoda*) and epizoic turbellearians (*Temnocephalida*). Additionally, the crustacean fauna, including amphipods, copepods, and isopods, is extremely rich.

The karst landscape has a strong cultural heritage dating back centuries. Significant settlements were constructed near natural springs, and natural and human-made pools were used for watering domestic animals. With the demise of agricultural activities, some caves have become popular tourist destinations. Groundwater from the karst is a very important source of domestic water supply for almost half of Slovenia's inhabitants, making recharge of this source a very important function of the landscape.

1986 and 1997, the country had a net gain of about 72,870 hectares of upland wetlands, mostly due to Federal protection and restoration programs and an increase in the area of lakes and reservoirs by 47,000 hectares due to creation of new impoundments and artificial lakes (Dahl 2000).

20.3.2 Status of Inland Water Species

Data on the condition and trends of freshwater species are for the most part poor at the global level, although some countries have reasonable inventories and indicators of change of inland water species (such as Australia, Canada, New Zealand, South Africa, and the United States) (Revenga and Kura 2003). This does not mean that data are not available; there are considerable data on freshwater species and populations, but they are not easily accessible. For example, there are many extensive records in museums and universities around the world, but these are often not centrally located or electronically archived.

Revenga and Kura (2003) assessed the level of knowledge of the distribution and condition of inland water biodiversity at the global level. Key conclusions from this assessment indicated that fish and waterbirds are by far the best studied groups of inland water species, although with considerable regional differences; that aquatic plants, insects, freshwater mollusks, and crustaceans are poorly known or assessed in most parts of the world, with very fragmentary information available; and that every group of organisms considered, including aquatic plants, invertebrate, and vertebrate animal species, contained examples of extinct, critically endangered, endangered, and vulnerable taxa.

Although small in global area compared with marine and terrestrial ecosystems, inland water systems are relatively species-rich (McAllister et al. 1997). (See Table 20.5.) Marine systems contain over six times as many known species as inland waters, but cover over two thirds of the globe, compared with inland water systems, which occupy less than 1% as much area. Over three quarters of known species are terrestrial, but these systems have similar relative species richness to inland water systems. Inland water systems also support a disproportionately large number of species of some taxonomic groups. For instance, some 40% of known species of fish inhabit inland waters (more than 10,000 species out of 25,000 species globally), and about 25–30% of all vertebrate species diversity is concentrated close to or in inland waters (Lévêque et al. in press). There are about 100,000 described species of freshwater fauna worldwide (Lévêque et al. in press). Half of these are insects (see Table 20.6), about 12,000 are crustaceans, 5,000 are mollusks, and some 20,000 are vertebrate species. It is anticipated that the number of aquatic animals will be far higher than current estimates as more species from inland waters are described every year—about 200 new fish species are described each year (Lundberg et al. 2000).

Because many inland wetlands are geographically isolated, levels of endemism of freshwater species are particularly high, especially in ancient lakes, such as the Great East African Lakes (Tanganyika, Malawi, and Victoria), Lake Baikal, Lake Biwa, and Lake Ohrid, which have been isolated for millions of years (Lévêque et al. in press).

The *IUCN Red List,* a widely used indicator for assessing the conservation status of plants and animals, does not comprehensively assess inland water species. For instance, only a very small proportion of the species in most freshwater taxa, such as aquatic plants, mollusks, crustaceans, and insects, have been assessed. However, among the taxa that have been comprehensively assessed, such as amphibians and birds, a high number of species are threatened with extinction (IUCN 2003), as described further later in this section.

Another global measure of the status of animal species is the Living Planet Index developed by WWF and UNEP-WCMC (Loh and Wackernagel 2004). The LPI provides a measure of the trends in more than 3,000 populations of 1,145 vertebrate species around the world. It is an aggregate of three separate indices of

Table 20.5. Relative Species Richness of Different Ecosystems (McAllister et al. 1997)

Ecosystems	Habitat Extent	Species Diversity	Relative Species Richness [b]
	(percent of world)	*(percent of known species)*[a]	
Freshwater	0.8	2.4	3.0
Marine	70.8	14.7	0.2
Terrestrial	28.4	77.5	2.7

[a] Does not add up to 100 because 5.3% of known symbiotic species are excluded.

[b] Calculated as the ratio between species diversity and habitat extent

Table 20.6. Current State of Knowledge of Global Species Richness of Inland Water Animal Groups (Lévêque et al. in press; Revenga and Kura 2003; IUCN et al. 2004)

Phylum	Described Species
	(number)
Porifera (sponges)	197
Cnidaria (hydra, freshwater jelly fish)	30
Nemertea (ribbon worms)	12
Plathelminthes (flatworms)	c. 500
Gastrotrichia	c. 250
Rotifers	1,817
Nematods (microscopic worms)	3,000
Annelids (segmented worms)	c. 1,000
Bryozoa (moss animals)	70—75
Mollusks (mussels, snails, slugs, etc.)	c. 6,000
Crustaceans (crabs, crayfish, etc.)	c. 12,000
Arachnids (spiders, etc.)	5,000
Insects	> 50,000
Vertebrates	
Fish	13,400
Amphibians	3,533
Reptiles	c. 250
Birds	c. 1,800
Mammals	c. 122

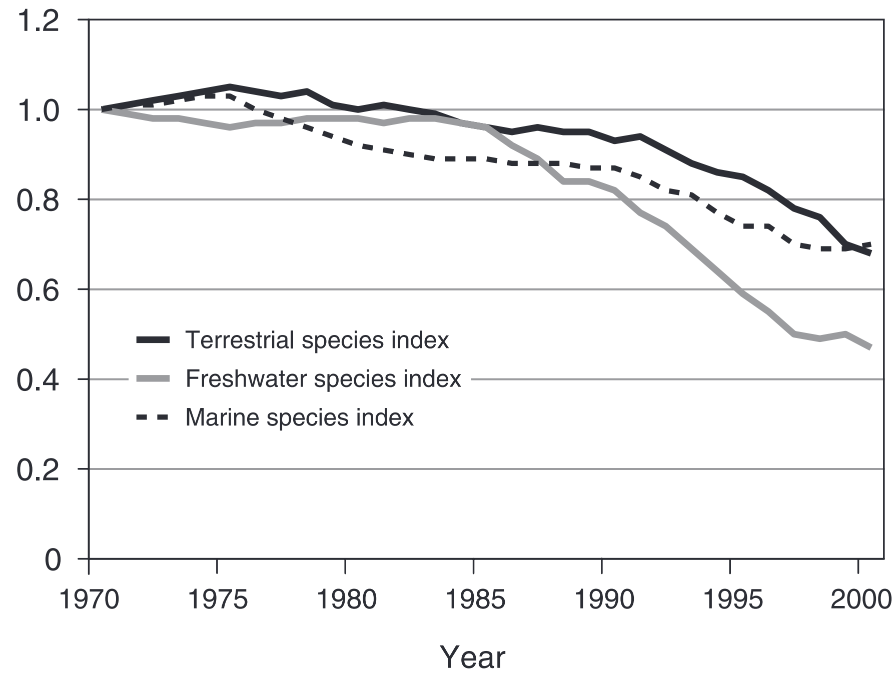

Figure 20.3. Living Planet Index for Terrestrial, Inland Water, and Marine Systems (Loh and Wacknernagel 2004)

change in freshwater, marine, and terrestrial species. The 2004 freshwater species population index, which took into account trend data for 269 temperate and 54 tropical freshwater species populations (93 of which were fish, 67 amphibians, 16 reptiles, 136 birds, and 11 mammals), shows that freshwater populations have declined consistently and at a faster rate than other species groups assessed, with an average decline of 50% between 1970 and 2000. Over the same period, both terrestrial and marine fauna decreased by 30%. (See Figure 20.3.) While the index has a bias in the available data toward North America and Europe, and particularly toward bird populations, data collection and collations have been undertaken each year to extend the veracity of this index, with initial indications of a continuing decline remaining constant (Loh and Wackernagel 2004).

20.3.2.1 Aquatic Plants and Fungi

The definition of aquatic plants has been and is still debated, but in general plants that tolerate or require flooding for a minimum duration of time are considered wetland plants. Aquatic macrophytes include angiosperms (flowering plants), macroalgae, pterophytes (pteridophytes, ferns), and bryophytes (mosses, hornworts, and liverworts). Gymnosperms (conifers, cycads, and their allies) do not have strictly aquatic representatives, but include a number of tree species that tolerate waterlogged soil, such as the bald cypress.

It is estimated that up to 2% (250 species) of pterophytes and 1% (2,500 species) of angiosperms are aquatic, but their geographic distribution, diversity patterns, or conservation status have not been summarized globally, although information exists for specific regions. Some families of aquatic angiosperms show highest diversity at tropical latitudes, while others show higher diversity in temperate regions, making it evident that the typical latitudinal gradient found in terrestrial species diversity does not apply. Locally, many macrophyte species may be threatened or lost, especially in lakes undergoing eutrophication; as an example, many isoetid species are widespread but increasingly threatened throughout their range (e.g. Nichols and Lathrop 1994). The maximum diversity of bryophytes is found in highly oceanic regions, where cool or temperate and consistently moist climate conditions persisted over geological time (Groombridge 1992). Bryophytes found in lowland aquatic environments, including pools and reservoirs, tend to have very restricted distribution and therefore are rare and threatened (Revenga and Kura 2003).

A relatively small fraction (over 600 species) of fungi are considered freshwater species, but recent studies indicate that there are many more freshwater fungi to be discovered in temperate and tropical regions; the total number estimated at between 1,000 and 10,000 (Palmer et al. 1997). Information on the conservation status of aquatic fungi is very limited.

20.3.2.2 Invertebrates

Information on aquatic invertebrate species diversity is fragmentary, with a few descriptive global overviews of particular taxa and some more detailed regional inventories. The conservation status of aquatic invertebrates has not been comprehensively assessed, except for regional assessments of certain taxonomic groups such as Odonata (dragonflies and damselflies; see Box 20.2) (Clausnitzer and Jodicke 2004), freshwater mollusks (mostly mussels), and freshwater crustaceans (Master et al. 1998; IUCN 2003). Assessments of the status of known mollusk species have been conducted for a limited number of taxa and regions, including the Mekong, which has a very diverse freshwater mollusk fauna (Dudgeon 2002a, 2002b, 2002c); Lake Biwa, Japan, which has 73% of the freshwater mussel species described in the country, of which 43% are endemic; and Lakes Baikal, Tanganyika, and Titicaca. (See Box 20.3.)

IUCN (2003) reports 130 freshwater species of aquatic insects, 275 species of freshwater crustacean, and 420 freshwater mollusks as globally threatened, although no comprehensive global assessment has been made of all the species in these groups. For the

BOX 20.2

Status of Odonata (Dragonflies and Damselflies)
(Clausnitzer and Jodicke 2004)

A recent global review of the threat status of dragonflies and damselflies in 22 regions covering most of the world (except for parts of Asia) found that there are many more dragonfly species now regarded as threatened than are listed in the *IUCN Red List,* which currently lists 130 species (*medium certainty*). It is important to note, however, that the criteria and categories used to assess conservation status are not harmonized across regions.

In Australia, for example, there are 4 species currently on the *Red List* as globally threatened but another 25 are considered to be in critical condition and an additional 30% of species are data-deficient in regional assessments. In North America, 25 species (6%) are of conservation concern; in the Neotropics, 25 species are considered globally threatened and a further 45 species are considered of high conservation priority, with many others being data-deficient. In eastern Africa, 90 species are considered appropriate for globally threatened status. And in southern Africa, although 2 species are currently recognized as globally threatened, a further 11 are now considered threatened in regional assessments. In Madagascar, 2 species are currently recognized as globally threatened, but because of high diversity and endemism, a large number—111 species, 64% of the fauna—are of conservation concern, although all species are data-deficient. In the Western Indian Ocean Islands, 3 species are recognized as globally threatened and 33 are now regarded as critical; in Sri Lanka, no species are currently on the *Red List,* although 47 species (all endemic) are regarded as threatened with extinction. Finally, in Europe 6 species are *Red-listed,* although two of these are now considered out of danger, and a further 22 species are of concern as their populations are declining. And in Turkey, Iran, and the Caucasus, there are 5 species on the *Red List* and 27 regarded as critical.

In most areas assessed, habitat loss and degradation of wetlands (and forests) were considered the major drivers of declines in Odonate species, often associated with overabstraction and pollution of water as well as the impacts of alien invasive species.

BOX 20.3

Endemism of Mollusks in Inland Waters

Twenty-seven areas of special importance for freshwater mollusk endemism worldwide have been identified, in three types of wetlands:

- ancient lakes: Baikal, Biwa, and Tanganyika, where 70%, 52%, and 64% of molluscan species are endemic respectively;
- lower river basins: 93% of the total freshwater mollusk species found in the Mobile Bay region of the Alabama-Tombigbee River basin in the United States are endemic; another notable center of endemism is found in the Lower 500 kilometers of the Mekong River basin, where 92% of molluscan species are endemic; and
- springs and underground aquifers (Australia, New Caledonia, the Balkans, western United States, Florida, and the Cuatro Cienegas basin in Mexico).

Inland Waters	Gastropods	Bivalves	Total
	%	%	%
Ancient lakes			
Baikal	78	52	73
Biwa	50	56	52
Sulawesi	c. 80	25	c. 76
Tanganyika	66	53	64
Malawi	57	11	46
Victoria	46	50	48
Ohrid	76		
Titicaca	63		
Major river basins			
Mobile Bay Basin	93	54	78
Lower Uruguay River and Rio de la Plata	48	21	37
Mekong River (lower 500 km)	92	13	73
Lower Congo basin	25	n/a	
Lower Zaire basin	25	n/a	

United States, one of the few countries to assess freshwater mollusks and crustaceans comprehensively, 50% of known crayfish species and two thirds of freshwater mollusks are at risk of extinction, and at least one in 10 freshwater mollusks are likely to have already gone extinct (Master et al. 1998).

20.3.2.3 Freshwater Fish

Most global and regional overviews of freshwater biodiversity include more information on fish than any other taxa (Cushing et al. 1995; Gopal et al. 2000; Groombridge and Jenkins 1998; Maitland and Crivelli 1996). A number of regional overviews of the status of freshwater fish are available, yet many of the existing overviews underestimate the number of species, as there are still many species to be described and assessed. There is, therefore, a high level of uncertainty about the status of fish in many inland waters. Estimates of the number of freshwater fish in Latin America vary from 5,000 to 8,000; in tropical Asia and Africa, there are an estimated 3,000 species on each continent (Revenga and Kura 2003), although these figures are almost certainly underestimates. The Mekong River alone is considered to have 1,200–1,700 species (WRI et al. 2003). (See Box 20.4.) North America is estimated to have more than 1,000 species, and Europe and Australia have several hundred species each (Revenga and Kura 2003).

With respect to their conservation status, estimates are that in the last few decades more than 20% of the world's 10,000 described freshwater fish species have become threatened or endangered or are listed as extinct (Moyle and Leidy 1992). The *IUCN Red List* (2004) classifies 648 freshwater ray-finned fish species as globally threatened. However, the coverage for freshwater fish is highly biased to particular regions for which more data are available, such as North and Central America or the African Rift Valley Lakes. For example, of the ray-finned fishes listed as threatened in the *IUCN Red List,* 122 are found in the United States and 85 in Mexico, partially reflecting the high level of knowledge in these two countries (IUCN 2003).

In the 20 countries for which assessments are most complete, an average of 17% of freshwater fish species are globally threatened. In addition, there are a few well-documented cases that show clearly this level of threat. The most widely known is the apparent disappearance of between 41 and 123 haplochromine cichlids in Lake Victoria (Harrison and Stiassny 1999), although taxonomic questions remain a problem in accurately assessing this group of fish. In Europe (including the former Soviet Union),

BOX 20.4

Species Diversity of the Mekong River (Information supplied by A. Lopez; see Mattson et al. 2002)

The vertebrate fauna of the Mekong River basin is difficult to quantify due to the incomplete state of the inventory and taxonomic effort. Many published figures are considered to be underestimates. The Mekong River Commission (1997) estimated that in the Laotian, Vietnamese, Cambodian, and Thai part of the basin there were some 830 mammal species, 2,800 bird species, 1,500 fish species, 250 amphibians, and 650 reptiles.

Many of these species are threatened. For example, among the mammals this includes the fishing cat (*Prionailurus viverrinus*), the hairy-nosed otter (*Lutra sumatrana*), the smooth-coated otter (*Lutrogale perspicillata*), and the Oriental small-clawed otter (*Aonyx cinerea*). A high proportion of bird species are in decline (Dudgeon 2002), particularly those that rely on sandbars and large river stretches for breeding or feeding. These include the Plain Martin (*Riparia paludicola*) and the now extinct White-eyed River Martin (*Pseudochelidon sirintarae*). Two crocodile species occur, although the population of the estuarine crocodile (*Crocodylus porosus*) is likely very low. A number of aquatic and semi-aquatic turtles, snakes, and lizards occur, many of which are hunted for subsistence or sold for food and medicine in local markets. A substantial illegal market also exists for many wildlife products.

The fish fauna is considered to be diverse, although this has not been well documented. There are an estimated 700 freshwater fish species in Cambodia. The diversity at a family level seems to be high, with some 65 families in the Cambodian and 50 in the Laotian parts of the basin. Fish introductions have occurred with the Nile tilapia (*Oreochromis niloticus*) and mosquito fish (*Gambusia affinis*), now considered as pests. A number of large native species have declined—the giant catfish (*Pangasianodon gigas*), river catfish (*Pangasius sanitwongsei*), thicklip barb (*Probarbus* labeamajor), and the giant barb (*Catlocarpio siamensis*) are now rare (Mattson et al. 2003).

there are 67 threatened species of freshwater fish, including sturgeons, barbs, and other cyprinids (IUCN 2003).

20.3.2.4 Amphibians

Amphibians are found in many types of freshwater habitats—from ponds, streams, and wetlands to leaf litter, trees, underground, and vernal (temporary) pools. Although some amphibians thrive in cold or dry conditions, the group reaches its highest diversity and abundance in warm, humid climates.

The recent Global Amphibian Assessment (IUCN et al. 2004) lists 5,743 known species of frogs, toads, salamanders, and caecilians, of which 3,908 species depend on fresh water during some stage of their life cycle, while the rest do not require fresh water to breed or develop. The study also shows nearly one third (1,856 species) of the world's amphibian species are threatened with extinction, a large portion of which (964 species) are freshwater—a far greater level of threat than for birds (12% of all species) and mammals (23% of all species). In addition, at least 43% of all species are declining in population, indicating that the number of threatened species can be expected to rise in the future. In contrast, less than 1% of species show population increases.

The rate of decline in the conservation status of freshwater amphibians is far worse than that of terrestrial species. As amphibians are excellent indicators of the quality of the overall environment, this underpins the notion of the current declining condition of freshwater habitats around the world.

Species associated with flowing water were found to have a higher risk of extinction than those associated with still water. For species of known status (that is, excluding those that are data-deficient), as many as 42% are globally threatened and as many as 168 amphibian species may already be extinct—at least 34 amphibian species are known to be extinct, while another 134 species have not been found in recent years and are possibly extinct. Salamanders and newts have an even high level of threat (46% globally threatened or extinct) than frogs and toads (33%) and Caecilians (2%, although knowledge of these is poor, with only one third assessed).

The largest numbers of threatened species occur in Latin American countries such as Colombia (208 species), Mexico (191 species), and Ecuador (163 species). However, the highest levels of threat are in the Caribbean, where more than 80% of amphibians are threatened in the Dominican Republic, Cuba, and Jamaica, and 92% in Haiti (IUCN et al. 2004). The major threat to amphibians is habitat loss, but a newly recognized fungal disease is seriously affecting an increasing number of species. Those species dependent on flowing water (usually streams) have a much higher likelihood of being threatened than those that use still water (often temporary rain-fed pools or other small freshwater pools). (See Figure 20.4 in Appendix A.) Basins with the highest number of threatened freshwater amphibians include the Amazon, Yangtze, Niger, Parana, Mekong, Red and Pearl in China, Krishna in India, and Balsas and Usumacinta in Central America. All these basins have between 13 and 98 threatened freshwater species.

20.3.2.5 Reptiles

There are around 200 species of freshwater turtles throughout the warm temperate and tropical regions of the world; information on the distribution of these species is available through the World Turtle Database (emys.geo.orst.edu), which contains maps of all the known localities of every freshwater (and terrestrial) turtle species. Of the 200 species of freshwater turtles, 51% of the species of known status have been assessed as globally threatened, and the number of critically endangered freshwater turtles more than doubled in the four years preceding 2000 (van Dijk et al. 2000). Of 90 species of Asian freshwater turtles and tortoises, 74% are considered globally threatened, including 18 species that are critically endangered and one, the Yunnan box turtle, which is already extinct (van Dijk et al. 2000).

Crocodiles, alligators, caimans, and gharials are widespread throughout tropical and sub-tropical aquatic habitats. Of the 23 species of crocodilians, which inhabit a range of wetlands including marshes, swamps, rivers, lagoons, and estuaries, 4 are critically endangered, 3 are endangered, and 3 are vulnerable (IUCN 2003). The other species are at lower risk of extinction, but depleted or extirpated locally in some areas (Revenga and Kura 2003). The most critically endangered crocodilian is the Chinese alligator, which is restricted to the lower reaches of the Yangtze River; it is estimated that only 150 individuals remain in the wild (IUCN/SSC Crocodile Specialist Group 2002). The major threats to crocodilians are habitat degradation and overexploitation (Revenga and Kura 2003).

There are several species of freshwater snakes in the world. The wart or file snakes (*Acrochordidae*) are adapted to aquatic life, with two species occurring in freshwater habitats (Uetz and Etzold 1996); there is little information on their conservation status. In addition, there are many semi-aquatic snakes, with some being considered vulnerable (IUCN 2003).

20.3.2.6 Birds

Waterbirds (bird species that are ecologically dependent on wetlands), particularly migratory waterbirds, are relatively well studied, with time series data available for some populations in North America and Southern and Northwest Europe for up to 40 years. Global information on waterbird population status and trends is compiled and regularly updated (Wetlands International 2002).

Detailed information and review of status for waterbird species has been compiled in North America (Morrison et al. 2001; Brown et al. 2001; U.S. Fish and Wildlife Service 2004) and for the Western Palaearctic and Southwest Asia (e.g., Delany et al. 1999). For African-Eurasian waterbird populations, comprehensive analyses have been compiled for Anatidae (ducks, geese, and swans) (e.g., Scott and Rose 1996) and waders (Charadrii) (Stroud et al. 2004). In East Asia, Bamford et al. (in press) have collated and reviewed the current status and trends of waders, while information for Gruidae (cranes) and Anatidae is available from Miyabayashi and Mundkur (1999) and the Asia-Pacific Migratory Waterbird Conservation Committee (2001). Networks of both large and small wetlands along migratory flyways are of key importance as resting and feeding sites. In semiarid landscapes, many waterbirds migrate in response to periodic and regionalized flooding that produces a temporally dispersed array of habitats (Roshier et al. 2001). The wetlands in the Sahel region of Africa provide a good example. (See Box 20.5.)

In all regions, population sizes of waterbirds are better known than population trends. Trends have been estimated for half of all waterbird populations and almost three quarters of European populations, but for only one third of populations in the Neotropics, and many trends are yet to be statistically quantified. The status of sedentary populations is much less well known that that of migratory ones.

Many waterbird species are globally threatened (Davidson and Stroud 2004), and the status of both inland and marine/coastal birds is deteriorating faster than those in other habitats (*high certainty*). Of the 35 bird families whose species are wholly or predominantly coastal/marine or inland wetland-dependent, 20% of the 1,058 species for which assessment data exist are currently globally threatened or extinct. Of these, 42 species—half of which are island-endemic rails—are extinct and 41 species (4%) are critically endangered. There are globally threatened species in 60% of these families. The percentage of globally threatened waterbirds (including seabirds) is shown in Figure 20.5.

The status of birds continues to deteriorate in all parts of the world and across all major habitat types (*high certainty*). Waterbirds dependent on freshwater ecosystems, especially those using marine and coastal ecosystems, have deteriorated in status faster than the average for all threatened species (see Figure 20.6), but similarly to other migratory bird species.

Shorebirds are declining worldwide: of populations with a known trend, 48% are declining (Stroud et al. 2004). Other waterbirds have as bad or worse global status as shorebirds, including

BOX 20.5

Sahel Wetlands (Information supplied by J. Brouwer: www.iucn.org/themes/cem)

The Sahel area of Africa is an important area for migratory birds, situated between the Sahara desert to the north and the more humid savanna and forests to the south. It is semiarid, with 200–600 millimeters of rainfall per year, and comprises the wetlands of the Senegal River, the Inner Delta of the Niger in Mali, the Hadejia-Nguru wetlands in northern Nigeria, Waza-Logone in northern Cameroon, and Lake Chad, as well as thousands of smaller, isolated wetlands.

In Niger, an estimated 1.1 million waterbirds are present during January-February, with 750,000 on the smaller, isolated wetlands. As in other semiarid regions, the waterbirds depend on a network of wetlands that are variously wet and dry, spatially and temporally. The water chemistry and vegetation composition also varies between wetlands, providing a diversity of habitats that is essential for the many birds that migrate through the region.

The wetlands are also used extensively by local people, as they are highly productive and important for grazing, fishing, and market gardening. As the human population has increased, so has pressure on these wetlands—land use is becoming more intensified, and many wetlands are threatened with change, which in turn is likely to adversely affect the waterbird populations that depend on these.

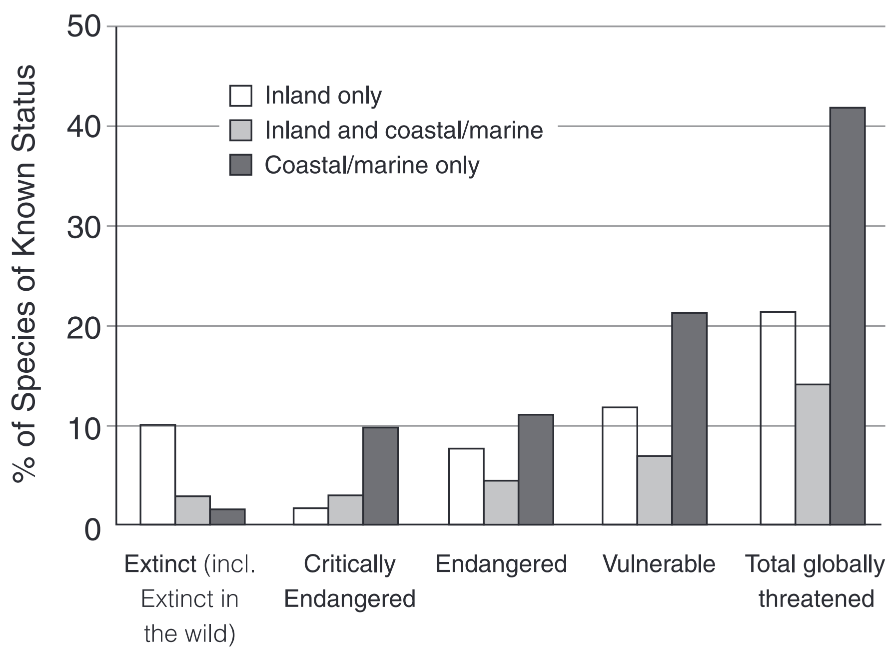

Figure 20.5. Percentage of Globally Threatened Waterbirds, Including Seabirds, in Different Threat Categories. Each waterbird family is allocated as either depending on only inland wetlands, depending on only coastal/marine systems, or depending on both inland and coastal/marine systems. (BirdLife International 2004)

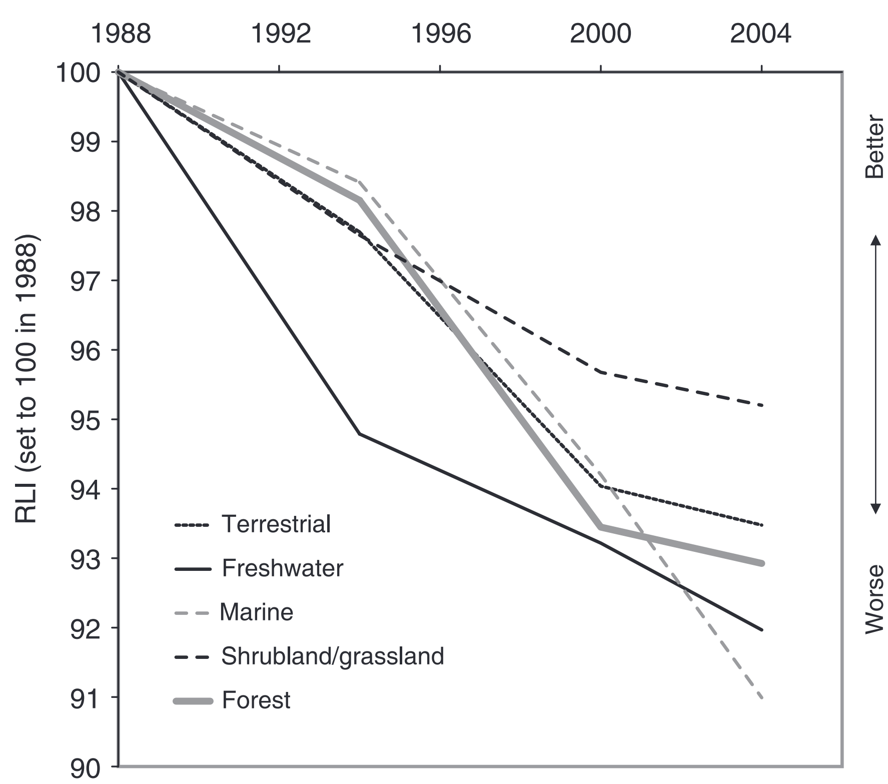

Figure 20.6. Red List Indices for Birds in Marine, Freshwater, and Terrestrial Ecosystems and for Birds in Forest and Shrubland/Grassland Habitats (Butchart et al. in press)

divers (67% of populations of known trend decreasing), cranes (47%), rails (50%), skimmers (60%), darters (71%), ibis and spoonbills (48%), storks (59%), and jacanas (50%). Only gulls (18%), flamingos (18%), and cormorants (20%) appear to have a relatively healthy status. A similar picture emerges for at least one region, Africa-Eurasia, where the status of some waterbird families is even worse than their global status. In this region, only grebes and gulls (9% decreasing) appear to have a relatively healthy status.

20.3.2.7 Mammals

Although most mammals depend on fresh water for their survival, and many feed in rivers and lakes or live in close proximity to freshwater ecosystems, as exemplified by many large mammals in Africa, only a few are considered aquatic or semi-aquatic mammals. Revenga and Kura (2003) provide an analysis of the status of aquatic and semi-aquatic mammals, including water otters, shrews, demans, tenrecs, marsh and swamp rabbits, aquatic rodents such as beavers, muskrats, nutria, and the capybara. Otters, seals (such as the Lake Baikal seal (*Phoca sibrica*)), manatees, river dolphins, and freshwater porpoises are among the most threatened mammals in the world. For example, of the five species of Asian freshwater cetaceans, four are threatened with extinction and one species, the Irrawaddy River dolphin, is data-deficient (IUCN 2003). Some 37% of inland water-dependent mammals are globally threatened, compared with 23% of all mammals (Revenga et al. in press). This includes otters (50% of species of known status threatened), seals (67% threatened), manatees (100% threatened), river dolphins and porpoises (100% threatened), and wetland-dependent antelopes (29% threatened) (Revenga et al. in press).

20.4 Drivers of Change in Inland Water Systems

Analyses over the past two decades have identified a suite of drivers of change in inland water systems (e.g. Ellison 2004; Revenga and Kura 2003; Beeton 2002; Brinson and Ines Malvarez 2002; Junk 2002; Malmqvist and Runndle 2002; Tockner and Stanford 2002; Finlayson et al. 1992; Finayson and Moser 1991; Moser et al. 1993, 1996; Whigham et al. 1993; Mitsch 1994; McComb and Davis 1998; Williams 2002). These reviews have focused mainly on biophysical pressures that are currently directly affecting adversely, or are likely to in the future, the ecological condition of inland water systems. The direct drivers of change in inland water systems are presented diagrammatically in Figure 20.7 (in Appendix A) (Ratner et al. 2004). The importance of also addressing the indirect drivers of wetland change has been increasingly recognized—for example, in Australia (Finlayson and Rea 1999) and most emphatically in the Mediterranean (Hollis 1992).

The direct drivers of wetland and riverine loss and degradation include changes in land use or cover due to vegetation clearance, drainage, and infilling; the spread of infrastructure whether for urban, tourism and recreation, aquaculture, agriculture, industrial, or even military purposes; the introduction and spread of invasive species; hydrologic modification to inland waters; overharvesting, particularly through fishing and hunting; pollution, salinization, and eutrophication; and, more recently, global climate change. These issues have been explored in many site-based analyses and comprehensive databases, and inventories for some exist or are being developed, while others are only now being assessed in a systematic manner (Kira 1997; Finlayson et al. 1999; Jorgensen et al. 2001; Revenga and Kura 2003).

In some cases many drivers operate together. For example, Finlayson et al. (1993) provide an analysis of the effects of multiple drivers on wetland habitats in the lower Volga, Russia, and further information on the multiple drivers and changes in the Caspian Sea is given in Box 20.6. Too often, though, these pressures are addressed in isolation and without an adequate information base; climate change is expected to exacerbate the problems. While the effect of such drivers on inland water systems is known with *medium*-to-*high certainty,* management responses are often undermined by an absence of sufficient information. The same drivers that affect surface waters, especially those associated with agricultural, urban, and industrial development, have also contributed to the degradation of groundwater systems (Danielopol et al. 2003).

20.4.1 Physical Change, Including Drainage, Clearing, and Infilling

Outside Western Europe and North America (including Mexico), there is very little systematic information available on the extent of loss of inland waters. The loss of wetlands worldwide has been speculated at 50% of those that existed in 1900 (Dugan 1993)—a figure that includes inland wetlands and possibly mangroves, but not large estuaries and marine wetlands. Although the accuracy of this figure has not been established due to an absence of reliable data (Finlayson et al. 1999), it is *well established* that much of the loss of wetlands has occurred in the northern temperate zone during the first half of the twentieth century.

BOX 20.6

Caspian Sea (Adapted from many sources, including www.grida.no/soe.cfin?country = caspian_*sea* and www.caspiamenvironment.org)

The Caspian Sea is the largest inland water body and is surrounded by Azerbaijan, Iran, Kazakhstan, Russia, and Turkmenistan. It is a major economic asset to the region, being rich in hydrocarbon deposits and many species of fish, crustaceans, and shrimp. Some waterbirds and the Caspian seal are also commercially hunted. The Volga River in the northwest provides about 80% of the annual 300 cubic kilometers of freshwater inflow. Evaporation is more than one meter per year, while salinity ranges from fresh to highly saline in the Kara Bogaz Gol, a small basin along the Turkmen coastline. The sea supports a diverse range of habitats and species, including many endemic aquatic taxa.

The sea is under great pressure from desertification and deforestation, river regulation, urbanization and industrial development, agricultural and aquacultural development, and pollution. The water is polluted and eutrophic and has been invaded by many non-native species. There are growing fears of further contamination from oil and gas developments. The comb jelly fish (*Mnemiopsos leidyi*) has invaded and spread throughout the Caspian more rapidly than it did in the Black Sea. (See Chapter 19.)

The value of the caviar industry has been greatly affected by an 80% decrease in sturgeon landings between 1985 and 1995. This has been caused by reduced access to breeding grounds due to the construction of large dams along the inflowing rivers, pollution, overfishing, and conversion of surrounding habitat to rice cultivation. Fluctuating sea levels over many decades have also resulted in major changes to the aquatic flora and vegetation of the Volga delta and riparian forests of the Samur delta. Mass mortalities of Caspian seals, one of only two freshwater species, have been reported, likely as a consequence of pollution by heavy metals and persistent organic pollutants.

The health and lifestyle of many people in the region have been adversely affected by changes to the sea and the surrounding landscape. This has included health effects of pollution as well as reduced access to resources and basic food commodities.

Since the 1950s, many tropical and sub-tropical wetlands, particularly swamp forests, have increasingly been lost or degraded. (See Box 20.7.) In South America, peatlands linked with the Andean paramos ecosystems, also called the high mountain water towers, are increasingly targeted for agriculture, including the practices of drainage and burning (Hofstede et al. 2003). A recent inventory of Patagonian peatlands (Blanco and Balze 2004) identified agriculture and forestry as the main causes of peatland disturbance, with peat mining (mainly for use in agriculture and horticulture) as a third, but increasing, threat.

It is highly certain that clearing or drainage for agricultural development is the principal cause for wetland loss worldwide. By 1985 it was estimated that 56–65% of available wetland had been drained for intensive agriculture in Europe and North America, 27% in Asia, 6% in South America and 2% in Africa—a total of 26% loss to agriculture worldwide (OECD 1996). In China, some of the most extensive peatland areas (> 5,000 square kilometers) occur at 3,500-meters elevation on the Tibetan Plateau, the source of the Yellow and Yangtze Rivers. Large networks of drainage canals were constructed there in the 1960s and 1970s to increase the area for livestock grazing, leading to a dramatic drop in peatland area and a subsequent degradation and loss of the peat, desertification, and loss of water retention capacity (UNDP/GEF/GOC 2003).

BOX 20.7

Southeast Asian Peatlands

In Southeast Asia, most of the once-extensive tropical peat swamp forests have been heavily degraded, and large extents have been lost over the last four decades. The main cause of this has been logging for timber and pulp. This started with selective logging of forests, but it has increasingly been replaced by clear-felling. Over the last two decades, this has been exacerbated by the conversion of peat swamp forests to agriculture, particularly oil palm plantations. The peatlands of Malaysia and Indonesia are especially threatened by persistent changes. Drainage and forest clearing threatens their stability and makes them susceptible to fire. Attempts have been made to harness the deeper peat soils, often with a high rate of failure and resulting in one of the environmental disasters of the last century, with millions of hectares of peatlands burned and emitting large amounts of CO_2 into the atmosphere.

In 1997, during a drought linked with the El Niño-Southern Oscillation, land clearing and subsequent uncontrolled fires severely burned about 5 million hectares of forest and agricultural land on the Indonesian island of Borneo (Glover and Jessup 1999; Wooster and Strub 2002). The amount of carbon released into the atmosphere from these fires reached an estimated 0.8–2.6 billion tons (Page et al. 1997). BAPPENAS-ADB (1999) reported an estimated 156.3 million tons from the 1997/98 Indonesia peat fires, based on an estimate of only 750,000 hectares being burned. Revised estimates by Tacconi (2003) of the actual area burned brings the total to 442 million tones or 27% of global emissions from land use change in 1989–95. In economic terms (using $7 per ton), this would amount to over $3 billion. A noxious, yellow haze covered the region for several months, which had a serious economic and health impact—some 200,000 people were hospitalized with respiratory, heart, and eye and nose irritations. There are ongoing concerns for the health of the 70 million people in six countries affected by the haze.

Early economic assessments place the damage to timber, agriculture, and other benefits derived from the forests at $4.5 billion in addition to the actual cost of fighting the fires (Glover and Jessup 1999). The fires compound the loss of peatlands through clearing and failed attempts to cultivate large areas for rice, such as has occurred in large areas in Kalimantan (Rieley and Page 1997).

Conversion of peatlands for intensive agriculture has been a common feature in most parts of the world for many centuries, particularly in Europe, but also more recently in the highlands of the Andes, China, and parts of Africa. The most dramatic loss of peatlands to agriculture has been in some of the countries with a rich peatland heritage, such as Finland, the Netherlands, Estonia, Denmark, and the United Kingdom. The Netherlands (once one third peatland) lost virtually all (>99%) of its natural peatlands over the last two centuries (Brag et al. 2003; Joosten 1994).

Irrigated agriculture is the leading driver in water withdrawals worldwide, resulting in large changes in river flows (Revenga et al. 2000; see also Chapter 7)—flows that are essential in sustaining ecosystem services and species. The global extent of irrigated agricultural land has increased from 138 million hectares in 1961 to 271 million hectares in 2000, and it currently accounts for an estimated 40% of total food production even though it represents only 17% of global cropland area (Wiseman et al. 2003). (See Chapter 26.) Its negative impacts on inland waters tend to be disproportionate to the irrigated land area involved.

Well-documented examples include the biodiversity losses and human health impacts seen in the Aral Sea in Central Asia and the impacts of water diversions on the wetlands in the Murray-Darling Basin of Australia (Kingsford and Johnson 1998; Lemly et al. 2000). The important Turkish wetland bird–breeding site, Kus Cenneti, is currently being adversely affected by low flows due to diversions during the bird breeding season, which is also the main irrigation period (De Voogt et al. 2000). Numerous detrimental changes in the ecological condition of the Hadejia-Nguru wetland complex in Nigeria have also been associated with the Kano River Irrigation Project (Lemly et al. 2000).

The Aral Sea in Central Asia represents one of the most extreme cases in which water diversion for irrigated agriculture has caused severe and irreversible environmental degradation of an inland water system. (See Box 20.8 here and Figure 20.8 in Appendix A.) The volume of water in the Aral basin has been reduced by 75% since 1960, due mainly to large-scale upstream diversions of the Amu Darya and Syr Darya flow for irrigation of close to 7 million hectares of land (UNESCO 2000; Postel 1999). This loss of water, together with excessive chemical inputs from agricultural runoff, has caused a collapse in the fishing industry, a loss of species diversity and wildlife habitat, and an increase in human pulmonary and other diseases in the area resulting from the high toxicity of the salt concentrations in the exposed seabed (Postel 1999; WMO 1997).

There are many other well-documented examples where diversion of water for agriculture has caused a decline in the extent and degradation of inland water systems and their species richness. In the majority of the cases, the most affected people are the poor, who depend on freshwater resources (whether from wetlands, rivers, and lakes) not only for drinking water but as a source of food supply, especially animal protein, and of income from fisheries, reed harvesting, and so on. Lake Chad provides an example where major ecosystem change has occurred (see Figure 20.9 in Appendix A) as a consequence of both human-induced and natural changes, with subsequent loss of many species and ecosystem services as the lake shrank from about 25,000 square kilometers in surface area to one twentieth its size over 35 years at the end of the twentieth century. A drier climate and high agricultural demands for water in more recent years are the primary reasons for Lake Chad's degradation (Coe and Foley 2001).

BOX 20.8

Aral Sea (Information supplied by Elena Kreuzberg-Mukhina, Nikolay Gorelkin, Alex Kreuzberg, Vladislav Talskykh, Elena Bykova, and Vyacheslav Aparin, and taken from Micklin 1993; Beeton 2002; UNEP 2002)

The degradation of the Aral Sea as a consequence of the expansion of the area under cotton and abstraction of water for large-scale irrigation is well known. The hydrological change has included the construction of at least nine water reservoirs and 24,000 kilometers of channels, with 40% of the annual water inflow of 80–100 cubic kilometers withdrawn for irrigation. The consequences for the Aral Sea have been enormous, and although estimates of the extent of change vary, the sea is now only about 20% of its former volume. The surface area has been reduced by a half or two thirds, the water level is some 16–22 meters lower, and the salinity has increased somewhere between three and twelve times. The shoreline has retreated 100–150 kilometers and exposed something like 45,000 square kilometers of former seabed, creating a salty desert and more than 100 million tons of salty dust.

The sea now has three separate entities: the Small Sea, with an area of 3,000 square kilometers, a volume of 20 cubic kilometers, and a salinity of 18–20 grams per liter; the eastern part of the Large Sea, with an area of 9,150 square kilometers, a volume of 29.5 cubic kilometers, and a salinity of 120 grams per liter; and the western part of the Large Sea, with an area of 4,950 square kilometers, a volume of 79.6 cubic kilometers, and a salinity of 80 grams per liter.

These changes have caused a collapse of the fishing industry, and many plant and animal species have been lost. Only a few of the former 34 fish species survive, with some becoming extinct, such as the Aral sturgeon, Aral trout, Chu sharpray, Tukestan dace, and Kessler's loach. Waterbirds have similarly been drastically affected, with a loss of breeding and stopover habitats for migratory species, such as those in the deltas of the Amu Darya and Syr Darya. This has seen a decline in habitat for breeding mute swan, Dalmatian and Great White pelican, and Pygmy cormorant, among others. New habitats have been created through the construction of irrigation areas, but these do not compensate adequately for the losses.

The local climate has been dramatically affected. For example, the average humidity has decreased from around 40% to 30%, leading to increased desertification, with subsequent loss of pasture productivity and impacts on human well-being. The latter is also associated with the pollution of the water and increased occurrence of dust storms. The consequences of the management decisions for the Sea have been drastic, but some at least were foreseen, and deliberate trade-offs were made in favor of economic outcomes. In 1995, the cost of making a net water saving of 12 cubic kilometers was estimated as $16 billion, but the prospects for funding were limited, and so it is likely that current conditions will prevail, with the continuing demise of the aquatic ecosystem and human well-being.

However, with the collapse of the agricultural industry in the region in recent years, the demand for water has decreased to some extent, and partly alleviated the situation. (For further information on the human well-being consequences of changes to the Aral Sea, see Chapter 5.)

20.4.2 Modification of Water Regimes

Water regimes of inland waters have been modified by humans for centuries, with the last 50 years in particular witnessing large-scale changes in many parts of the world, often associated with drainage and infilling activities as described earlier (Brinson and Ines Malvarez 2002; Junk 2002; Malmqvist and Rundle 2002; Tockner and Stanford 2002; see also reviews cited earlier). Modifications include construction of river embankments to improve navigation, drainage of wetlands for agriculture, construction of dams and irrigation channels, and the establishment of inter-basin connections and water transfers. (See Table 20.7 and Boxes 20.9 and 20.10; see also Chapter 7.) These changes have improved transportation, provided local flood control and hydropower, boosted fisheries, and increased agricultural output by making more land and irrigation water available. At the same time, physical changes in the hydrological cycle have resulted in the disconnection of rivers from their floodplains and wetlands, caused seasonal changes in water flows, increased the likelihood and severity of flooding (see Chapter 16), disrupted links with groundwater systems, and enabled saline water to intrude on freshwater systems in many coastal regions.

Further, these changes have also altered the flow velocity in rivers—transforming some to large lakes, such as the Kariba lake

Table 20.7. Alteration of Freshwater Systems Worldwide (Revenga and Kura 2003)

Alteration	Pre–1990	1900	1950–60	1985	1996–98
Waterways altered for navigation (km)	3,125	8,750	–	> 500,000	
Canals (km)	8,750	21,250	–	63,125	–
Large reservoirs[a]					
Number	41	581	1,105	2,768	2,836
Volume (sq. km.)	14	533	1,686	5,879	6,385
Large dams (>15 m high)	–	–	5,749	–	41,413
Installed hydro capacity (megawatts)	–	–	< 290,000	542,000	–660,000
Hydro capacity under construction (megawatts)	–	–	–	–	–126,000
Water withdrawals (cu. km. per year)	–	578	1,984	–3,200	–3,800
Wetlands drainage[b] (cu. km.)	–	–	–	160,000	–

– Data not available.

[a] Large reservoirs are those with a total volume of 0.1 cubic kilometers or more. This is only a subset of the world's reservoirs.

[b] Includes available information for drainage of natural bogs and low-lying grasslands as well as disposal of excess water from irrigated fields.

BOX 20.9

Danube River

Engineering structures have inexorably altered the Danube River, one of the major rivers of central and eastern Europe. Since 1950, hundreds of artificial lakes have been constructed along the Danube and its tributaries to provide storage and release of water for flood control, hydropower, navigation, irrigation, and domestic and industrial water supply. The construction of dikes and reservoirs has led to the loss of floodplain zones, with important loss of habitats and modification of the Danube's hydrological and sediment regimes.

Structures built along the first 1,000 kilometers of the river have formed an almost uninterrupted artificial waterway through a chain of 59 hydropower dams. The delta has also been changed with the construction of polders, canals, dikes, and fish farms, which along with eutrophication have led to major ecological changes in the river (IUCN 1992). These changes have altered the nature of the river and the delta, negatively affecting both services and the biodiversity, such as the extent of fisheries and a reduction or even loss in some places of the filtering capacity provided by reed beds and riparian vegetation. Further adverse change is expected with construction of the Bystroye navigation canal through the delta.

BOX 20.10

South American Wetlands and Rivers

The construction of hydroelectricity schemes poses a major threat to wetlands in South America. In Brazil, rapidly rising energy demands have stimulated ambitious plans to build dams on nearly all major rivers, except the main stream of the Amazon (Junk and Nunes de Mello 1987; World Energy Council 2003). However, many rivers have low gradients, and in such cases dams inundate large areas and provide little energy; for example, the Balbina reservoir on the Uatuma River in the Brazilian Amazon covers 2,300 square kilometers and produces $<$10 megawatts per square kilometer. There are likely to be significant socioeconomic trade-offs from the construction of these reservoirs to produce hydroelectricity (Fearnside 1989).

In Brazil, rapidly expanding agriculture, mainly for soybean production, has increased demand for inexpensive transport along the rivers. Waterways (*hidrovias*) have been constructed or are under construction (Brito 2001), which involves straightening sinuous stretches of the river channels, dragging, removing obstacles such as logs and rocky outcrops, and placing signals for ship traffic. Environmental impact analyses are lacking in most cases. In 2000, the Brazilian government stopped plans to construct a *hidrovia* through the Pantanal of Mato Grosso. This project would have threatened one of the largest wetlands in the world (Ponce 1995; Hamilton 1999). Plans have not yet been abandoned by private enterprises, however, and infrastructure construction is proceeding.

in southern Africa; creating a chain of connected deep reservoirs, such as those along the Volga River, Russia; leading to channelization, such as that along the Mississippi and Missouri Rivers in the United States; or significantly reducing flows to floodplains and downstream habitats, including deltas such as the Indus in Pakistan. Similarly, converting wetlands for agricultural purposes without completely destroying them, as with much of sub-Saharan agriculture or paddy (rice), still results in hydrological change.

Modifications to water regimes have drastically affected the migration patterns of birds and fish and the composition of riparian zones, opened up access to exotic species, and contributed to an overall loss of freshwater biodiversity and inland fishery resources (Revenga et al. 2000), as well as led to alterations to upstream and downstream habitats. Dams also affect the magnitude and timing of water flow and sediment transport of rivers, often for long distances downstream. The Aswan High Dam in Egypt, for example, has led to reduced sediment transport for more than 1,000 kilometers downstream (McAllister et al. 1997). A further example of the downstream effects of dams is illustrated in the Indus delta, where rapidly accelerating mangrove loss as a result of reduced freshwater flows has seriously jeopardized the livelihoods of 135,000 people who rely on mangrove products to a total economic value of $1.8 million a year for fuelwood and fodder, as well as a coastal and marine fisheries sector that generates domestic and export earnings of almost $125 million annually (Iftikhar 2002).

Other examples of large-scale drivers of change in inland water systems are those affecting the Dead Sea (ILEC and UNEP 2003) and the Mesopotamian marshlands in Iraq (Partow 2001; UNEP 2002). Lying in the heart of the Syrian-African rift valley at the southern outlet of the Jordan River, the Dead Sea—417 meters below sea level—is the world's saltiest large water body. It is severely threatened by excessive water withdrawals in the north and dams and industrial development in the south as a result of ever-increasing industry, agriculture, and tourism. The annual flow of the Jordan River was approximately 1,370 million cubic meters in the 1950s, while today the total river discharge to the Dead Sea is about 300 million cubic metes a year. As a result, the level of the lake is dropping by about one meter each year (ILEC and UNEP 2003).

The Mesopotamian marshlands have also been severely affected in recent decades. These covered an area of 15,000–20,000 square kilometers before being reduced by drainage and dam construction along the Tigris and Euphrates Rivers (Partow 2001). Now they cover less than 400 square kilometers. The capacity of dams along these rivers currently exceeds the annual discharge of both rivers, drastically reducing the supply of downstream floodwaters that were so important in delivering sediments and nutrients to the marshland. Further, in the early 1990s drainage schemes were used to divert large amounts of water from the marshlands—an event that was made easier by the upstream damming. (See Figure 20.10 in Appendix A.)

There are now more than 45,000 large dams (more than 15 meters high) (WCD 2000), 21,600 of which are in China. This represents a 700% increase in the water stored in river systems compared with natural river channels since 1950 (Vörösmarty et al. 1997). Water storage and sediment retention from dams have had enormous impacts on suspended sediment and carbon fluxes, as well as on the waste processing capacity of aquatic habitats (Vörösmarty et al. 1997). The construction of large dams has doubled or tripled the residence time of river water (Revenga et al. 2000), with enormous impacts on suspended sediment and carbon fluxes, waste processing, and aquatic habitat, and has resulted in fragmentation of the river channels. Revenga et al. (2000) found 37% of 227 river basins around the world were strongly affected by fragmentation and altered flows, 23% moderately affected, and 40% unaffected. (See Figure 20.11 in Appendix A.) Strongly or moderately fragmented systems are widely distributed globally. Small dams can also have major affects on the ecological condition of inland water systems (Oritz Rendan 2001), and many inland surface and groundwater systems have also been affected by modifications at smaller scales.

The extent of recent change is illustrated by figures collated for Asia and South America. In Asia, 78% of the total reservoir volume has been constructed in the last decade, and in South America almost 60% of all reservoirs have been built since the 1980s (Avakyan and Iakovleva 1998). The debate about the construction of dams is ongoing (WCD 2000)—weighing up, for example, the benefits against the potential adverse consequences of constructing further dams in the upper Mekong in China (Dudgeon 2003).

The effects of modification of flow regimes on fish migrations have been reviewed by Revenga and Kura (2003). The direct impacts of dams on diadromous fish species such as salmon are now *well established.* Indirect impacts of flow alteration, such as the reduction of floods and loss of lateral connections on floodplains, are also important. In many instances the construction of reservoirs has resulted in the disappearance of fish species adapted to river systems and the proliferation of species adapted to lakes, many of which were non-native. Examples include the decline of the sturgeon and the caviar industry in rivers such as the Volga in Russia (Finlayson et al. 1993). In West Africa, a sharp decline of *Mormyridae* (an elephant-nosed fish family of Osteoglossiformes) was observed in Lakes Kainji and Volta after the inundation of their preferred habitats as a result of dams (Lévêque 1997).

Cases of adverse impact on the structure of riparian vegetation and morphology from dams, embankments, and canals are also widely reported (Nilsson and Berggren 2000). In tropical Asia, change in flooding patterns due to river modification has affected riverine and wetland-dependent mammal populations, such as marshland deer and the Asian rhino in Thailand, India, and China, and diadromous fish stocks, such as sturgeons in China (Dudgeon 2000c). Similar cases have been reported by Pringle et al. (2000) for North and South America.

20.4.3 Invasive Species

The introduction of some non-native (alien) invasive species has contributed to species extinction in some freshwater systems (see Malmqvist and Rundle 2002; Tockner and Stanford 2002; see also reviews cited earlier). The problems caused by invasive species are very much a global concern (Mooney and Hobbs 2000). The spread of exotic species in inland waters is increasing with the spread of aquaculture, shipping, and global commerce. (See Boxes 20.11 and 20.12.) Examples include the pan-tropical weeds salvinia (*Salvinia molesta*) and water hyacinth (*Eichhornia crassipes*) that originated in South America but which are now widely distributed across the tropics. The cane toad (*Bufo marinus*), bullfrog (*Rana catesbeiana*), European domestic pig (*Sus scrofa*), carp (*Cyprinus carpio*), and zebra mussel (*Dreissena polymorpha*) are examples of animals that have become established outside of their native range and disrupted the inland water systems that they have invaded.

Species such as the water hyacinth, Canadian pondweed (*Elodea canadensis*), and mimosa (*Mimosa pigra*) have spread around the globe (Sculthorpe 1967; Gopal 1987; Walden et al. 2004) and remain largely unaffected by extensive and expensive control or management programs. Canadian pondweed illustrates the dilemma caused by invasive species. It is the first documented example of the explosive growth of an aquatic weed that originated in North America and in the late nineteenth century invaded the waterways of Europe. In becoming established, it grew rapidly, reproducing vegetatively, and reached maximum population densities within a period of a few months to four years. These population densities were maintained for up to five years and then declined to levels that were not considered a nuisance. The reasons for the rapid increase and subsequent decline were not determined, and this paradox still affects efforts to manage invasive species in inland waters.

Efforts to determine which of the many species that are introduced into new environments have not been fully successful have done little other than illustrate that only a small proportion of introduced species are likely to flourish and become serious problems (Williamson 1996; Manchester and Bullock 2000). While many species have features that enable them to take advantage of changed ecological conditions, there are likely as many factors that would limit establishment and growth.

Water hyacinth is an example of a widespread alien species that has caused considerable economic and ecological damage in inland water systems around the world (Gopal 1987). It is believed to be indigenous to the upper reaches of the Amazon basin, was spread in the mid-nineteenth century throughout much of the world for ornamental purposes, and now has a pan-tropical distribution. The plant spreads quickly to new rivers and lakes, clogging waterways and infrastructure, reducing light and oxygen in freshwater systems, and causing changes in water chemistry and species assemblages that affect fisheries. Water hyacinth control and eradication has become one of the top priorities for many environmental government agencies, with biological control being increasingly successful. (See Chapter 10.)

Many fish species have been spread beyond their native ranges, often as an important component of aquaculture (FAO

BOX 20.11

Invasive Species and European Rivers (Information supplied by H. Ketelaars)

For many centuries canals have been constructed between rivers and other water bodies in Europe, through which species actively migrated or were aided by shipping traffic, either in ballast water or outside on the hull of ships. The Volga-Baltic Waterway, reconstructed in 1964, connecting the Caspian basin with the Baltic region, is one example that has enabled translocation of many aquatic species, such as copepods, rotifers, the onychopod *Bythotrephes longimanus,* and several fish species to the Volga basin. The Main-Danube Canal, officially opened in 1992, is another that has allowed many Ponto-Caspian invertebrate species to reach the Rhine basin and from there to disperse to other basins, mainly in ballast water.

Intentional introductions of aquatic species have occurred mainly in the past two centuries. The North American amphipod *Gammarus tigrinus* was deliberately introduced in 1957 in the German rivers Werra and Weser because the local gammarid fauna had disappeared due to excessive chloride pollution. The mysid *Mysis relicta* has been introduced in many Scandinavian lakes to stimulate fish production. Three North American introduced crayfish species have established themselves in many European waters and introduced "crayfish plague" (*Aphanomyces astaci*), which has almost eliminated the native crayfish (*Astacus astacus*).

At least 76 non-European freshwater fish have been introduced into European fresh waters, with approximately 50 establishing self-sustained populations. When introductions between areas within Europe are also considered, the number of introduced species is more than 100. The numerically most important families are cyprinids and salmonids, of which grass carp (*Ctenopharyngodon idella*), silver carp (*Hypophthalmichthys molitrix*), rainbow trout (*Oncorhynchus mykiss*), and brook char (*Salvelinus fontinalis*) are now widely distributed in Europe. Only a few introductions have resulted in the spread of economically important species.

BOX 20.12

North America's Great Lakes and Invasive Species

Alien invasive species have threatened the Great Lakes ever since Europeans settled in the region. And since the 1800s, more than 140 exotic aquatic organisms of all types—including plants, fish, algae, and mollusks—have become established in the Great Lakes. The rate of introduction of exotic species has increased with human activity in the watershed. More than one third of the organisms have been introduced in the past 30 years, a surge coinciding with the opening of the St. Lawrence Seaway (Great Lakes Information Network 2004).

Approximately 10% of the Great Lakes' non-indigenous species have had significant impacts, both economic and ecological. For example, the sea lamprey has cost millions of dollars in losses to recreational and commercial fisheries and millions of dollars in control programs. Alewife fish littered beaches each spring and altered food webs, thereby increasing water turbidity before salmonids such as chinook salmon (themselves exotic) were stocked as predators and the foundation of a new recreational fishery.

Since 1991, the Great Lakes Panel on Aquatic Nuisance Species has worked to prevent and control the occurrence of aquatic alien invasive species in the Great Lakes, although efforts have not been totally successful.

1999). Introductions are usually done to enhance food production and recreational fisheries or to control pests such as mosquitoes and aquatic weeds. Introduced fish, for example, account for 96% of fish production in South America and 85% in Oceania (Garibaldi and Bartley 1998). The introduction of non-native fish, however, has had severe ecological costs. A survey of 31 studies of fish introductions in Europe, North America, Australia, and New Zealand found that in 77% of the cases, native fish populations were reduced or eliminated following the introduction of non-native fish. In 69% of cases, the decline followed the introduction of a single fish species, with salmonids responsible for the decline of native species in half of these (Ross 1991). The introduction of salmonids is attracting increased attention, as they have reduced the genetic diversity of wild stocks. In Canada and the United States, 68% of the recorded extinctions of 27 species and 13 sub-species of fish were due in part to the introduction of alien species (Miller et al. 1989). Similarly, in Mexico and Colombia, introduced fish pose a major risk to native fish and fisheries stock (Contreras-Balderas 2003; Alavrado and Gutiérrez 2002).

Fish introductions to tropical Asia and Latin America over the last 150 years have occurred mainly either to enhance food production (carps and tilapias, for instance) or for recreational purposes (piscivorous fish such as trout and bass for sport fishing) (Revenga and Kura 2003). The impacts of these species on the native fish fauna and ecosystems have not been well documented, although Fernando (1991) reports that introduced fish were not found to have caused severe damage to indigenous species except for some incidents in Latin America where piscivores were introduced.

In recent decades, tilapia species have been established and become a substantial contributor to inland fisheries in Mexico, the Dominican Republic, northeast Brazil, and Cuba (where as much as 90% of the fishery is tilapia species) (Fernando 1991). Although this has not resulted in the collapse of native fish stocks in most cases, it does indicate a significant shift in the composition and structure of biological communities in those systems.

In tropical Asia, herbivores and omnivores, such as Indian, Chinese, and common carps, account for the majority of introductions (Revenga and Kura 2003). Except in China, these temperate species of carps have not contributed much to fishery yield in the tropics. In comparison, tilapias have had a similar effect here as in Central America, boosting capture fishery in Sri Lanka and Thailand and aquaculture in Philippines, Taiwan, and Indonesia (Fernando 1991). In China, the world's largest producer of inland fisheries, carp contributes significantly to fisheries production. Although research on the impact of introduced species on the native aquatic ecosystems of China is limited, a few well-documented cases exist, such as Dianchi Lake in Yunnan Province, and Donghu Lake in Hunan Province, where it has been shown that indigenous and endemic fish species assemblages have significantly changed and many of their populations have declined (Xie et al. 2001).

Further information on invasive aquatic species can be found on the Global Invasive Species Program web site. Analyses of the economic costs of non-native invasive species are becoming more common, as shown by the fishery examples just mentioned, as are risk assessments of important species (e.g. Finlayson et al. 2000; van Dam et al. 2000, 2002a). The importance of alien invasive species in inland waters is likely to increase in response to global change (van Dam et al. 2002b).

20.4.4 Fisheries and Other Harvesting

Inland fisheries are a major source of protein for a large part of the world's population. People in Cambodia, for example, obtain roughly 60–80% of their total animal protein from the fishery resources of the Tonle Sap alone (MRC 1997). In some land-locked countries, this percentage is even higher; for example, in Malawi about 70–75% of the total animal protein for both urban and rural low-income families comes from inland fisheries (FAO 1996).

Global production of fish and fishery products from inland waters in 2002 amounted to 32.6 million tons (FAO 2004)—8.7 million tons from wild capture fisheries and the rest (23.9 million tons) from inland aquaculture. There is little dispute that major increases in the harvest of freshwater fish have occurred over the last two decades, mostly in the developing world, but as these statistics show, much of this increase is the product of aquaculture operations and enhancement efforts such as fish stocking and the introduction of non-native fish species in lakes and rivers.

Increased freshwater harvests, however, do not indicate healthy freshwater fish stocks or healthy aquatic ecosystems. In fact, FAO's last major assessment of inland fisheries (1999) reported that most inland capture fisheries that rely on natural reproduction of the stocks are overfished or are being fished at their biological limit and that the principal factors threatening inland capture fisheries are fish habitat loss and environmental degradation. In addition, one of the limitations in monitoring the state and condition of inland fish stocks is that the catch from inland fisheries is believed to be underreported by a factor of two or three, due to the large volume of harvest that is consumed locally, and remains unrecorded (FAO 1999). Asia and Africa are the two leading regions in inland capture fisheries, accounting for 90% of the catch in 2002 (FAO 2004). China alone accounts for at least one quarter of the inland catch, followed by India (9% of the catch), Bangladesh (8%), and Cambodia (4%) (FAO 2004).

Aquaculture continues to grow more rapidly than any other animal food-producing sector, at an average rate of 8.9% per year since 1970—a much higher rate than that for capture fisheries (1.2%) or terrestrial farmed meat products (2.8%) (FAO 2004). Most aquaculture production (58%) comes from the freshwater environment, the main producer by far being China. Between

1970 and 2000, inland water aquaculture production in China increased at an average annual rate of 11%, compared with 7% for the rest of the world (FAO 2004). However, many aquaculture operations, depending on their design and management, can and have contributed to habitat degradation, pollution, introduction of exotic species, and the spread of diseases through the introduction of pathogens (Naylor et al. 2000; see also Chapter 26).

Many other species of vertebrates are also harvested from inland waters, some in large numbers—such as turtles, waterbirds, crocodiles, and frogs. Overharvesting, whether for food, medicinal purposes, or recreation, has become a problem in many countries, and many species are locally or regionally threatened. For example, the increase in the harvesting and trade of freshwater turtles in South and Southeast Asia is causing severe declines in species populations, putting some of these species at risk of extinction (van Dijk et al. 2000). Because of the increase in trade, 11 proposals to list turtle species under Appendix II of CITES were accepted by consensus at the CITES Conference of the Parties in November 2002 (CITES 2002).

20.4.5 Water Pollution and Eutrophication

It is *well established* that nutrient concentrations have increased substantially in rivers throughout the world (Heathwaite et al. 1996; Revenga et al. 1998), resulting in eutrophication, harmful algal blooms, and high levels of nitrate in drinking water (Malmqvist and Rundle 2002). (See Chapters 7, 12, 15, and 19.) Many specific examples are available for inland water systems (e.g. Malmqvist and Rundle 2002; Tockner and Stanford 2002). For instance, the agricultural sector contributes an average of 50% of the total load of nitrogen and phosphorus to the Danube River in Europe, domestic sources contribute about 25%, and industry or atmospheric deposition 25%. Hazardous substances of particular concern are pesticides, ammonia, PCBs, polyaromatic hydrocarbons, and metals (IUCN 1992). (See also Chapter 15.) Industry and mining are responsible for most of the direct and indirect discharges of hazardous substances into the Danube and Volga Rivers in Europe, while transport is an important source of oil pollution (IUCN 1992; Popov 1992). Microbiological contamination by pathogenic bacteria, viruses, and protozoa is an important water quality problem in many regions of the world (see Chapters 7 and 15), and diffuse discharges from agriculture are important sources of micro-pollutants for both surface and groundwaters.

Jorgensen et al. (2001) notes that eutrophication is the most widespread problem in lakes and reservoirs and also one of the most difficult to abate. Cyanobacteria blooms have increased and are a major problem in inland and coastal waters worldwide. The problem of increased eutrophication from land-based activities is well shown for the Mississippi River in the United States, with problems along the length of the river and in the coastal zone—the so-called dead zone in the Gulf of Mexico.

It is *well established* that pollution from point sources such as mining has had devastating impacts on the biota of inland waters in many parts of the world. For example, the release of stored tailings (mine wastes) from the Aznalcollar mine some 50 kilometers from the Doñana National Park in Spain illustrated the problems that can occur to both ecological and socioeconomic activity of the areas downstream (Bartolome and Vega 2002). Following a spillage in 1998, an estimated 5.5 million cubic meters of acidic, metal-enriched water and 1.3–1.9 million tons of toxic tailings were spread over 4,600 hectares of downstream habitats—with fatal consequences for much of the biota in the affected area and a consequent disruption to the tourism industry. The cost of removing the tailings and contaminated soil reached about 3.8 billion euros.

In developing countries, an estimated 90% of wastewater is discharged directly to rivers and streams without any waste processing treatment, and in some locations both surface and groundwater have been so polluted that they are unfit even for industrial uses (WMO 1997). Threats of water quality degradation are usually most severe in areas where water is scarce due to the reduced capacity for waste dilution. These threats are exacerbated by industrial and agricultural practices that channel waste products into inland waters, including caves and other underground water.

Meybeck (2003) provides an overview of water pollution problems for inland waters. (See Table 20.8.) In industrial countries, fecal contamination has been largely eliminated, while new problems, particularly from agriculture run-off, are increasing everywhere. In other countries this is not the case, and fecal contamination is a major problem. In developing countries, urban and industrial pollution sources are increasing faster than related wastewater treatment.

Contamination by pesticides has increased rapidly since the 1970s, with many different substances being involved. In the Seine basin, in France, for example, more than 100 different active molecules are known to occur (Chevreuil et al 1998). The use of persistent chemicals is now increasingly regulated in Western Europe and North America. Records of PCBs and DDT in sedimentary archives peaked in the 1970s and are now markedly decreasing (Valette-Silver 1993). The persistence of these products can be high, however, and their degradation products can be more toxic than the parent molecule. (See Chapter 15.) Additionally, it is extremely difficult to assess and address the effects of multiple chemicals together in inland waters, both in the short and the long term.

Toxic substances are known to be a serious and increasing threat in developing countries as land use in watersheds changes. Chemical pollution from urban domestic and industrial sources and from pesticides is increasing in many key lake watersheds such as Lake Baikal and the African Great Lakes (Ntakimazi 1992;

Hecky and Bugenyi 1992). Lake Baikal water, fish, and seals all contain measurable levels of organochlorine compounds (Kucklick et al. 1994). Concentrations of chlorinated organic compounds have declined in some North American Great Lakes fish species but remain high for all fish species in Lakes Michigan and Ontario (Rowan and Rasmussen 1992). There have also been recent discoveries of endocrine-disrupting toxics in pulp wastewater that have caused abnormal male sexual organs to develop in alligators, feminization of male fish and turtles, and masculinization of female fish (Mathiessen and Sumpter 1998; Mathiessen 2000). Further information on human health and toxic substances can be found in Chapter 14.

20.4.6 Climate Change

It is arguable whether or not climate change has already affected inland waters and their species, but it is anticipated (*medium certainty*) that it will directly or indirectly affect the biota and services provided by inland waters (van Dam et al. 2002b; Gitay et al. 2002). As climate change will increase the pressure on habitats that are already under severe pressure from other drivers just described and will interact in a synergistic manner, it is considered briefly here.

The certainty with which with which we can attribute cause and effect of climate change is undermined by the extent of our data and existing knowledge; in all but a few cases the data are inadequate. We are, however, highly confident that many inland waters are vulnerable to climate change. Particularly vulnerable are those at high latitudes and altitudes, such as Arctic and sub-Arctic bog communities, or alpine streams and lakes (Gitay et al. 2002; IDEAM 2002), as well as those that are isolated (Pittock et al. 2001) or are low-lying and adjacent to coastal wetlands (Bayliss et al. 1997). Groundwater systems will also suffer as climate change affects recharge of aquifers (Danielopol et al. 2003).

The major expected impacts to inland waters include warming of rivers, which in turn can affect chemical and biological processes, reduce the amount of ice cover, reduce the amount of dissolved oxygen in deep waters, alter the mixing regimes, and affect the growth rates, reproduction, and distribution of organisms and species (Gitay et al. 2002). It is *very certain* that sea level rise will affect a range of freshwater systems in low-lying coastal regions. For example, low-lying floodplains and associated swamps in tropical regions could be displaced by salt-water habitats due to the combined actions of sea level rise and larger tidal or storm surges (Bayliss et al. 1997; Eliot et al. 1999). Plant species not tolerant to increased salinity or inundation could be eliminated, while salt-tolerant mangrove species could expand from nearby coastal habitats. Changes in the vegetation will affect both resident and migratory animals, especially if these result in a major change in the availability of staging, feeding, or breeding grounds for particular species (Boyd and Madsen 1997; Zockler and Lysenko 2000).

The most apparent faunal changes will probably occur with migratory and nomadic bird species that use a network of wetland habitats across or within continents. The cross-continental migration of many birds is at risk of being disrupted due to changes in habitats (see references in Walther et al. 2002). Reduced rainfall and flooding across large areas of arid land will affect bird species that rely on a network of habitats that are alternately or even episodically wet and fresh or drier and saline (Roshier et al. 2001). Responses to these climate-induced changes will be affected by fragmentation of habitats or disruption or loss of migration corridors or even by changes to other biota, such as increased exposure to predators by wading birds (Butler and Vennesland 2000), as a consequence of adaptation to and mitigation of climate change (Gitay et al. 2002).

It is anticipated with *medium certainty* that fish species distribution will move toward the poles, with cold-water fish being further restricted in their range, and cool and warm-water fish expanding in range. Aquatic insects, on the other hand, will be less likely to be restricted, given that they have an aerial life stage. Less mobile aquatic species, such as some fish and mollusks, will be more at risk because is it thought that they will be unable to keep up with the rate of change in freshwater habitats (Gitay et al. 2002). Climate change may also affect the wetland carbon sink, although the direction of the effect is uncertain due to the number of climate-related contributing factors and the range of possible responses (Gitay et al. 2002). Any major change to the hydrology and vegetative community of a wetland will have the potential to affect the carbon sink. Vegetation changes associated with the water drawdown in northern latitudes, for example, result in increased primary production, biomass, and slower decomposition of litter, causing the net carbon accumulation rate to remain unchanged or even increase. Other aspects of climate change, such as longer and more frequent droughts and the thawing of permafrost, will have negative effects on the carbon balance in peatland.

The extent of change in inland waters as a consequence of climate change should not be addressed in isolation of other drivers of change, as many of the adverse effects of the abovementioned drivers of change will be exacerbated by climate change (Gitay et al. 2002; van Dam et al. 2002). Further, the affects of climate change will be felt across many of the services delivered by inland waters; as an example, a sensitivity projection for Canada's river regions in response to climate change indicates that there will be an increase in flood and river erosion that will affect the use and value of rivers for recreation, conservation, fisheries, water supply, and transportation (Ashmore and Church 2001).

20.5 Trade-offs, Synergies, and Management Interventions for Inland Water Systems

Management of inland waters worldwide has been regularly based on decision-making mechanisms that have not included sufficient consideration of the wider implications or outcomes of specific actions or responses (see Finlayson et al. 1992; Finlayson and Moser 1991; Whigham et al. 1993; Mitsch 1994; Jaensch 1996; McComb and Davis 1998; Ali et al. 2002). The assessment and case studies provided in this chapter illustrate the outcomes of management decisions that have not considered the trade-offs between services provided by inland waters. These decisions have often resulted in the degradation of inland waters, and the loss or decline in the multiple services they provide, in favor of a smaller number of services, such as the supply of fresh water for drinking or irrigation or the supply of hydroelectricity or transport routes. The case studies cited earlier of the Aral and Caspian Seas illustrate the adverse effects that such sectorally based decisions can have. More multisectorally based responses and decisions are required if we are to reverse the loss and degradation of inland waters and the decline in the services that they deliver. Further information on management responses is provided in the MA *Policy Responses* volume in chapters on biodiversity (Chapter 5), nutrient management (Chapter 9) and freshwater (Chapter 7).

The past loss and degradation of inland waters and their services is increasingly being recognized through international conventions and treaties as having exceeded the value gained through such actions. In response, the Ramsar Wetlands Convention has provided leadership and worked collaboratively with other organizations, both informally and through formal agreements, such as the joint work plans agreed with the Convention on Biological Diversity, to develop more multisectoral approaches to stop and reverse the loss and degradation of wetlands. This includes working collaboratively to address the Millennium Development Goals (see MA *Policy Responses,* Chapter 19) and to reduce the rate of loss of biodiversity by 2010 (see Chapter 4 in this volume and MA *Policy Responses,* Chapter 5). Many other international collaborative efforts and initiatives are underway, some linked with and many others independent of the Ramsar Convention.

The Mediterranean wetland program (MedWet) is one collaborative, multisectoral initiative that is formally linked with the Ramsar Convention and has resulted in strident calls and actions to not only halt the loss and degradation of wetlands but to reverse their consequences. The program has evolved considerably since the initial declaration of intent was made in Grado, Italy, in February 1991 (Anon 1992). The declaration contained a recommendation that all supranational organizations, Mediterranean governments, NGOs, and concerned individuals adopt the following goal: to stop and reverse the loss and degradation of Mediterranean wetlands.

It further recommended a number of actions that should be included in a strategy to support this goal:

- identification of priority sites for wetland restoration and rehabilitation and the development and testing of techniques for their complete rehabilitation;
- evaluation of existing and proposed policies to determine how they affect wetlands;
- increased institutional capacity to conserve and effectively manage wetlands through vigorous education and training programs;
- integrated management of all activities concerning wetlands, their support systems, and the wider area surrounding them carried out by properly funded and well-staffed multidisciplinary bodies with active participation of representatives of government, local inhabitants, and the scientific and nongovernmental community;
- open consultation and free flow of information when managing wetlands; and
- adoption and enforcement of national and international legislation for better management.

The declaration was not received with enthusiasm by some key sectors; however, the individual recommendations have since been repeated or extended in many fora and with widespread acceptance, the most recent being in the Chilika Statement agreed at the Asian Wetland Symposium 2005, Bhubaneswar, India, in February 2005 (www.wetlands.org/news&/docs/AWS_Declaration.pdf).

In the early 1990s, the concept of replacing lost wetlands received increasing support (e.g., see Finlayson and Larsson 1991; Finlayson et al. 1992; Hollis et al. 1992), and more attention is now directed toward wetland restoration worldwide (see Eiseltova 1994; Eiseltova and Biggs 1995; Zalidis et al. 2002).

However, current rates of restoration are inadequate to offset the continued rate of wetland loss in many regions. Given this situation, the Ramsar Convention on Wetlands has proposed a series of guidelines to assist in reversing the loss of wetlands. These cover the current thinking and agreement on priority topics for management of inland waters, but due to political considerations many are not as prescriptive as requested by some parties, especially when dealing with indirect drivers of change, such as trade and population growth. The current guidance covers these topics:

- wise use of wetlands;
- national wetland policies;
- laws and institutions;
- river basin management;
- participatory management;
- wetland communication, education, and public awareness;
- designation of Ramsar sites;
- management of wetlands;
- international cooperation;
- wetland inventory;
- impact assessment;
- water allocation and management;
- coastal management; and
- peatlands.

One of the key barriers in developing management responses to prevent further loss and degradation of wetlands is the unwillingness to undertake effective actions. Sufficient knowledge is generally now available to know what actions are required to stop further loss and degradation and when these are most likely to be effective. (The general reviews cited at the start of section 20.3 provide guidance to a wealth of useful information.) There is also inadequate adoption and understanding of ''ecosystem approaches'' for managing inland waters, including the precautionary principle, as espoused by the Convention on Biological Diversity and the Convention on Wetlands (Ramsar Convention Secretariat 2004). The World Commission on Dams (WCD 2000) illustrated some of the contradictory issues faced in managing inland waters. Ongoing debate about the allocation of water for environmental outcomes in rivers and associated wetlands illustrates the trade-offs that have long been inherent features in water management, especially at a river basin scale. Further dialogue is required to ensure the delivery of water allocations from dams to support a wider range of services than has generally been the case.

The extent of loss and degradation of wetlands, and trade-offs in services have resulted in an increasing number of large and small restoration projects, driven by legislation and public attitude, particularly in North America and Europe, and increasingly in Australia. The cost and complexity of large-scale restoration are shown by the plan for the restoration of the Everglades, USA (CERP 1999). A comprehensive plan containing more than 60 components has been prepared to restore, protect and preserve the water resources of central and southern Florida, including the Everglades wetlands. The plan has important environmental and economic benefits and is anticipated to cost US$7.8 billion over 30 years. The responses to the accidental release of tailings (mine wastes) from the Anzacollar mine site upstream of the Donana wetlands in Spain in 1998 also illustrate the complexity of large-scale restoration programmes involving both environmental and economic issues (Gallego Fernandez and Garcia Nove 2002; G. Schmidt personal communication). The removal of the waste, treatment of contaminated water, acquisition of contaminated land and rehabilitation cost the regional and central governments and the European Union some E208 million; the mining company spent a further E79 million and suffered an operational loss of E17 million; with another E81 million from the European Union being allocated for inter-related rehabilitation, including re-establishing some of the separately altered hydrological features of this important wetland.

In response to the complex nature of many management issues for inland waters, a good deal of effort has been invested in developing collaborative and integrated management structures that address common interests and differences between agencies or states over the services provided by shared inland water systems. (See Iza 2004 for an analysis of international agreements for the conservation of freshwater ecosystems.) In some instances, integrated and comprehensive strategies and action plans have been developed in support of active interventions, regionally and locally.

The Mediterranean wetland initiative, for example, is a successful mechanism for the conservation and wise use of wetlands throughout the Mediterranean region through local and regional actions and international cooperation (Papayannis 2002). More specific thematic initiatives or action plans cover the management of invasive species (e.g., Wittenberg and Cock 2001; McNeeley et al. 2001), the reintroduction and maintenance of biodiversity (e.g. Bibby et al. 1992), or the integration of development with conservation (e.g., Davies and Claridge 1993).

In some cases, specific technical methods suitable for local application have been developed (see Zalidis et al. 2002 for information on wetland restoration in the Mediterranean), with increasing recognition that integrated collation, collection, and use of data and information are essential aspects of an effective management mechanism, whether they are focused on local or regional issues. This recognition has resulted in the development of models that provide a basis for standardized inventory, risk assessment and evaluation, and monitoring, such as that proposed for an Asian wetland inventory, and integrated analyses incorporating community consultation and communication (Finlayson et al. 2002; Finlayson 2003; Ramsar Convention Secretariat 2004).

There has in recent years been increased interest in the development of mechanisms to encourage and support the capacity of local communities to contribute to the management of inland waters, particularly where local knowledge and experience can be constructively used (Ramsar Convention Secretariat 2004). Recognition of the beneficial outcomes that can occur when local people are involved in the management of inland waters and their services now underpins efforts by the Ramsar Convention to encourage best management practices. This concept is implicit in the guidance provided by the Convention covering policy and legal instruments, economic and social interactions, and technical tools (Ramsar Convention Secretariat 2004).

The challenge for the Convention and others is to ensure that such instruments and tools are used effectively and, as required, improved. This can be done within an adaptive management regime, noting that this necessitates active learning mechanisms, the involvement of key stakeholders, and the balancing of vested interests. All too often, however, the involvement of local communities has not occurred or has not been effective at resolving conflict between users and resource managers (Carbonell et al. 2001), or indeed, between competing users of sites listed as Wetlands of International Importance.

The Ramsar concepts of wise use and ecological character can be used to guide management interventions for wetlands (Ramsar Convention Secretariat 2004). Wise use of wetlands has been defined by the Convention as "their sustainable utilisation for the benefit of humankind in a way compatible with the maintenance of the natural properties of the ecosystem." "Sustainable utilisation" is in turn defined as "human use of a wetland so that it may yield the greatest continuous benefit to present generations while maintaining its potential to meet the needs and aspirations of future generations." "Ecological character" is defined under the Convention as "the sum of the biological, physical, and chemical components of the wetland ecosystem, and their interactions, which maintain the wetland and its products, functions, and attributes."

A suggested redefinition of this is under discussion, which would ensure that ecosystem services (referred to as products, functions, and attributes, in the definition above) are considered as central components of ecological character and not just dependent on the ecological components and processes. Such a definition could read "the combination of the ecosystem components, processes, and services that characterize the wetland." Wise use could similarly be redefined to reflect the emphasis on ecosystem services and human well-being. These redefinitions further emphasize the close match between the Ramsar concepts and the conceptual framework of the Millennium Ecosystem Assessment, with the latter being more explicit about the emphasis on ecosystem services and human well-being.

20.6 Inland Water Systems and Human Well-being

It is *well established* that the services provided by inland waters are vital for human well-being and poverty alleviation (Dugan 1990; Revenga and Kura 2003; Finlayson et al. 1992; Finlayson and Moser 1991; Whigham et al. 1993; Mitsch 1994; McComb and Davis 1998; Lundqvist and Gleick 2000). A list of the services provided by inland waters was provided at the start of this chapter in Table 20.1. The benefits of these services to human well-being, and hence the consequences of reduced availability and supply for human well-being, are discussed in more detail in individual chapters that cover services derived from inland water systems—in particular, fresh water (Chapter 7), food (Chapter 8), nutrient cycling (Chapter 12), waste processing and detoxification (Chapter 15), regulation of natural hazards (Chapter 16), and various cultural and amenity services (Chapter 17). An analysis of human well-being and its relationship to ecosystem services is provided in Chapter 5. This section provides a brief assessment of specific examples of the relationship between the degradation of inland waters and human well-being. (See Table 20.9.)

The ecosystem services of inland water systems provide a basis for human well-being for people who live in close proximity to the system as well as those who live much further away. As human well-being is strongly affected by the extent to which people are able to meet their most basic needs (water, food, shelter, and health) in a secure manner, the sustainable use of inland waters for ensuring human well-being is vital. (See Box 20.13, as well as Box 20.8 earlier in the chapter.) This is well illustrated by the infrastructure and trade networks that have been developed to supply, for example, drinking water, food, and energy from lakes and reservoirs that can be located far from densely populated urban areas. It is also *well established* that in both rural and urban areas the poor are likely to suffer most when the availability and quality of water and food is reduced, whether due to failures in the infrastructure and trade networks or the demise of the systems themselves. (See Chapters 6, 7, and 8.) The impacts on human well-being of degraded supporting and regulating services from inland waters is often not recognized as readily, but it can be as significant as changes to provisioning services—for example, a reduction in the capacity of a wetland to filter water or to detoxify wastes can have significant consequences for human health, even if food provision remains adequate.

It is also known with *high certainty* that maintenance of an adequate flow of good-quality water is needed to maintain the health of inland water systems as well as estuaries and deltas. The reverse is also true: healthy inland water systems generate and maintain adequate flows of good-quality water. As the supporting services of inland waters are the result of interactions among the ecological components within the system and those in the catchment, human well-being is inexorably linked to the maintenance of the ecological character of inland water systems. Because of

Table 20.9. Summary of Critical Changes in Inland Water Systems and Services and Their Impacts on Human Well-being (WWDR 2003)

Major Drivers of Change in Inland Waters	Major Impacts on Services Derived from Inland Waters	Function(s) at Risk	Major Impacts on Human Well-being	Vulnerable People or Places
Population and consumption growth	increases water abstraction and acquisition of cultivated land through inland water drainage; increases requirements for all other activities, with consequent risks	virtually all ecosystem functions, including habitat, production, and regulation functions	increased health risks reduced quality and quantity of water	urban communities
Infrastructure development (dams, dikes, levees, diversions, interbasin transfers, etc.)	loss of integrity alters timing and quantity of river flows, water temperature, nutrient and sediment transport, and thus delta replenishment; blocks fish migrations; increases mosquito breeding	water quantity and quality, habitats, floodplain fertility, fisheries, delta economies	increased agricultural productivity reduced food security reduced economic opportunities increased health risks	downstream communities
Land conversion	eliminates key components of aquatic environment; loss of functions, integrity, habitat, and biodiversity; alters runoff patterns; inhibits natural recharge; fills water bodies with silt	natural flood control, habitats for fisheries and waterfowl, recreation, water supply, water quantity and quality	reduced household security loss of productive land increased release of carbon dioxide into the atmosphere reduced recreational, cultural, historical, or religious values	
Overharvesting and exploitation	depletes living resources, ecosystem functions (leading to fire and drought), and biodiversity (groundwater depletion, fisheries collapse)	food production, water supply, water quality, and water quantity	reduced food security reduced economic opportunities (e.g., tourism) increased risk of natural disasters	communities living adjacent to and dependent on inland water resources
Introduction of exotic species	outcompetes native species, alters production and nutrient cycling, loss of biodiversity	food production, wildlife habitat, recreation	reduced food security (e.g., reduced genetic variety and resilience)	
Release of pollutants to land, air, or water	pollution of water bodies alters chemistry and ecology of rivers, lakes, and wetlands	water supply, habitat, water quality, food production	reduced quality of water reduced food security reduced household security	
Climate change	greenhouse gas emissions produce dramatic changes in runoff and rainfall patterns, loss of coastal areas to sea level rise, increased erosion of shorelines, degradation of water quality by rising temperatures, changes in water flow volume, increased salt-water intrusion, increased water demand for irrigation, increased flood damage, increased drought frequency	shoreline protection, water quality, dilution capacity, transport, flood control	reduced household security reduced quality and quantity of water reduced productive land	

the complexities of these interactions, management of supporting services is likely to be best served by a holistic river basin approach, within which the resource base is assessed and managed in an integrated manner (Hollis 1998; Ramsar Convention Secretariat 2004). Implementation of a river basin or ecosystem approach implies stakeholders' acceptance that there may need to be trade-offs between them for access to the services provided by the river and its associated habitats.

It is widely accepted that the loss and degradation of inland waters has reduced their natural ability to buffer or ameliorate the impacts of floods (see Chapter 16) and hence threaten the security of individuals and entire communities. For example, in Southern Africa in 1999 and 2000, devastating floods affected more than 150,000 families (Mpofu 2000); degradation of wetlands such as the Kafue in Zambia, damming of rivers, deforestation, and overgrazing led to a reduced absorption of excess water and magnified the impact of the floods (Chenje 2000; UNDHA 1994). The same applies to floodplains where increasing human habitation, drainage of wetlands, and river canalization have severely restricted the capacity to buffer floods in many places and increased people's vulnerability to flooding. (See Chapters 7 and 16.) In Central Europe in 2002, extreme flooding as a consequence of

BOX 20.13

Afghanistan (Adapted from UNEP 2003)

Three to four recent years of drought have compounded a state of widespread and serious resource degradation in Afghanistan, which has largely been brought about by two decades of conflict. These droughts have lowered water tables, dried up wetlands, denuded forests, eroded land, and depleted wildlife populations. With rainfall low and erratic in much of Afghanistan (and with large areas of desert or semi-desert), rivers, streams, and other inland waters are crucial for human needs, such as drinking water and agriculture, and for maintaining populations of wild plants and animals, many of which provide potential for economic opportunities.

Over 80% of Afghan people live in rural areas, yet many of their basic resources—water for irrigation, trees for food and fuel—have been lost in just a generation. In the Helmand River basin, 99% of the Sistan wetland dried up between 1998 and 2003. Without a stable source of water, much of the natural vegetation of inland water areas has been lost, and it has often been collected for fuel. This has contributed to soil erosion and significant movement of sand onto roads and into settlements and irrigated areas.

Up to 100 villages in the vicinity of the Sistan wetland have been submerged by windblown dust and sand, and many agricultural fields have also been affected. If the sedimentation continues, the risks are clear: as the storage capacity of the lakes, reservoirs, and irrigation networks is reduced, opportunities to store water will be lost, and at the same time vulnerability to both drought and flooding will increase. The construction of deep wells to meet immediate humanitarian needs, coupled with the collapse of traditional water management systems and decision-making structures at the community level, has resulted in many downstream users losing access to traditional supplies, leading to disputes over access to water resources.

unusually high rainfall was exacerbated by physical alterations along the rivers and changes in the water retention capacity of the riparian zone and upper catchment. Floods and droughts also typically affect the poorest people most severely, as they often live in vulnerable areas and have few financial resources for avoidance, mitigation, or adaptation. (See Chapters 6 and 16.) Few countries have been free of damaging floods during the last few decades (Kundzewicz and Schellnhuber 2004).

Although largely eliminated in wealthier nations, water-related diseases are among the most common causes of illness and mortality affecting the poor in developing countries. The extent of water pollution and its link with human health in many countries is well known. The World Health Organization has estimated that there are 4 billion cases of diarrhea each year in addition to millions of other cases of illness associated with a lack of access to clean water. (See Chapter 7.) Water-borne diseases that result in gastrointestinal illness (including diarrhea) are caused by consuming contaminated water. (See Chapter 14.)

Perhaps less recognized as a major influence on human well-being, but as potentially debilitating to people, are actions that degrade inland water systems and result in a reduction in water supply or encourage the spread and abundance of disease vectors. (See Chapters 5 and 14.) Schistosomiasis, for example, has been spread by the construction of dams and large lakes in many countries, and interference with the hydrology of wetlands has exacerbated the incidence of mosquito-borne diseases. In 2000, the estimated mortality due to water sanitation hygiene–associated diarrheas and some other water sanitation–associated diseases (schistosomiasis, trachoma, intestinal helminth infections) was 2,213,000. There were an estimated 1 million deaths due to malaria, and more than 2 billion people were infected with schistosomes and soil-transmitted helminths, of whom 300 million suffered serious illness. The majority of those affected by water-related mortality and morbidity are children under five (WWDR 2003). Since many illnesses are undiagnosed and unreported, the true extent of these diseases is unknown (Gleick 2002).

Water-related diseases that are exacerbated by the degradation of inland waters (see Chapter 14) include those caused by the ingestion of water contaminated by human or animal feces or urine containing pathogenic bacteria or viruses, such as cholera, typhoid, amoebic and bacillary dysentery, and other diarrheal diseases; diseases passed on by intermediate hosts such as aquatic snails or insects that breed in aquatic ecosystems, such as dracunculiasis, schistosomiasis, and other helminths as well as dengue, filariasis, malaria, onchocerciasis, trypanosomiasis, and yellow fever; and diseases that occur when there is insufficient clean water for washing and basic hygiene or when there is contact with contaminated water, such as scabies, trachoma, typhus, and flea-, lice-, and tick-borne diseases.

In addition to disease from inland waters, water-borne pollutants have a major effect on human health, often through their accumulation in the food chain. Many countries now experience problems with elevated levels of nitrates in groundwater from the large-scale use of organic and inorganic fertilizers. Excess nitrate in drinking water has been linked to methemoglobin anemia in infants, the so-called blue baby syndrome. Arsenicosis, the effect of arsenic poisoning when drinking arsenic-rich water over a long period, is also known and is a particularly severe problem in Bangladesh and Western Bengal, where some 35–77 million inhabitants are exposed to excessively high levels of arsenic in water drawn from wells (Bonvallot 2003). On the whole, though, it is still extremely difficult to quantify the cumulative effects of long-term exposure to a variety of chemicals at what seem like low concentrations. (See Chapter 15.)

There is increasing evidence from wildlife studies that humans are at risk from a number of chemicals that mimic or block the natural functioning of hormones, interfering with natural body processes, including normal sexual development. (See Chapter 15.) Chemicals such as PCBs, DDT, dioxins, and those from at least 80 pesticides are regarded as ''endocrine disrupters,'' which may interfere with human hormone functions, undermining disease resistance and reproductive health. Pharmaceuticals in the environment represent an emerging environmental issue, with many being only partially removed by conventional wastewater treatment and therefore being deposited into a variety of receiving waters. The presence of these compounds in inland waters is considered harmful for humans even though the extent of harm remains uncertain. It is certain, though, that the degradation of inland water systems reduces the potential of these systems to mitigate the effects of pollutants through detoxification and waste processing and results in an overall reduction in human well-being.

It is expected that continued degradation of inland water systems will result in further reduction in human health, especially for vulnerable people in developing countries where technological fixes and alternatives are not as readily available. The evidence that the degradation of inland waters results in a loss of services and reduction in human health is incontrovertible, and yet degradation continues at a global scale. Conserving and using sustainably the services derived from inland waters is an ongoing challenge for society, as is reducing the negative downstream consequences of inland waters degradation. Failure to reduce and reverse the loss and degradation of inland water systems will further undermine human well-being. The problem of continued loss and degradation is both environmental and social—it is *well established* that the loss and degradation of inland waters has and continues to reduce the ecosystem services available for people.

Main Messages

Forest ecosystems are extremely important refuges for terrestrial biodiversity, a central component of Earth's biogeochemical systems, and a source of ecosystem services essential for human well-being. The area and condition of the world's forests has, however, declined throughout recent human history. In the last three centuries, global forest area has been reduced by approximately 40%, with three quarters of this loss occurring during the last two centuries. Forests have completely disappeared in 25 countries, and another 29 countries have lost more than 90% of their forest cover. Although forest cover and biomass in Europe and North America are currently increasing following radical declines in the past, deforestation of natural forests in the tropics continues at an annual rate of over 10 million hectares per year—an area larger than Greece, Nicaragua, or Nepal and more than four times the size of Belgium. Moreover, degradation and fragmentation of many remaining forests are further impairing ecosystem functioning.

Information about the world's forest is limited and unevenly distributed. The *Global Forest Resources Assessment 2000* (FRA-2000) done by the Food and Agriculture Organization of the United Nations reports that only 22 out of 137 developing countries possess a series of time-series inventories, 28 countries have no inventory, and 33 have only partial inventories. Further, 34 countries only have national forest inventories from before 1990, while only 43 have inventories completed after 1990. More than half the inventories used to compile FRA-2000 were either more than 10 years old or incomplete. Forest information is also inadequate—and sometimes statistically unreliable—for many industrial countries. Despite the proliferation of new remote sensing technologies, the reliability of remote sensing products remains uncertain.

Forests, particularly those in the tropics, provide habitat for half or more of the world's known terrestrial plant and animal species. This biodiversity is essential for the continued health and functioning of forest ecosystems, and it underlies the many ecosystem services that forests provide.

Forests and woodlands play a significant role in the global carbon cycle and, consequently, in accelerating or decelerating global climate change. Forests contain about 50% of the world's terrestrial organic carbon stocks, and forest biomass constitutes about 80% of terrestrial biomass. Forests contribute over two thirds of global terrestrial net primary production. Slowing forest loss and restoring forest cover in deforested areas could thus help mitigate climate change.

More than three quarters of the world's accessible freshwater comes from forested catchments. Water quality declines with decreases in forest condition and cover, and natural hazards such as floods, landslides, and soil erosion have larger impacts.

The provisioning services obtained from forests have substantial economic value. Forests annually provide over 3.3 billion cubic meters of wood (including 1.8 billion cubic meters of fuelwood and charcoal), as well as numerous non-wood forest products that play a significant role in the economic life of hundreds of millions of people. The combined economic value of "non-market" (social and ecological) forest services may exceed the recorded market value of timber, but these values are rarely taken into account in forest management decisions.

The rural poor are particularly dependent on forest resources. As many as 300 million people, most of them very poor, depend substantially on forest ecosystems for their subsistence and survival. The 60 million indigenous people who live in forest areas are especially dependent on forest resources and the health of forest ecosystems. Although use of forest resources on its own is often insufficient to promote poverty alleviation, forest loss and degradation has significant negative consequences on human well-being.

Forests play important cultural, spiritual, and recreational roles in many societies. For many indigenous and otherwise traditional societies, forests play an important role in cultural and spiritual traditions and, in some cases, are integral to the very definition and survival of distinct cultures and peoples. Forests also continue to play an important role in providing recreation and spiritual solace in more modernized, secular societies, and forests and trees are symbolically and spiritually important in most of the world's major religious traditions.

Forest loss and degradation are driven by a combination of economic, political, and institutional factors. The main direct drivers of tropical deforestation are agricultural expansion, high levels of wood extraction, and the extension of roads and other infrastructure into forested areas. Indirect drivers include increasing economic activity and associated market failures, a wide range of policy and institutional weaknesses and failures, the impacts of technological change, low public awareness of forest values, and human demographic factors such as population growth, density, and migration. While temperate and boreal forest cover has stabilized and even increased, the quality of these forests is still threatened by air pollution, fire, pest and disease outbreaks, continued fragmentation, and inadequate management. Climate change threatens forests in all biomes.

Many forests are used almost to their full potential to provide fiber and fuel. By 2020, demand for wood and woodfuel is expected to grow considerably. This growth in demand is likely to stimulate the establishment of more industrial plantations, more-careful management of natural forests, and technological improvements in the efficiency of wood use. However, the establishment of plantations often results in trade-offs with services other than fiber production and with biodiversity.

Many developing countries have not effectively used forest resources in support of development efforts. Widespread corruption in the forestry sector has resulted in valuable forest resources frequently being seized and controlled by political and economic elites. The poor have often seen access to forest resources diminish and have not widely shared in the benefits of forest resource exploitation.

The paradigm of sustainable forest management has been widely embraced at national and international policy levels, but it has not yet been implemented to the point where it is appreciably mitigating the negative trends affecting the world's forests. SFM provides an increasingly sophisticated set of policies and tools for setting forest management on a more sustainable trajectory. Implementing SFM, however, requires overcoming many of the same economic, political, and institutional hurdles that drive deforestation and forest degradation. In addition, forest management would benefit from anticipating and incorporating resilience to the present and likely future impacts of climate change on forest ecosystems. Past policies aspired to control change in forest ecosystems assumed to be stable. The new imperative is to develop policies to manage the capacity of forest to cope with, adapt to, and shape changes. Responding to this imperative requires new information and new knowledge, including advanced science and technology, more effective national and global systems for forest inventory and monitoring, involvement of people in decision-making about forest management and use, and strengthened dialogue and cooperation with decision-makers in other sectors.

21.1 Introduction

Forest ecosystems, which for the purposes of this chapter include woodlands with an interrupted tree canopy, serve important ecological functions and provide wood and numerous other products that contribute significantly to human well-being at local, national, and global levels. The diverse ecosystem services provided by forests include the conservation of soil and water resources, positive influences on local climate, the mitigation of global climate change, the conservation of biological diversity, improvement of urban and peri-urban living conditions, the protection of natural and cultural heritage, subsistence resources for many rural and indigenous communities, the generation of employment, and recreational opportunities. Research indicates that forests supply about 5,000 different commercial products (Chiras 1998), and the forestry sector contributes about 2% of global GDP (FAO 1997). The centrality of forests for humanity has been acknowledged internationally in recent environmental agreements and processes including the United Nations Framework Convention on Climate Change, the Convention on Biological Diversity, the United Nations Convention to Combat Desertification, and the United Nations Forum on Forests.

While it is clear that the value of forest ecosystem services is very high, there are many gaps in scientific understanding and few practical solutions to reconciling the conflicts that arise from the competing values that different user groups ascribe to different forest services. Interests of landowners, local communities, governments, and the private sector vary and frequently conflict in both spatial and temporal terms. The time horizon for using individual forest services is substantially different, for example, for forest-dependent indigenous communities and large logging companies.

About 8,000 years ago, forest covered an estimated 6.2 billion hectares of the planet—about 47% of Earth's land surface (Billington et al. 1996). Peoples of the preagricultural era likely had significant impacts on these forest ecosystems. Some aboriginal tribes are thought to have caused numerous extinctions (such as of North American and Australian megafauna) (Flannery 1994, 2001), and forest has been actively cleared and manipulated in composition through fire and other means for thousands of years (Williams 2003).

From today's perspective, however, preagricultural impacts on overall forest cover appear to have been slight. Since that time, the planet has lost about 40% of its original forest (*high certainty*), and the remaining forests have suffered varying degrees of fragmentation and degradation (Bryant et al. 1997; Matthews et al. 2000; Ball 2001; Wade et al. 2003). Most of this loss has occurred during the industrial age, particularly during the last two centuries, and in some cases much more recently. Some analyses have yielded substantially smaller estimates. Richards (1990), for example, estimates global loss of forests to have been only about 20%.

Much of the progress of human civilization has been made possible by the conversion of some forest areas to other uses, particularly for agricultural expansion. However, this process has resulted in many trade-offs with forest ecosystem services, many of which have not been recognized.

Extensive biodiversity loss—including losses of genetic, species, and habitat diversity—has been one result of the shrinking of the world's forests (Myers 1996; McNeely et al. 1995; Reid and Miller 1989). There is also evidence that forest genetic resources as a whole have declined in quality, especially in areas where high-quality timber has been selectively extracted (Rodgers 1997; Kemp and Palmberg-Lerche 1994). Forest loss has also had a negative impact on the provision of ecosystem services, such as regulation of hydrological cycles. The negative impacts of deforestation appear most directly at the local level, where communities lose access to timber, fuelwood, and bushmeat or suffer increased flooding and landslides. Impacts have also been felt on a much larger scale as well. The widespread salinization of land and rivers in Australia, for example, is the result of extensive woodland clearing and the subsequent introduction of European agriculture (McFarlane et al. 1992; MDBC 1999).

Public awareness of the importance of forests and public concern over forest loss has grown substantially over the past several decades. Numerous international bodies such as the World Commission on Environment and Development (WCED 1987) and the World Commission on Forests and Sustainable Development (WCFSD 1999) have voiced concern about the deepening forest crisis, and the theory and practice of making the transition to "sustainable forest management" is a topic of intensive national and international debate. (See Box 21.1.)

The forest issue was a contentious topic at the 1992 U.N. Conference on Environment and Development, which sought—and ultimately failed—to reach agreement on an international convention on forests. Instead, UNCED adopted a nonbinding set of "Forest Principles," which gave life to a series of U.N. forest initiatives: the Intergovernmental Panel on Forests (1995–97), the Intergovernmental Forum on Forests (1997–2000), the United Nations Forum on Forests (2000–05), and the Collaborative Partnership on Forests (2000). These bodies have provided an important international "soft law" forum to debate global forest policy and have catalyzed a considerable amount of technical work on forest management and policy. It is nevertheless unclear to what extent this international forest policy architecture influences the government and private-sector decisions that actually affect forests on the ground (Chaytor 2001; Bass 2003). Current international and national processes addressing forest management are discussed in detail in MA *Policy Responses,* Chapter 8.

Reliable and comprehensive data and information are essential for determining forest conditions and trends and for development of national and international forest policies. As a whole, information on the world's forests has improved over the past few decades. This is partly a result of the emergence of new technologies such as remote sensing, but it is also due to improving data collection in some countries and to the efforts of scientific researchers and international institutions.

FAO holds the mandate within the U.N. system to compile, analyze, and supply global forest information, and the organization has steadily improved its capacities in this regard, resulting most recently in the *Global Forest Resources Assessment 2000,* discussed at length in this chapter. The UNEP World Conservation Monitoring Centre is another institution that has developed extensive information sources on the conservation aspects of forests. National reporting requirements under environmental conventions such as UNFCCC, CBD, and UNCCD are also a relatively new source of forest information. Many important contributions have been made by the scientific community as well (see, e.g., Wade et al. 2003). Finally, a number of international nongovernmental organizations such as IUCN–World Conservation Union, the World Wide Fund for Nature, and the World Resources Institute have developed their capacities to compile, analyze, and disseminate high-quality forest information.

Despite this progress, available information on the world's forests still contains many gaps and shortcomings. National data for some countries are not reliable, and the overall state of knowledge about the condition and trends of forests in many regions is incomplete. In addition, improvements in forest information have not been accompanied by effective sustainable forest management. Instead, increasing information capacities have provided an ever-more detailed picture of forest decline and its impacts on human well-being.

BOX 21.1

Defining and Measuring "Sustainable Forest Management"

It is well established that "sustainability" means satisfying present needs without compromising future options, but it is not obvious what this means in practical terms for forest management. The concept of "sustained yield" forest management for timber—based on the concept of equilibrium between growth and timber harvest that can be sustained in perpetuity (Thang 2003)—has evolved in line with the broader view of sustainable development articulated by the World Commission on Environment and Development (WCED 1987) and endorsed by the 1992 UNCED Forest Principles, subsequent international processes, as well as many national forest policies. The MA thus differentiates "sustained yield management"—the management and yield of an individual resource or ecosystem service—and "sustainable management," which refers to the goal of "ensuring that a wide range of services from a particular ecosystem is sustained" (MA 2003).

Although sustainable forest management is now widely accepted as the overriding objective for forest policy and practice, it is not easy to define. The problem is that "what is defined as sustainable forestry will vary greatly over space and time as society's needs and perceptions evolve." The Center for International Forestry Research therefore adopted a broad definition in which sustainable forest management means "maintaining or enhancing the contribution of forests to human well-being, both of present and future generations, without compromising their ecosystem integrity, i.e., their resilience, function and biological diversity" (Sayer et al. 1997). Further specification can only be accomplished through the elaboration of SFM criteria and both quantitative and qualitative indicators to measure progress in meeting those criteria. Accordingly, the Intergovernmental Panel/Forum on Forests process identified the development of SFM criteria and indicators as a high priority for international and national action, and nine regional processes involving 149 countries have been launched since 1992 to develop and implement SFM C&I (ECOSOC 2004).

Each of these processes is developing its own distinctive set of C&I to measure progress toward SFM in particular regions and forest biomes (Anonymous 1994, 1995; ITTO 1998; CCFM 2003). CIFOR, meanwhile, has developed a "C&I Toolbox" for the forest management unit level, which includes a generic C&I template (CIFOR C&I Team 1999). The template elaborates C&I within the framework of six SFM objectives:

- policy, planning, and institutional framework are conductive to sustainable forest management;
- ecosystem integrity is maintained;
- forest management maintains or enhances fair intergenerational access to resources and economic benefits;
- concerned stakeholders have acknowledged rights and means to manage forests cooperatively and equitably;
- the health of the forest actors, cultures, and the forest is acceptable to all stakeholders; and
- yield and quality of forest goods and services are sustainable.

The experience of CIFOR and the many regional processes attempting to develop and implement operational SFM C&I make two things clear. First, there is no one, neat definition of SFM that can be applied everywhere, although there are a number of core common elements. Second, "SFM is to a great extent a social issue. . . . In other words, forest policy must be part of comprehensive economic policy as expressed through agricultural policy, land use and population policy, tax codes, forest and recycling policy and other approaches to managing demand and supply" (Funston 1995; see also Folke et al. 2002). Kaimowitz (2003) notes that past efforts to promote sustainable forest management did not focus enough on macroeconomic, agricultural, infrastructure, finance, and energy policies that slowed progress in implementation of the SFM paradigm. In this respect, Canadian initiatives on SFM (such as partnership in forests, models forests, and so on) are a promising tool for implementing sustainable forest management (e.g., Collate 2003; Weaver 2003).

Despite negative trends in some regions, the world's forests still demonstrate considerable vitality and resilience and retain the potential to meet growing human needs—if, that is, they are managed more sustainably. The recent history of boreal forests, for example, has demonstrated their strong regeneration capacity despite high levels of natural and anthropogenic disturbance. The total area of closed forests in Russia has registered a net increase of about 80 million hectares over the past 40 years, even though about 55 million hectares were clear-cut during this period (Shvidenko and Nilsson 2002). Studies also show that tropical forests can regenerate when agriculture in an area is abandoned (such as around the ancient city of Angkor in Cambodia, on Mexico's Yucatan peninsula, and in old sugarcane fields in Venezuela) (Richards 1996; Hamilton 1976).

A number of countries and regions have undergone periods of extensive forest loss but then developed solid legislative, economic, and social backgrounds for the transition to sustainable forest management. For example, Europe lost 50–70% of its original forest cover, mostly during the early Middle Ages, and North America lost about 30%, mostly in the nineteenth century (WRI et al. 1996; Chiraz 1998; UNECE 1996). Forest policies and economic development in the twentieth century in these regions, however, have encouraged forest restoration and plantation development, restoring a significant part of the forest cover in both Europe and North America. Yet many forests in these regions continue to decline in quality, are becoming increasingly fragmented, and suffer the impacts of industrial pollution.

In many parts of the developing world, deforestation continues to accelerate in tandem with poverty and high levels of population growth. For these regions, the transition to sustainable forest management is a much greater challenge. And the stakes for the global community are much higher: if tropical developing countries must wait until they reach the levels of economic development—and deforestation—of Europe before making this transition, a large percentage of known terrestrial species may become extinct in the meantime due to the disproportionate number of species found within their forests (Rodrigues et al. 2003).

This chapter assesses the condition of the world's forest ecosystems and trends in the services they provide for human well-being. It begins with a presentation of some key definitions and a brief discussion of some of the data and methodological issues the authors confronted in compiling and assessing the information presented. The chapter then reviews forest and woodland extent, condition, and changes. Subsequent sections assess the services provided by forest ecosystems and the direct and indirect drivers of changes in forest and woodland cover and condition. Finally, the chapter reviews the implications of these changes for human well-being. This chapter should be read in conjunction with Chapter 9 of this volume, on timber, fuel, and fiber, and Chapter

8 of the *Policy Responses* volume, on wood, fuelwood, and nonwood forest products.

21.2 Definitions, Methods, and Data Sources

The choices of definitions, methods, and data sources made for this chapter have a profound influence on the presentation of statistics and findings on global forest conditions and trends. This section therefore discusses the choices made, the rationale behind them, and the strengths and limitations of the definitions, methods, and sources used. These should be borne in mind when reviewing the data presented in subsequent sections.

21.2.1 Definitions of Forest and Woodland

There is no single, agreed definition of ''forest,'' due to varying climatic, social, economic, and historical conditions. The situation is complicated by the fact that for many governments, ''forest'' denotes a legal classification of areas that may or may not actually have tree cover.

A variety of definitions of forest are in use. For example, the *Global Biodiversity Outlook* (Secretariat of the Convention on Biological Diversity 2001) defines forests as ''ecosystems in which trees are the predominant life forms'' and notes that a more precise definition than this remains surprisingly elusive because trees occur in many different ecosystems, at different densities, and in different forms. Most definitions refer to canopy or crown cover, which is essentially the percentage of ground area shaded by the crowns of the trees when they are in full leaf. The U.N. Framework Convention on Climate Change process has adopted a nationally defined threshold of between 10% and 40% canopy closure. A number of remote sensing products of the last decade (MODIS, GLC-2000) have introduced other approaches (see edcddac.usgs.gov/glcc/glcc.html, glcf.umiacs.umd.edu/data/lanfcover/data.shtml, www.gvm.sai.jrc.it/glc2000/defaultGLC2000.htm, duckwater.bu.edu/lc/dataset). Estimates of forest or woodland area thus vary widely depending on the definitions used. The precise definitions employed should therefore be borne in mind when comparing forest cover data provided by different institutions.

This chapter mainly follows the definition of forest used by FAO's *Global Forest Resources Assessment 2000* (FAO 2000, 2001c). The FAO definition covers ecosystems that are dominated by trees (defined as perennial woody plants taller than 5 meters at maturity), where the tree crown cover (or equivalent stocking level) exceeds 10% and the area is larger than 0.5 hectares (FAO 2000, 2001b, 2001c). The term includes forests used for production, protection, multiple use, or conservation, as well as forest stands on agricultural land (such as windbreaks and shelterbelts of trees with a width of more than 20 meters) and plantations of different types. It also includes both naturally regenerating and planted forests. The term excludes stands of trees established primarily for agricultural production, such as fruit tree plantations, and trees planted in agroforestry systems (but rubber and cork oak stands are included). Billions of trees outside the forest in cities, along roads and rivers, on farms, and so on are not included in the two categories just described.

The threshold of 10% is crucial in this definition. In many countries, ''forest'' is typically defined as areas with substantially higher levels of canopy closure, for example 30–40%, depending on age, in Russia (FFSR 1995) and 60% in South Africa (Scholes 2004). In the classification of forests introduced by UNEP-WCMC, all forest classes have a minimum threshold of 30% except for the class including sparse trees and woodlands, for which canopy closure is from 10% to 30% (UNEP-WCMC 2004). Another controversial feature of the FAO definition is its inclusion of ''temporarily unstocked areas'' (clear-cuts, burnt areas, and so on) as forest. This means that a country may have logged or burned most of its forest, but—unless it converts the area to another officially noted productive land use—it will appear to have retained the same forest area as before (WRM 2002; Wunder 2003). These definitional issues generate some problems with analysis of FRA-2000 data and the conclusions that flow from that analysis.

Nonetheless, the FAO definition has been adopted because it is the first consistent definition of forests to be applied globally. A global assessment such as this one obviously requires a consistent global definition of ''forest'' and a global dataset that adheres to that definition. The strengths and limitations of FRA-2000 are summarized in Box 21.2.

FRA-2000 defines ''closed forests'' as those with a canopy cover of more than 40% (and it is this class of forest that is incorporated into the system maps and analysis throughout this volume). ''Open forests'' have a canopy cover of between 10% and 40%. ''Fragmented forests'' (which are not quantitatively defined by FRA-2000) refer to mosaics of forest patches and non-forestland. Closed forests, open forests, and fragmented formerly closed forests, as a rule, are ecologically substantially different from one another.

In this chapter, ''woodland'' refers to the type of land cover characterized by trees and shrubs: ''other wooded land.'' Other wooded land, or OWL, is defined by FRA-2000 as land with a tree crown cover (or equivalent stocking level) of 5–10% of trees able to reach a height of 5 meters at maturity, a crown cover of more than 10% of trees not able to reach a height of 5 meters at maturity (such as dwarf or stunted trees), or shrub and bush cover of more than 10%. OWL excludes areas with the tree, shrub, or bush cover just specified but of less than 0.5 hectares and width of 20 meters, as well as land predominantly used for agricultural practices (FAO 2000, 2001c). Trees growing in areas that do not meet the forest and OWL definitions are excluded (FAO 2001c). Such trees are included in assessments of ''trees outside forests.''

Plantations are defined by FRA-2000 as ''forests established by planting or/and seeding in the process of afforestation or reforestation, and consisting of introduced species or, in some cases, indigenous species.'' There is a substantial difference between plantations in the tropics and those in temperate and boreal countries. Broadly, there are two different types of plantations: short-rotation, fast-growing species plantations (such as *Eucalyptus* and *Pinus*) and plantations of long-rotation, slow-growing species of valuable hardwoods. In the tropics, important hardwood plantation species include teak (*Tectona grandis*) and rosewood (*Dalbergia spp.*). Common hardwood plantation species in the temperate zone include oak (*Quercus spp.*), ash (*Fraxinus spp.*), poplar (*Populus spp.*), and walnut (*Juglans spp.*). This is not, however, a hard-and-fast distinction, since some medium-rotation softwood sawlog plantations (in South Africa, for instance, and New Zealand) also produce valuable timber.

21.2.2 Variations in National-level Forest Information

Thirty years ago, it was noted that ''more is known about the surface of the moon than about how much of the world's surface is covered by forests and woodlands'' (Persson 1974). Since then, the quantity and quality of available information has improved in some countries but has declined in others and overall remains inadequate. Information about the status of forest inventories in

BOX 21.2

Strengths and Limitations of the *Global Forest Resources Assessment 2000* (FAO 2001c; Matthews 2001; R. Persson, personal communication, 2004)

FRA-2000 is the most comprehensive, globally consistent assessment of global resources available and is the basis for the assessment presented in this chapter. The definitional and methodological choices made by FRA-2000, however, substantially affect the conclusions of the assessment and are therefore important to understand and take into account.

FRA-2000 presents new estimates of global forest cover in both 2000 and 1990. The *1990 FAO Global Forest Resources Assessment* (FRA-1990) used different crown-cover thresholds for industrial (20%) and developing (10%) countries that hindered consistent global analyses and comparisons. FRA-2000 uses a consistent threshold of 10% for all countries and has adjusted the FRA-1990 estimate of forest cover using the 10% global threshold as well. As a result, the FRA-2000 estimate of 1990 forest cover—the baseline from which changes in forest cover are calculated—has been revised upward, to 3.95 billion hectares from 3.44 billion hectares, a 15% increase over the original estimate made in 1990, with the biggest revisions occurring in industrial countries.

In many regions of the world, the use of 10% crown cover as a minimum threshold conflicts with scientific definitions of "forest" as a vegetation type as well as with traditional use and understanding of the term. While the need for a consistent global definition of "forest" is clear, the rationale for setting the threshold at such a low percentage is contested by many, and a number of other FRA methodological decisions remain questionable. The definition of plantations as "forest," for example, affects estimates of net forest loss in the tropics and obscures the actual rates of natural forest loss.

While most industrial countries have relatively good forest cover data, there are serious problems with the way forest cover data are reported in Canada and Russia. Because these two countries account for more than 65% of all forests in industrial countries, these national methodological inconsistencies skew results for the entire temperate and boreal region.

FRA-1990 used mathematical models to compensate for poor data availability in developing countries. The FRA-2000 analysis, however, is based on national forest inventory data supplemented by remote sensing information and expert opinion. While many national data used by FRA-2000 were obsolete or incomplete, the remote sensing survey used to supplement national data relied on images covering only 10% of total tropical forest area, focusing on the same randomly selected 117 sites surveyed in 1990. Deforestation, however, is not randomly distributed—it is highly concentrated along roads and rivers (Stokestad 2001)—and it is therefore arguable that a 10% sampling rate is insufficient to identify accurately how much forest survives intact and how much is being lost.

different countries can be found in the forest resources assessment publications of FAO (FAO 1982, 1993, 1995b, 1999a, 2000, 2001a, 2001b, 2001c). (The text of this section is largely based on Janz and Persson 2002.)

Most industrial countries have some kind of forest inventory. In 1990, 18 of 34 of these countries (containing 76% of the forest area in industrial countries) derived their forest area information from sampling-based national forest inventories, some of which were quite old. In the other 16 countries, information had been compiled by aggregating local inventories, which were usually carried out for forest management purposes (FAO 1995a). Such information contains unknown errors and is usually biased, as the aggregation method is known to produce significant underestimates of volumes and increment. A good example can be taken from Germany, where at the end of the 1980s a sampling-based national forest inventory was introduced that reported a stock-per-hectare increase from 155 cubic meters per hectare in 1985 to 298 cubic meters in 1990 (ECE/FAO 1985, 1992). Overall, it has been noted that the situation in several industrial countries (particularly in the former Soviet Union) is less than satisfactory for national and international forest policy development and implementation (FAO 2001d).

For developing countries, the quality of forest resources information also varies greatly. FRA-1990 reported that all but seven developing countries had at least one estimate of forest cover dating from between 1970 and 1990, usually based on remote sensing. Only 25 out of 143 countries had made more than one assessment. On average, the figures supplied to FAO were about 10 years old (FAO 1995a). FRA-2000 (FAO 2001d) reports that only 22 countries (of 137) have repeated inventories, 28 countries have no inventory, and 33 have a partial forest inventory; 34 have an inventory from before 1990 and 43 have one from after 1990. More than half the inventories used by FAO were either more than 10 years old or incomplete. Very few developing countries have up-to-date information on forest resources, and fewer have a national capacity for generating such information.

Knowledge of area and condition of forests in many countries does not seem to be improving, and in many cases it is actually declining. Additional issues of concern relate to the quality rather than the quantity of forestry-related information:

- There is often a strong interest in new technologies and the production of "showpiece" maps. Modern forest inventories are sometimes only forest mapping exercises, which do not contain all the information needed for sustainable forest management.
- There is a great deal of reliance on remote sensing technologies. However, remote sensing cannot provide information in many areas for which there is a need for better information, such as forest ownership and tenure, protection status, purpose and success rate of plantations, biodiversity, and production and consumption of forest-derived services.
- Few forest inventories are undertaken as part of regular monitoring schemes—most are one-time undertakings. As a result, comparable inventory information for different time periods is frequently unavailable.

The demand for forest information is increasing (for example, in response to the Intergovernmental Panel/Forum on Forests Proposals for Action and to report to international conventions), but there is no corresponding allocation of resources. The funds available for forest inventories are actually decreasing in many countries due to budget cuts and structural adjustment policies. For example, 20–30 years ago forest inventories in many countries were supported financially by international agencies, including FAO. Today hardly a single inventory of this type is being supported financially.

The trend in reliability of national data on forests for countries of Africa, Asia, and Latin America and the Caribbean can be estimated by classification of countries as having low (L), medium (M), or high (H) quality data (Persson 1974; FAO 1993; FAO 2001c). National inventory methods have been used as the main criterion for data quality classes. The ratio L:M:H (in percent to total amount of countries included in the survey) was 27:63:10 in 1970, 23:56:21 in 1990, and 11:25:64 in 2000. While there is an improving trend, progress has been slow, despite the increasing capabilities and utilization of remote sensing and other modern techniques. And some countries, such as Gabon and Côte d'Ivoire, have been covered by extensive inventories in the past but are now placed in the ''low'' category. Indeed, across Africa the number of countries in the ''low'' category increased between 1970 and 1990. The trend is more positive in Asia, but some of this improvement may due to the use of rapid assessment remote-sensing inventories.

21.2.3 Data Collection Methodology for FRA-2000

The FAO FRA process aims to collect statistical information on forests directly from countries. Information on temperate and boreal zones in industrial countries is collected through questionnaires. The national figures are then adjusted to fit FRA forest definitions. The data in FRA for developing countries, however, result from a dialogue between FRA and the countries, which included a number of steps: countries are requested to supply information; independent information (such as remote sensing) is used to corroborate the information received; estimates and outputs (partly by countries) are produced; and validation by and dialogues with countries are held. For FRA-2000, over 1,500 national and international reports were analyzed, and the information obtained was reclassified to fit FRA definitions in consultation with the providing countries.

It is evident, however, that official national statistics have many shortcomings following from weaknesses in national inventory methods and the varying political, administrative, and economic conditions of individual countries. In its analysis of the reliability of FRA-2000 data, FAO has pointed out that global results cannot be more accurate than national data and that all gaps and uncertainties of countries' statistics inevitably affect the FRA-2000 conclusions (FAO 2001c:350–51). Improvement in the information provided by international assessments such as FRA requires improvement in the information supplied at the national level. By using national statistics, however, FRA-2000 allows for ongoing improvement in the assessment process, whereby new information can be incorporated as it becomes available.

21.2.4 Global Forest Mapping Methodologies

In an effort to provide spatial definition of forests, the MA used two global maps produced by FRA-2000: the FRA-2000 global forest cover map (see Figure 21.1 in Appendix A) and the FRA-2000 global ecological zone map (see Figure 21.2 in Appendix A). In this assessment, these two datasets have been combined with a global continent map (ESRI 1998), in order to demonstrate forest class area geographically by continent and ecoregion. For the global summary statistics of the MA, the forest system was calculated from >40% forest cover classes of the Global Land Cover 2000 dataset.

The GLC2000 land cover database has been chosen as a core dataset for the MA—in particular, as a main input dataset to define the boundaries between systems such as forest, grassland, and cultivated systems. GLC2000 used the VEGA2000 dataset, providing a daily global image from the vegetation sensor onboard the SPOT4 satellite from November 1999 to December 2000. The GLC2000 dataset identified globally a total of 10 tree cover types: broadleaf evergreen; broadleaf deciduous (closed); broadleaf deciduous (open); needle-leaved evergreen; needle-leaved deciduous; mixed leaf type; regularly flooded fresh; regularly flooded saline; mosaic: tree cover/other natural vegetation; and burnt. Forests were identified as having a minimum of 15% tree cover and 3 meters height. Closed forests were defined as having more than 40% tree cover. When aggregated, forest areas in the GLC2000 compare spatially well with the forest areas defined in the FRA2000. (For further details of GLC2000, see Chapter 2.)

The forest map in Figure 21.1, developed using coarse resolution satellite imagery, relied mainly on the Global Land Cover Characteristics Database. Source data for the forest map were drawn from the 1995–96 dataset and consisted of five calibrated advanced very high resolution radiometer bands and a normalized difference vegetation index (FAO 2001c). Results of an accuracy assessment showed that overall map accuracy is approximately 80%. Closed forests are more accurately mapped than the average accuracy, with open and fragmented forests less accurately mapped and other wooded lands least accurately mapped (FAO 2001c).

The ecological zone map in Figure 21.2 was developed using national and regional maps of potential vegetation and climate data. A globally consistent classification was adopted, based on the Köppen-Trewartha climate system in combination with natural vegetation characteristics. A total of 19 global ecological zones have been defined and mapped, ranging from the evergreen tropical rain forest zone to the boreal tundra woodland zone (FAO 2001c).

Although this chapter uses some estimates of forest area derived from these two maps, it should be noted that FRA-2000 only uses these maps to indicate the spatial distribution of forests and does not use data derived from the maps in its statistics on forest extent and cover.

Remote sensing methods are becoming an important tool for improving data and knowledge on the world's forests in the future. New and planned satellite sensors appear to be very promising in this regard, and several global initiatives (GTOS, GOFC-GOLD) are focusing on their further development. Experiences over the last decade, however, illustrate a number of problems with the estimation of forest cover and extent from space. (See Box 21.3.)

21.3 Condition and Trends in Forest and Woodland Systems

21.3.1 Forest Area

FRA-2000 estimates the total area of global forests at 3,869 million hectares (0.6 hectares per capita), or about 30% of the world's land area (see Table 21.1), with closed forests accounting for 3,335 million hectares. (Table 21.1, unlike FRA-2000, divides Russian forests into their European and Asian parts based on national statistics in order to give a more accurate assessment of the relative areas of forest on the European and Asian continents.) This can only be taken as an approximate estimate, however, due to the methodological problems that the FAO faced with respect to data weaknesses and inconsistencies among countries, as described in the preceding section. As noted there, national data for many developing countries are scarce and unreliable, and inconsistencies also exist for some industrial countries. Data for Canada, for example, are aggregated from provincial sources and report only ''productive forestland,'' while ''unproductive forests'' are reported by FRA-2000 as other wooded land, even though many of them meet the FAO definition of forest. This anomaly resulted

BOX 21.3

Forest in Recent Global Land Cover Assessments Using Remote Sensing Methodologies

During the past decade, a number of attempts have been made to estimate forest area in the framework of global land cover assessments using various remote sensing methodologies. The major features of four satellite-based 1-kilometer land cover products in wide use by the international scientific community (McCallum et al. 2004) are compared and analyzed here.

The International Geosphere-Biosphere Program product (version 2.0) is derived from advanced very high resolution radiometer data from April 1992 to March 1993. This methodology employed a multi-temporal unsupervised classification of a normalized difference vegetation index with post-classification refinement using multi-source data. In total, 17 land cover classes were considered (USGS 2003).

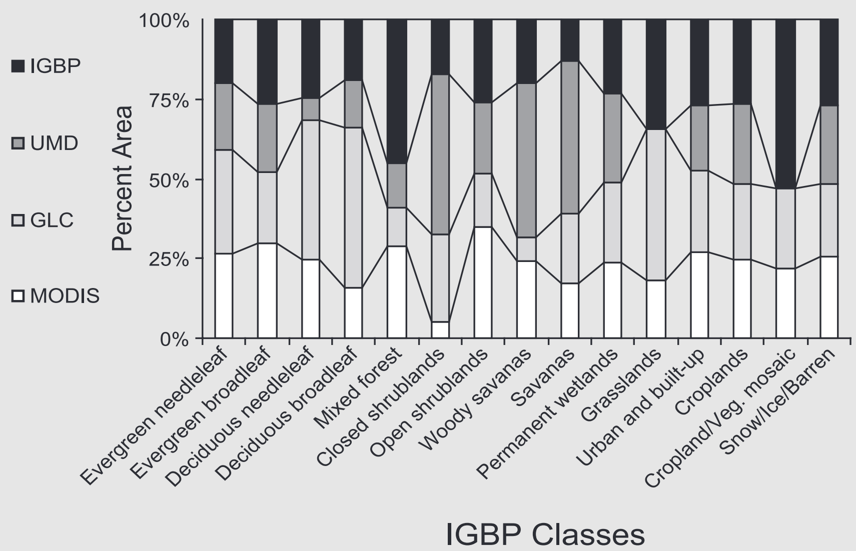
The University of Maryland product used the IGBP AVHRR dataset, utilizing all five AVHRR channels as well as the NDVI, to derive 41 multi-temporal metrics from monthly composites to represent the phenology of global vegetation. UMD used a supervised classification tree method, resulting in a total of 14 land classes (Hansen and Reed 2000).

Global Land Cover 2000 is based on daily mosaics of four spectral channels and NDVI from VEGETATION-SPOT 4 imagery acquired from November 1, 1999, to December 31, 2000; data from other sensors have been used to solve specific problems. A total of 22 classes were produced (JRC 2003).

The MODIS-Terra product utilized monthly composites of eight input parameters from October 2000 to October 2001. The classification, which resulted in 20 land cover classes corresponding to IGBP classes, was produced using a supervised approach with a decision tree algorithm (MODIS 2002).

Land classifications differed between some of these remote sensing methodologies. McCallum et al. (2004) carried out a comparison of these four products, applying physiognomic aggregation of different land classes (cf. Hansen and Reed 2000) using the IGBP classification (with 17 classes) as a base. Differences in estimated areas of the same classes are significant. (See Figure.)

All these remote sensing methodologies contain forest classes. Comparisons of the satellite-derived data and FRA-2000 are presented in the accompanying Table. Area estimates by all four remote sensing methodologies are less than those by FRA-2000, averaging −26.4% and varying from −13.5% (GLC 2000) to −43.6% (UMD, although in this case the large difference is additionally affected by incompatible classifications). The four remote sensing estimates, when compared for each aggregated IGBP class, vary from 12% to 74%. The reasons for the significant underestimates of forest area by these remote sensing methodologies compared with FRA-2000 are not completely clear. The remote sensing underestimates can probably be explained by the coarse resolution of the remote sensing technology used, fragmentation of forests in many regions, lack of satisfactory ground truth data for proper validation and verification of the remote sensing data, and the use of different classifications. By contrast, in this chapter's attempt to use the FAO global forest map the total area of the world's forests was estimated to be 4,356 million hectares—that is, about 12% more than the total provided by the FRA-2000 data.



Comparison of Forest Classes Derived from Four Global Land Cover Projects Using the IGBP Classification Terminology. The areas are presented as the percentage of an individual class to the total area of all forest classes inside of each product. (McCallum et al. 2004)

Forest Area: Comparison of Four Global Remote Sensing Land Cover Products and FRA2000 Using IGBP Classes 1–5 (McCallum et al. 2004)

IGBP Forest Classes	GLC-2000	IGBP	MODIS	UMD	Average	Range of Variation from Average
	Area by RS Global Products (*million hectares*)					(*percent*)
1 – Evergreen needleleaf	943	480	598	521	636	33.2
2 – Evergreen broadleaf	1,281	1,342	1,502	1,108	1,308	12.4
3 – Deciduous needleleaf	377	193	201	56	207	63.6
4 – Deciduous broadleaf	627	221	172	174	298	73.9
5 – Mixed forests	320	981	696	323	580	55.2
Total	3,548	3,217	3,168	2,182	3,029	19.5
	(*percent*)					
Difference with FRA2000	–13.5	–21.6	–23.7	–46.8	–26.4	

in underreporting of more than 170 million hectares (40%) of Canadian forestland. With this and similar adjustments, the global forest cover corresponding to the FAO definition would probably increase by about 5%.

Forests are not distributed evenly across the globe, as Figures 21.1 and 21.2 indicate. Although average forest cover on all continents except Antarctica exceeds 20%, vast territories are either completely bereft of forests or have negligible forest cover. FRA-2000 estimated that 56 countries have an average of only 3.9% forest cover. On the other hand, the six biggest forest countries—Russia, Brazil, Canada, the United States, China, and Australia—contain about 56% of the world's forests.

Table 21.1. Forest Area by Region in 2000 (FAO 2001c, modified for Europe and Asia; see explanation in text)

Region	Land Area	Forest Area: Natural Forests	Plantation	Total	Forest Coverage
	(million hectares)				*(percent)*
Africa	2,978	642	8	650	22
Asia	4,362	1,105	120	1,225	28
Europe	983	334	28	362	37
North and Central America	2,137	532	18	549	26
Oceania	849	194	3	198	23
South America	1,755	875	10	886	51
World total	**13,064**	**3,682**	**187**	**3,869**	**30**

Note: In this chapter, Russian forests are divided into European and Asian parts based on national statistics.

The area of the world's forests estimated using satellite-based methods is 4,356 million hectares (see Table 21.2), which is close to the recent estimate made by the UNEP World Conservation Monitoring Centre—4,540 million hectares (UNEP-WCMC 2002). The total area of closed forests is estimated at 2,860 million hectares (about two thirds of the total), with major areas in Asia, North America, and South America. The different values derived from FRA2000 and satellite data are mostly due to the different national thresholds of closed forests (in Russia, for instance, forests are classified as closed if canopy closure is more than 25%).

The threshold used for national inventories substantially changes estimates of forest area, as is clearly illustrated in Figure 21.3. Nonetheless, estimates of the extent of the world's forests are of the same order of magnitude. The satellite-based total area of global forests is only 11% more than FRA-2000 data in Table 21.2. The total area of global forests plus OWL is estimated to be 5,576 million hectares (about 42% of Earth's land area), which is very close to the corresponding FRA-2000 estimate of 5,532 million hectares.

The estimate in Table 21.2 for the area of tropical closed forests (1,229 million hectares) is in the range of previous estimates, such as those of IUCN at 1,140 million hectares (Collins et al. 1991; Sayer et al. 1992; Harcourt and Sayer 1996), project TREES at 1,165 million hectares (Mayaux et al. 1998), and Achard et al. (2002) at 1,116 million hectares for 1997, without Central America and Oceania. The FRA-1990 estimate was 1,298 million hectares (FAO 1996).

Of the total area of 1,494 million hectares of open and fragmented forests in Table 21.2, more than half (53%) is situated in tropical ecoregions and about 22% is in the boreal zone. A significant part of these forests in the tropics consist of sparse forests in dryland areas and degraded forests. By contrast, the majority of

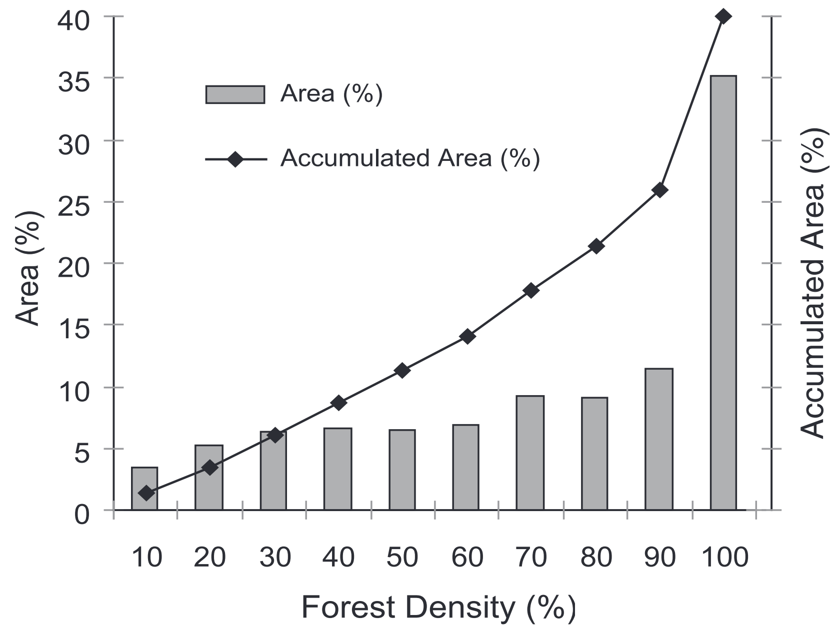

Figure 21.3. Distribution of World's Forests by Canopy Closure

boreal open forests are naturally sparse woodlands in the transition belt of the taiga-tundra ecotone.

The estimate derived from satellite data of the global area of other wooded land is 1,220 million hectares (see Table 21.3), which is 15% lower than the FRA-2000 statistical estimate. OWL plays a significant environmental and protective role in many regions, particularly in the arid tropics and sub-tropics, where it is also known as open savanna woodland. In the boreal ecoregion, areas of OWL are relatively small (about 11% of the total) and often represented by shrubs such as dwarf pine (*P. pumila*) and dwarf birches in Northern Eurasia. Although OWL has a low commercial value, these woodlands have a large and mostly unrecorded value to local people, provide soil and water protection services, and harbor biodiversity across vast landscapes.

Data derived from the FRA-2000 statistical tables and the FRA-2000 global maps are not completely consistent, and making specific area comparisons between these two sources is rather difficult. This is largely due to the different compilation methods used. In particular, differences between the two methods for North America and Oceania are noticeable. In the case of North America, the reported forest cover for Canada and the United States both appear to refer to productive or commercial forest cover only, as mentioned earlier. Therefore, the FRA-2000 forest cover map identifies a greater forest cover than is reported in the country statistics. In the case of Oceania, the forest map underestimates the amount of forest cover compared with the statistics. One likely reason for this is the lack of good satellite imagery (due to persistent cloud cover) preventing the mapping of several Pacific islands (FAO 2001c). In addition, differences in classification between open and fragmented forest and other wooded land may be a factor.

21.3.2 Distribution by Aggregated Forest Types (Ecological Zones)

Different global classifications of the world's forests by forest type are generally largely incompatible. The classification by UNEP-WCMC includes 26 aggregated forest types—15 in tropical forests and 11 in non-tropical biomes (UNEP-WCMC 2004). Based on criteria equivalent to Köppen-Trewartha climatic groups, FRA-2000 considered five domains (biomes)—tropical, sub-tropical, temperate, boreal, and polar, which are divided in 20 global ecological zones (FAO 2001c, Table 47–2). The latter classification is used in this section, and distribution estimates are based on the remote sensing data sources rather than the FRA-2000 statistical datasets.

Three quarters of the world forests is located in two biomes—tropical (46%) and boreal (29%). Tropical rain forest is the most extensive forest type in the world, constituting 26% of global forest area and nearly 60% of tropical forest area. Most rain forests are in South America (582 million hectares), Africa (270 million hectares), and Asia (197 million hectares). Tropical rain forests are closed-canopy evergreen broadleaf forests that generally require continual temperatures of at least 25 Celsius and annual rainfall of at least 1,500 millimeters (Richards 1996). Tree diversity in tropical rain forests is very high, with often more than 100 tree species per hectare.

Tropical moist deciduous forests cover some 510 million hectares. They develop in areas with a dry season of three to five months, and they vary from closed forests to open savanna forests, depending on dry-season length, human pressures, and fire regimes. Only about one third of these forests are closed primary forest areas; the rest are open and fragmented forests, including significant areas of secondary forest created by disturbances such as agricultural clearing and fire. The soils are in general better than in rain forests areas, and human population pressure is therefore higher. In Asia, these forests contain commercially important species like teak (*Tectona grandis*) and *sal* (*Shorea robusta*). In tropical dry forests the dry season is longer than in the moist deciduous (open tropical) forests. Remaining areas of tropical dry forests are relatively small, consisting mostly of open forest.

The temperate and boreal forests occur from the sub-tropics to the arid steppes and sub-Arctic, with the northernmost growing at 72°30′ in central Siberia (Abaimov et al. 1997) at an annual average temperature of −15° to −17° Celsius. They are mostly distributed in 55 industrial countries (in Europe, the former Soviet Union, North America, Australia, Japan, and New Zealand). Detailed and reasonably reliable information concerning these forests is available (FAO 2000). The total area of forest in these countries was estimated to be 1,914 million hectares, supplemented by an additional 795 million hectares of other wooded lands. Thus the total area of forest and other wooded land is estimated to be 2,478 million hectares, which accounts for 47% of global tree cover. More that one third (38%) of the total in these zones is located in the former Soviet Union, 29% in North America, 9% in Europe, and 25% in Australia, Japan, and New Zealand. On average, these countries have 1.3 hectares of forest per capita—about double the global average, although there is great variation between countries (from nearly none in Malta and Azerbaijan to 6 hectares per capita in Russia and 31 hectares per capita in Australia). These statistics do not include China, which has significant areas of temperate and boreal forests—30% and 8% respectively of the country's total forest area of 163.5 million hectares.

Countries of these biomes accounted for in the *Temperate and Boreal Forest Resources Assessment* contain 47% of predominantly coniferous forest (mostly genera *Pinus, Picea, Larix, Abies*), 26% of predominantly broadleaf forest (many genera, including *Populus, Betula, Quercus, Fraxinus, Tilia*), and 27% of mixed coniferous and broadleaf forests. Other forests types (bamboos, palms, and so on) cover small areas in Japan. Coniferous forests serve as a major source of global industrial wood, and the broadleaf forests include a number of high-value commercial species. (See Chapter 9.)

21.3.3 Wood Volume and Biomass

Wood volume, woody biomass, and total live biomass are important indicators of the potential of forests to provide various products and services, including carbon sequestration. Based on available information from 166 countries (about 99% of the world's forest area), FRA-2000 estimated the total global standing volume (aboveground volume of all standing trees, living or dead, with diameter at breast height over 10 centimeters) to be 386 billion cubic meters and the global aboveground woody biomass to be 432 billion tons (dry matter), which gives average values of 100 cubic meters and 109 tons per hectare, respectively. IPCC (2000) estimated the total carbon stock of vegetation in forest to be 359 billion tons of carbon. These data vary greatly over continents and countries. Average standing volume, for example, varies from about 60 cubic meters per hectare in Oceania and Asia to 125 cubic meters in North and South America, while the ratio of aboveground biomass (tons) to standing volume (cubic meters) varies from about 0.5 in Europe to 1.6 in South America (FAO 2001c).

21.3.4 Extent of Natural Forests

There are numerous ways of characterizing the degree of ''naturalness'' of forests—old growth, ancient, intact, frontier, natural, secondary, modified, and so on—and although there are no consistent, agreed definitions and information with which to classify forests in this manner is poor, FAO has defined natural forests as forests composed of indigenous trees regenerated naturally (FAO 2000c, 2002b).

Although FRA-2000 considered all forests except plantations to be ''natural'' (FAO 2001c), FRA-2005, which is currently under preparation, considers four classes of decreasing ''naturalness''—primary forest, modified natural forest, semi-natural forest, and forest plantations (FAO 2004). Forest inventories as a rule do not characterize forests by their degree of naturalness, however, and so only limited assessments are available.

One attempt to inventory the extent of natural forests by the World Resources Institute identified the global extent of ''frontier forests''—remaining large, intact natural forest ecosystems big enough to maintain all of their biodiversity (Bryant et al. 1997). These represent only 40% of the planet's remaining forests, and 39% of these are threatened by logging, agricultural clearing, and other human activities. Seventy-six countries were found to have lost all of their frontier forests, while 70% of what remains lies within three countries (Brazil, Canada, and Russia), and only 3% lies within the temperate zone.

This chapter uses a simplified three-class approach to forest naturalness, limiting the classification to ''natural'' (self-regenerating, generally multi-species, mixed age stands of native species, with a natural disturbance regime); ''semi-natural'' (some degree of human intervention in regeneration, species selection, and disturbance); and ''anthropogenic'' (established or significantly transformed by humans). Using regional expertise and some published sources (e.g., Vorob'ev et al. 1984; Bryant et al. 1997; Atlas 2002) it can be tentatively estimated that about 70% of the world's forests can be considered to be natural, 20% semi-natural, and 10% anthropogenic (half of which are plantations).

21.3.5 Trees Outside of Forests

Trees outside of forests, or TOF, occur in many formations, such as shelterbelts, shade and other elements of agroforestry, roadside plantings, village and urban plantings, orchards, and individual trees on farms and other private land. Although there are no consistent global data on the coverage or extent of TOF, FRA-2000 provides a global review of this, acknowledging the diversity of the multiple functions and benefits (FAO 2001c). For example, about 70% of the land area of Java (Indonesia) has trees but only 23% of this is classified as forest (Persson 2003).

TOF provide important services, including contributing to food security, particularly for rural populations (Auclair et al. 2000; Glen 2000; Klein 2000). In many Asian countries, particularly those with low forest cover, TOF supply the majority of fuelwood (Arnold et al. 2003). For example, more than 75% of fuel production comes from non-forestland (mostly from TOF) in Bangladesh, India, the Philippines, and Thailand, although with significant variation among countries (Bhattarai 2001). Shelterbelts are an important component of agroforestry landscapes in many countries of the northern hemisphere (see, e.g., Yukhnovsky 2003). Quantitative data on TOF are scarce and not comparable, however, since they are mostly limited to regional and national case studies (FAO 2003b), although some counties (such as France, the United States, India, and Bangladesh) have initiated efforts to gather national-scale quantitative information on TOF (FAO 2001c).

21.3.6 Distribution of People in Forest Areas

The current distribution of people living in and adjacent to forest and woodland areas is the result of a long historical process of social and economic development. Significant factors influencing population distribution include topography, degree and direction of landscape transformation, and forest types. Currently, about three quarters of humanity lives in three ecological zones classified as aggregated forest ecoregions (needle-leaved evergreen, closed broadleaf deciduous, and broadleaf evergreen), although a far smaller number actually live in or adjacent to forested areas (CIESIN 2000).

As a rule, more-densely populated regions have less natural forest and more plantations than less populated regions (Persson 2003). Typical examples are China and India, with a combined population of about 2.3 billion and forest area of just 228 million hectares (FAO 2001c). Based on U.N. population statistics, UNEP-WCMC has derived detailed information on the ratio of forest area to people at both the national level and for 12 large regions in 1996 (UNEP-WCMC 2004). The overall global number was 0.7 hectares per person, with a large variation between regions—from 0.07 for Middle East to 5.6 for Russia and 6.5 for Australasia—and by ecological zones. In the tropics, the highest ratio (1.85 hectares per person) was in rain forest areas and the lowest (0.24 hectares per person) in dry deciduous forests (FAO 1993).

Tropical rain forests typically have low human population densities. This is largely because rain forest soils are frequently low in nutrients and therefore unsuitable for continuous agriculture. Although many rain forest areas can support traditional forms of extensive rotational ("shifting") cultivation, and have done so for millennia, this form of agriculture is unable to support high human population densities. In areas with good soils (such as volcanic or sedimentary soils), rain forests have long since been converted to agricultural landscapes.

Forests are a significant source of employment. Global recorded forest-based employment is about 47 million full-time equivalents, 17 million of whom are in the formal sector (ILO 2001; Blombaeck and Poschen 2003). Labor force trends and dynamics vary among countries and regions, but in general forestry sector employment is decreasing. (See Chapter 9.) The forestry sector labor force in Europe and the former Soviet Union, for example, is expected to decrease by 7% during the coming decade (ECE 2003).

21.4 Changes in Global Forest Area and Condition

21.4.1 Parameters of Change

Four basic change processes determine trends in global forest area and are defined for this chapter as follows:

- *Deforestation* is the conversion of forests to another land use or the long-term reduction of the tree canopy cover below 10%.
- *Afforestation* is the establishment of forest plantations on land that, until then, was not classified as forest. It implies transformation from non-forest to forest.
- *Reforestation* is the establishment of forests plantations on temporarily unstocked lands that were considered as forest in the recent past.
- *Natural expansion of forests* means the expansion of forests through natural succession on land that, until then, was under another land use (such as forest succession on land previously used for agriculture). It implies a transformation from non-forest to forest.

Net changes in forested area are a superimposition of these four major processes. While net changes are important to monitor, it is also important to disaggregate exactly what is being lost and what is being gained. A focus on net changes—for example, plantation establishment offsetting natural forest loss, and gains in forest cover in industrial countries offsetting forest losses in tropical developing countries—may obscure the severity of natural forest losses in tropical regions.

Forest degradation and *forest improvement* describe changes in forest condition, but not changes in an area's land use or land cover status. FRA-2000 defined these as changes within the forest, which negatively (forest degradation) or positively (forest improvement) affect the structure or function of the stand or site and thereby lower (degrade) or increase (improve) the capacity to supply ecosystem services (FAO 2001c). As previously noted, though, there is little consensus among definitions of forest degradation and deforestation. Some logged areas, for example, are severely degraded to the point of being virtually devoid of trees and previous ecological characteristics and functions, and many would argue that such areas should be counted as effectively deforested, irrespective of their formal legal or management status.

21.4.2 Changes in Global Forest Cover

Clearing of forests for other land uses, particularly agriculture, has accompanied human development for the whole of documented human history. Historically, deforestation has been much more intensive in temperate regions than in the tropics, and Europe is the continent with the least amount of original forests remaining. As a whole, clearance prior to the industrial era was a slow and steady process over a long period of time. In the more recent past, many countries and regions experienced much higher rates of forest conversion, and many currently industrialized countries experienced deforestation rates in the nineteenth century very similar to those now occurring in many tropical developing countries.

The relationship between agricultural expansion and forest decline has been analyzed, and the following preliminary conclusions emerge: agricultural land is expanding in about 70% of countries, declining in 25%, and is static in 5%; forest area is decreasing in two thirds of countries where agricultural land is expanding, but expanding in the other one third of those countries; and forests are expanding in 60% of countries where agricultural land is decreasing and are declining in 36% of this group of countries (FAO 2003b). A complicated combination of economic and social development factors, levels of agricultural productivity and urbanization, climatic and geographical peculiarities, and countries' previous histories determine rates of deforestation in particular places.

Significant deforestation in tropical forests has been documented for 1990–2000. The total loss of natural tropical forests is estimated for this period at 15.2 million hectares per year (FAO 2001c). Taking into account relatively small natural expansion of tropical forests (+1.0 million hectares a year) and plantations that have been developed at +1.9 million hectares annually, the net change in tropical forest area was estimated by FRA-2000 to be −12.3 million hectares. In contrast, during this period a net increase of forest area was observed in temperate and boreal zones (+2.9 million hectares a year, of which +1.2 million hectares were forest plantations and +1.7 million were due to the change in area of natural forests). In total, then, the net change in global forest area is estimated at −9.4 million hectares per year. (See Table 21.4 and Figure 21.4.)

The net annual change in forest area for 1980–90 was estimated to be −13 million hectares (FAO 1995b) (including losses of 6.1 million hectares per year in tropical moist forests and 3.8 million hectares per year in tropical dry forests), and −11.3 million hectares for 1990–95 (FAO 1997). This would indicate that net global forest loss has slowed down since the 1980s (FAO 2001c). However, much of this is due to increases in plantation forestry, and although the global net change in forest area was lower in the 1990s than in the 1980s, the rate of loss of natural forests remained at approximately the same level.

Table 21.4. Forest Area Changes, 1990–2000, in Tropical and Non-tropical Areas (FAO 2001c)

	Natural Forest					Forest Plantations			Total Forest
	Losses			Gains		Gains			
Domain	Deforestation	Conversion to Forest Plantation	Total Loss	Natural Expansion	Net Change	Reforestation	Afforestation	Net Change	Net Change
	(million hectares per year)								
Tropical	–14.2	–1.0	–15.2	+1.0	–14.2	+1.0	+0.9	+1.9	–12.3
Non-tropical	–0.4	–0.5	–0.9	+2.6	+1.7	+0.5	+0.7	+1.2	+2.9
Global	–14.6	–1.5	–16.1	+3.6	–12.5	+1.5	+1.6	+3.1	–9.4

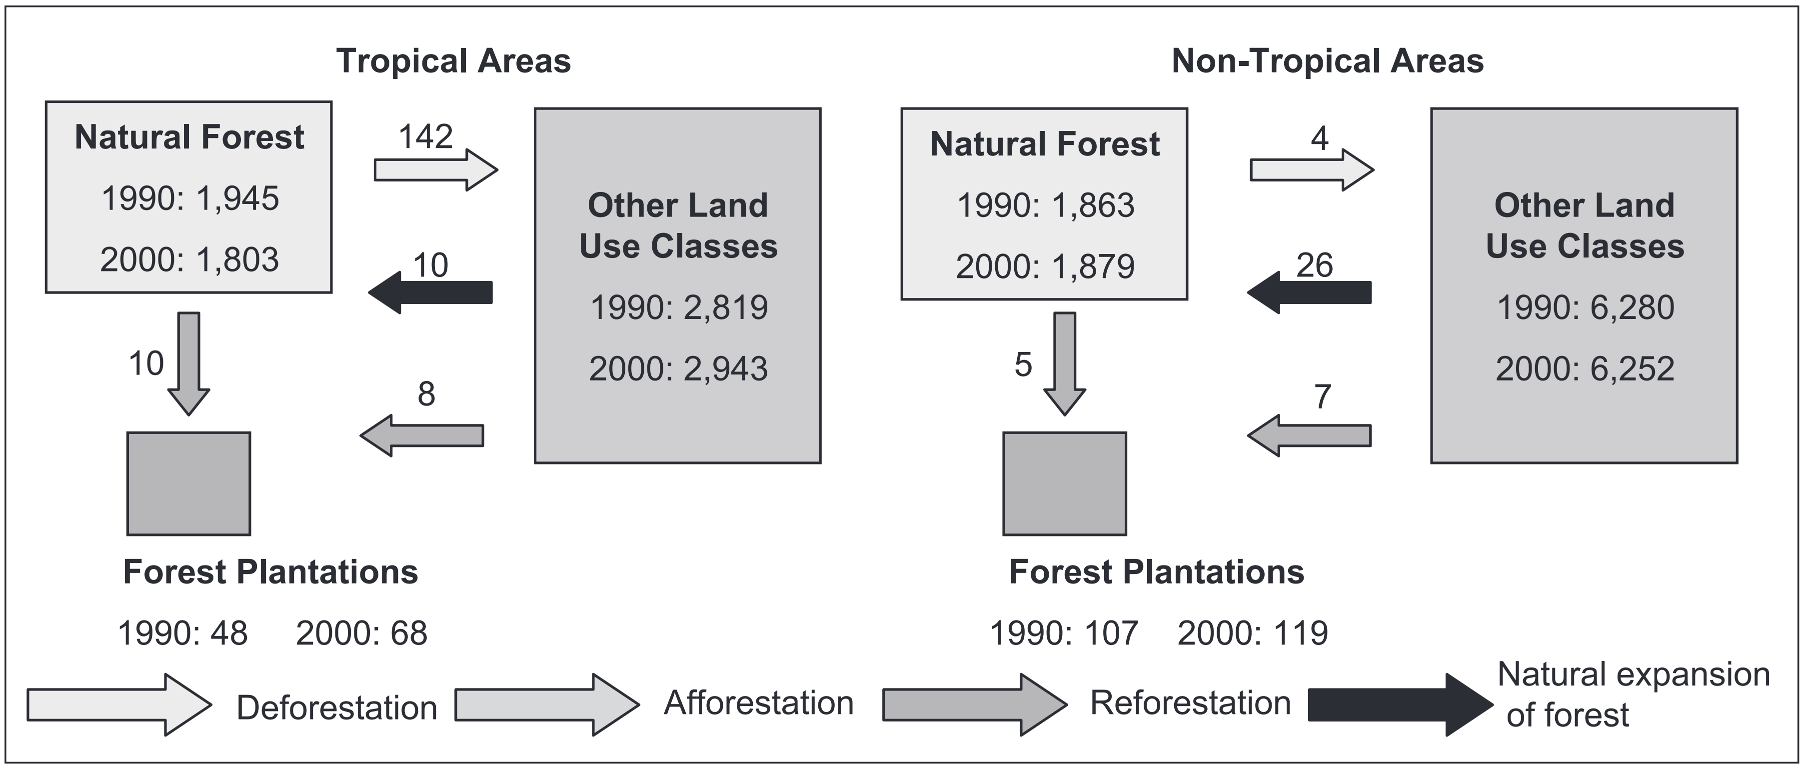

Figure 21.4. Major Change Processes in World's Forest Area, 1990–2000 (in million hectares) (FRA 2000; FAO 2001c)

Matthews (2001), however, reached a different conclusion, finding that in absolute terms, more tropical forest was lost in the 1990s than in the 1980s. According to this estimate, net deforestation rates have increased in tropical Africa, remained constant in Central America, and declined only slightly in tropical Asia and South America. The certainty of this estimate is unknown.

It is likely that deforestation in developing countries has continued since 2000 at practically the same rate as during the 1990s, about 16 million hectares per year, corresponding to 0.84% for the 1990s and 0.80% since 2000. The difference in these estimates is definitely within the uncertainty limits of the techniques used. However, both national inventories and remote sensing data often do not adequately record the regrowth of secondary forests in many areas. If better data on this were available, they would likely reduce the net area change in forest cover for many regions (see, e.g., Faminov 1997).

Recent remote sensing surveys of individual biomes and forest types have reported different, often lower, rates of deforestation than those reported in FRA-2000. The research program TREES (Tropical Ecosystem Environment observation by Satellite) estimated annual losses of humid tropical forests on three major continents between 1990 and 1997 at 5.8 ± 1.4 million hectares with a further 2.3 ± 0.7 million hectares of visibly degraded forests (Achard et al. 2002). This is about one fifth less than the estimates provided from the sources just discussed. However, estimated uncertainties of forest cover were substantial (1,150 ± 54 million hectares and 1,116 ± 53 million hectares for 1990 and 1997 respectively).

On the other hand, a study by DeFries et al. (2002) found that the rate of tropical deforestation actually increased by about 10% from the 1980s to the 1990s, in contrast to the 11% reduction reported by FRA-2000, and supporting Matthews (2001). This is not surprising, since methods vary among different surveys. It must therefore be realized that coarse-resolution remote sensing data still cannot provide detailed reliable information about changes in forest area. Rather, existing published figures provide only estimates of the order of magnitude of forest cover change (DeFries et al., 1995, 2000; Holmgren and Turesson 1998; McCallum et al. 2004).

Trends in deforestation and net changes in forest area vary across regions, although there are many commonalities within major biomes across regions. The major areas with rapid deforestation are currently in the tropics. Africa accounts for over 50% of net recent global deforestation, although the continent hosts only 17% of the world's forests. Ten tropical countries (six of them in Africa) had net annual change in forest areas of more than 3%, and four countries (three in Africa plus Nicaragua) had change rates of 2.5–3.0% between 1990 and 2000 (FAO 2001c). Net change of forest area by continent is presented in Figure 21.5.

Quantitative data on the dynamics of other wooded land are weak. Many national sources reported substantial transformation

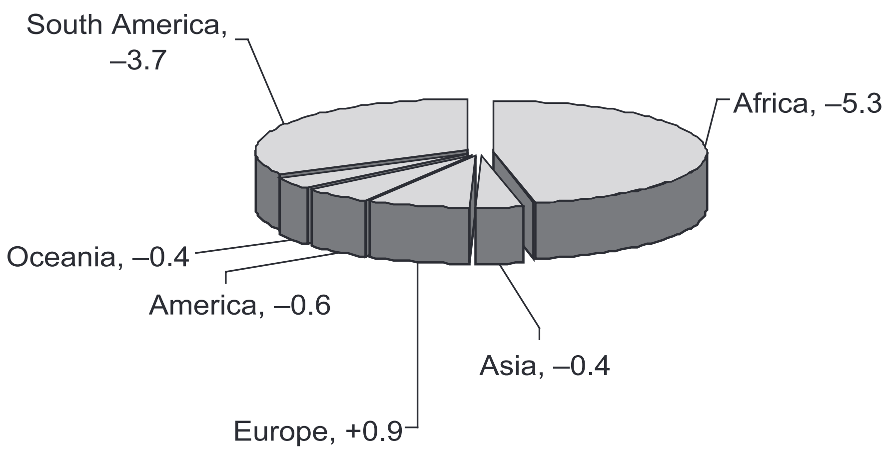

Figure 21.5. Net Change in Forest Area by Continent (in million hectares per year) (FRA 2000; FAO 2001c)

and decline of woodlands, in particular in dry regions, due to extensive conversion for agriculture and excessive harvesting by rural communities (Hassan 2002). Open savanna woodlands in South Africa, for example, have lost about half of their original extent of approximately 42 million hectares (Low and Rebello 1996).

21.4.3 Forest Plantations

Development of forest plantations can have significant impacts on the dynamics of forest areas in some regions. Forest plantations covered 187 million hectares in 2000, with significant regional variation—62% are in Asia and only 17 % in Europe. Ten countries account for 79% of global forest plantation area, and six of these account for 70%. Globally, broadleaf-species account for 40% of forest plantation area, with *Eucalyptus* the principal genus (10% of the global total); coniferous species account for 31%, with *Pinus* constituting 20% of the global total. Genus is not specified in FAO statistics for the remaining 29% (FAO 2001c).

According to national data supplied to FRA-2000, the tropical forest plantation estate has increased from 17.8 million hectares in 1980 to 43.6 million hectares in 1990 and about 70 million hectares in 2000 (Brown 2000; FAO 2001c). However, these and other data on the growth and extent of plantations are not fully comparable due to different definitions, incomplete statistics from different countries, and different approaches to estimation of coverage. For example, Europe and North America are not included in the FAO figures for 1980 and 1990 (FAO 1995a). According to official national data, the annual increase in plantations is 4.5 million hectares globally, of which 3 million hectares are estimated to be successful (FAO 2001c). About 90% of new plantations are in Asia and South America. Although plantations constitute only 5% of global forest cover, they were estimated to supply about 35% of global roundwood in 2000, and it is expected that this figure will increase to 44% by 2020 (ABARE-Jaakko Pöyry 1999; see also Chapter 9).

Other estimates of the rate of increase of plantations are also available. Pandey (FAO 1995a), for example, claimed that the total area of plantations for 1990 in tropics should be reduced by one third (although even this analysis is likely to have overestimated the extent of plantations in some countries such as India) due to peculiarities of the system of accounting for and estimation of plantations. Persson (1995) estimated the planted area in 1990 for all countries in the range of 148–173 million hectares, pointing out that plantation data for China are uncertain, and he estimated annual forest plantation increase in the tropics to have been about 0.5–1 million hectares for the 1970s, 1–1.5 million hectares for the 1980s, and about 2 million hectares for 1990–95. According to Persson (1995), plantations covered nearly 100 million hectares in 1970 and 120 million (100–30 million) hectares in 1980.

Based on socioeconomic analysis, Trexler and Haugen (1995) estimate that the total area of plantation in the tropics is likely to grow by 66.8 million hectares from 1995–2045, including 37.8 million hectares in Asia, 24.5 million hectares in Latin America, and 4.6 million hectares in Africa. Nilsson and Schopfhauser (1995) estimated the global availability of lands suitable for plantations and agroforestry at 345 million hectares. The reliability of these estimates is difficult to assess, however, because they do not consider specifics of many local socioeconomic and social processes, including the potential for expanded plantation establishment to cause social conflicts.

It can be seen from this short review that data on plantations are very uncertain and often contradictory. There are a number of reasons for this. The number of countries assessed for FRA-1980, FRA-1990, and FRA-2000 plantation estimates varied considerably, ranging from only 76 tropical developing countries in 1980 to all 213 countries in 2000. Plantation area is often overestimated if it is calculated from the number of plants produced or planted rather than from actually reforested or afforested areas. The area actually planted is often less than the planned area of plantation, which is often the reported area. Loss of plantations is often not included in national reporting, while the officially planted area is added each year. And finally, there is an inherent bias to exaggerate the success of plantation establishment.

Globally, 48% of forest plantation trees are destined for industrial end-use, 26% for nonindustrial uses, and 26% for unspecified uses (FAO 2001c). Industrial plantations provide raw material for commercial wood and paper products and can generate significant local employment opportunities. (See Chapter 9.) For example, some 1.5 million hectares of plantations in South Africa provide 1.63% of the global supply of pulp, 0.76% of paper, and 0.3% of sawn timber (Bethlehem and Dlomo 2003). Nonindustrial plantations are established to provide soil and water conservation, combat desertification, maintain biodiversity, absorb carbon, supply fuelwood, and rehabilitate fragile and degraded lands. During the last two decades, the major trend has been an increase in plantations established for industrial purposes, which have increased by about 25% since 1980 (FAO 2001c).

Forest plantations have potentially high productivity. On average, mean annual increments of *Eucalyptus* and *Pinus* are in the range of 10–20 cubic meters per hectare per year, but some species (e.g., *E. grandis, E. saligna, P. caribea*) can reach an MAI of up to 50–60 cubic meters, while *Araucaria* and *Acacia* can attain an MAI of up to 20–25 cubic meters per hectare per year. MAI for *Pinus, Picea,* and *Larix* plantations on the best sites in temperate and southern boreal zones can reach 12–15 cubic meters per hectare per year (Webb et al. 1984; Wadsworth 1997; Sagreev et al. 1992). The length of the rotation period for plantations varies from 5–10 to 30 years for major tropical species to 100–200 or more years for major boreal species. Along with the high MAI, the rotation period substantially affects the capacity of plantations to provide carbon sequestration services.

Many plantations do not in practice achieve these high potential growth rates. A number of studies (e.g., Nilsson 1996; McKenzie 1995; White 2003) have concluded that it is seldom possible to achieve high productivity in large-scale plantations, that insufficient forest management results in low survival rates and poor plantation condition, that monocultural plantations increases risks of pest and disease outbreaks, that production costs are often substantially underestimated, that knowledge about plantation growth and yield is poor, and that reliable and operative monitoring systems on plantation condition and dynamics only exist in a few countries. Many of these risks can be overcome where good management practices have been applied.

Plantations have been criticized for their environmental and social impacts—particularly in the tropics, where plantations have replaced natural forests, degrading water and soil resources, and resulting in negative impacts on local and indigenous communities who lose access to lands that formerly supplied them with subsistence resources and livelihoods (e.g., Carrere and Lohmann 1996; Carrere 1999; White 2003). Kanowski (2003) notes that in addition to the suboptimal performance of some plantations, many plantations have been established without appropriate consideration or recognition of trade-offs that were made with other forest services and with the rights and interests of various stakeholders. In Indonesia, for example, the timber plantation program has been a significant driver of natural forest loss, and the establishment of plantations (both for timber and oil palm) was a significant driving force behind the forest and land fires that beset Indonesia during 1997 and 1998 (Barber and Schweithelm 2000). A number of studies have also highlighted the risk of invasive alien species that can escape from plantations (e.g., Richardson 1998; Allen et al. 1997; De Wit et al. 2001).

Development of forest plantations can generate significant social conflicts. For example, in dryland areas plantation species may use more water than the natural vegetation, resulting in less recharge of groundwater and a reduction in streamflow available for other uses (Carrere and Lohmann 1996). Plantations can have social impacts because they employ fewer people than would find jobs on the agricultural land that they may replace and they can increase the price of farmland. They may also influence the viability of agro-enterprises if too many people in an industry sell their land for plantations. Cossalter and Pye-Smith (2003) evaluated such concerns for ''fast wood'' (fast-growing, short rotation species grown for charcoal, pulp, and wood-fiber panel products) plantations, which make up a relatively small but rapidly growing segment of global plantations. They concluded that the impacts of fast-wood plantations depend largely on their management. When poorly planned and executed, fast-wood plantations can cause significant social and environmental problems, but when well planned and executed, they can deliver not just large quantities of wood but a range of other environmental and social benefits.

Similar issues are raised, if not so acutely, by longer-rotation softwood and hardwood plantations. The long-established teak plantations on Java, for example, have been a perennial source of social conflict between local communities and the state forestry corporation that manages them (Peluso 1992). Although fast-wood plantations in the tropics appear to be the type most often responsible for negative environmental and social impacts (Cossalter and Pye-Smith 2003), they are nevertheless also expected to increase the fastest relative to other types of plantations. This is because increasing globalization of the markets for pulp and fiber exerts strong pressure in favor of the lowest-cost producers, based on the interaction of land, labor, and capital costs, combined with productivity. The trend is therefore toward short crop rotations in locations that can provide the highest productivity and the lowest costs (Kanowski 1997).

21.5 Services Provided by Forests and Woodlands

The 1992 U.N. Forest Principles identified the multifunctional and multiservice purpose of the world's forests: ''Forest resources and forest lands shall be managed and used sustainably to fulfill social, economic, ecological, cultural and spiritual needs of present and future generations'' (Forest Principles 1992). The services provided by forests and woodlands are numerous and diverse on all spatial and temporal levels, and include provisioning, regulating, cultural, and supporting services. Some national classifications account for as many as 100 different kinds of forest services, such as delivery of industrial and fuelwood, water protection and regulation, ecotourism, and spiritual and historical values (e.g., Sheingauz and Sapozhnikov 1988; Mather 1999). (See Figure 21.6.) These various forest services relate to each other in many different ways, ranging from synergistic to tolerant, conflicting, and mutually exclusive. The multiservice paradigm of forest management is therefore quite clear in theory but is often very difficult to implement, as it frequently requires difficult choices and trade-offs.

Market approaches can only be used to estimate the value of a few forest services, mostly the ones related to provisioning and that enter formal markets, although markets are also developing for carbon and biodiversity (Scherr et al. 2004). There is no consistent methodology, and usually insufficient information, to estimate credible values for many other forest services. (See Chapter 2.) One recent (and controversial) estimate of the annual value of forest ecosystem services totaled $4.7 trillion, roughly 15% of the global GNP (Costanza et al. 1997). An estimate for the value of Mexico's forests is some $4 billion a year (Abdger et al. 1995). The annual total annual loss to Indian society as a result of forest degradation is estimated at about $12 billion (Joshi and Singh 2003). Ricketts et al. (2004) showed that during 2000–03, pollination services from two forests with a total area of about 150 hectares translated into $60,000 a year for a Costa Rican coffee firm due to increased coffee yield (by 20%) and quality.

Approaches such as these do provide at least an order-of-magnitude insight into the importance of forests for people (Agarwal 1992). Many researchers successfully apply monetary methods to ''nonmarket'' and often ''nontraditional'' services. The concept of total economic value (Pearce 1990; see also Chapter 2) has become one of most widely used frameworks for identifying and categorizing forest benefits (Emerton 2003). TEV aims to account comprehensively for all forest services, estimating direct values (such as timber, fuelwood, NWFPs, grazing and fodder, and recreation), indirect values (including watershed protection, erosion control, macro-climate regulation, and carbon sequestration), option values (considering future economic options in all affected sectors, such as industrial, agricultural, pharmaceutical, and recreational) and existence values (landscape, aesthetic, heritage, cultural, religious, ritual, and so on). In spite of substantial progress in the theory, conceptual basis, and methodology of TEV during the last two decades (Bishop 1999; Lette and de Boo 2002), forest valuation studies often remain a purely academic exercise and rarely have an impact on practical planning and management (Emerton 2003).

The loss and degradation of natural forest as described in the preceding section has been accompanied by a decline in supply of many forest services. These impacts are felt most acutely by rural communities living in or near forests, who suffer a decline in livelihood resources and well-being (Byron and Arnold 1999), although urban dwellers are also affected. For example, based on the comparison of satellite images of 448 U.S. urban areas, over the last 10 years American cities have lost 21% of their forested areas, the damage of which has been estimated to be over $200 billion, although no estimates of the benefits provided by the land use change were calculated (ENN–Reuters 18 September 2003 on American Forests).

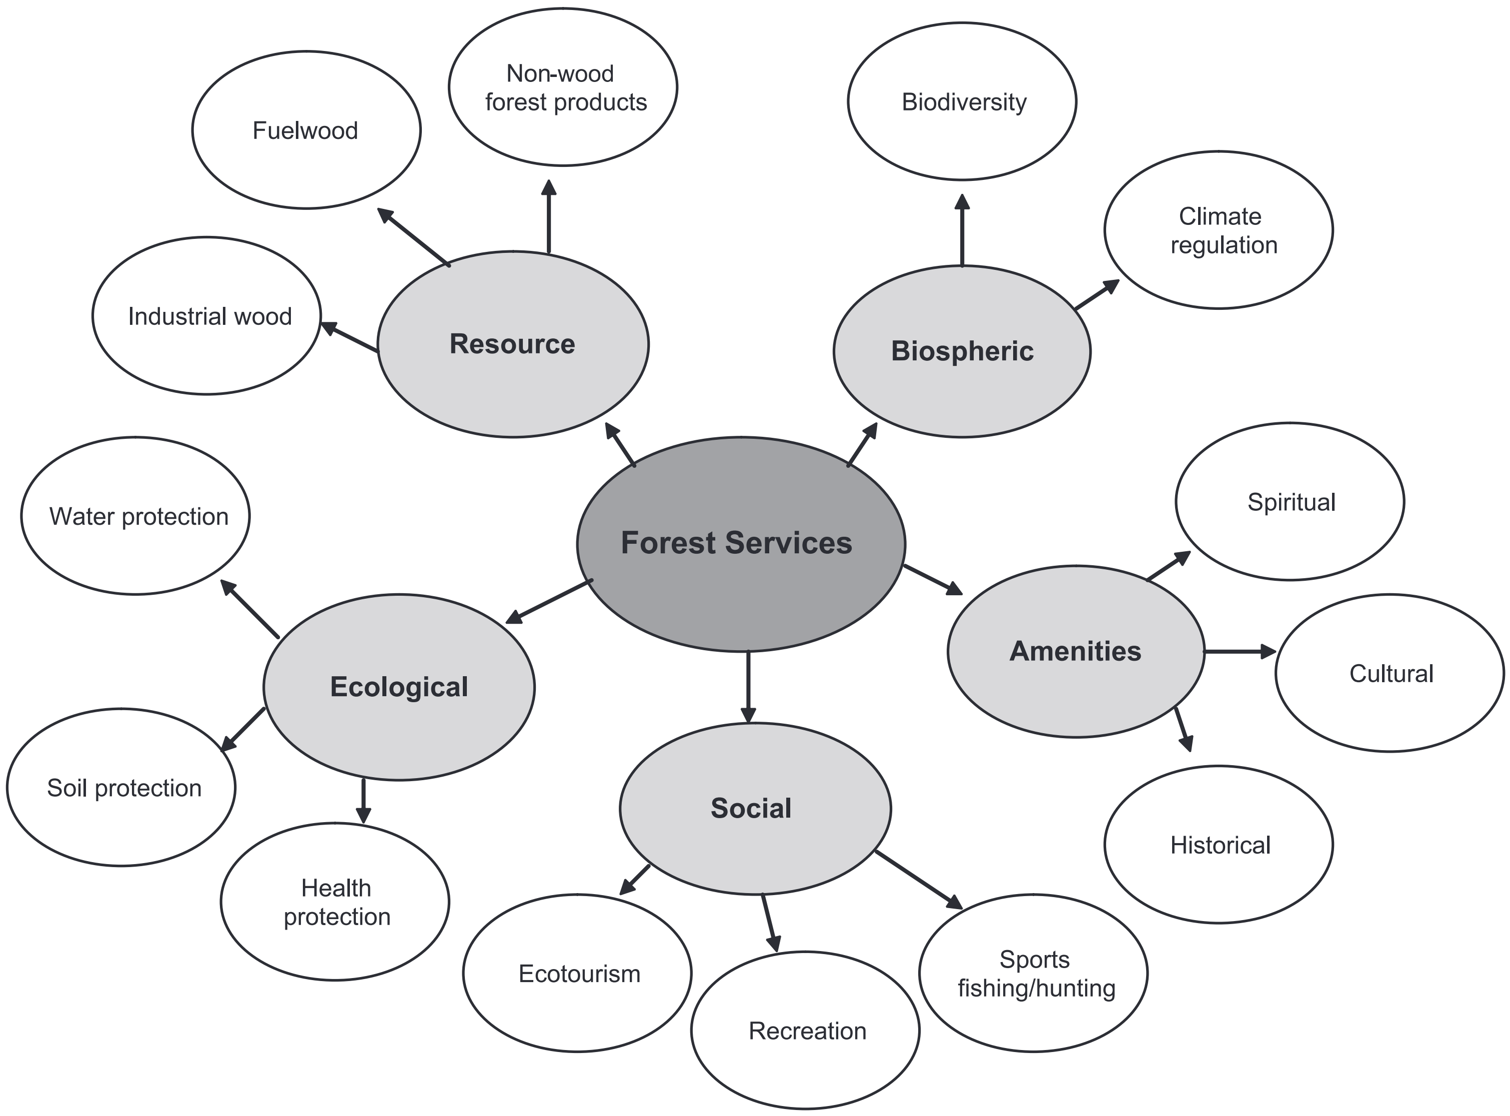

Figure 21.6. Major Classes of Forest Services

21.5.1 Biodiversity

Forests are an important repository of terrestrial biodiversity across three important dimensions: structural diversity (such as areas of forests, natural and protected forests, species mixture, and age structure), compositional diversity (numbers of total floral/faunal species, for example, and endangered species), and functional diversity (the impact of major processes and natural and human-induced disturbances) (Noss 1990; Paumalainen 2001).

Tropical forests cover less than 10% of Earth's land area but harbor between 50% and 90% of Earth's terrestrial species (WRI et al. 1992). The ancient tropical forests of Malaysia, for example, are home to 2,650 tree species, 700 species of birds, 350 species of reptiles, 165 species of amphibians, 300 species of freshwater fish, and millions of invertebrate species (Isik et al. 1997). Other types of forests are not as species-rich as tropical ones but are relatively species-rich ecosystems within their own contexts. Even boreal forests, which harbor only a small number of indigenous tree species (fewer than 100 in Northern Eurasia, for instance) (Atrokhin et al. 1982), have a high diversity at the ecosystem level, and some of their major tree species exhibit high adaptability to extreme climatic conditions. Larch forests, for example, grow at annual average temperature from $+8°$ to $-17°$ Celsius (Sherbakov 1975).

The importance of forest biodiversity for both its existence value as a major component of global biodiversity and its utilitarian value as the source of innumerable biological resources used by people has been recognized by the Convention on Biological Diversity and numerous other bodies and studies (e.g., Heywood et al. 1995; WRI et al. 1992). More recently, studies have shown that biodiversity is also an essential factor in sustaining ecosystem functioning and hence the ecosystem services that forests provide (Naeem et al. 1999). Biodiversity thus provides the underpinning for many of the other forest services discussed in this section. It can also be viewed as a vast storehouse of information from which future services can be derived.

Considerable information on forest-related biodiversity has become available over the past decade (e.g., Heywood 1995; Secretariat of the Convention on Biological Diversity 2001; Groombridge and Jenkins 2002), but consistent global assessments and monitoring are still difficult due to data insufficiency and incompatibility, different standards and definitions, and geographical and thematic gaps in available assessments. Efforts to assess the nature and distribution of biodiversity rely on the selection of particular subsets of species, species assemblages, or environmental features that can be used as surrogates to measure biodiversity as a whole (Margules et al. 2002). A recent global analysis of gaps in protection of biodiversity within the global network of protected areas, for example, used recently completed surveys on the global spatial distribution of over 11,000 species of mammals, amphibians, and threatened bird species as surrogates (Rodrigues et al. 2003).

Forest decline threatens biodiversity at all levels. IUCN estimates that 12.5% of the world's species of plants, 44% of birds, 57% of amphibians, 87% of reptiles, and 75% of mammals are threatened by forest decline (IUCN 1996, 1997). *The World List of Threatened Trees* (Oldfield et al. 1998) indicates that more than 8,000 tree species (9% of the total) are currently threatened with extinction.

It is difficult to say with precision the extent to which forest habitat loss results in population or species extinctions, because our knowledge of forest biodiversity is so incomplete. Nonetheless, it is clear that deforestation, particularly in the tropics, is having extremely negative impacts on biodiversity. Fifteen of the 25 biodiversity "hotspots" originally identified by Myers (1997)—areas with high levels of plant endemism and high levels of habitat loss and threat that between them contain the remaining habitat of 44% of all plant species and 35% of all vertebrate species worldwide—contain tropical forests. These areas once covered nearly 12% of Earth's land surface, but their remaining natural habitat has been reduced to only 1.4% of that surface—that is, 88% of the hotspots' original natural habitat has disappeared. Brooks et al. (2002) concluded that habitat loss in the world's biodiversity hotspots has left extremely large numbers of species threatened, with a high probability of extinction in the absence of immediate conservation action.

Development of protected area systems has been the primary strategy for conserving biodiversity generally (see MA *Policy Responses,* Chapter 5), and significant amounts of forest have come under protected status over the past several decades. (See Box 21.4.) Given the multiple functions of forests, however, and the impracticality of placing enough forests in protected areas to conserve the full range of forest biodiversity substantially, maintenance of the diversity of forest-dependent species in managed forests (such as logging concessions) is also an important strategy (Sayer et al. 1995).

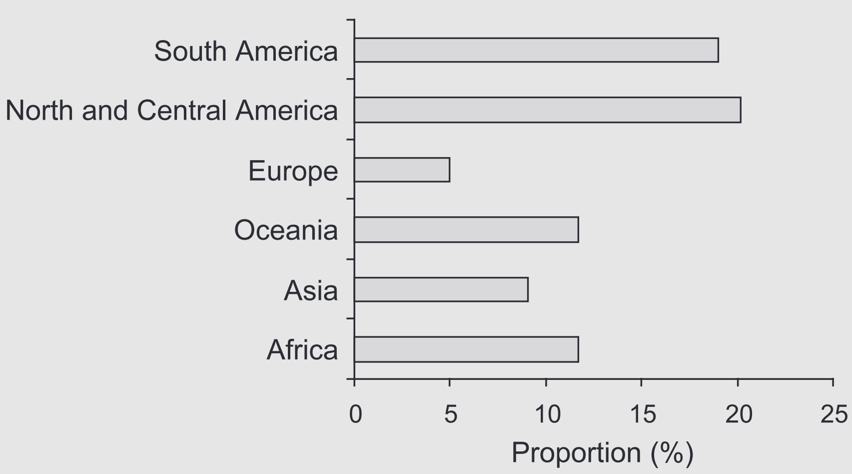
Modification of forest management practices to include biodiversity conservation objectives may not generally require large additional investments, at least in tropical forests (Johns 1997). Some of the simple but important measures that can be taken to this end include retention of small refuge areas and the maintenance of riparian buffer strips at the level of the management unit, and distributing logged and unlogged areas in an appropriate way across the broader landscape. There is also a growing awareness among tropical ecologists that secondary forests recovering from alternative land uses may play an important role in conserving biodiversity (Brown and Lugo 1990; Dunn 2004). It is generally accepted that forest plantations, particularly even-aged and single-species plantations, are less favorable as habitat for a wide range of taxa in different regions of the world (Allen et al. 1997; Davis et al. 2000; Hartley 2002; Humphrey et al. 2002; IUFRO 2003), although there may be some exceptions, such as in degraded landscapes or areas with low original forest cover (Brockie 1992; Kwok and Corlett 2000).

Managing forests to conserve biodiversity (and other non-wood services) requires that a management regime be in place. This is not the case for many countries, particularly developing ones. Eighty-three non-tropical (including all industrial) countries reported that 89% of their forests are managed, although data for developing countries indicate that only 123 million hectares (about 3% of forest area) are managed under formal long-term plans. Regional variation is very high: about 1% of the total forest area in Africa, about 25% in Asia, 85% in Oceania, 55% in North and Central America, and 3% in South America are managed according to such plans. While areas in the tropics seem slightly

BOX 21.4

Forest Protected Areas

A proportion of forests in most countries have protected status. Recent statistics from the UNEP World Conservation Monitoring Centre (UNEP-WCMC 2002) reveal that around 10.4%—470 million hectares—of the world's 4,540 million hectares of forests are under various forms of protection. Countries use a variety of systems for classifying their protected areas. Some have very detailed classifications (up to 20–25 forest protected area categories), although many use some variant of the simpler international IUCN classification system. A CD-ROM published by UNEP-WCMC and the Center for International Forestry Research (Iremonger et al. 1997) contains a detailed analysis of forest protected areas by ecological zone, country, and region. About 7.8% of the world's forests are included in areas that are protected to the level of IUCN categories I-VI.



Percentage of Forest Area in Protected Status by Continent
(FRA 2000)

According to the global map of protected forest areas produced by FAO and UNEP-WCMC as a part of FRA-2000, protected areas cover 479 million hectares—12.4% of the world's forests. Some 15.2% of tropical forests are protected, 11.3% of sub-tropical forests, 16.3% of temperate forests, and 5% of boreal forests. The highest percentage of protected forests is found on the American continent (about 20%) and the lowest in Europe (5%). (See Figure.) These data are not, however, completely consistent (cf., e.g., FFSR 1999; WDPA 2003).

Biodiversity conservation is now widely recognized as the most important objective of protected areas (although many current protected areas were not designed with this in mind), and this objective generates specific size and distribution requirements. Many studies have shown, for example, that conservation of a great deal of biodiversity is not viable in small fragmented areas. Experience in some countries, however, yields examples where even small protected areas can meet some biodiversity conservation objectives (Isaev 1991). This is particularly the case where small protected areas are surrounded by sustainably managed forests. Some countries have established specific categories of protected areas for particular purposes, such as water or soil conservation. TBFRA-2000, for example, reported such designations for soil protected in most industrial countries such as Russia (90.8 million hectares), Kazakhstan (9.3 million hectares) and Greece (2.5 million hectares).

Formal designation of protected areas, however, does not guarantee their effective management. In many developing countries, protected areas often exist on paper but lack active management and are in fact subject to illegal logging and wildlife poaching, agricultural encroachment, and settlement. In some cases they may be completely or partially treeless. As a result, experts and policy-makers frequently debate how best to divide limited financial and technical resources between designating new protected areas, strengthening management of existing protected areas, and establishing novel forms of community-based conservation—working with local and indigenous communities outside of formal state-run protected areas (Barber et al. 2004).

underestimated, the data for some large non-tropical forest countries should be used with caution due to different national definitions of "managed forests" (FAO 2001c; Shvidenko 2003).

21.5.2 Soil and Water Protection

The global condition of the world's soils and hydrological systems is not well known, but it is considered to be far from satisfactory. (See Chapters 7, 20, and 22.) From 1945 to 1990, a vast area (1.2 billion hectares) of land is estimated to have suffered moderate to extreme soil degradation, and degraded areas accounted for 17% of Earth's vegetated lands (Oldeman et al. 1990; WRI 1992). The major causes for this extensive degradation are a number of current practices in agriculture, forest management, and grazing.

In many regions, forest is a major stabilizing component of natural landscapes, providing protection of soil and water, households, and fields and reducing or preventing floods and landslides. In the Ukraine, for example, soils on 11% of the territory are in good condition, 18% satisfactory, 22% in conflict, 25% pre-critical, and 24% in critical ecological condition. The relative conditions in different areas are strongly correlated with the extent of forest cover, which varies from 26% to 3% across the country (Yukhnovsky 2003). Levels of soil erosion in the tropics may be 10–20 times higher on areas cleared of forests, due to construction of roads, skidder tracks, and log landings during mechanical logging, than in undisturbed natural forests, and this is particularly the case in mountainous and other areas characterized by fragile soils (Wiersum 1984; Dickinson 1990; Baharuddin and Rahim 1994; Douglas 1996; Chomitz and Kumari 1998).

Regulation of hydrological cycles and processes is one of the important services provided by forests at large scales. Globally, forests' hydrological functions have been claimed to include increasing precipitation and decreasing evaporation; regulating the total and redistribution of surface and belowground runoff; smoothing out the seasonal course of river discharges; increasing total annual river runoff; protecting landscapes against soil erosion and landslides, in particular in mountains; preventing and mitigating the consequences of floods; maintaining water quality; protecting river banks against destruction (abrasion); and preventing siltation of reservoirs (e.g., Protopopov 1975, 1979; Rakhmanov 1984; Rubtsov 1990; Pielke et al. 1998; Bruijnzel 2004).

While forests play an undeniably important hydrological role across the globe, the specifics of this role vary substantially among biomes, landscapes, and forest types. Differences between tropical, temperate, and boreal zones, for example, can be great (e.g., Hamilton and King 1983; Bruijnzeel 1989; Versfeld et al. 1994; Sandström 1995). Research in tropical forest areas indicates that the roles of forests in watershed hydrology may have been overestimated in some cases: in arid areas, for example, trees evaporate more water than other vegetation types, and there is little evidence that forests attract precipitation (with the exception of cloud forests); forests reduce runoff but are not always effective at flood prevention, since tropical forest soils become rapidly saturated in tropical rainstorms. Some studies do conclude, however, that forests promote an even seasonal and annual flow, particularly in the dry season (Hamilton and King 1983; Dhawan 1993; Cossalter and Pye 2003; Kaimowitz 2004).

Because of the important role that forests play in protecting watersheds, many countries grant protected status to forests that serve this purpose. Such forests often include protective belts along rivers, lakes, artificial water reservoirs, and other bodies of water, and forests on steep slopes (Dudley and Stolton 2003; DePhilip 2003).

Many of the world's major rivers begin in mountain highlands, and more than half the planet relies on fresh water flowing from these areas. (See Chapter 24.) One third of the world's 105 largest cities obtain their water supply from forested watersheds. However, 42% of the world's main river basins have lost more than 75% of their original forest cover, and there is a clear relationship between population density and forest loss in the river basin (Revenga et al. 1998). The Yangtze watershed in China (home to some 400 million people) has lost 85% of its original forest cover, and in 1998 severe flooding along the Yangtze killed more than 3,800 people and caused over $20 billion in damage (Eckholm 1998). Many countries in the arid zone face an acute water deficit. In South Africa, for example, 54% of available runoff is currently used, and the level of use is expected to increase by 75% during the next 25 years. Twenty-eight countries experienced shortages of fresh water in 1998, and this number is expected to increase to 56 countries by 2026 (Versfeld et al. 1994; Sandström 1995).

Water and soil protection services of forests depend critically on the area and spatial distribution of forests over landscapes. It has been suggested that in the temperate zone, the minimal forest coverage that provides significant protection of landscapes over large territories varies from 7% to 30%, depending on region, climate, vegetation type, specific landscape features, and other factors (Protopopov 1975; Shvidenko at al. 1987). In semiarid and arid conditions, under a system of protective tree shelterbelts and trees outside of forest over the area to be protected, significant levels of protection for water and soil services can be attained with forest cover of 3.5% to 5–6%, as in the steppe zone of Ukraine and Russia, for example (Pilipenko et al. 1998).

21.5.3 Protection of Fragile Ecosystems: Forests in Mountains, Drylands, and Small Islands

Forests play a specific and very important environmental and social role in fragile ecosystems and landscapes, such as mountains, drylands, and small island ecosystems, particularly at the local level. People in these areas often have a high dependence on forest services. (See Chapters 22, 23, and 24.)

Forests in mountains have local and regional value as regulators of water supplies, centers of biological diversity, providers of forest products, and stabilizers of land against erosion. Due to the generally greater precipitation in mountains and the high ability of montane (in particular cloud) forests to capture atmospheric water, mountains play an extremely important role in maintenance of hydrological cycles affecting large territories. The alpine catchment of the Rhine River, for example, occupies only 11% of the river basin but supplies 31% of the annual flow and more than 50% of the summer flow (Price 1998). In semiarid and arid areas, over 90% of river flow comes from the mountains.

Trees and forests in dryland areas provide fuelwood, small roundwood (poles for building houses and fences), non-wood forest products (foods, medicinal products, bushmeat, fodder, and so on), and diverse regulating and cultural services. Their most critical functions in many dryland areas are soil conservation, shade, and shelter against wind.

The forest cover of 52 small island states and territories is insignificant in global terms—only 0.2% of global forest area in 1995 (FAO 2003b). But forests and trees on these islands are extremely important for the well-being of the local populations, the conservation of biological diversity, and the maintenance of environmental conditions both on land and in surrounding marine ecosystems. (See Chapter 23.) They play an important role in protecting watersheds, maintaining water supply, and protecting the marine environment.

Mangroves and other tidal forests are highly productive ecosystems that are important feeding, breeding, and nursery backgrounds for numerous commercial fish and shellfish, including most commercial tropical shrimp. (See Chapter 19.) FAO (2003b) has reported decreases in the extent of mangrove forest from 1980 to 2000 at an annual rate exceeding 1%.

Forests on small islands are extremely important for coastal protection against the strong winds, high rainfall, and storm surges of cyclones and hurricanes, and they serve as sediment traps for upland runoff sediments (Roennbaek 1999). Biodiversity conservation is another crucial service provided by forests on small islands. High endemism is an intrinsic feature of small island biodiversity: about 30% of higher plant species, 20–25% of birds, and 25–50% of mammals are island endemics (WRI et al. 1996).

21.5.4 Fiber, Fuel, and Non-wood Forest Products

Wood is currently the most economically important forest product. During 1996–2000, about 3.3 billion cubic meters of wood were harvested annually from the world's forests, and roundwood production has steadily increased by approximately 0.8% per year (FAO 2002a). By region, the largest annual increases during this time were observed in Europe (4.8%) and Oceania (3.5%). Only Asia experienced a substantial decrease in harvested wood (–1.2% per year), which is explained by dramatic decreases in three countries: Malaysia (–33%), Indonesia (–16%, due to economic and political disturbances during this period), and China (–8%, due to the drastic national measures taken in 1998 to restrict harvesting). A significant proportion of harvested wood and wood products is traded internationally. For a detailed assessment of wood production, see Chapter 9.

In the temperate and boreal zone, 63% of forests are classified as available for wood supply. The average growing stock of forest available for wood supply is between 105 and 145 cubic meters per hectare, with considerable variation among countries (from less than 50 to over 250 cubic meters for some European countries with strong silvicultural traditions). On average, the growing stock of forest available for wood supply increased by about 640 million cubic meters a year during the last decade, mostly in Europe and North America, due to forest management and global change (in particular, a longer growing period in the boreal zone, increased temperature and precipitation, elevation of the atmospheric concentration of CO_2, and increasing nutrient deposition) (e.g., Myneni et al. 2001; Ciais et al. 2004).

Removal as a percentage of mean annual increment is an indicator of sustainability of wood supply. For the temperate and boreal region as a whole, this figure is estimated to be 52.6%, with strong regional variations between North America (78.6%), Europe (59%), and the former Soviet Union (16.8%). Conifers are used more intensively (62.5%) than broadleaf forests (42.2%). Annual felling in the temperate and boreal domain (1,632 million cubic meters, of which over half is in the United States and Canada and 28% in Europe) is, however, substantially higher than the level of removals (1,260 million cubic meters)—implying a high level of harvest loss (FAO 2002a).

The total area under timber harvesting schemes in 43 selected countries accounting for approximately 90% of the world's tropical forests is estimated to be about 50 million hectares (55% in tropical forests of Asia and Oceania, 33% in Latin America, and 12% in Africa). Annually harvested area is estimated to be about 11 million hectares (29% in Africa, 54% in Asia and Oceania, and 17% in Latin America), although harvesting intensity is highly variable by country, ranging from 1 to 34 cubic meters per hectare (FAO 2001c).

Accessibility of forests is also an important factor for assessing the sustainability of wood supply. Approximately 51% of the world's forests are within 10 kilometers of major transportation infrastructure, including big rivers (from 38% in South America to 65% in Africa), and 78% are within 50 kilometers. Boreal and tropical forests are more remote than others. Some 14% of the world's forests were considered unavailable for wood supply, as they are located either in protected areas (12.4%) or in inaccessible mountain areas (FAO 2001c).

The importance of plantations as a source of timber is likely to continue to increase. For example, it is expected that forest plantations in China (currently about 47 million hectares) will provide up to 150 million cubic meters of wood annually (Jiang and Zhang 2003).

Fuelwood meets about 7% of energy demand worldwide, including about 15% in developing countries and 2% in industrial countries (WEC 1999). Globally, about 1.8 billion cubic meters of wood is used annually for fuel (including charcoal production). However, there is a large amount of variation in these figures, and more than 70% of energy needs in 34 developing countries and more than 90% in 13 countries (of which 11 are in Africa) are met through fuelwood. Woodfuel constitutes about 80% of total wood use in developing countries, where about one third of the total forest plantations were established primarily for that purpose. More than 60% of these plantations are in Asia and 25% are in Latin America. Plantations currently supply 5% of woodfuel, although it is estimated that woodfuel supply from plantations will grow 3.5-fold by 2020 (FAO 2001c).

Estimates of the potential of the world's forests to meet most of the world's demand for fibers and fuel in the future vary considerably and are significantly affected by economic accessibility and protection status of forests. Hagler (1995) estimated that only 2.1 billion hectares of forest are usable for fiber and fuel and that this forest area can sustain a long-term harvest of 3.7 billion cubic meters of wood per year. This study did not, however, consider current and potential wood supply from trees outside forests. Nilsson (1996) estimated that by 2020 the world demand for industrial roundwood and fuelwood (including charcoal) will be 2.4 billion and 4.25 billion cubic meters, respectively. However, a forecast by Broadhead et al. (2001) for fuelwood is only about 1.9 billion cubic meters for the same year (including charcoal).

According to these analyses, the world's forests are very close to exhausting their fiber and fuel potentials, and intensive measures will be needed to satisfy the deficit projected for 2020. Nilsson (1996) argues that even if the high forecasts are accurate, the deficit will not occur in reality due to market mechanisms, which are likely to achieve equilibrium between supply and demand. Broadhead et al. (2001) argue that fuelwood demand has in fact already peaked. More detailed information on this issue may be found in Chapter 9, where considerable evidence is presented in support of the conclusion that a global shortage of wood, per se, is not likely to occur in the near future, although there are likely to be significant regional disparities, such as unsatisfied market demand for large-dimension timber of high quality. Overall, land use changes and policy decisions will likely have a greater impact on forest ecosystems than timber harvest.

No doubt, wood has a great future. As construction material (25% of the annual global wood harvest), wood outperforms steel and concrete on an environmental basis (CWC 1999). Wood is a renewable resource and can also be recycled or reused. Development of new wood-processing technologies and products, environmental scrutiny, new applications, and new markets are some of trends that are expected to influence wood supply and demand over the next few decades (Roche et al. 2003; Pisarenko and Strakhov 2004), and rapid urban growth in developing countries has substantially increased the demand for industrial wood and fuel (Scherr et al. 2002).

Non-wood forest products (defined as goods of biological origin other than wood, derived from forests, other wooded land, and trees outside the forests) (FAO 1999b) include a tremendous diversity of items—some of which enter formal markets, but many that do not (FAO 2001b, 2001c, 2001f; UNECE 1998). They can be classified in a number of broad categories according to their end use: edible products; fodder for domestic animals; medicines; perfumes and cosmetics; colorants; ornamentals; utensils, handicrafts, and construction materials; and exudates like gums, resins, and latex. Overall, they play an important role in the daily life and well-being of hundreds of millions of people worldwide as well as in the national economies of many countries.

At least 150 NWFPs are of major significance in international trade, and the annual export value of these products was estimated at $11 billion in 1994. China is the leading exporter of NWFPs, followed by India, Indonesia, Viet Nam, Malaysia, the Philippines, and Thailand (Iqbal 1995). NWFPs provide subsistence, employment, and income, particularly for the rural poor, and support small, household-based enterprises, especially in developing countries (e.g., Arnold 1998; Ciesla 1998). The most reliable estimates indicate that from 200 million to 300 million people earn much of their subsistence income from nonindustrial forest products (Byron 1997). From 150 million to 200 million people belonging to indigenous groups in over 70 countries, mostly in tropics, depend on NWFPs to sustain their way of life, including their culture and religious traditions (CIDA 1998).

Edible NWFPs—vegetables, fruits, nuts, seeds, roots, mushrooms, spices, bushmeat, bee products, insects, eggs, nests, and so on—are particularly important in tropical and sub-tropical regions. For example, bushmeat and fish provide more than 20% of the protein in 62 least developed countries (Bennet and Robinson 2000). And in rural areas of many countries, a significant relationship exists between food security and the degree of contribution of NWFPs to households (Odebode 2003). From 8% to 46% of indigenous tree species serve as a source for food and fodder in the Pacific region (Siwatibau 2003).

Many edible products are increasingly exported, including honey and beeswax from Africa, bamboo from China (1.6 million tons of fresh shoots exported in 1999), and wild edible mushrooms, mostly morel mushrooms (a trade with a total annual value of $50–60 million). In the mid-1990s, the cost of importing of edible NWFPs to three main markets—Europe, the United States, and Japan—was estimated at about $2.5 billion (Iqbal 1995).

Fodder is of great importance in many regions, particularly in the arid and semiarid zones and in animal-based production systems. In many developing countries, 30–40% of domestic animals depend on forests for grazing and fodder (FAO 2001c).

About three quarters of the people in developing countries use traditional medicines, and the ratio of traditional healers to western-trained doctors reaches 150:1 in some African countries (FAO 2001c). Medicinal plant species (mostly from the forest) used by local populations and as trade products number in the thousands, and some 4,000 commercially important medicinal plant species are used in Southeast Asia alone. The value of the world trade in medicinal plants in 1992 was on the order of $171 million (Iqbal 1995). Medicinal plant exports are economically important for some countries, such as Morocco and Egypt, which export from 7,000 to 15,000 tons of medicinal plants annually (Lange and Mladenova 1997).

Forest plants are also widely used in the development of modern medicines for heart disease, cancers, leukemia, and HIV/AIDS. According to one survey, 90% of the most-prescribed pharmaceuticals in the United States contain compounds of forest origin (Lyke 1995). This is particularly remarkable in light of the fact that only 5–15% of higher plant species have been investigated for the presence of bioactive compounds (ten Kate and Laird 1999).

Rattan is the most important internationally traded NWFP. There are more than 600 species of rattan, some 10% of which are commercially used. Bamboo (more than 500 species) is the most commonly used NWFP in Asia, where about 20 million tons are produced annually. (See Chapter 9.) The average annual value of the world trade in bamboo ware is on the order of $36 million (FAO 2001c).

Global estimates of the total monetary value of NWFPs are very approximate and express an order of magnitude rather than documented market prices, particularly for subsistence uses. A number of studies (Myers 1997; UN-CSD/IPF-CSD 1996; Michie et al. 1999) have attempted to estimate the value of the subsistence use of NWFPs, arriving at figures ranging from $90 billion to $120–150 billion. This aggregate figure includes valuation of fodder and grazing ($40–50 billion); edible products ($20–25 billion); traditional medicines derived from plants, insects, and animals ($35–40 billion); and non-wood construction materials, such as thatch grass and bamboo, and other similar items ($25–35 billion).

21.5.5 Carbon Sequestration

Forests play an important role in the global carbon cycle and consequently in regulating the global climate system. Two main features of forests define this role. First, the world's forests accumulate a major part of the planet's terrestrial ecosystem carbon. Second, forests and wetlands are the two major land cover classes that are able to provide long-term sequestration of carbon. Accumulation of carbon in wood and soils results in a more significant share of total net primary productivity being stored in the long term than in other land cover classes and can represent as much as 10–15% of NPP (Field and Raupach 2004; Shvidenko and Nilsson 2003).

Estimates for the carbon stock in the world's forest ecosystems vary in the range of 352–536 billion tons of carbon (Dixon et al. 1994; Houghton 1996; Brown 1998; Saugier et al. 2001). The IPCC estimate of carbon content for three major forest biomes (covering 4.17 billion hectares) is 337 billion tons in vegetation and 787 billion tons in the top 1 meter layer of soils (IPCC 2001a). FRA-2000 estimated the aboveground tree biomass at 422 billion tons of dry matter (or 5.45 kilograms of carbon per square meter). The estimate by Kauppi (2003), based on FRA-2000, is 300 billion tons of carbon for tree biomass of forest ecosystems. Previously reported estimates—8.6 kilograms carbon per square meter by Dixon et al. (1994), 10.6 kilograms by Houghton (1999), and 6.6 kilograms by Kauppi (2003)—significantly overestimated densities. Based on analysis of all available sources and taking into account the above analysis of global forest area, it is estimated here that the total biomass of forest ecosystems is likely to include 335–365 billion tons of carbon (a priori confidence interval 0.9).

Forest carbon stocks and fluxes, and the major drivers of their dynamics, have been quantified for certain globally important forest areas (Zhang and Justice 2001; Houghton et al. 2001b; Fung et al. 2001; DeFries et al. 2002; Dong et al. 2003; Birdsey and Lewis 2003; Baker et al. 2004). Four major processes define whether forests serve as a net carbon sink or source: net primary productivity, decomposition (heterotrophic respiration), natural and human-induced disturbances (including harvest and consumption of forest products), and transport of carbon to the lithosphere and hydrosphere. The rate of accumulation of carbon over a whole ecosystem and over a whole season (or other period of time) is known as the net ecosystem productivity. In a given ecosystem, NEP is positive in most years and carbon accumulates, even if only slowly. However, major disturbances such as fires or extreme events that cause the death of many components of the biota release greater-than-usual amounts of carbon. The average accumulation of carbon over large areas or long time periods is called net biome productivity.

Productivity of forests varies significantly by continents, ecological zones, and countries, and no consistent global inventory of forest net primary productivity exists. Current estimates are based on potential (but not actual) forest cover and do not adequately take disturbances into account. This results in overestimation of biomass by 40–50% and overestimates of NPP by 25–35% for some large regions of the planet (Haberl 1997; Shvidenko et al. 2001).

Based on current understanding of the terrestrial vegetation global carbon cycle, NPP is estimated at 60 billion tons of carbon per year (e.g., Melillo et al. 1993; Goldweijk et al. 1994; Alexandrov et al. 1999), decomposition at 50 teragrams of carbon per year, net ecosystem productivity at 10 billion tons of carbon per year, and net biome productivity at 1 billion tons of carbon per year (0.7 ± 1.0 billion tons during 1988–99). The proportion of global NPP provided by forests is different in different climate zones and remains rather uncertain. Factors that influence the net uptake of carbon by forests include the direct effects of land use and land cover change (such as deforestation and regrowth), harvest and forest management, and the response of forest ecosystems to CO_2 fertilization, nutrient deposition, climatic variation, and disturbances.

Deforestation in the tropics has the greatest impact on the carbon cycle of any land use and land cover change. It is reported that land use change (mostly deforestation) is the source of 1.6 ± 0.8 billion tons of carbon per year (Houghton et al. 1999, 2001), although other estimates of net mean annual carbon fluxes from tropical deforestation and regrowth were 0.6 (0.3–0.8) and 0.9 (0.5–1.4) billion tons for the 1980s and 1990s (DeFries et al. 2002). Dixon et al. (1994) estimated that global forests were a net source of 0.9 ± 0.4 billion tons of carbon in the 1990s, including large sources in the low-latitude forests (1.6 ± 0.4 billion tons a year) and net sinks in mid-latitude (0.26 ± 0.09 billion tons a year) and high-latitude (0.48 ± 0.1 billion tons a year) forests.

Inversion studies using atmospheric-transport models indicate that land in the temperate and boreal latitudes of the Northern Hemisphere was a sink for 0.6–2.7 billion tons of carbon a year during the mid-1980s to mid-1990s, although patterns of spatial distribution of this sink are rather contradictive (Fan et al. 1998; Bousquet et al. 2000; Rayner et al. 1999; Battle et al. 2000; Prentice et al. 2001), and there is substantial interannual variation of forest NBP, which can reach three- to fivefold for large regions. Goodale et al. (2002) estimated that northern forests and woodlands provided a total sink for 0.6–0.7 billion tons of carbon a year during the early 1990s, consisting of 0.21 tons in living biomass, 0.08 tons in forest product, 0.15 tons in dead wood, and 0.13 tons in soil organic matter.

Russian forests, which account for about two thirds of total boreal forests, experienced severe disturbances during this period, which resulted in an estimated annual carbon sink for 1988–92 of 0.11 billion tons of carbon (Goodale et al. 2002). Later it has been shown that the forest sink in Russia during this period was minimal over the last four decades: the annual average NBP of Russian forests has been estimated at 0.43 billion tons of carbon per year from 1961 to 1998 (Shvidenko and Nilsson 2003). Canadian forests served as a net carbon sink before the 1980s but became a carbon source as the result of increased disturbances and changes in the age class distribution (Kurz and Apps 1999).

Recently disturbed and regenerated forests usually lose carbon from both soil and remnant vegetation, whereas mature undisturbed forests maintain an overall neutral carbon balance (Apps et al. 2000). The rate of carbon sequestration depends upon age, site quality, species composition, and the style of forest management. Mature and over-mature boreal forests in many cases actually serve as a net carbon sink (Schulze et al. 1999), which probably relates to accumulation of carbon in forest soils and uneven-aged forest structure.

The post-Kyoto international negotiation process envisages an important role for forests in current and future efforts to mitigate climate change. Forest management operations that simultaneously improve the condition and productivity of forests and stabilize natural landscapes are able to increase the carbon stock of forest ecosystems and ensure its persistence. These activities include afforestation and reforestation, thinning, improving forest protection, increasing efficiency of wood processing, and use of wood for bioenergy. Numerous studies show significant potential of the world's forests in this respect. Implementation of special carbon management programs in Russia, for example, allows for sequestration of 200–600 teragrams of carbon annually during the next 100 years in a globally competitive carbon market (Shvidenko et al. 2003). The ability of forests to sequester carbon effectively takes on special significance since the Kyoto Protocol entered into force in 2005. Implementation of successful carbon management will require improvements in national forest policies, legal instruments, monitoring and reporting in many countries, and general progress in the transition of world forestry to sustainable forest management.

Plantations are also increasingly established as a response to climate change. A number of countries already have programs to establish forest plantations for carbon sequestration. In Costa Rica, for example, reforested conservation areas are credited with income for the carbon sink and watershed protection services they provide (Chichilnisky and Heal 1998). By 2000, about 4 million hectares of plantations worldwide were established with funding for carbon sequestration. However, despite much progress in the post-Kyoto Protocol international negotiation process, some important political and economic questions concerning the use of forestry and land use change for mitigating climate change remain to be resolved. The protocol allows carbon sequestered by afforestation or reforestation after 1990 to be counted as an offset for emissions under certain circumstances. Some observers (e.g., Schulze et al. 2002) fear that this might offer incentives to fell older, natural woodland (for which no offsets are available) and replace them with plantations. However, the accounting and verification procedures, such as those agreed in the Marrakesh Accords to the protocol, are designed to eliminate such perverse incentives.

21.5.6 Sociocultural Values and Services

Forests are highly valued for a host of social, cultural, and spiritual reasons. Forests and people have co-developed, with people shaping the physical nature of most forests (including those we today consider "natural") and the forest, in turn, exerting a powerful influence over human cultures and spiritual beliefs (Laird 1999; Posey 1993; UNESCO 1996). For many indigenous and traditional societies, forests are sacred and sometimes supernatural places, linked to both religious beliefs and the very identity of some communities and peoples (Parkinson 1999). The widespread existence of "sacred groves" in many societies is a physical manifestation of this spiritual role and has contributed to forest conservation. (See Chapter 17.)

Forests provide spiritual and recreational services to millions of people through forest-related tourism. Nature-based tourism has increased more rapidly than the general tourism market, evolving from a niche market to a mainstream element of global tourism, with annual growth rates estimated to be in the range of 10–30%. (See Chapter 17.) Although it is difficult to estimate with any precision what proportion of regular tourism has been redefined as "nature-based" or how many "nature-based tourists" are drawn to destinations because they are forested, it is nevertheless evident that forests, woodlands, and the species they support are a significant element of many ecotourism destinations—from the national parks of North America to the megafauna-rich savannas of Africa.

21.5.7 Services Provided by Agroforestry Systems

Although forests and woodlands can be a substantial component of agroforestry systems, trees outside forests are also a crucial component of these systems. Services provided by agroforestry systems vary between different climate regions and include woody and non-woody forest products for commercial and subsistence use; maintenance of soil fertility via organic matter input to the soil, nitrogen fixation, and nutrient recycling (Szott and Palm 1996; Buresh and Tian 1998); reduction of water and wind erosion (Beer et al. 1998; Yukhnovsky 2003); conservation of water via greater infiltration (Bharati et al. 2002); enhanced carbon capture (Lopez et al. 1999); and maintenance and management of biodiversity in agricultural landscapes (Beer et al. 2003).

21.5.8 Discussion

While it is clear that the value of forest services is very high, there are many gaps in scientific understanding and few practical solutions to reconciling the conflicts that arise from the competing values that different user groups ascribe to different forest services. Interests of landowners, local communities, governments, and the private sector vary and frequently conflict in both spatial and temporal terms. The time horizon for using individual forest services is substantially different, for example, for forest-dependent indigenous communities and large logging companies.

There are many similarities in the importance and use of forest services in industrial and developing countries, as well as clear geographical, national, and user group differences. For example, the relative importance of wood production has been ranked as "high" and "medium" by 78% and 89% of respondents in United States and France, respectively, but estimates for grazing were 33% and 4%, and for nature protection 50% and 100% (Agarwal 1992).

Expert estimates presented in Tables 21.5 and 21.6 indicate, to some extent, current understanding of the relative importance of different forest services for tropical and non-tropical forests. Although it is not easy to predict future trajectories of changes for these estimates, demands on forests as sources of both fiber and other services will undoubtedly grow significantly. Two central factors of global change, however, will likely be determinative: the extent to which development challenges are met and poverty is reduced in many parts of the world (IIASA and FAO 2002) and the extent to which the direct and indirect impacts of climate change on the capacity of forests to provide services might exceed the resilience of forest ecosystems in many regions.

21.6 Drivers of Change in Forest Ecosystems

Understanding the drivers of change in forest condition at different spatial and temporal scales is a complicated task. As a rule, such changes are the result of interactions among many factors—social, ecological, economic, climatic, and biophysical. (See Chapter 3.) Rapid population growth, political instability, market forces, institutional strengths or weaknesses, natural and human-induced disturbances, and many other factors may be important. Biophysical factors, such as a region's history of landscape transformation (Mertens and Lambin 2000), the high sensitivity of forest soils to machinery used for logging (Protopopov 1979), or the high flammability of boreal forests (Kasischke and Stocks 2000) can also play a significant role (McConnell 2004).

21.6.1 Tropical Forest Ecosystems

Forest degradation and conversion to other land uses are the two main processes of change occurring in natural tropical forest ecosystems. Numerous studies have attempted to ascertain the direct and indirect drivers of tropical deforestation and the relationships among them, and broadly conclude that in many situations it is impossible to isolate a single cause due to the complex socioeconomic processes involved, and the diverse circumstances in which it occurs, which often obscures underlying patterns (Walker 1987; Roper 1996). Despite this complexity, it is clear that tropical deforestation is caused by a combination of direct and indirect drivers, that these drivers interact with each other, often synergistically, and that the specific combinations of drivers vary between regions of the globe, countries, and even between localities within countries.

The assessment of tropical deforestation provided by Geist and Lambin (2001, 2002) and further elaborated in Lambin et al. (2003) is presented here. It provides a comprehensive review and synthesis of recent literature and draws on analysis of 152 subnational case studies.

21.6.1.1 Direct Drivers

Direct drivers of tropical deforestation are human activities or immediate action at the local level, such as agricultural expansion, that originate from intended land use and directly affect forest cover (Geist and Lambin 2002). These direct drivers can be broadly categorized into those related to agricultural expansion, wood extraction, and infrastructure extension.

Agricultural expansion includes shifting cultivation (both traditional swidden agriculture and the more destructive "slash-and burn" cultivation); permanent agriculture, which may be at large or small scales and, in the latter case, for either commercial or subsistence purposes; pasture creation for cattle ranching; and sponsored resettlement programs with the objective of converting forest to agriculture, estate crops, or timber plantations.

Wood extraction includes commercial wood extraction (state-managed or private logging concessions), fuelwood extraction and charcoal production for both domestic and industrial uses, and polewood extraction for both domestic and urban uses. Most timber extraction in tropical regions is done without effective management, and logging often inflicts a great deal of damage on the remaining forest stand (Verissimo et al. 2002; Schneider et al. 2002), although technologies of reduced impact logging have been successful on an experimental scale (Sist et al. 1998; Ceder-

gen 1996; Mårn and Jonkers 1981; Applegate et al. 2004) (See also MA *Policy Responses,* Chapter 8.) Illegal logging is also a major concern in many tropical countries. (See Chapter 9.) Illegal logging drives harvesting above planned legal limits, thereby impairing efforts at sustainable forest management, and is a powerful element of organized crime (e.g., Curry et al. 2001; Tacconi et al. 2003). According to assessments by international institutions such as the World Bank and WWF, about 70 countries have substantial problems with illegal logging, leading to annual losses of government income exceeding $5 billion and total economic losses of about $10 billion (Pisarenko and Strakhov 2004).

Infrastructure extension includes transport infrastructure (roads, railroads, and rivers); market infrastructure (such as sawmills and food markets); settlement expansion; and a variety of resource extraction, energy, and industrial infrastructure (such as hydropower, oil exploration, mining, and electrical grids).

Agricultural expansion is by far the most important direct driver of deforestation (in as much as 96% of cases studied) (Geist and Lambin 2002), and higher prices for agricultural products are a key indirect driver (Angelsen and Kaimowitz 1999). There is considerable regional variation in the kinds of agricultural expansion affecting tropical forests. Slash-and-burn clearing in Asia, for example, is more prevalent in uplands and foothills, whereas in Latin America, it is mainly limited to lowland areas. Pasture creation for cattle ranching is a major direct driver of forest loss in mainland South America, but much less so in other regions.

Similar regional variation exists for commercial wood extraction, which was a factor in 67% of cases studied, but varied from being a direct driver of deforestation in 78% of Asian cases to 40% of Latin American cases and 26% of African cases. This is not surprising, since significant industrial logging for the international tropical timber trade now occurs only in seven Asian countries (Indonesia, Malaysia, Myanmar, Cambodia, Laos, Papua New Guinea, and the Solomon Islands), although many other countries have commercial logging operations for domestic and international markets (FAO 2002a). In some cases, large timber corporations have taken advantage of weaker or more corrupt governments (Forests Monitor 2001), which have ceded large tracts of forests to logging firms—for instance, 75% of Cameroon's forest area (WRI 2000b) and 50% of the forest area of Gabon (WRI 2000a).

By contrast to the relative importance of commercial logging in Asia, fuelwood gathering for domestic use was found to be a direct driver in 53% of African cases but only 33% of Asian and 18% of Latin American cases.

Infrastructure expansion was found to be a direct driver in 72% of cases overall, varying from 47% in Africa to 66% in Asia and 83% in Latin America. In particular, road extension was found to be one of the main specific direct drivers of tropical deforestation, especially in Latin America. The extension of roads, rail, and water transport now leaves 65% of forests in Africa 10 kilometers or less from a transportation line (FAO 2001c). By contrast, the development of private enterprise infrastructure (dams, mines, oil exploration) appears to be a minor direct driver of tropical deforestation globally, although it is important in some regions (such as hydropower development in Southeast Asia and oil development in the Peruvian, Ecuadorian, and Colombian Amazonian lowlands).

Tropical deforestation can rarely be explained by a single direct driver. In the Geist and Lambin assessment, single direct drivers only explained 6% of the cases. In particular, agricultural expansion in tandem with infrastructure development and/or logging are the most frequent combinations of direct drivers (''tandems'') causing deforestation. The infrastructure-agriculture tandem explained more than one third of the cases and was relatively evenly distributed across regions. In 90% of these cases, the extension of road networks caused extension of permanently cropped land and cattle pasture, thereby resulting in deforestation. The logging-agriculture tandem explained only 10% of all cases in the study but was an important direct driver of deforestation in Southeast Asia and parts of China: the leading specific driver in most Asian cases is commercial, chiefly state-run logging activities, leading to the expansion of cropped land.

21.6.1.2 Indirect Drivers

Indirect drivers of deforestation are fundamental social processes, such as human population dynamics or agricultural policies, that underpin the direct drivers and either operate at the local level or have an indirect impact from the national or global level (Geist and Lambin 2002). These indirect drivers fall into five broad categories: economic, policy and institutional, technological, cultural/sociopolitical, and demographic. Each of these is complex even at the level of a general typology. (See Table 21.7.) They are of course even more complex in particular countries and contexts, and, like direct drivers, indirect drivers rarely function alone.

Economic factors, particularly those related to economic development through a growing cash economy, are highly important across many regions. Many cases are characterized by the marginalization of farmers who have lost their resource entitlements, combined with development brought about through public or private investments (Geist and Lambin 2002).

Institutional factors are also frequently important and are closely tied to economic drivers. These may involve formal pro-deforestation policies and subsidies (for colonization, agricultural expansion, or logging, for instance) as well as ''policy failures'' such as corruption or forestry sector mismanagement. Property rights issues, although much discussed in the deforestation literature, were only a major indirect driver in the cases Geist and Lambin analyzed for Asia and tended to have an ambiguous effect on forest cover: both tenurial insecurity (such as open access conditions and denial of indigenous land rights) and the legalization of land titles (enhanced tenurial security) were reported to influence deforestation in a similar manner. While property rights issues may not be the most dominant factors driving deforestation, it is widely recognized that clear property rights are a fundamental basis for instituting sustainable forest management. (See Box 21.5.)

Among demographic factors, only in-migration of colonists to sparsely populated forest areas appeared to be significant; population increase due to high fertility rates has not been a primary driver of deforestation at a local scale or over a few decades. Population increases are always combined with other factors (Geist and Lambin 2002).

21.6.1.3 Summary of Drivers

In summary, while it is possible to identify with some certainty the factors underlying tropical deforestation in a general sense, it is very difficult to pinpoint a uniform set of drivers and their relative contributions that can be said to apply generally at a global or even regional level. In a separate review of 140 models analyzing the causes of tropical deforestation, Angelsen and Kaimowitz (1999) raised significant doubts about many conventional hypotheses in the debate about deforestation; they found that more roads, higher agricultural prices, lower wages, and a shortage of off-farm employment generally lead to more deforestation, although how technical change, agricultural input prices, household income levels, and tenure security affect deforestation remains unknown. The role of macroeconomic factors such as population growth, poverty reduction, national income, economic growth and foreign debt was also found to be ambiguous. Moreover, the study found that the ''win-win'' hypothesis that economic growth and removal of market distortions will benefit both people and forests is not well supported by the available evidence. Rather, economic liberalization and currency devaluations tend to yield higher agricultural and timber prices that, in general, will promote deforestation (Angelsen and Kaimowitz 1999).

21.6.2 Temperate and Boreal Forest Ecosystems

Contrary to the situation in tropical forests, an important feature of forest dynamics in temperate and boreal zones is natural reforestation and expansion of forests. This process has been typical for the entire boreal zone during the last 40 years, and in Northern Eurasia this was due largely to the great restoration potential of boreal forests and the suppression of fire from the 1960s to the mid-1990s (Shvidenko and Nilsson 2002). Data for North America are less available, but fragmented satellite observations suggest that reforestation and forest expansion has been common for the entire circumpolar zone. Indeed, many temperate counties have initiated programs of reforestation and improvement of existing forests (UNECE/FAO 2003), resulting in increased net forest cover in temperate and boreal forest ecosystems.

Drivers of increasing forest cover in temperate industrial countries include the intensification of agriculture and agricultural overproduction, resulting in set-aside policies; loss of soil fertility; the increasing value of forests' amenity services; climate protection and watershed protection uses; and growing public understanding of the environmental values of forests.

In Europe, many forests were cleared centuries ago to allow agricultural expansion. Some of that agricultural land has become uneconomic to farm (see Chapter 26); meanwhile, the values of other forest services (amenity, conservation and protection, timber) have increased. Thus, the economically optimal land use has changed over the last century and trees have been either replanted or allowed to regenerate naturally. A number of countries in Europe have developed national polices aimed at conversion of some agricultural and marginal land into forest. And in Russia, the economic situation and social changes during the past decade have led to abandonment of over 30 million hectares of arable land, which is regenerating naturally into forest, trees, and bushes (Kljuev 2001).

Forest quality, however, has not necessarily improved across the temperate and boreal zones. Indeed, forests in Europe showed

Table 21.7. Generalized Typology of the Indirect Drivers of Tropical Deforestation (Adapted from Geist and Lambin 2001)

Economic change (economic growth, development, commercialization)	market growth and commercialization	rapid market growth (especially exports), rise of cash economy, increasing commercialization, incorporation into global economy increased market accessibility (especially of semi-urban and urban markets) lucrative foreign exchange earnings growth of demand for forest-related consumer goods due to rise in well-being
	specific economic structures	large individual (mostly) speculative gains poverty and related factors economic downturn or crisis indebtedness, heavy foreign debt
	urbanization and industrialization	urbanization; growth of urban markets industrialization: rapid expansion of new basic, heavy, and forest-based or forest-related industries
	special economic parameters	comparative advantage due to cheap, abundant production factors in resource extraction and use artificially low-cost production conditions (e.g., through subsidies) price increases or decreases for cash crops, fuel, land
Policy and institutional factors	formal policies	taxation, charges, tariffs, prices credits, subsidies, licenses, concessions, logging bans economic development (e.g., agriculture, land use policy, infrastructure) finance, investment, trade population (including migration and resettlement) other forestry sector policies
	informal policies (policy climate)	corruption and lawlessness growth or development coalitions bureaucratic mismanagement and poor performance clientelism, vested (private) interests role of civil society (e.g., NGOs)
	property rights regimes	insecure tenure and resulting open access in forest areas privatization of public lands state assertion of control over private, communal, or customary lands inequality in land access, ownership, and control
Technological change	agro-technological change	land use intensification land use extensification other changes (landholding, production orientation, etc.)
	technological applications in the wood sector	damage and waste due to poor logging performance waste in wood processing, poor industry performance lack of cheap technological alternatives to fuelwood; poor industrial and domestic furnace performance
	other production factors in agriculture	low level of technological inputs land-related factors (landlessness, land scarcity) labor-related factors (limited availability) capital-related factors (no credit, limited irrigation)
Cultural/socio-political factors	public attitudes, values, and beliefs	public unconcern or lack of (public and political) support for forest protection and sustainable use; low educational levels; frontier mentality; dominance of other public values (e.g., modernization, development) unconcern about the welfare of others and future generations; low perception of public citizenship and responsibilities beliefs about how environmental change affects other things that individuals value
	individual and household behavior	unconcern by individuals about the environment as reflected in increasing levels of demands, aspirations, and consumption, commonly associated with commercialization and increased income situation-specific behavior of actors: rent-seeking, nonprofit orientation, extent of adherence to traditional resource use modes
Human population dynamics	population growth, density, spatial distribution, and life cycle features (e.g., age, gender structure)	

BOX 21.5

Influence of Property Rights on Forest Cover Change and Forest Management

From the colonial period until recently, governments have legally owned most forests. The tradition of government ownership originated in medieval Europe and was transported to most colonies and adopted by imperial states in the sixteenth and seventeenth centuries (White and Martin 2002). Except for in the United States, Mexico, China, and Papua New Guinea, government ownership of forests spread throughout Africa, the Americas, and South and East Asia as new governments took rights from native peoples and centralized the control and management of forest resources in public forest agencies. Currently, about half (51%) of forests and other wooded lands are in public ownership in Europe (without Russia) and the rest is privately owned. National variation of ownership in temperate and boreal countries is significant: in a number of countries (such as Canada, Russia, Ukraine, and Bulgaria), forests and OWL are almost exclusively owned publicly; in others, forests are owned privately (for example, 92% in Portugal, 82% in Austria, and 80% in Sweden) (UNECE/FAO 2003).

By 1982, over 80% of the closed forests in developing countries were public land (FAO 1982). A 2002 study (White and Martin 2002) estimated that about 77% of the world's forest are owned and administered by governments based on national laws, at least 4% are reserved for communities, at least 7% are owned by local communities, and approximately 12% are owned by individuals. (See Table.)

In general, governments in countries with large amounts of forest have traditionally opted to transfer access rights and management authority to large-scale private industry through logging concessions. Gillis (1992) estimated that in 1980 about 90% of all industrial roundwood was derived from logging concessions. Data from 16 countries in Africa, the Americas, and Southeast Asia for which concession information is available reveal that 396 million hectares (44.2% of the total forest area) are under concessions. In some of these areas, particularly in Southeast Asia, the access and use rights granted to forest concessions have contributed to the massive exploitation of forest resources and the marginalization of forest-dependent communities (Broad 1995; Kummer 1992).

In the last decade or so, some governments have introduced reforms in forest ownership policies in favor of community access and ownership. These reforms were propelled by at least three factors: government recognition of the claims of indigenous and other local communities; growing evidence of the capacity of local communities to carry out sustainable forest management, due to their traditional management practices and their direct stake in forest sustainability; and the increasing realization that governments and public forest agencies have often not been good mangers of public forests (White and Martin 2002). Currently, small farms, communities, and indigenous people own or have usufruct rights over one fifth of forests in developing countries. India's Joint Forest Management Programme can be cited as one generally positive example of implementation: over 35,000 village organizations now participate in the program, covering 18% of all state forests where 147 million people live in and around forests (Forest Trends 2002), although the process is not simple and the results have not all been positive (Arnold 2001).

Social conflicts often accompany the process of change and redistribution of property rights, in particular use of lands of indigenous communities for industrial forestry and agricultural purposes, including forcible or illegal seizure of land. Reservation of indigenous territories is considered an important tool for conserving natural forests in many countries, particularly in the tropics. Recognized indigenous territories constitute 20% of the Brazilian Amazon, for example. Conflicts, however, between indigenous peoples in these territories and newcomers—such as illegal farmers associated with the Landless Rural Workers Movement—are quite common.

There is no single, "correct" forest property rights regime for all cases. Each country must find its own balance among public, private, and community rights. Whatever particular balance a country strikes, however, forest property rights need to be clear and enforceable. Formal legal establishment of property rights does not guarantee their effective implementation or enforcement. In many developing countries (and some countries in transition), forest property rights are legally mandated but are not implemented due to weak enforcement capacity or corruption.

Estimated Distribution of Forest Ownership for Selected Categories (White and Martin 2002)

	Public		Private	
	Administered by Governments	Reserved for Community and Indigenous Groups	Community/ Indigenous	Individual/Firm
Categories	*(percent of total)*			
Global forest estate	77	4	7	12
Developing countries	71	8	14	7
Developed countries	81	1	2	16
Tropical countries	71	6	13	10
Top 17 megadiverse countries	65	6	12	17
Top five roundwood products	80	7	6	7

a continuous deterioration from 1986 to 1995 due to air pollution, with the proportion of healthy trees falling from 69% in 1988 to 39% in 1995. Results for 1995–2001 show stabilization at a high level of damage, with almost a quarter of the sample trees rated as damaged due to air pollution (EC-UN/ECE 2002). For example, sulfur from the world's biggest source of sulfur emissions, Norilsk in northern Siberia (about 2 million tons of sulfur dioxide per year), caused tree mortality and degradation of more than 2 million hectares of surrounding forest tundra landscapes during the last four decades (Nilsson et al. 1998; Bruce et al. 2004).

Air pollution induces changes in tree physiology, phenology, and biochemical cycling. Among air pollutants affecting forest health, sulfur, nitrogen, heavy metals, and ozone are the most pervasive, although the complexity of forest decline in relation to air pollution suggests that decline in condition has been due to the combined impacts of eutrophication, acidification, and climate change (Nelleman and Thomsen 2001; see also Chapter 25).

The impacts of pollution on forests are not confined to industrial countries. Although anthropogenic emissions of sulfur dioxide have recently declined in most industrial countries in Europe and North America, emissions have increased in a number of countries of Asia, Africa, and Central and South America. Emissions of nitrogen oxides due to human activities remain constant or have increased over vast regions. (See Chapter 13.)

Pest outbreaks also seriously affect the quality of temperate and boreal forest ecosystems. Between 2000 and 2003, harmful forest insect outbreaks in Canada and Siberia affected more than 20 million hectares of boreal forests. The area affected by bark beetles in British Columbia increased during 2002–03, doubling to 4.2 million hectares (Berg and Henry 2003), from which the expected loss of timber is estimated to be CAN$20 billion, in addition to the increased risk of catastrophic fires. In northern Siberia, more than 10 million hectares of larch forests were defoliated by Siberian silkworm in 2001 and 2002 (MNR 2003). The main underlying cause of these increases in natural disturbances in the boreal zone was the extremely hot and dry summers and mild winters that occurred between 1998 and 2003 (e.g., Ivanov 2003).

21.6.3 Fires in Forest Ecosystems

Fire is a crucial disturbance factor affecting tropical, temperate, and boreal forests. In many regions (the boreal zone, for instance, and savannas), fire is an essential and ecologically important process that organizes structure and functioning of forest ecosystems and substantially affects flows of energy and matter. For many other forest ecosystems, however, fire is a negative factor that severely damages forests and can lead to long-term degradation (FAO 2001e; WGWF 2003).

The incidence and severity of forest fires appears to have accelerated over the past few decades (Kasischke and Stocks 2000). (See also Chapter 16.) Until recently, for example, fire in tropical evergreen forests had a negligible distribution and impact. However, tropical rain forest conversion to rangeland and agricultural systems, slash-and burn practices, and landscape fragmentation, exacerbated by the El-Niño Southern Oscillation, have resulted in the dramatic increase of wildfires in tropical rain forests during the last two decades (Muller-Dombois and Goldammer 1990; WGWF 2003; Mutch 2003).

The El Niño–driven fires of 1997–98 burned more than 20 million hectares in Latin America and Southeast Asia. The burnt area in Kalimantan (Indonesian Borneo) alone was about 6.5 million hectares, of which 3.2 million hectares was forest or forest areas that had recently been severely degraded or converted to plantations and other agricultural uses (Tacconi 2003). The complete economic, social, and ecological consequences of these fires have not been quantified, although some studies have yielded at least partial estimates of lost wood and impacts on wildlife and human health (e.g., Barber and Schweithelm 2000; WWF-Indonesia and EEPSEA 1998). The cost of carbon loss from the forests due to the 1998 fires in Latin America is roughly estimated at $10–15 billion, and severe respiratory health problems together with widespread transport disruption were estimated to cost $9.3 billion (WGWF 2003).

Increased fire activity has also been observed in other forest biomes. During the last two decades, forest fires in boreal North America (Canada and Alaska) have burned an average of 3 million hectares annually (national statistics available from the Global Fire Monitoring Center, www.fire.uni-freiburg.de). Apart from the influence of weather, shortcomings in forest fire management contributed to this increase. Human activities since 1900 have altered forest structure and fuel loadings to such an extent that they have eliminated the natural fire regime on over half the land area (260 million hectares) of the conterminous United States (Schmidt et al. 2002). In 2002, about 3 million hectares of U.S. forests burned, causing the deaths of 21 firefighters. In Russia, about 15 million hectares of forest burned in 2003. In that same year, forest fires destroyed 5% (386,000 hectares) of Portugal's forest and killed 20 people (the average annual burned area during the previous decade was about 50,000 hectares (Baptista and Carvalho 2002)), and the official estimate of economic damage of fire in 2002 was about $1 billion.

Although an inventory of the global fire situation was prepared as part of FRA-2000 (FAO 2001d), available national information is incomplete, and the certainty of data for many regions in unknown. The satellite-based Global Burned Area Product for the year 2000 reported the global burned area of terrestrial vegetation to be 351 million hectares (JRC 2000). The reliability of this estimate is not known, however, due to the coarse resolution of the remote sensing data used and the absence of ground-truthing for many large regions. Nevertheless, the main conclusion is evident: forest fires have become a global factor negatively affecting the condition and functioning of terrestrial biota, and experiences over the past decade show that the risk and threats of forest fires are widespread across the globe.

21.6.4 Climate Change and Forests

During the last 30 years the world has experienced significant temperature increases, particularly in northern high latitudes (IPCC 2001a). (See Chapter 25.) The climatic scenarios considered by the Third Assessment Report of the IPCC projects the increase in global annual average surface temperature by the year 2100 to be 1.4–5.8° Celsius higher than the mean over the period 1990 to 2001. In some regions, this projected warming will generate a climate not experienced in recent evolutionary history. Western North America, for example, could be 2–5° Celsius above the range of temperatures that have occurred over the past 1,000 years, and vast regions in Siberia could be warmer by 6–10° Celsius. Moreover, temperatures are projected to continue to increase beyond 2100 even if atmospheric concentrations of greenhouse gases were to be stabilized by that time (Houghton et al. 2001).

As a whole, precipitation patterns are also predicted to increase, although this is mostly expected in winter precipitation, and many regions will face either a very small change or a decrease in summer precipitation. In particular, the latter is expected in regions of dry forests and woodlands. Finally, climate variability, such as the frequency of extreme events and occurrence of dry and hot periods, are expected to increase substantially (IPCC 2001a, 2001b).

These dramatic changes will be accompanied by the ''fertilization effect'' of increasing CO_2 concentration and nutrient deposition, which may substantially affect the state, functioning, and dynamics of the world's forests (Chapin et al. 2004). Although there is a lack of knowledge on the adaptive capacity of tree species, it is likely that an increase of temperature of a few degrees may accelerate productivity of forests, but any further increase will affect forest ecosystems in a clearly negative way (Walker et al. 1999). In spite of the fact that many experiments with leaves, shoots, and tree seedlings indicate a significant increase of productivity due to CO_2 fertilization, these effects on forests will be saturated in a short time (Scholes et al. 1999). There are also experimental data that do not support CO_2 fertilization models (Pacala 2004).

In many regions, adaptation of some forests, such as those on peat and wetlands covered by trees and shrubs, may be practically impossible. Melting of permafrost at high latitudes will cause dramatic changes in hydrological regimes of huge areas (Chapin et al. 2004). Satellite-based measures of the greenness of the boreal forest zone indicate a lengthening of the growing season over the past two decades (Nemani et al. 2003). In dry forests, net decreases in available soil moisture will decrease forest productivity. Many of these regions are also affected by El Niño/La Niña and other climatic extremes, and significant increases in land degradation and impoverishment of forests are likely (IPCC 2001a, 2001b).

Tropical montane cloud forests are especially vulnerable to climate change (Markham 1998). Various lines of evidence show that these have already been affected by climate change (Bubb et al. 2004), either through declines in the species they support (Pounds et al. 1999) or through rising cloudbanks (Still et al. 1999), which are a consequence of both climate change and regional land use change (e.g., see Lawton et al. 2001).

However, the degree to which changes in climate have already affected (e.g., see Walther et al. 2002) and continue to affect (Aber et al. 2001) productivity indicators of forests and their ability to supply services varies across space and time. This is because of the varying life cycles of forests, where climate changes within the former life cycle have a more immediate effect on regeneration success following disturbances (Price et al. 1999a, 1999b); differing values placed on forests by society (Spittlehouse 1997); disagreement on whether impacts of climate change are positive or negative (Körner and Arnone III 1992); and the varying priorities of governments for addressing other impacts (Spittlehouse 1997).

The impacts of changing climate also vary among different measures of ecosystem productivity. For example, because short growing seasons and the sum of active temperatures are the main factors limiting growth in boreal and alpine forests (Stewart et al. 1998), a projected increase in temperature may lead to higher net primary productivity values in most of these forest stands (Bugmann 1997, but see possible limitations in Barber et al. 2000), while net ecosystem productivity values will show decreases due to increased decomposition (Valentini et al. 2000, but see Giardina and Ryan 2000). On the other hand, should higher temperatures together with lower summer precipitation values occur in these forest stands, then harsher summer drought conditions may decrease NPP values as a result of lowered photosynthetic rates associated with reduced stomatal conductance (Sellers et al. 1997). Such a scenario will lead to a further decrease in NEP values due to decomposition.

The possible negative climatic effects caused by drought could be partly or fully mitigated by elevated CO_2 levels. High CO_2 levels have been found to be associated with increased photosynthetic rates and increased water use efficiency of various forest species; this could potentially lead to increased forest productivity. Evidence for this, however, is still inconclusive (Kirschbaum and Fischlin 1996). In humid evergreen tropical forest in Costa Rica, annual growth in the period 1984–2000 varied inversely with the annual means of daily minimum temperature because of increased respiration at night (Clark et al. 2003). On the other hand, a network of Amazon forest inventory plots shows a carbon accumulation rate of 1 ton of carbon per hectare per year since 1979 (Baker et al. 2004). Tree recruitment and mortality have increased significantly in the Amazon in the past two decades, with recruitment consistently exceeding mortality (Phillips et al. 2004).

Finally, warmer and drier conditions will result in increased forest and woodland fires (Laurance and Williamson 2001; Kasischke and Stocks 2000), leading to reduced transpiration and increased carbon emissions and thus creating a positive feedback whereby more-frequent and severe fires result in complete deforestation (Cochrane et al. 1999). It has been estimated that in 1997–98 net forest fire emissions (from biomass and soil losses) may have released carbon that was equivalent to 41% of worldwide fossil fuel use (Houghton et al. 2001). Therefore drier conditions will clearly add pressure to both ecosystem services (such as negative net biome productivity) (Apps et al. 2000) and the economic potential of these natural resources (see Dixon et al. 1994 for the economic importance of forests) and will also affect human health due to smoke-related impacts as a result of forest fires (Cochrane 2003).

Because climate change alters the spatial and temporal patterns of temperature and precipitation (the two most fundamental factors determining the distribution and productivity of vegetation), climate change will cause geographical shifts in the ranges of individual species and vegetation zones. In West Africa, lower rainfall and higher temperature due to climate change and desertification have shifted the Sahel, Sudan, and Guinean vegetation zones 25–30 kilometers southwest toward areas of higher rainfall and lower temperature in the period of about 1945–93 (Gonzalez 2001). In New Mexico in the United States, a 1954–58 drought caused a permanent 2-kilometer shift of xeric piñon-juniper woodland into mesic ponderosa pine forest (Allen and Breshears 1998), and some climate modeling shows extensive latitudinal and altitudinal shifts of vegetation zones across North America and Siberia (Iverson and Prasad 1998; Pan et al. 1998; Bachelet et al. 2001).

The dynamic nature of the environment within which sustainable forest management must take place means that simple representation of the more tangible forest elements, such as productivity indicators, in static areas (such as protected areas) is unlikely to be sufficient for long-term protection and hence sustainability (Stewart et al. 1998; Rodrigues et al. 2000; Hannah et al. 2002). Consequently, flexible forest and woodland management will be needed to adapt to some of the effects of future climate change, which will certainly have widespread affects on forest and woodland systems (Dixon et al. 1994; Cohen and Miller 2001; Spittlehouse and Stewart 2003).

21.7 Human Well-being and Forests and Woodland Systems

Forests and woodlands supply essential services to human well-being across the world, and human-forest interactions manifest themselves in many direct and indirect ways, each depending variously on the amount of forest, its condition, and its distribution over the landscape.

More than 1.7 billion people live in the 40 nations with critically low levels of forest cover, in many cases hindering prospects for sustainable development. The number of people living in low-forest-cover nations will probably triple by 2025, reaching 4.6 billion, and 13 additional countries will experience forest resources scarcity (Gardner-Outlaw and Engelman 1999). Human population growth has drastically shrunk the forest-to-people ratio from 1.2 hectares per capita in 1960 to 0.6 hectares per capita at present. By 2025, the ratio is predicted to decline further, to 0.4 hectares per capita (Gardner-Outlaw and Engelman 1999).

The expected decline in the per capita availability of forests in developing countries generates additional problems for sustainable development. In many parts of the developing world, direct harvesting of forest products by rural families contributes to more than 50% of total consumption and other household needs (Cavendish 2000; Hassan 2002; Hassan et al. 2002; Godoy and Bawa 1993; Kusters and Belcher 2004; Peters et al. 1989; Sheil and Wunder 2002; Sunderland and Ndoye 2004). This large group of people is particularly vulnerable to the negative impacts of declining forest cover.

Diminishing access to forest products significantly affects human well-being in developing countries. Inadequate supplies of paper could emerge as a significant impediment to development during this century, and 80% of the world's population has yet to achieve the level of paper use deemed necessary to meet basic needs for literacy and a minimal level of education and communication (Gardner-Outlaw and Engelman 1999). About 2.4 billion people use energy derived from biomass, mostly from forests and woodlands (Arnold et al. 2003; see also Chapter 9), and most of the 240 million poor people in forested regions in developing countries depend heavily on forests and trees for their livelihoods (World Bank 2003).

Development of modern forest industries can generate local employment and thereby improve the standard of living of forest communities. Still, a significant proportion of wood harvested in tropical countries is exported as unprocessed logs. For instance, 38–48% of unprocessed roundwood was imported from net export African member countries of the International Tropical Timber Organization during 1995–2000 (Buttoud et al. 2002), and domestic demand for wood products in these countries remains very low, at around 0.1 cubic meters per person a year for timber.

Population-related pressure on forests is greatest in countries where per capita forest cover is low, and although forests are often protected or planted as population pressures increase, this is usually only in high-productivity zones (such as Bangladesh, Java, parts of Kenya, and India) but rarely in areas of low productivity (Persson 2003). Many countries in the developing world are facing local woodfuel and NWFP scarcity, and the situation is expected to become more acute (FAO 2003a). Because it is often women and children who search for fuel and edible forest products and so on, such shortages have particularly negative impacts on these sectors of the population.

Of course, not all deforestation is necessarily undesirable, and many areas of forest have been lost after the negative consequences of such loss have been carefully considered and weighed against the benefits. For many countries, past and present, converting some forestlands to agricultural, infrastructural, industrial, and urban uses has been a necessary and accepted mechanism for economic development and progress. Unfortunately, deforestation, particularly in the tropics, has often resulted in conversion to unsustainable land uses and has not delivered the anticipated benefits to economic development.

It is projected that tropical deforestation will likely continue unabated through 2020 and that demand for fuelwood will continue to rise in Africa and some other regions of the developing world, watershed protection will continue to deteriorate, and countries will not likely improve efforts to implement sustainable forest management (FAO 2003a; Kaimowitz 2003). National forest services generally remain underequipped to counter these trends. A survey of government expenditures in 24 African countries in 1999 showed that forest expenditures averaged 82¢ per hectare, of which international financing accounted for 37¢ (FAO 2003a). Most national funding goes to staff salaries, while the international component generally goes to investments in material and information systems.

The condition of forests in individual countries and the well-being of forest-dependent peoples are closely tied to economic development levels and trends. Russia is an interesting and informative example, as the severe economic situation of the last 15 years has led to large-scale decline of the forest sector. The production of major forest products decreased between 1988 and 1998 by three- to fivefold (Bourdin et al. 2000), dramatically affecting the well-being of about 3 million people in regions where forests are a major source of employment and subsistence. Many hundreds of forest settlements now suffer from unemployment and a lack of basic living conditions; subsistence farming, gathering mushrooms and wild berries and fruits, fishing, and poaching have become major sources for subsistence in many forest regions. This situation is heavily influenced by an inadequate forest policy, although in recent years there has been a slow but evident restoration of the Russian forest sector, driven largely by market mechanisms (Shvidenko 2003).

The extent and distribution of forests are important at all spatial levels, from the local to the continental. Even if a country as a whole has a sufficient amount of forested area in the aggregate, forest cover in particular regions or landscapes may still be insufficient to meet the demand for services. Redistribution of forest cover over a landscape is difficult, however, and requires long-term, consistent policies at the national level. Improving the condition of forests and their contribution to human well-being is an important and urgent task, both nationally and internationally. Recent history, such as international efforts working with the Tropical Forestry Action Plan (FAO 1985; Winterbottom 1990), clearly shows both how difficult it is to achieve sustainable forest management in the contemporary world and that many problems remain to be solved in order to realize the potential benefits that forests and woodlands have to offer.

Main Messages

Drylands cover about 41% of Earth's land surface and are inhabited by more than 2 billion people (about one third of world population). Drylands are limited by soil moisture, the result of low rainfall and high evaporation, and show a gradient of increasing primary productivity, ranging from hyper-arid, arid, and semiarid to dry subhumid areas. Deserts, grasslands, and woodlands are the natural expression of this gradient.

Dryland populations on average lag far behind the rest of the world on human well-being and development indicators (*high certainty*). The current socioeconomic condition of dryland peoples, about 90% of whom are in developing countries, lags significantly behind that of people in other areas.

Existing water shortages in drylands are projected to increase over time due to population increase, land cover change, and global climate change. From 1960 to 2000, global use of fresh water (drylands included) expanded at a mean rate of 25% per decade. The availability in drylands is projected to decline further from the current average of 1,300 cubic meters per person per year (in 2000), which is already below the threshold of 2,000 cubic meters required for minimum human well-being and sustainable development. This increased water stress will lead to reduced productivity of croplands and availability of fresh water, resulting in further adverse impacts on human well-being in drylands. There is a high degree of certainty that global climate change, land use developments, and land cover changes will lead to an accelerated decline in water availability and biological production in drylands.

Transformation of rangelands and other silvipastoral systems to cultivated croplands is leading to significant, persistent decrease in overall dryland plant productivity. Extreme reduction of rangeland vegetation cover through grazing of forage and collection of fuelwood exposes the soil to erosion. Transformation of rangelands to cultivated systems (approximately 15% of dryland grasslands, the most valuable dryland range, were converted between 1950 and 2000), in combination with inappropriate dryland irrigation and cultivation practices has led to soil salinization and erosion. These processes reduce the provision of water-related services, which affects the provision of many other significant dryland services and goods, culminating in persistent reduction of primary production.

Among dryland subtypes, ecosystems and populations of semiarid areas are the most vulnerable to loss of ecosystem services (*medium certainty*). Population density within drylands decreases with increasing aridity from 10 persons per square kilometer in the hyper-arid drylands to 71 persons in dry subhumid drylands. Conversely, the sensitivity of dryland ecosystems to human impacts that contribute to land degradation increases with increasing aridity. Therefore, the risk of land degradation is greatest in the median section of the aridity gradient (mostly the semiarid drylands), where both sensitivity to degradation and population pressure (expressed by population density) are of intermediate values.

It is thought that some 10–20% of the world's drylands suffer from one or more forms of land degradation (*medium certainty*). Despite the global concern aroused by desertification, the available data on the extent of land degradation in drylands (also called desertification) are extremely limited. In the early 1990s, the Global Assessment of Soil Degradation, based on expert opinion, estimated that 20% of drylands (excluding hyper-arid areas) was affected by soil degradation. A recent MA commissioned desk study (Lepers 2003) based on regional data sets (including hyper-arid drylands) derived from literature reviews, erosion models, field assessments and remote sensing found much lower levels of land degradation in drylands. Coverage was not complete, but the main areas of degradation were estimated to cover 10% of global drylands. Most likely the true level of degradation lies somewhere between the 10% and 20% figures. To identify precisely where the problems occur and the true extent of degradation will require a more in-depth follow-up to these exploratory studies.

Desertification, which by definition occurs only in drylands, causes adverse impacts on non-dryland ecosystems (*high certainty*). Desertification has both direct and indirect impacts on non-dryland ecosystems and peoples. For example, dust storms resulting from wind soil erosion, driven by degradation of the dryland vegetation cover, may affect people and ecosystems elsewhere. Similarly, transport of sediments, pesticides, and nutrients from dryland agricultural activities affects coastal ecosystems. Droughts and loss of land productivity are considered predominant factors in the migration of people from drylands to other areas (*medium certainty*).

Traditional and other current management practices contribute to the sustainable use of ecosystem services. Many existing practices help prevent desertification. These include enhanced and traditional water harvesting techniques, water storage and conservation measures, reuse of safe and treated wastewater for irrigation, afforestation for arresting soil erosion and improving ground water recharge, conservation of agrobiodiversity through diversification of crop patterns, and intensification of agriculture using technologies that do not increase pressure on dryland services. Policies that involve local participation and community institutions, improve access to transport and market infrastructures, and enable land users to innovate are essential to the success of these practices.

Alternative livelihoods have a lower impact on dryland ecosystem services. These livelihoods still depend on the condition of drylands services but rely less on vulnerable services and make use of the competitive advantages drylands can offer over other systems. They can include dryland aquaculture for production of high-value food and industrial compounds, controlled-environment agriculture (such as greenhouses) that requires relatively little land, and tourism-related activities.

Depending on the level of aridity, dryland biodiversity is relatively rich, still relatively secure, and is critical for the provision of dryland services. Of 25 global "biodiversity hotspots" identified by Conservation International, 8 are in drylands. The proportion of drylands designated as protected areas is close to the global average, but the proportion of dryland threatened species is lower than average. At least 30% of the world's cultivated plants originated in drylands and have progenitors and relatives in these areas. A high species diversity of large mammals in semiarid drylands supports cultural services (mainly tourism); a high functional diversity of invertebrate decomposers in arid drylands supports nutrient cycling by processing most arid primary production; a high structural diversity of plant cover (including microphyte diversity of soil crusts in arid and semiarid areas) contributes to rainfall water regulation and soil conservation, hence to primary production and its generated diversity of the dryland wild and cultivated plants.

22.1 Introduction

This chapter describes the current condition of dryland systems with respect to the services they provide and the drivers that determine trends in their provision. Within the context of the mounting global concern caused by land degradation in drylands (defined as desertification in the text of the United Nations Convention to Combat Desertification), the chapter assesses desertification as a persistent reduction in the services provided by dryland ecosystems, leading to unsustainable use of the drylands and their impaired development. The chapter also explores options for the sustainable use of drylands and points to human and societal responses that have succeeded or failed.

"Desertification" means land degradation in arid, semiarid, and dry subhumid areas resulting from various factors, including climatic variations and human activities. Land degradation means reduction of or loss in the biological or economic productivity and complexity of rain-fed cropland, irrigated cropland, range, pasture, forest, or woodlands resulting from land uses or from processes arising from human activities and habitation patterns (UNCCD 1992). Though this definition excludes the hyper-arid drylands, this chapter explores land degradation in all global drylands, including the hyper-arid areas.

22.1.1 Definition and Subtypes of Dryland Systems

Drylands are characterized by scarcity of water, which constrains their two major interlinked services—primary production and nutrient cycling. Over the long term, natural moisture inputs (that is, precipitation) are counterbalanced by moisture losses through evaporation from surfaces and transpiration by plants (evapotranspiration). This potential water deficit affects both natural and managed ecosystems, which constrains the production of crops, forage, and other plants and has great impacts on livestock and humans.

Drylands are not uniform, however. They differ in the degree of water limitation they experience. Following the UNEP terminology, four dryland subtypes are recognized in this assessment—dry subhumid, semiarid, arid, and hyper-arid—based on an increasing level of aridity or moisture deficit. The level of aridity typical for each of these subtypes is given by the ratio of its mean annual precipitation to its mean annual evaporative demand, expressed as potential evapotranspiration. The long-term mean of this ratio is termed the aridity index.

This chapter follows the *World Atlas of Desertification* (Middleton and Thomas 1997) and defines drylands as areas with an aridity index value of less than 0.65. The UNCCD, although excluding the hyper-arid dryland from its consideration, adopted the classification presented in the *World Atlas,* which is based on a global coverage of mean annual precipitation and temperature data collected between 1951 and 1980. The temperature data, together with the average number of daylight hours by month, were used to obtain a global coverage of corrected Thornthwaite's potential evapotranspiration values (Middleton and Thomas 1997). Aridity index values lower than 1 indicate an annual moisture deficit, and the *World Atlas* drylands are defined as areas with AI $\leq$ 0.65—that is, areas in which annual mean potential evapotranspiration is at least ~1.5 greater than annual mean precipitation.

Using index values, the four dryland subtypes can be positioned along a gradient of moisture deficit. Together, these cover more than 6 billion hectares, or 41.3% of Earth's land surface. (See Table 22.1.) Though the classification of an area as a dryland subtype is determined by its aridity index, which relates to the mean values of precipitation, it is important to remember that these areas do experience large between-year variability in precipitation.

Dryland subtypes can also be described in terms of their land uses: rangelands, croplands, and urban areas. (See Table 22.2.) Rangelands and croplands jointly account for 90% of dryland areas and are often interwoven, supporting an integrated agropastoral livelihood.

Drylands occur on all continents (between 63° N and 55° S; see Figure 22.1) and collectively comprise nearly half of the global landmass. The rest of the land area is primarily taken up by polar and by forest and woodland systems (the latter overlapping with the dryland system; see Box 22.1).

Drylands are not spread equally between poor and rich countries: 72% of the global dryland area occurs within developing countries and only 28% within industrial ones. Furthermore, the proportion of drylands occupied by developing countries increases with aridity, reaching almost 100% for the hyper-arid areas. (See Figure 22.2.) Consequently, the majority of dryland peoples live in developing countries (that is, from 87% to 93%, depending on how the former Soviet Union countries are categorized), and only 7–15% reside in industrial countries. (See Figure 22.3.)

22.1.2 Ecosystems in Drylands

Although there are only four dryland subtypes, there are a greater number of dryland ecosystems within the subtypes. These are aggregated into large, higher-order units known as biomes, which are characterized by distinctive life forms and principal plant species (such as tundra, rainforest, grassland, or desert biomes). Whereas the MA dryland subtype boundaries are determined by two climatic factors (precipitation and evaporation), many environmental factors are used to delineate the boundaries of the different biomes. Many different systems of biome classification are presently used. Five well-recognized classification systems of terrestrial biomes identify 12–17 biomes within drylands, depending on the scheme adopted. (See Chapter 4.)

This chapter uses the classification of the World Wide Fund for Nature that designates terrestrial biomes as "terrestrial ecoregions." Each ecoregion delineates large land units containing a distinct assemblage of ecosystems, with boundaries approximating the extent of natural ecosystems prior to major land use change (Olson et al. 2001). These are further aggregated into four "broad" dryland biomes—desert, grassland, Mediterranean (mainly scrubland), and forest (mainly woodland)—that successively replace each other along the aridity gradient (see Figure 22.4), with decreased aridity leading to an increase in plant cover, stature, and architectural complexity. However, there is no exact match between the four dryland subtypes and the four broad dryland biomes, such that forest and grassland, for example, may occur at different areas of the same dryland subtype. The number of broad biomes that may occur within a dryland subtype increases with reduced aridity, and the diversity of biomes peaks in the semiarid subtype, which also covers the largest area of the various subtypes.

The presence of different biomes within each dryland subtype demonstrates that biological species respond not only to overall moisture deficit but also to other environmental variables, such as soils and geomorphological and landscape features. Furthermore, a greater degree of species richness and diversity of ecosystem services is observed as aridity declines. Although dryland services are provided by the biomes' ecosystems, the MA opted to report on ecosystems, or simply "systems," unified primarily by their range of aridity. This approach is justified for two reasons. First, it bypasses the many inherent differences in biome classification systems. Second, it better reflects current trends, as many dryland ecosystems have been and continue to be transformed into more simplified, cultivated ecosystems whose functioning is overwhelmingly dominated by the moisture deficit.

22.2 Ecosystem Services

The MA categorized ecosystem services into supporting, provisioning, regulating, and cultural services. (See Chapter 1.) The

[a] Rangeland figures are based on available data on rangelands in drylands of developing countries (Reid et al. 2004; Thornton et al. 2002) and estimates for rangeland areas in the remaining drylands based on the assumption of uniformity in the rangeland's share of each dryland subtype.

[b] Inland water systems in drylands (3%) and other areas unaccounted for by the assessed land uses (5%).

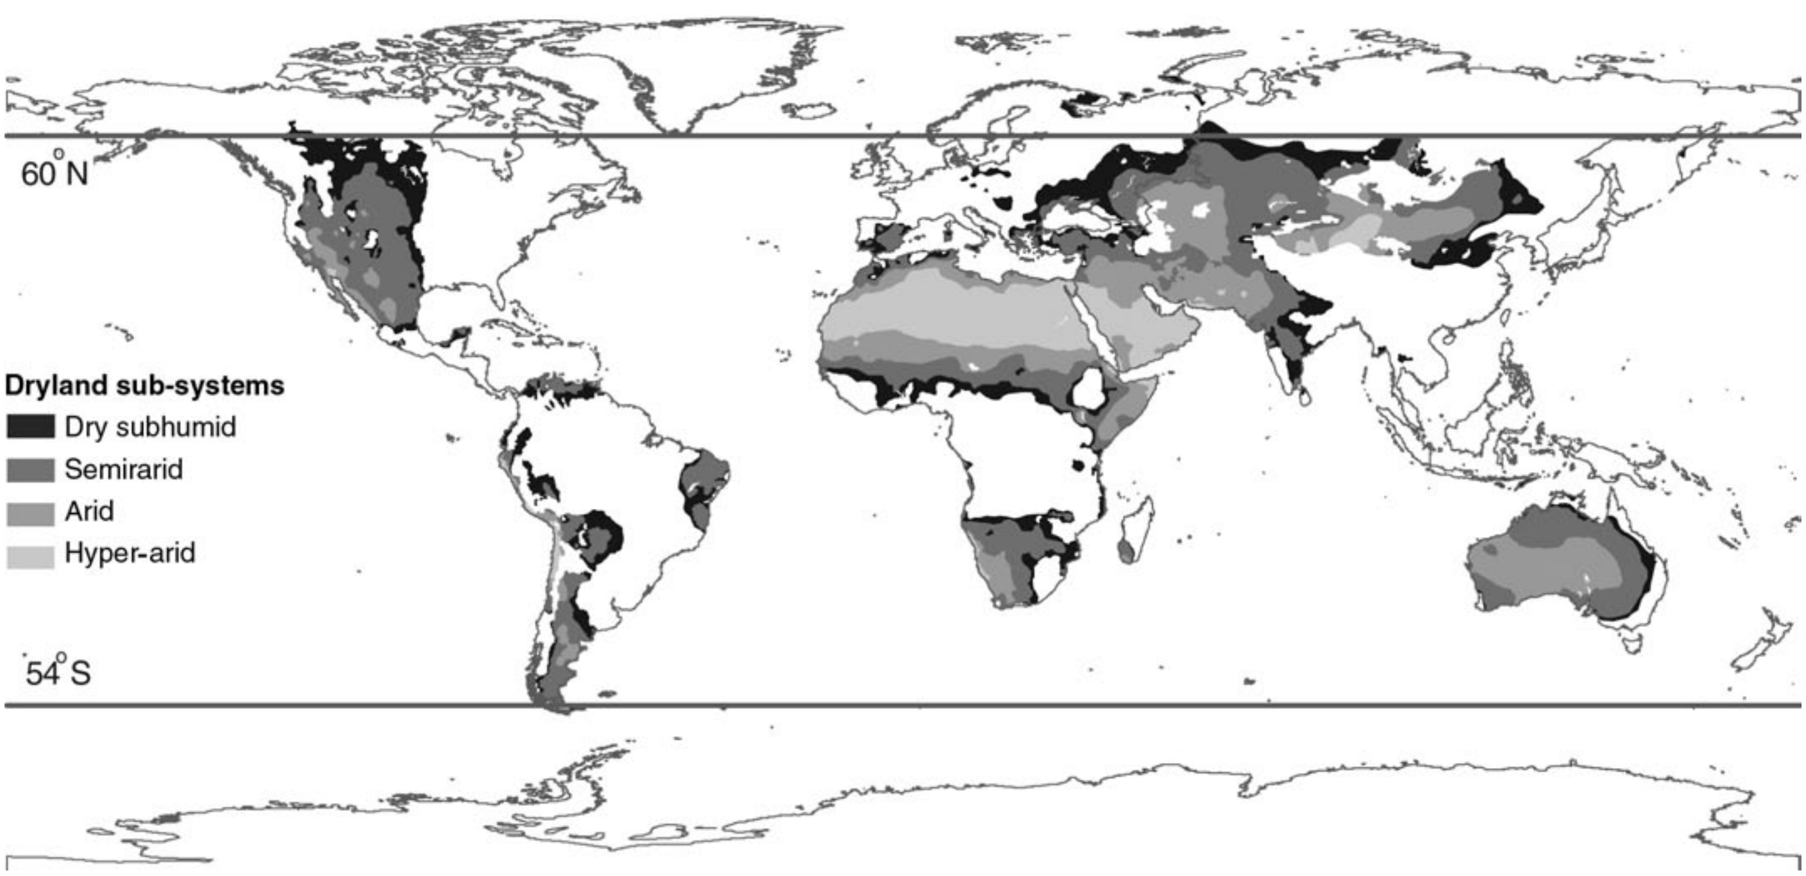

Figure 22.1. Dryland Systems and Subtypes

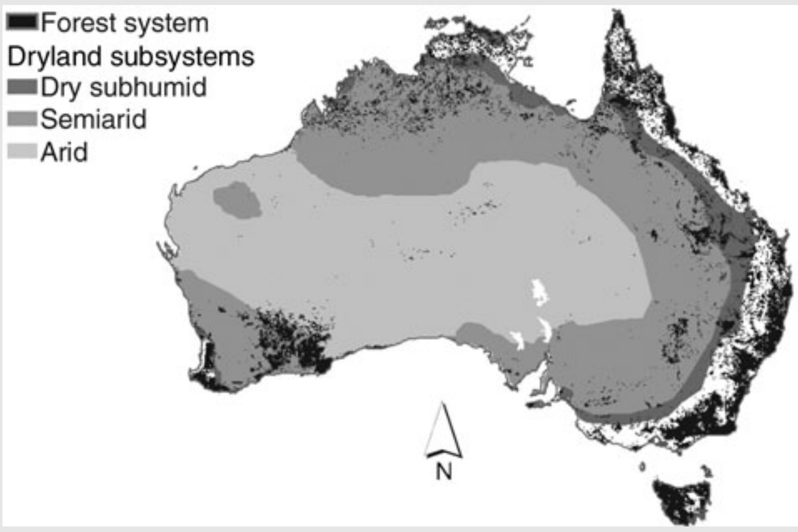
BOX 22.1

Forests in Drylands

This is not an oxymoron—forests do occur in drylands. Eighteen percent of the area of the dryland system is occupied by the forest and woodland system, though the probability of encountering forests in drylands decreases with their aridity. Australia is a good example, as seen in the Figure (which is a magnification of a section of Figure 20.1).



In general, aridity increases inland, and the forest and woodland system prevails along the coasts. The dry subhumid dryland subtype that is adjacent to the forest and woodland system has the greatest amount of overlap between the two systems, as compared with other drylands subtypes. But the distribution of forest in dry subhumid areas is patchier than it is within the forest and woodland system outside the drylands. Forests also occur in the much wider semiarid zone of Australia but are there mostly confined to the less dry seaward direction.

Forests occur in the dry subhumid subtype in Africa but are very scattered and rare in the semiarid zone. In China and India, with dry subhumid areas wider than in Australia, forests penetrate deep into dry subhumid areas. In Europe, where many dry subhumid areas are surrounded by non-drylands, forests are scattered all over the dryland areas. In the Americas, forests are patchily distributed in dry subhumid and semiarid regions. If forests do occur in the relatively humid range of the drylands and seem well adapted to these dryland conditions, why is their distribution patchy and not contiguous? Do the dryland forest patches occur in patches of locally less arid conditions, or is the patchiness a result of human exploitation? Answers to these questions may be critical for evaluating the use of the carbon sequestration service of these two dryland subtypes, which constitute nearly a quarter of Earth's surface area.

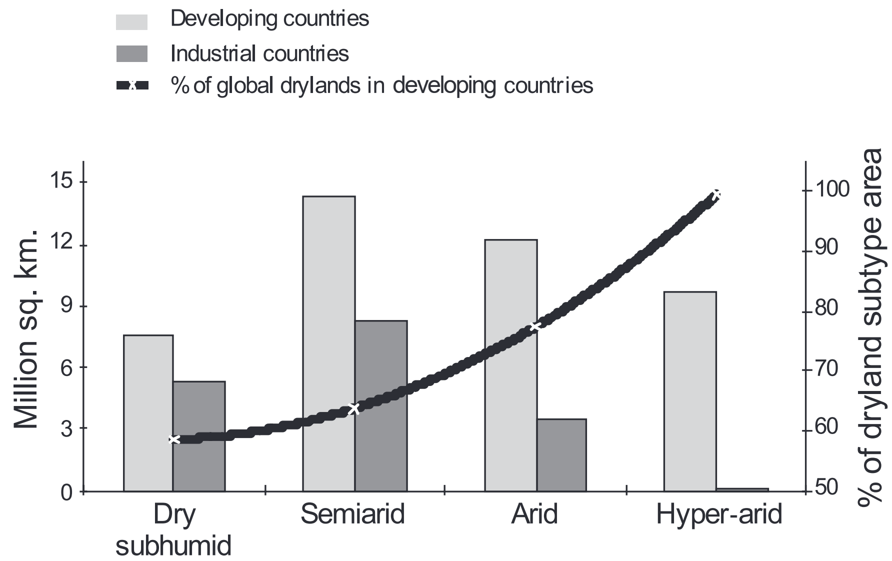


Figure 22.2. Dryland Subtypes and Socioeconomic–Political Status. The relative share of developing and industrial countries in the global drylands, by area and percentage taken up by developing countries. (MA core data)

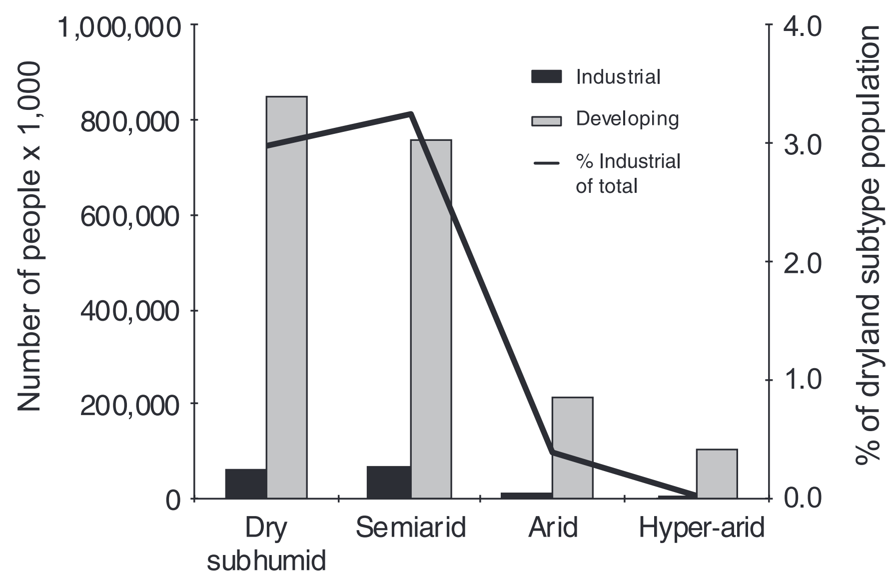

Figure 22.3. Population of Developing and Industrial Countries in Different Dryland Subtypes and Population of Industrial Countries in each Dryland Subtype as Percentage of Total Global Dryland Population (CIESIN 2004)

condition of dryland-significant services in each of these groups and the trends in their provision to dryland peoples are assessed in this section. For many services, however, data about global condition and trends are not readily available, and only generic information about processes governing the condition of these services is provided.

22.2.1 Supporting Services

22.2.1.1 Soil Development: Formation and Conservation

Though primary production in drylands is constrained by water, it is soil properties that determine how much of the rainfall will be stored and subsequently become available during dry periods. The availability of moisture in soil is also an important factor in nutrient cycling, a requisite for primary production. Therefore, soil formation and soil conservation are key supporting services of dryland ecosystems, the failure of which is one of the major drivers of desertification.

The slow process of soil formation, in which plants and microorganisms are intimately involved, is frequently countered by faster soil degradation expressed through erosion or salinization. Hence the services of soil formation and conservation jointly determine the rate of soil development and its quality. The rate of soil formation (hundreds to thousands of years) (Rust 1983) and its degree of development (depth of soil, infiltration depth, and organic content) decline with aridity (Nettleton and Peterson 1983; Sombroek 1990).

In hyper-arid areas, surfaces are often capped with mineral crusts that reduce infiltration and help generate soil-eroding flashfloods. In many arid drylands, dispersed plant clumps are often embedded in a matrix of apparently bare soil covered by a thin crust of photosynthetic cyanobacteria, with mosses and lichens added in semiarid drylands (Büdel 2001). The crusts reduce water penetration and thus channel runoff, sediments, nutrients, and seeds to the plant clumps, which then become active sites of

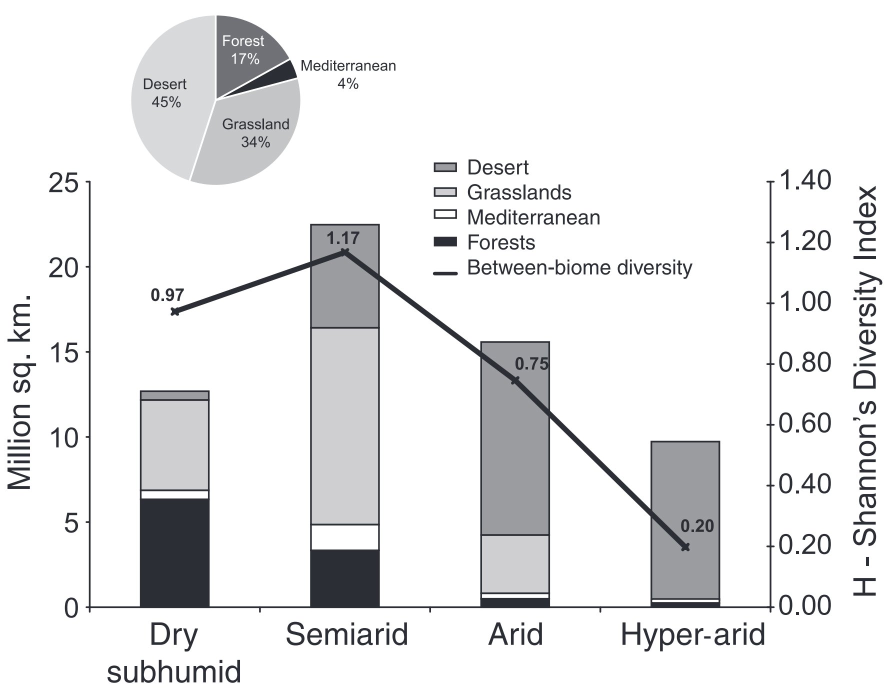

Figure 22.4. Global Area Covered by Dryland Subtypes and Their Broad Biomes. The line, points, and figures stand for the broad biome diversity index (Shannon's H); the pie chart shows the aggregated percentages for broad biomes by dryland subtypes.

soil formation and organic matter decomposition (Puigdefabregas et al. 1999). These crusts are therefore instrumental in soil development in and around the clumps and in soil conservation in the surrounding matrix (Aguiar and Sala 1999). However, they develop slowly and are sensitive to trampling or air pollution. Dry subhumid soils, on the other hand, are protected from erosion by multilayered, structurally complex vegetation (Poesen et al. 2003) that permits high water infiltration and storage, as well as water extraction by the same vegetation (Puigdefabregas and Mendizabal 1998).

22.2.1.2 Nutrient Cycling

This service supports the services of soil development and primary production through the breakdown of dead plant parts (thus enriching the soil with organic matter) and the regeneration of mineral plant nutrients. Unlike non-drylands, where soil microorganisms are major players in nutrient cycling, invertebrate macro-decomposers are the most important in drylands, and their significance increases with aridity. The significance of microorganisms, such as microbes and fungi, declines with aridity due to their strict moisture dependence. In addition, the role of large herbivores in nutrient cycling in arid and hyper-arid areas is limited due to lack of drinking water sources. Therefore macro-decomposers such as termites, darkling beetles (*Tenebrionidae*), and other invertebrates (many of which are soil dwellers) that are less water-sensitive become important for nutrient cycling in drylands. These organisms "prepare" the litter for microbial activity and increase the soil infiltration capacity.

When arid drylands are used as rangelands, however, most of the primary production takes place through the livestock rather than the macro-decomposers. Due to the high metabolic needs of mammalian herbivores (compared with cold-blooded macro-decomposers), much of the organic carbon consumed by the livestock does not return to enrich the soil but is respired or extracted from the ecosystem as meat, hair, milk, and other animal products. In addition, while most of the excreta of macro-decomposers is deposited within the soil, much of the livestock waste on the surface is volatilized and removed from the soil nutrient pool. Thus, livestock have the potential to gradually deplete the rangeland nitrogen reserve and further exacerbate the nutrient limitations for primary production in arid and hyper-arid rangelands (Ayal et al. 2005). However, this depletion may be partially mitigated by biological nitrogen fixation and by dust deposition (Shachak and Lovett 1998).

When drylands are used for crops, tillage and excessive use of pesticides can reduce the role of soil-dwelling macro-decomposers. This, together with low root biomass of annual crops, can impair nutrient cycling and reduce soil organic carbon and its associated nutrients. Whereas wastes from subsistence cropping systems in drylands are locally recycled and only small proportions of crop products are exported, cropping systems that export products lose nutrients, hence their fertilizer inputs are high.

22.2.1.3 Primary Production

The net primary production for global drylands, based on satellite observations at an 8-kilometer and 10-day resolution from 1981 to 2000, was 703 ± 44 grams per square meter (Cao et al. 2004), significantly lower than the values for the MA's cultivated system ($1,098 \pm 48$ grams) and the forest and woodland system (869 ± 34 grams). But averaging over all the dryland subtypes masks the effect of the aridity gradient.

The NPP of rangelands is mostly generated by the natural dryland plant community, in contrast to cultivated drylands, where the NPP is generated by agricultural crops and is often elevated due to two imported inputs—irrigation water and fertilizers. Whereas the NPP of monitored rangeland sites was 40–90% higher in non-dryland than in dryland countries, in the same years the yield of wheat in the croplands was more than three times greater in the non-dryland countries. (See Table 22.3.) Further analysis that includes wheat yield data for more countries and more years suggests a relative advantage of cultivation in non-drylands, but at the same time highlights the significance of socio-economic conditions, which apparently determine the amount of resources that can be mobilized for promoting the service of primary production. On average, industrial dryland countries produced wheat yields nearly as high as those produced by non-dryland developing countries. The yield of developing dryland countries was low compared with that of non-dryland countries; even among industrial countries, non-dryland ones did much better than dryland ones.

In order to distinguish between the relatively low NPP of drylands that is due to their inherent moisture deficit and the additional decline in primary production due to land degradation, rain use efficiency—the ratio of NPP to rainfall—can serve as a measure of primary production service condition (Le Houerou 1984; Le Houerou et al. 1988; Pickup 1996): it separates out reduced NPP due to reduced rainfall from declines in NPP driven by land degradation (Prince et al. 1998) and also separates increased NPP due to increased rainfall from the effects of added irrigation and fertilizer use.

Several global MA systems, drylands included, show a trend of NPP increase for the period 1981 to 2000 (Cao et al. 2004). The slope of the linear regression for drylands (regression coefficient = 5.2) does not significantly differ from those of cultivated and forest and woodland systems. However, high seasonal and interannual variations associated with climate variability occur within this trend on the global scale. In the drylands, this variation in NPP was negatively correlated with temperature and positively with precipitation (Cao et al. 2004)—two drivers that are expected to further affect dryland primary production through global anthropogenic climate change.

Table 22.3. Primary Production Expressed in NPP of Rangelands and Wheat Yield in Croplands. The first Table shows the relations between aboveground biomass in monitored rangelands[a] and total wheat yield in each country's croplands[b] for the same year,[c] with dryland countries compared with non-dryland ones. The second Table is a comparison of mean annual wheat yields for selected dryland countries (in which most of the area is categorized as dryland) and temperate non-dryland countries, industrial and developing.[b]

Area	Country (year NPP measured)	Mean Annual Rainfall in Rangeland	Mean Aboveground Biomass in Rangeland	Wheat Yield of Country
		(millimeters)	*(grams per sq. meter)*	*(tons per hectare)*
Dryland countries[d]	Mongolia (1990)	280	100	1.3
	Kazakhstan (1978, 1992)	351	83	1.3
Non-dryland countries[e]	Sweden (1968)	537	141	4.3
	United Kingdom (1972)	858	188	4.2

Area	Country	Mean of Yields 1994–2003	Mean Annual Yield for Country Categories
		(tons per hectare)	
Dryland, developing	Kazakhstan	0.9	1.3
	Morocco	1.2	
	Iran	1.8	
Dryland, industrial	Australia	1.8	2.0
	Israel	1.8	
	Spain	2.5	
Non-dryland, developing	Uruguay	2.2	2.2
	Belarus	2.3	
	Bangladesh	2.1

22.2.2 Regulating Services

22.2.2.1 Water Regulation

Water is the limiting resource for dryland biological productivity, and thus water regulation is of major significance. This regulation determines the allocation of rainfall for primary production (enrichment of soil moisture); for irrigation, livestock watering, and domestic uses (storage in groundwater and surface reservoirs); and for the occurrence of flashfloods and their associated damages (soil erosion, reduced groundwater recharge, excessive clay and silt loads in downstream water bodies). Vegetation cover modulates the water regulation service, and its efficiency in intercepting rainfall determines the fraction available for human use. In rangelands, vegetation removal and livestock trampling can increase soil water erosion through disintegration of the biological soil crust. Similarly, in croplands tillage increases the risk of sealing and crusting (Hoogmoed 1999). Water regulation may be augmented by landscape management (terraces, small dams, and so on), which slows down surface runoff, thereby promoting water infiltration and flood avoidance.

22.2.2.2 Climate Regulation

Dryland ecosystems regulate their own local climate to some extent as their vegetation cover determines the surface reflectance of solar radiation as well as water evaporation rates. Drylands are also involved in regulation of the global climate, through local carbon sequestration by their vegetation. Both these phenomena are described here in some detail.

22.2.2.2.1 Regulation of local climate through surface reflectance and evaporation

The vegetative cover of drylands depends on inputs of incident solar radiation and rainfall. Conversely, the outputs from drylands, the fraction of the incident radiation reflected by the surface (the albedo), and the fraction of soil water transpired and evaporated (evapotranspiration) drive atmospheric energy- and water-balance processes. The provision of this service becomes apparent when it has either been degraded, as in the Sahel drought (Xue and Dirmeyer 2004), or enhanced, as in the rainfall patterns in Israel (Steinberger and Gazit-Yaari 1996) and the U.S. Great Plains (Barnston and Schickedanz 1984). Vegetation cover in drylands can either reduce albedo, resulting in increased surface and near-surface temperatures, or shade the surface leading to low surface temperatures. Both contrasting effects may lead, through different paths, to an identical effect on rainfall. (See Figure 22.5.)

The overexploitation of vegetation (Xue and Dirmeyer 2004) and the removal of the crust by trampling in arid and semiarid drylands (Warren and Eldridge 2001) lead to increased albedo, lower surface temperatures, lower convective activity, and reduced rainfall (Charney et al. 1975). Albedo may also increase due to surface dust cover, a result of dust storms promoted by greater surface exposure after vegetation removal (Williams and Balling 1995). Thus, the conservation of vegetation cover promotes the service of local climate regulation directly through its effect on albedo and indirectly through arresting dust generation.

A degraded vegetation cover also leads to reduced shade, increased surface and near-surface temperatures, and a rapid decrease in soil moisture, which leads to reduced evaporation. This reduction in overall evaporation links to reduced rainfall generation—low evaporation, reduced water flux into the atmosphere, a decrease in the amount of energy used to evaporate or transpire water, and reduced convective heating all combine to produce less rainfall (Williams and Balling 1995).

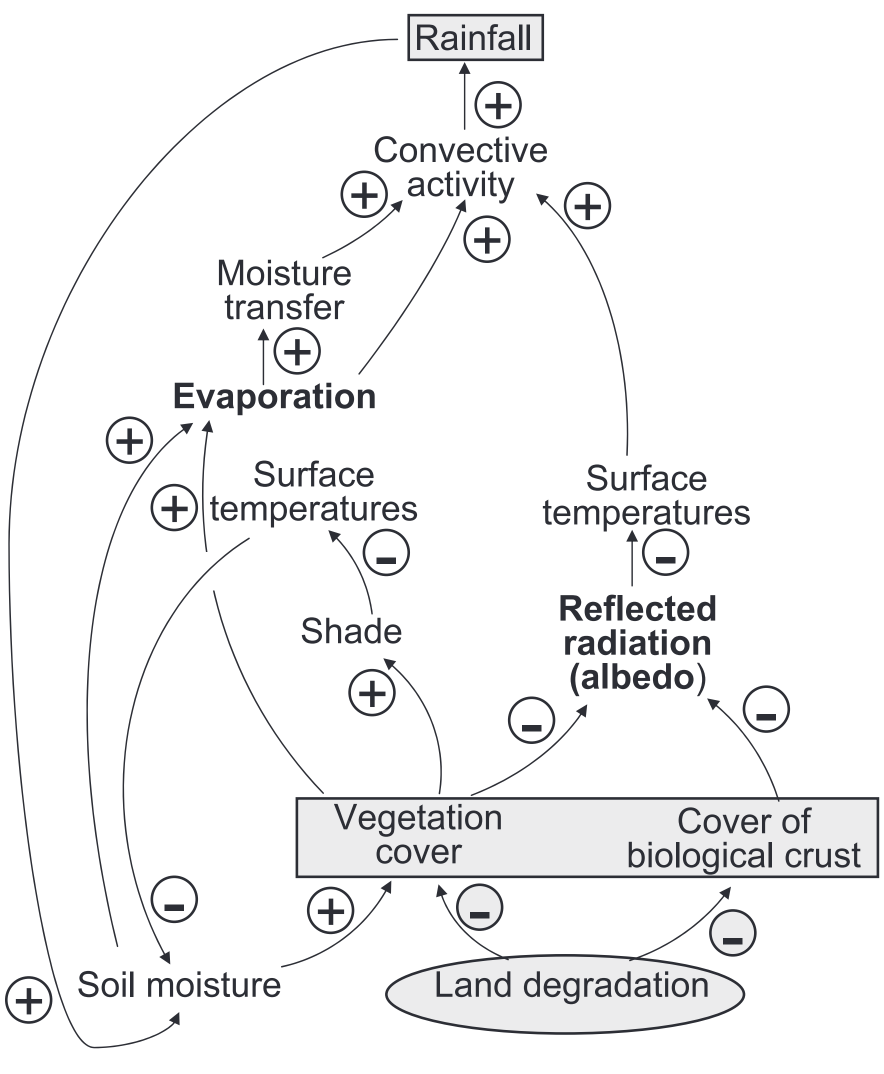

Figure 22.5. The Service of Climate Regulation in Drylands. The central grey box—the components of biodiversity involved in service provision—maintenance of soil moisture (bottom left) and modulation of rainfall (top). In bold—the major alternative/complementary function involved in the effect of live vegetation cover on rainfall; successive multiplication of signs along each trajectory generates an increase in rainfall (+) when service is ameliorated and a decrease in rainfall (–) when land is degraded. Land degradation (grey circle) degrades the service through affecting surface temperature; when surface temperatures increase along the albedo trajectory, it decreases along the evaporation trajectory; this trend is reversed when land is not degraded.

In climate modulated both by albedo and by evaporation, lower rainfall further reduces soil moisture and vegetation cover and induces further degradation in service provision. The prevalence of the climate regulation service is demonstrated by a few amelioration cases, such as the 10–25% increase in rainfall in the northern Negev of Israel attributed to reduced albedo resulting from controlled grazing, afforestation, and irrigated agriculture in a semiarid region (Otterman et al. 1990).

22.2.2.2.2 Regulation of global climate through carbon sequestration

Carbon sequestration (the uptake of atmospheric CO_2 by ecosystems and transformation into plant biomass) controls atmospheric CO_2 concentrations, which regulate the global climate through the "greenhouse effect." Part of the sequestered carbon is emitted back to the atmosphere through the respiration of plants and decomposers, but what is left—the live and the dead above- and belowground plant parts—constitutes the addition to the organic carbon reservoir. Some of the plant litter converts into recalcitrant humus, thereby enhancing the soil organic carbon pool and the formation of secondary carbonates through precipitation.

Plant biomass per unit area of drylands is low (about 6 kilograms per square meter) compared with many terrestrial ecosystems (about 10–18 kilograms). But the large surface area of drylands gives dryland carbon sequestration a global significance. Whereas organic carbon (in aboveground vegetation and soil) declines with aridity, inorganic soil carbon increases as aridity increases. (See Table 22.4.) Altogether, total dryland soil organic and inorganic carbon reserves comprise, respectively, 27% and 97% of the global soil organic and soil inorganic global carbon reserves.

22.2.2.3 Pollination and Seed Dispersal

Cases of tight associations between dryland plants and pollinators are known (such as Agava and its pollinator) (Arizaga et al. 2000), but the extent to which changes in land use in the drylands affect the pollination service and the dependence of dryland plant species on pollination has not been fully explored. Seeds of many dryland plant species are dispersed by fruit-eating birds, often prior to or after their cross-desert seasonal migration (for instance, in the Mediterranean basin) (Izhaki et al. 1991). Domestic and wild mammalian herbivores disperse seeds attached to their fur or through consuming them and then defecating, which promotes dispersal and enhances the chance of germination (as in African acacia trees) (Ward 2003). Livestock and other animals may also transfer seeds from improved pasture lands to neighboring non-managed rangelands (CGIAR 1997). Thus the services of pollination and seed dispersal are of significance, but assessment of their condition, importance, and trends requires more attention.

22.2.3 Provisioning Services

22.2.3.1 Provisions Derived from Biological Production

22.2.3.1.1 Food and fiber

The major dryland cereals and legumes (together with vegetable and fruits) constitute the main crops and basic food for 800 million farmers in drylands (CGIAR 1997). A large part of the dryland population depends on crop and livestock production as a livelihood and contributes significantly to the gross domestic product and trade. Livestock are raised mostly in rangelands or in agropastoral systems, and they constitute a major source of protein and income. Wool is provided by livestock and wild mammals

Table 22.4. Estimates of Dryland Carbon Reserves

	Biotic[a]	Soil Organic[b]	Soil Inorganic[c]	Totals	Share of Global
	(gigatons of carbon)				(percent)

such as guanacos (*Lama guanicoe*) and vicunas (*Vicugna vicugna*) in South America (Fernandez and Busso 1997).

Fiber is produced by both croplands and rangelands. For instance, cotton (*Gossypium* spp.) and sisal (*Agave sisalana*) are widely cultivated, while timber and silk are produced on a smaller scale. Fiber, vegetable oil, vegetables, fruits, and nuts provisioned by dryland ecosystems are also exported to non-dryland countries. The food provision service of drylands may be impaired by soil erosion (in rain-fed croplands, a long dry season with no plant cover challenges the soil conservation service), salinization (in irrigated croplands with poor drainage), and nutrient depletion (the removal of commodity crops challenges the nutrient cycling service). (For more on the condition and trends of food provision, see Chapter 8.)

22.2.3.1.2 Woodfuel

Most woodfuel (the collective term for fuelwood, charcoal, and other wood-derived fuels) is provided by trees or bushes inhabiting natural dryland ecosystems that are also often used as range. Hence the exploitation of this service is often a trade-off with the provision of forage. Overexploitation for woodfuel harvesting impairs the soil conservation service, and it leads to soil erosion and hindered vegetation regeneration. This downward spiral of service degradation encourages reforestation and afforestation for woodfuel provisioning, using drought and salinity-tolerant tree species and strains (Sauerhaft et al. 1998). Fuelwood is used predominantly at the household level, for cooking and heating (Amous 1997), and may constitute a sizable proportion of the energy consumed in many dryland countries—for example, 57% in Senegal in 1999 (IEA 2001).

22.2.3.1.3 Biochemicals

Many species of dryland plants are used by dryland peoples for medicinal and cosmetic purposes and as spices, which highlights the significance of dryland plant biodiversity. However, excessive exploitation puts many of these species at risk of extinction and contributes to soil loss and consequent erosion. Attempts to cultivate such species in order to reduce the pressure on natural ecosystems often fail, because the production of the active compounds by these plants is rather low under stress-reduced cultivation regimes. The adaptations of dryland plants to varying and extreme conditions are often derived from unique biochemicals they produce that are the key to environmental tolerance or that act to deter herbivores and parasites. Further investigation into the generation and activity of these chemicals helps promote drought- and salinity resistance in cultivated crops (Wang et al. 2002) and can lead to development of novel medicines, such as anti-cancer (Haridas et al. 2001) and anti-malarial compounds (Golan-Goldhirsh et al. 2000). Biochemicals are also manufactured as part of dryland aquaculture, providing a source of alternative livelihoods, as described later in this chapter.

22.2.3.2 Freshwater Provisioning

The freshwater provisioning service is linked to supporting and regulating services—soil development (conservation and formation), water regulation, and, to a lesser extent, climate regulation. Vegetation cover and its structural diversity control much of the water provisioning service. This vegetation depends on water provisioning, but it is also instrumental in generating and maintaining the quality of the service. The resultant water is used to support rangeland and cropland vegetation and also livestock and domestic needs. The water provision service is also critical for maintaining wetlands within the drylands, to enable these ecosystems to provide a package of services of great significance in drylands.

However, the total renewable water supply from drylands is estimated to constitute only around 8% of the global renewable water supply (about 3.2 trillion cubic meters per year) (Vörösmarty et al. 2005), and only about 88% of this is accessible for human use. Thus, almost one third of the people in the world depend on only 8% of the global renewable water resources, which makes per capita availability in drylands just 1,300 cubic meters per year. It is substantially less than the average global availability and even lower than the 2,000 cubic meters regarded as a minimum by FAO (FAO 1993).

To mitigate this shortage, exacerbated by the large within- and between-years variability in rainfall, a variety of practices have been developed. From the least to the most technology-laden ones, these are:

- watershed management, including conservation and rehabilitation of degraded vegetation cover for generating and capturing surface runoff for deep storage in the soil (protecting it from evaporation) (Oweis 2000);

- floodwater recharge and construction of dams and weirs for minimizing impact of floods and water loss;
- irrigation, to circumvent the temporal variability in provision (often based on extraction from aquifers, with frequent overpumping leading to salinization)—however, the transportation of water from other ecosystems that may be severely affected and the salinization of the irrigated drylands often make this option unsustainable;
- mining of nonrenewable fossil aquifers (which are quite common in drylands), for cultivation that is otherwise impossible;
- treatment of wastewater, mainly from urban sources, and reusing it for irrigation—a promising practice provided that concerns about adverse impacts on human health, crops, soils, and groundwater can be overcome (Karajeh et al. 2000); and
- desalination of brackish water and seawater for all uses (which is safe and uses renewable sources but has a high energy demand and is relatively costly, and the accumulated brine often poses a salinization risk).

These interventions are critical for relieving pressure on the water systems of drylands.

22.2.4 Cultural Services

22.2.4.1 Cultural Identity and Diversity

Dryland peoples identify themselves with the use of their surrounding ecosystem and create their own unique ecosystem-inspired culture. (See Chapter 17.) Drylands have high cultural diversity, in keeping with the ecosystem diversity along the aridity gradient. One expression of this is that 24% of global languages are associated with the drylands' grassland, savanna, and shrubland biomes. Typical to drylands are the diverse nomadic cultures that have historically played a key role in development of dryland farming systems (Hillel 1991). Ecosystem functions and diversity generate cultural identity and diversity that in turn conserve ecosystem integrity and diversity. A negative feedback loop is therefore expected between land degradation and cultural degradation in drylands.

22.2.4.2 Cultural Landscapes and Heritage Values

The term "cultural landscape" is a socioeconomic expression of the biophysical features of ecosystems that mutually contribute to the development of a characteristic landscape, and it signifies a heritage value. (See Chapter 17.) In drylands, the heritage value can be nurtured either by landscapes that reflect the human striving for "conquering the desert" or by ones reflecting aspirations to "live with the desert." Transformation of rural to urban ecosystems is an expression of changed livelihoods that modify the landscape and its cultural values and often degrade cultural heritages. Actions to conserve outstanding Cultural Heritage Sites that are cultural landscapes are under way (UNESCO 2004), and 21 such sites have been identified, of which 8 are in drylands.

22.2.4.3 Servicing Knowledge Systems

Dryland ecosystems also contribute to human culture through both formal ("scientific") and traditional knowledge systems. (See Chapter 17.) Drylands have generated significant contributions to global environmental sciences. Arid Cultural Heritage Sites (such as Lake Turkana National Park and Ngorongo Conservation Area) have generated knowledge of paleo-environments and of human evolution (UNESCO 2004); studies of desert organisms have revealed adaptations to extreme environmental stresses (e.g., Schmidt-Nielsen 1980); and studies of desert ecology have inspired modern community and ecosystem ecology (e.g. Noy-Meir 1973, 1974; Rosenzweig 1995).

Dryland traditional knowledge has co-evolved with the cultural identity of dryland peoples and their environment and its natural resources and has generated many unique systems of water harvesting, cultivation practices, climate forecasting, and the use of dryland medicinal plants. The degradation of this knowledge in many cases has often led to adoption of unsustainable technologies. The exploration, conservation, and integration of dryland traditional knowledge with adapted technologies have been identified as priority actions by the Committee of Science and Technology of the UNCCD (ICCD 2000).

22.2.4.4 Spiritual Services

Many groves, tree species, and individual trees have spiritual significance to dryland peoples due to their relative rarity, high visibility in the landscape, and ability to provide shade. In ancient times in the Middle East and North Africa, spiritually significant social and religious activities took place under tree canopies. The sites of individual trees have been used for anointing rulers, hosting legal hearings, burial of community and religious dignitaries, and religious rituals, and individual trees themselves have become sacred and named after deities. For instance, the Hebrew names of *Quercus* and *Pistacia* (the dominant species of the eastern Mediterranean shrubland and woodland biomes)—*Alon* and *Ela*—derive from the words for God and Goddess respectively. Protected from grazing and cutting, these sacred trees have reached dimensions far larger than they ever attain in their natural climax community (Zohary 1973: 505–07). These sacred groves often conserve islands of indigenous ecosystems in a transformed landscape and contribute to a unique cultural landscape. Similar services are also provided by other drylands, such as the religious, ceremonial, and historical sites of Native Americans (Williams and Diebel 1996) and aboriginal Australians. (See Chapter 17.) In hyper-arid drylands, trees are far rarer, and indigenous nomadic people do not generally identify individual trees as sacred, although they can have spiritual values.

22.2.4.5 Aesthetic and Inspirational Services

There are outstanding literary and historical examples for inspiration generated by dryland landscapes (such as the Old and New Testaments). The stark contrast between inland wetlands and surrounding dryland areas, linked with the significance of water bodies to the well-being of dryland people, could have generated the association of the Mesopotamian marshlands with the Garden of Eden (Hamblin 1987). Dryland ecosystems are also a source of inspiration for non-dryland people. The 1950s Walt Disney film "The Living Desert" brought desert ecosystems and biodiversity to the attention of millions prior to the television era and was declared "culturally significant" in the year 2000 by the U.S. Library of Congress.

The popular conception of dryland peoples among non-dryland groups is one of human struggle against harsh natural conditions producing rich cultures nurtured by strong moral values, as well as naive romantic notions of life in the desert (Fernandez and Busso 1997). However, while the media has largely promoted the conservation of desert heritage in recent years, others have responded by trying to "green" desert areas or make them "bloom," which has often resulted in an aesthetically appealing landscapes of oasis-like patches of agricultural land set in sharply contrasting surrounding desert (Safriel 1992)—but with a loss of dryland biodiversity.

22.2.4.6 Recreation and Tourism

Large, sparsely populated, low-pollution arid and hyper-arid areas provide attractive holiday destinations for many. There are significant constraints to dryland tourism, however, including the general remoteness and isolation, which increases the cost of travel; lack of recreation amenities and security; the harsh climate, which means residential facilities have high energy demands; the high water demand of tourists, which places already scarce water under extra pressure; and often a direct competition with other livelihoods over the use of natural resources and energy. These issues are being addressed through various approaches, including treatment and reuse of local wastewater (Oron 1996), construction and architectural solutions for passive cooling and heating (Etzion et al. 1999), and the use of the dryland-abundant solar energy as a power source (Faiman 1998).

Drylands are also attractive for cultural tourism associated with historical and religious sites, for coastal tourism (such as Mediterranean beaches), and for health-related tourism (such as the Dead Sea). Dryland biodiversity is also a major draw for ecotourism. Paradoxically, this is because most drylands are devoid of woodlands and dense high vegetation and hence free of obstructions to view wildlife. For instance, African savanna safaris are generally designed around a few ''charismatic'' large mammal species and mass seasonal migrations of large herbivores, and many tourists pack resorts along the route of the spectacular seasonal trans-Saharan bird migration. The significance of the dryland cultural service to tourism is demonstrated by Kenya, where 90% of tourists visit a game park (White et al. 2000). Finally, although ecotourism generates income for dryland peoples, it often causes habitat degradation, as described later (White et al. 2000).

22.2.5 Biodiversity and the Provision of Dryland Services

22.2.5.1 Dimensions, Structure, and Composition of Dryland Biodiversity

Species richness declines with decreasing primary productivity (Rosenzweig and Abramsky 1993) and vice versa (Tilman et al. 2001); hence dryland species richness should decrease with aridity. Indeed, the low number of flowering plant species in the hyper-arid subtype rapidly increases with reduced aridity (in agreement with an increase of between-''broad biome'' diversity) and peaks in the dry subhumid subtype. However, contrary to expectation, species diversity declines in non-dryland temperate humid areas. But as might be expected, it is nearly half that of tropical areas. (See Figure 22.6.) The significance of biodiversity for each of the major dryland biomes is discussed in this section. (See also Chapter 4.)

22.2.5.1.1 Deserts

Some 7,000 terrestrial amphibian, reptile, bird, and mammal species live in the desert biome. This covers 25% of global terrestrial fauna of these groups—22% of which also live in other biomes and 3% are found exclusively in deserts. For comparison, the richest terrestrial biome—tropical and sub-tropical moist broadleaf forests—supports around 70% of global terrestrial fauna, 28% of which are species endemic to that biome. Thus species richness of desert vertebrates is as much as a third of the most vertebrate-rich biome on Earth, signifying that desert biodiversity may be quite high in spite of harsh conditions. Because functional groups in deserts may each have only a few species, however, the redundancy in service provision is low, and human pressure may reduce it further (Huenneke 2001). Indeed, in spite of the remoteness and isolation, human impact on deserts in the form of settlements and infrastructure is mounting, and there has been a 6% loss of habitat between 1950 and 1990.

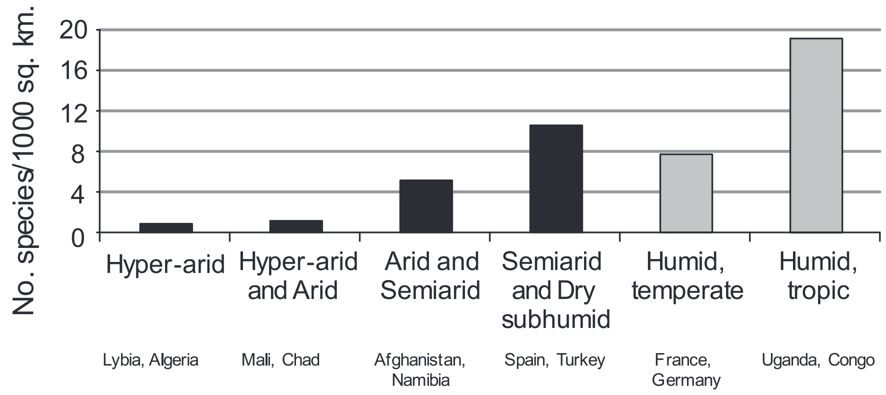

Figure 22.6. Number of Species of Flowering Plants in Selected Countries across the Aridity Gradient (per 1,000 sq. km). Each column represents a mean of two countries. Selected dryland countries are at least 95% dryland, either of one subtype, or two of roughly similar dimensions. Grey columns indicate non-dryland countries. (WRI 2004; CIA 2004)

22.2.5.1.2 Grasslands

Grasslands (the temperate grasslands, savannas, and shrubland biome and the tropical and sub-tropical grasslands, savannas, and shrubland biome) occur in the semiarid and the dry subhumid dryland subtypes, and their biodiversity is richer than that of deserts (12% and 28% respectively of the global terrestrial vertebrate fauna are found in these two biomes). Much is known of the functioning of natural grasslands, many of which function as rangelands: plant diversity increases productivity (Tilman et al. 2001), and communities with many functional groups generate higher production than those with fewer groups. Yet within a grassland community a few abundant species account for a large fraction of grassland ecosystem functions, whereas the many rare species account for a small fraction of its functions (Sala et al. 1996; Solbrig et al. 1996).

It is important to note that the relationships between diversity and function are not linear, and a threshold in species richness has been identified below which ecosystem function declines and above which it does not change (Vitousek and Hooper 1993). Unfortunately, many natural grasslands have been transformed to croplands and most dryland cultivated lands are in these biomes. This transformation continues, and some 15% and 14% of the natural habitats in the semiarid and dry subhumid subtypes were transformed between 1950 and 1990.

22.2.5.1.3 Mediterranean forests, woodlands, and shrublands biome

The Mediterranean biome, comprising xeric woodlands and shrublands, occurs within semiarid and dry subhumid areas with a Mediterranean climate and is subjected to intensive human impact, especially in the Mediterranean basin, resulting in plant adaptations to clearing, grazing, fires, and drought (Davis et al. 1996). Species richness is high (Mooney et al. 2001), with the Mediterranean basin supporting 25,000 vascular plants (10% of global species), of which 60% are endemic; 10% of the global vertebrates species inhabit the Mediterranean biome.

The biome's biodiversity is threatened by its small geographic coverage, fragmentation, high human population density, abandonment of traditional practices, tourism, continued habitat conversion (2.5% of Mediterranean habitat was lost between 1950 and 1990), and invasive alien species (Mooney et al. 2001). Agriculture, grazing, and frequent fires have decreased dryland forests, converting many to grasslands (Solbrig et al. 1996). At the same time, the abandonment of rangelands in the Mediterranean basin has influenced secondary succession, which has eliminated open-habitat species and reduced diversity. Consequently, many endemic and rare species are currently restricted to protected areas surrounded by degraded or altered landscapes that act as a barrier to migration in response to environmental change.

22.2.5.2 The Role of Biodiversity in the Provision of Dryland Ecosystem Services

22.2.5.2.1 Involvement of biodiversity in packages of services

There are many dryland species that are directly involved in the provision of a range of ecosystem services. One such example is African acacia (Ashkenazi 1995), which provides for soil development and conservation (roots, canopy, and litter), forage (leaves and pods eaten by livestock), fuelwood (dead twigs), and food (edible gums). It is also involved in nutrient cycling (symbiosis with nitrogen-fixing bacteria) and generates cultural services (as described earlier). And it supports other biodiversity: a large number of animal species depend on it for shelter, shade, nest sites, and food. (Often this is of mutual benefit: wild and domestic mammals disperse the seeds, thus determining the spatial distribution of the species.)

The numerous dryland plant species of different growth forms jointly provide a package of services through their ground cover and structure, which provide the drylands' most important services of water regulation and soil conservation as well as forage and fuelwood provision and climate regulation. In arid and semiarid areas, clumps of bushes and annuals embedded in the matrix of a biological soil crust—which consists of an assemblage of several species of cyanobacteria (that provide the added benefit of nitrogen fixation), microalgae, lichens, and mosses—jointly generate soil conservation and water regulation (Shachak and Pickett 1997). In many arid and semiarid areas, this biodiversity of "vegetation cover" and biological soil crusts is linked to a diversity of arthropod species that process most of the living plant biomass, constituting the first link of nutrient cycling.

22.2.5.2.2 Involvement of dryland biodiversity in a single service

Individual species can also be important providers of a single service, such as individual dryland plant species serving as a "biogenetic resource" for cross-breeding and improvement of domesticated species to which they are genetically related. These species are either the progenitors of currently cultivated species that were domesticated millennia ago (Higgs and Jarman 1972; Harlan 1977) or they are relatives of those progenitors. It is estimated that 29–45% of the world's currently cultivated plants originated from drylands (FAO 1998). The progenitors and wild relatives of these originally dryland-cultivated plants (such as wheat, barley, rye, millet, cabbage, sorghum, olive, and cotton) are an important component of dryland biodiversity. However, only a few of them inhabit dryland protected areas and enjoy active in situ conservation, and much of their potentially useful genetic diversity has not yet been fully screened and may be under threat due to habitat loss (Volis et al. 2004).

Assemblages of dryland species can also jointly generate a single service, such as populations of large mammalian herbivores—from antelopes to elephants—providing for the cultural service of ecotourism, especially in the eastern and southern grasslands and savannas of Africa. These now occur mainly in protected areas and in ranches, and their management for the sustainable provision of this service is a scientific, legal, and sociopolitical challenge.

22.2.5.2.3 Trends in the involvement of dryland biodiversity in service provision

Evidence for human impacts on specific dryland biodiversity components that affect service provision is associated with livestock grazing. Livestock often impair the service of forage provision when prime forage species are replaced by non-palatable, often invasive species, leading to replacement of the grassland vegetation by encroaching bush or the reduction of the litter-decomposing termite populations, which impairs nutrient cycling, primary production, and carbon sequestration (Zeidler et al. 2002; Whitford and Parker 1989). Human-induced climate change may also alter the primary production and other dryland services, since plants of the three photosynthetic pathways (C3, CAM, or C4) co-occur in drylands and are expected to respond differently to climate change and to elevated atmospheric CO_2 (Huenneke and Noble 1996).

The loss of biodiversity from drylands is not likely to affect all services uniformly. Rather, primary production and the provisioning services derived from it, as well as water provision, will be more resilient than recreation and ecotourism. (See MA *Scenarios,* Chapter 10.) This is based on the observation that ecosystem services performed by top predators will be lost before those performed by decomposers. The service of supporting biodiversity (by generating and maintaining habitats of required value and ample size) is expected to be degraded faster than the service of provisioning biological products.

The direct threats to the service of supporting biodiversity include not only land degradation but also habitat loss and fragmentation, competition from invasive alien species, poaching, and the illegal trade in biodiversity products. Indirect threats include the losses of the drylands-specific "keystone" species (Paine 1966) and "ecosystem engineer" species (which modify the dryland environment for the benefit of other species) (Jones et al. 1994). Finally, not only losses but also addition of species may impair service provision. For example, Eucalyptus tree species introduced to southern Africa have invaded entire catchments of natural vegetation, causing large-scale changes in water balance and depriving water from lower catchments (Van Wilgen et al. 1998).

22.2.6 Integration: Services, Biodiversity, Livelihoods, and Aridity

Figure 22.7 highlights the interrelationships between major ecosystem services, between services and biodiversity, and between services and the livelihoods they support across the aridity gradient. Water regulation is the overarching dryland service, and its effect cascades through the interrelated supporting services of soil conservation and nutrient cycling to primary production and water provision. Whereas the service of water provision is the most significant one supporting the farming livelihoods prevailing in the dry subhumid and the semiarid subtypes, the primary production-dependent service of forage provision is the most significant service for pastoralists. Other primary production-dependent services are the provision of biochemicals and fuelwood, which serve both farmers and pastoralists but also generate independent, alternative livelihoods based on medicinal plants and biomass-generated energy. Forage, fuelwood, and biochemicals are goods produced by a diversity of plant species, which are both a product and a generator of primary production.

The structural diversity of the vegetation cover is the most significant dryland biodiversity component, since it is instrumen-

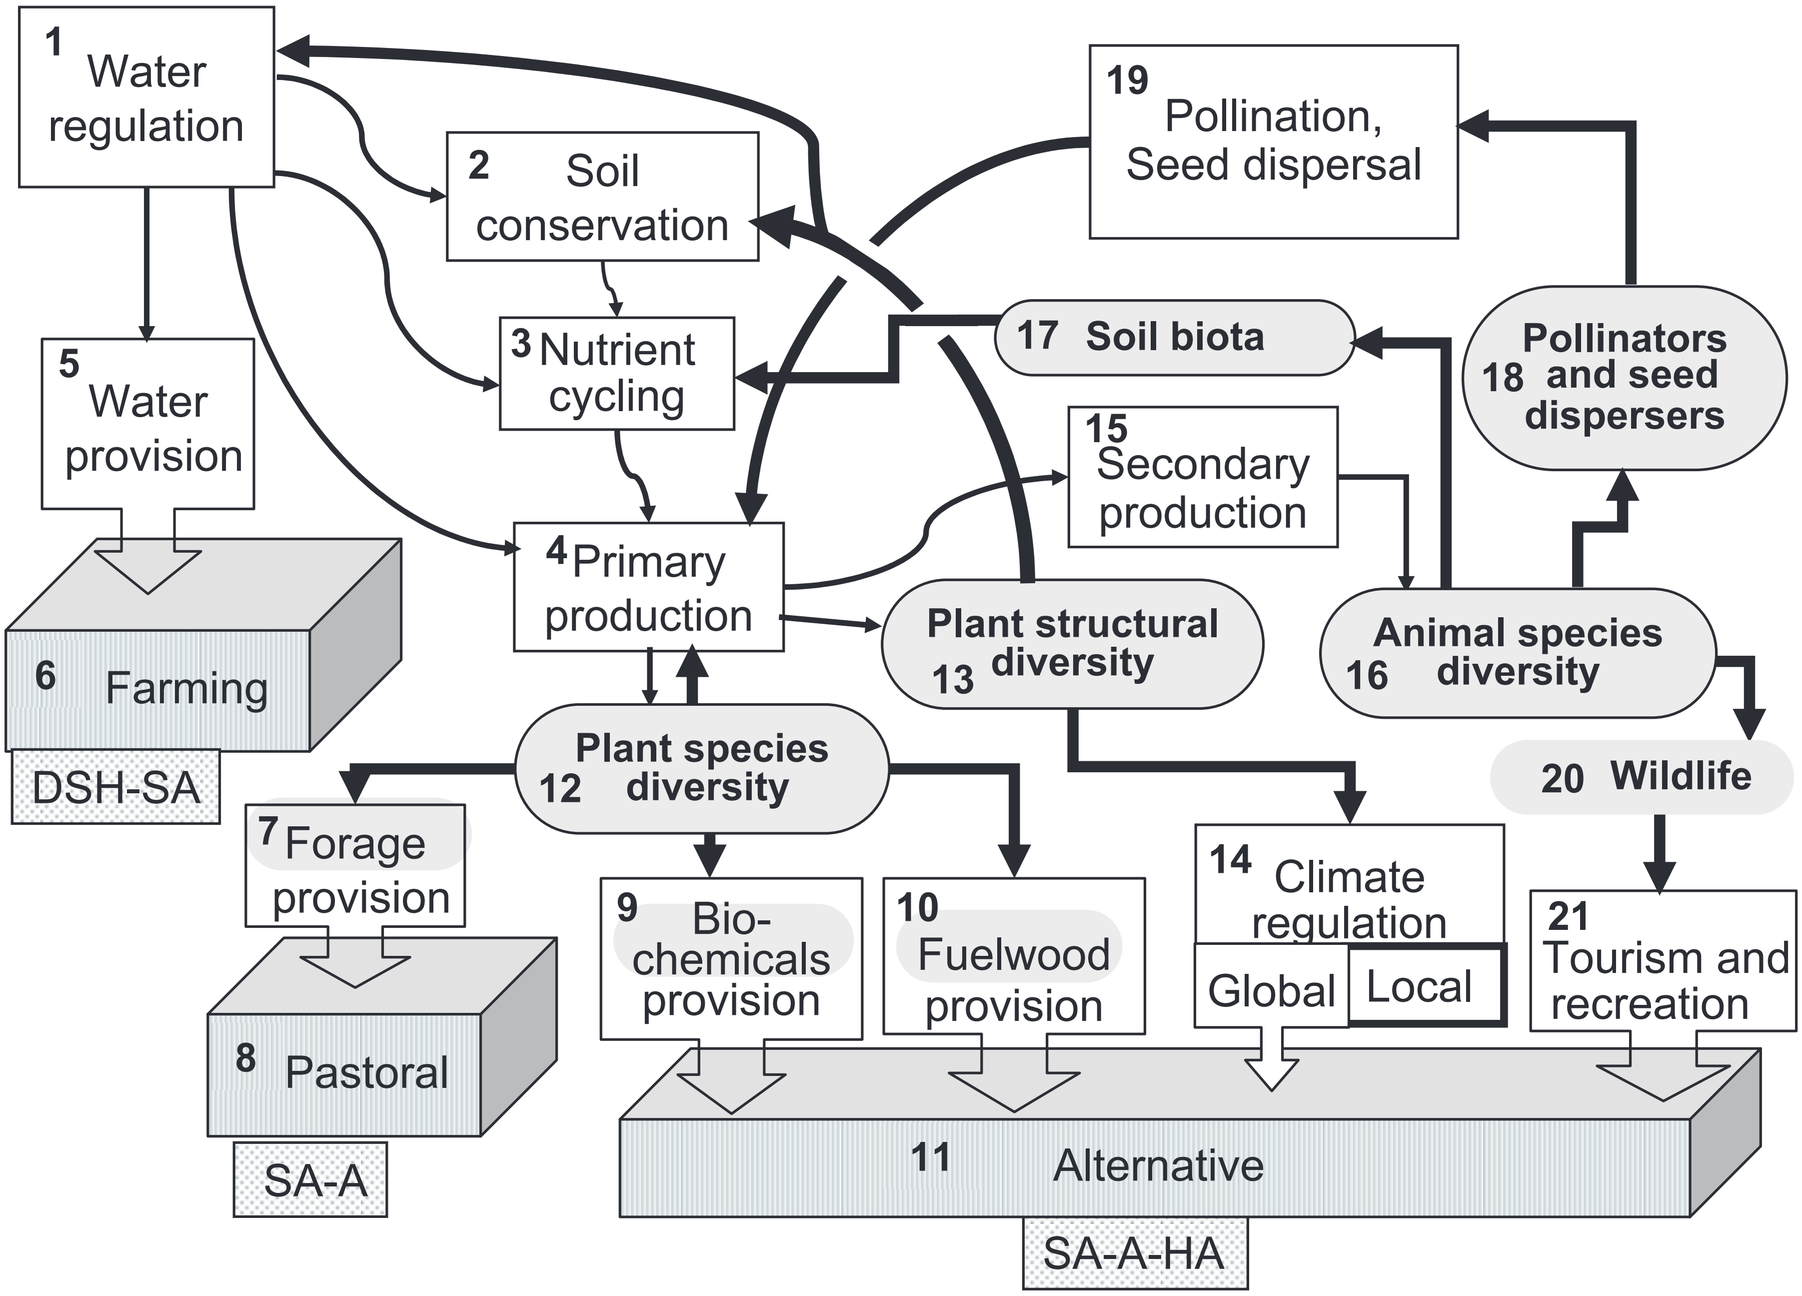

Figure 22.7. Linkages between Services, Biodiversity, Livelihoods, and Dryland Subtypes. Rectangular boxes—services; rounded boxes—components of biodiversity; three-dimensional boxes—livelihoods; dotted rectangles—dryland subtypes: DSH, SA, A, and HA—dry subhumid, semiarid, arid, and hyper-arid, respectively; thin arrows—direct effects of services; thick arrows—involvement of biodiversity. Follow the boxes in the order of their numbers, which streamlines with the text in section 22.2.6.

tal in the water regulation service. Plant structural diversity is also involved in soil conservation and water regulation, as well as in climate regulation. Plant biodiversity supports animal biodiversity since secondary production directly depends on primary production, and the diversity of animals is regulated by plant structural diversity through provisions of a diversity of habitats and shelters for animals. Critical components of dryland animal biodiversity are the diversity of surface and soil decomposers (supporting nutrient cycling) and larger wildlife (supporting the cultural service of tourism and recreation).

While pastoralists control the exploitation of rangeland services through managing stocking rates and livestock species composition, cropland cultivation constitutes more-intensive management (tillage, irrigation, and so on) that often taxes biodiversity and does not always generate the expected increased provision of services. While cultivation intends to increase service provision, it sometimes impairs the provision of all three supporting services and affects the water regulation service. One way out may then be turning to alternative livelihoods, as described later. Whereas the prevalence of traditional livelihoods decreases with aridity, existing and emerging alternative livelihoods, each supported by a different service, are expected to augment or even replace traditional livelihoods and hence may increase with aridity.

22.3 Condition and Trends in Dryland Systems

This section assesses the issue of greatest concern—land degradation in the drylands. The condition of service provision to each of the three major dryland livelihoods—pastoral, farming, and "alternative"—is also considered. There is an overarching trend toward further water scarcity, exacerbated by aridity, with reductions of 11%, 13%, 15%, and 18% in the annual per capita supplies of surface runoff augmented by flows from outside each subtype expected for the period 2000–10 in the dry subhumid, semiarid, arid, and hyper-arid subtypes respectively (Vörösmarty et al. 2005).

22.3.1 Land Degradation

22.3.1.1 How Much of the Drylands Is Degraded?

The critical drivers of change in drylands are those leading to a degraded condition of primary production. The process by which this service is degraded, compared with its provision prior to human pressures, is called "land degradation." Land degradation in drylands is termed "desertification" and can be viewed as an expression of a persistent decline in the ability of a dryland ecosystem to provide goods and services associated with primary productivity. Thus, an indicator of the condition of drylands is the degree of "land degradation" or desertification. (See Box 22.2.)

Despite the global importance of desertification, the available data on the extent of land degradation in drylands are limited. To date, there are only two studies with global coverage and both have considerable weakness. But in the absence of anything better they have been widely used as a basis for national, regional, and global environmental assessments.

The best known study is the Global Assessment of Soil Degradation (Oldeman et al. 1991). Intended as an exploratory study, it did not include any remote sensing or field measurements and was based on expert opinion only. A more detailed assessment—Soil Degradation in South and Southeast Asia—also relied heavily on expert opinion (Middleton and Thomas 1997). A more thorough, measurement-based global follow-up has not been conducted. Additionally, these studies only considered soil degradation and placed a strong emphasis on erosion, which is extremely hard to measure. These studies also formed the basis of the data and maps presented in the *World Atlas of Desertification* (Middleton and Thomas 1997). A reported 20% of the world's drylands (excluding hyper-arid areas) suffer from soil degradation, mainly caused by water and wind erosion, which is presented as the prime cause for 87% of the degraded land (Middleton and Thomas 1997; Oldeman and Van Lynden 1997; Lal 2001a).

The second study with global coverage is that of Dregne and Chou (1992), which covers both soil and vegetation degradation. It was based on secondary sources, which they qualified as follows: "The information base upon which the estimates in this report were made is poor. Anecdotal accounts, research reports, travelers' descriptions, personal opinions, and local experience provided most of the evidence for the various estimates." This study reported that some 70% of the world's drylands (excluding hyper-arid areas) were suffering from desertification (soil plus vegetation degradation).

Recognizing the lack of adequate data on land degradation, the MA commissioned a desk study (Lepers 2003; Lepers et al. 2005) that compiled more-detailed (and sometimes overlapping) regional data sets derived from literature review, erosion models, field assessments, and remote sensing. This study found less alarming levels of land degradation (soil plus vegetation) in the drylands (including hyper-arid regions). Achieving only partial coverage, and in some areas relying on a single data set, it estimated that only 10% of global drylands were degraded. This includes 17% of drylands in Asia degraded, but in the Sahel region in Africa—an area reported as highly degraded by the Global Assessment (Oldeman et al. 1991) and by Dregne and Chou (1992)—few localities with degradation were found. The global number of people who live on lands determined by Lepers (2003) as degraded is about 20 million, much lower than the 117.5 million people living on lands defined as degraded by GLASOD.

All these assessments have their weaknesses. Due to the poor quality of the information sources, Dregne and Chou's numbers are most likely an overestimation. For example, they report figures as high as 80–90% for both rangeland and cropland degradation in the drylands of individual countries (such as Kenya and Algeria). Such high levels are hard to reconcile with data from the FAOSTAT database, which show that over the last 40 years the average per hectare yields of major cereals cultivated in Kenya and Algeria have increased 400–600 kilograms. Most likely the true level of degradation lies somewhere between the figures reported by GLASOD and those of Lepers (2003). This implies that there is *medium certainty* that some 10–20% of the drylands are suffering from one or more forms of land degradation. And the livelihoods of millions of people, whether they actually reside in the degraded areas or just depend on them, are affected by this degradation, including a large portion of the poor in drylands.

Even if the most conservative estimate of 10% is used, however, a total land area of over 6 million square kilometers is affected by desertification, an area roughly twice the size of India, the seventh largest country in the world. It should be borne in mind, however, that to determine the true extent of degradation and identify precisely where the problems occur will require a more in-depth follow-up to the three exploratory studies discussed here, combining analysis of satellite data with extensive ground-truthing. (See Box 22.3.) The ongoing Land Degradation Assessment in Drylands project, an international U.N. initiative to assess the status of land degradation in the drylands, is an appropriate response to this daring challenge.

22.3.1.2 Land Use, Land Degradation, and the Aridity Gradient

Human populations and land uses change across the aridity gradient. The best way to express the effect of the gradient on dryland peoples and their land use is through estimating the amount of water per capita available in each dryland subtype. As expected,

BOX 22.2

Desertification as Land Degradation

The UNCCD defines desertification as land degradation in the drylands ("'Desertification' means land degradation in arid, semi-arid and dry sub-humid areas"), yet the two terms are often used as if they are distinct (for example, "Land degradation and desertification in desert margins," in Reich et al. 2000). The UNCCD also defines "land" by its primary productivity service ("'land' means the terrestrial bio-productive system") and "land degradation" as an implicit loss of provision of this service ("'land degradation' means reduction or loss . . . of the biological or economic productivity").

The definition of biological productivity and economic benefit depends on users' priorities. Transforming woodland to cropland may decrease biological productivity and degrade the economic benefit of firewood production, for example, but increase the economic benefit of food production. With respect to the mechanisms of land degradation, changes in the properties of the land (soil, water, vegetation) do not correspond linearly to changes in productivity. Loss of productivity can also be attributed to non-human-induced factors such as rainfall variability and human factors such as low labor input. Thus a range of interacting variables that affect productivity should be addressed in order to assess land degradation objectively and unambiguously.

Commonly considered degradation processes are vegetation degradation, water and wind erosion, salinization, soil compaction and crusting, and soil nutrient depletion. Pollution, acidification, alkalization, and waterlogging are often important locally (Oldeman 1994; Lal 2001a; Dregne 2002). Field experiments, field measurements, field observations, remote sensing, and computer modeling are carried out to study these processes. The higher the aggregation level in each of these study approaches, the more problematic each of the methods becomes, either because of upscaling issues or because of questionable extrapolations and generalizations (Stocking 1987; Scoones and Toulmin 1998; Matthews 2000; Mazzucato and Niemeijer 2000b; Lal 2001a; Warren et al. 2001; Dregne 2002).

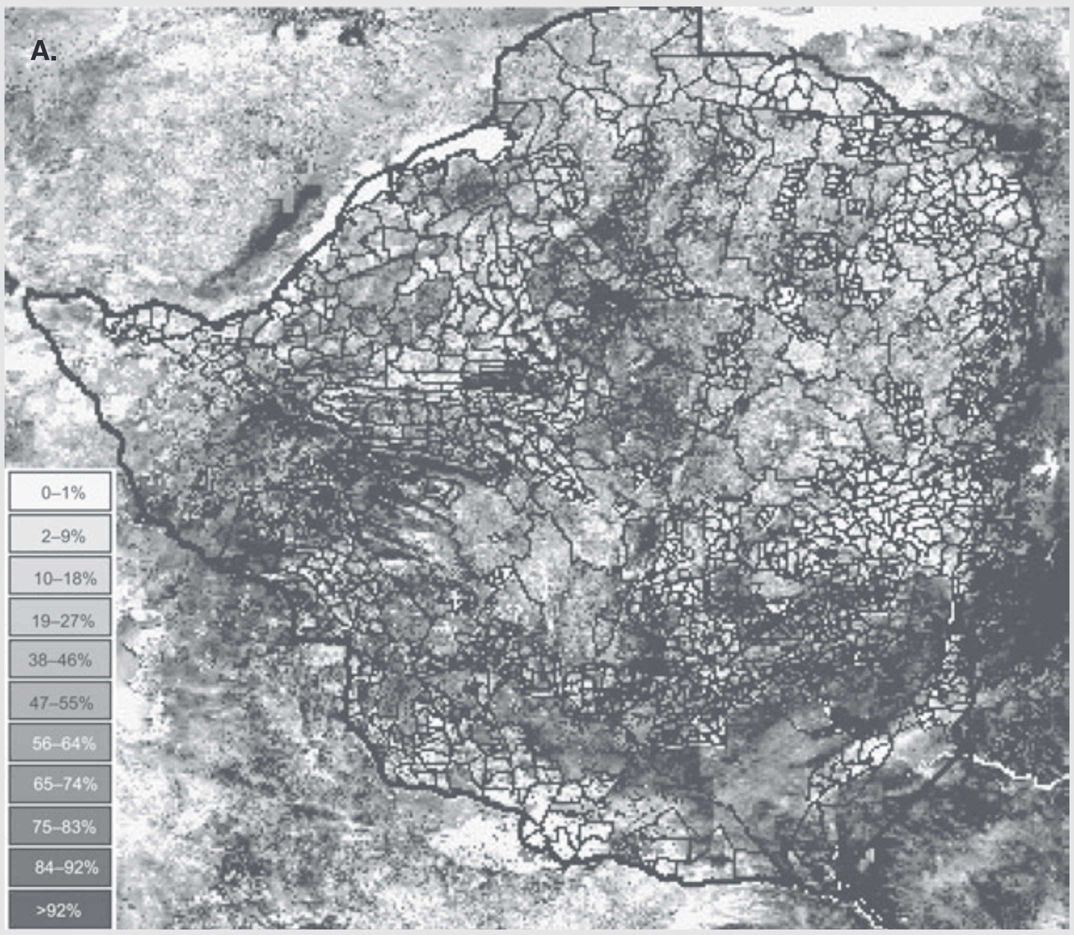
BOX 22.3

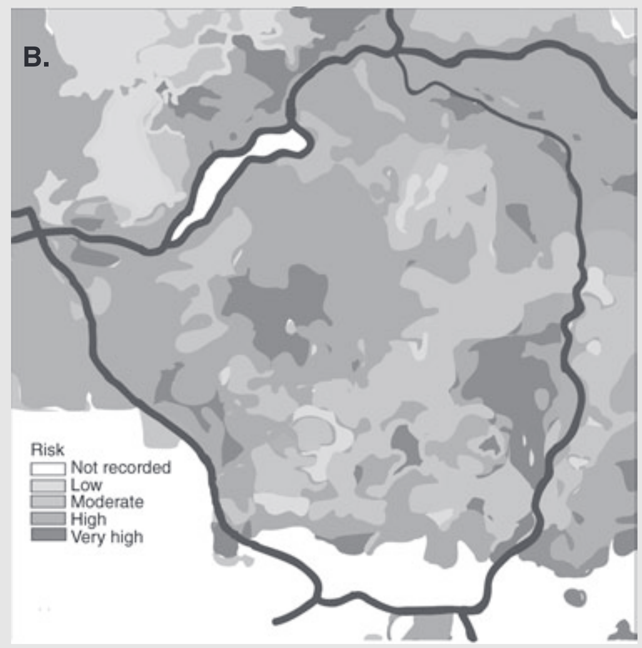
Satellite Remote Sensing and Desertification

Attempts to map desertification are often unsatisfactory. A key requirement for mapping desertification is that the term is defined in a way that leads to objective and practical measurement criteria. Earth-observing instruments carried on satellites (Prince 1999) routinely map land surface variables that respond to desertification, such as albedo, surface temperature, and vegetation cover—all with appropriate spatial resolution and regular global coverage. Unfortunately, factors that are not related to desertification also affect these properties; for example, AVHRR data have been used to monitor interannual changes of vegetation cover in dry regions (Tucker et al. 1991; Nicholson et al. 1998), but these are frequently caused by rainfall fluctuations, not desertification (Prince 2002).

Persistent reduction in productivity is an expression of desertification (Prince 2002), and it is routinely measured using satellite derived vegetation indices (such as the normalized difference vegetation index). NDVI measures the amount of solar radiation absorbed by the vegetation, from which simple methods can be used to estimate net primary production (Prince 1991). Prince (2002) has suggested that a persistent reduction of NPP below its potential, a reduction that does not disappear during wetter periods, could identify areas that may be experiencing desertification, a measure that is both practical and based on the underlying mechanism.

In the absence of human impacts the NPP is set by climate, soils, vegetation productive capacity, and growing season weather conditions.





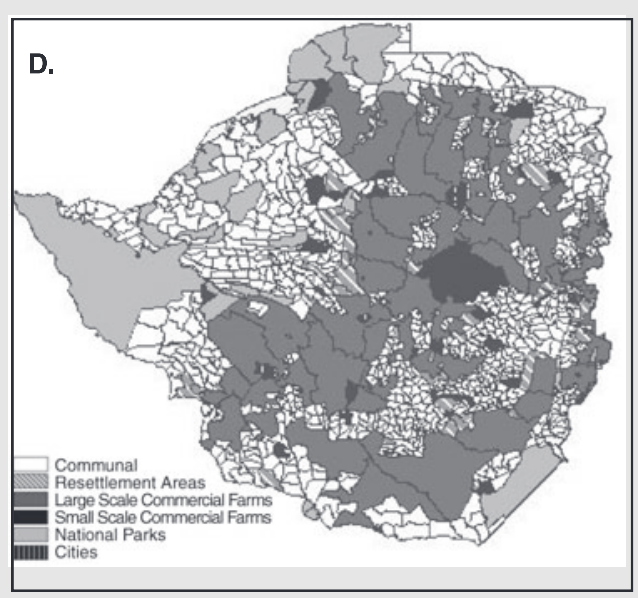


Figure A. Maps of Desertification in Zimbabwe. Map A. Local NPP Scaling (LNS) map. Gray scale indicates the LNS value, from white (LNS = 0–1%, i.e., desertified) to dark gray (LNS > 92%, near potential productivity). Note correspondence with fourth level administrative boundaries (See Map D) and the correlation of low LNS with the overcrowded communal lands that are known to be seriously degraded. LNS was calculated using NPP estimated from SPOT VEGETATION 1 sq.km. satellite NDVI data, 1998–2002. Map B. Desertification Risk Map (Eswaran and Reich 2003). This map is a combination of the NRCS global desertification map and a global population density map. Note that the spatial resolution is much less than in Map A and the values of "risk" unfortunately cannot be validated. Map C. Zimbabwe, excerpted from the Global Assessment of Soil Degradation (GLASOD) map (Oldeman et al. 1990). Letter symbols: Wt-loss of topsoil by water erosion; Wd-terrain deformation/mass movement by water erosion; Pc-physical deterioration by compaction/crusting; f-deforestation and removal of the natural vegetation; g-overgrazing; a-agricultural activities; e-overexploitation of vegetation for domestic use. Key to numeric symbols: x.y, where x indicates degree of degradation (1-light; 2-moderate; 3-strong; 4-extreme) and y indicates percentage of mapping unit affected (1-less than 5%; 2–5 to 10%; 3–10 to 25%; 4-more than 50%); ↑-medium rate. As in Map B, the resolution is low and hard to validate on the ground. Map D. Zimbabwe land tenure classes. Note the correspondence of communal lands (white) and commercial farms (dark) to low and high LNS in Map A, respectively.

BOX 22.3
continued

Unfortunately these cannot be measured at an adequate resolution in most desertification-prone regions. An alternative, however, is to use the NPP maps themselves and to employ a statistical method to estimate the NPP of non- or less-degraded areas (Prince 2004). A large region can be classified into homogeneous areas that consist of land having the same climate, soils, and vegetation structure, in which only the human impacts vary. The NPP of the grid cells (pixels) measured by the satellite instrument that fall in each area can be normalized, and the highest NPP values can be used to estimate the potential NPP. All other pixels in that area can then be represented as a percentage of the potential NPP for the same area.

In the example (Figure A), Zimbabwe was stratified into regions in which the principal natural characteristics and existing vegetation types are uniform, based on maps of land cover and rainfall. The regions varied in area but were typically 1,000–10,000 square kilometers. Following the earlier outlined procedure, a percentage reduction from potential NPP was calculated for each pixel. This method is known as the Local NPP scaling method. Other methods are possible, based on closer study of desertification and NPP; under development is Local NPP Ranking, which depends on the recent observation (Wessels et al. 2004) that the NPP of some long overused land in South Africa differs from non-degraded land by a constant proportion. (See Figure B.)

Satellite data are able to detect changes in the productivity of the vegetation; hence, future synoptic primary production mapping is likely to identify regions with persistent reductions in NPP, indicating changes that need closer investigation and ground verification. The definition of desertification used here is land that has suffered a shift to a reduced NPP, even when rainfall is not limiting or is equally limiting on desertified and non-desertified land. This newly emerging procedure detects shifts to reduced NPP relative to the potential NPP. Its validity, utility, and practicality, however, have yet to be demonstrated for global-scale desertification monitoring.

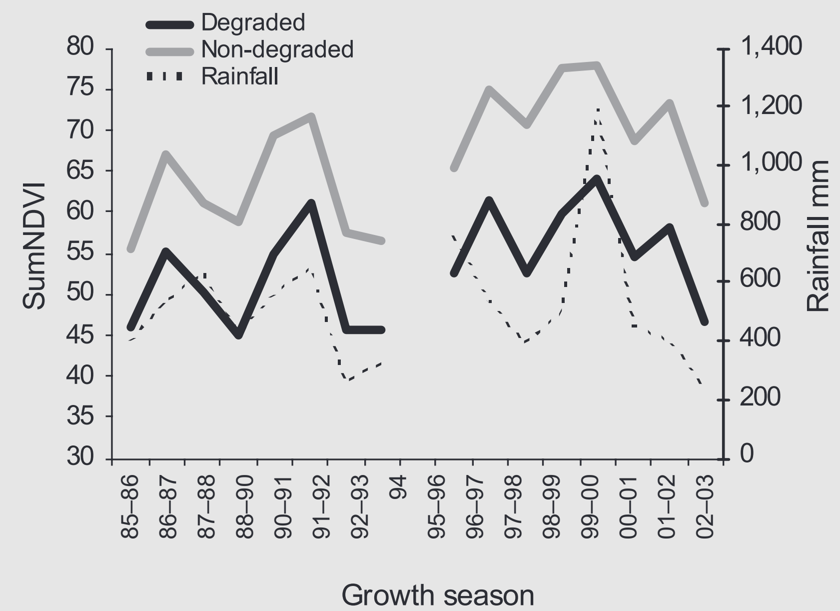

Figure B. Interannual Variation in Net Primary Production of Neighboring Non-degraded and Degraded Areas within the Same Land Potential Class in South Africa. Primary production was estimated using satellite measurements of the Normalized Difference Vegetation Index summed over the growing season. SNDVI is generally positively related to average rainfall. The SNDVI in the degraded areas relative to the non-degraded was reduced by a near constant proportion. Also, in wetter years, the SNDVI in degraded sites exceeded that of non-degraded sites in dry years (Wessels et al. 2004)

human population decreases with aridity. (See Figure 22.8.) It is also expected that annual runoff (as well as surface flows from non-drylands into drylands) will decrease with aridity. However, water supply per person also decreases with aridity (Vörösmarty et al. 2005 Figure 20.8b). Namely, the rate of decrease in water supply with aridity is greater than the rate of decline of the human population with aridity. This suggests that as aridity increases, the ability of the ecosystem to provide the water required by the local population decreases. Thus not only does water supply become low with increased aridity, but there is a mismatch between the supply and the number of people, and the increased aridity-linked gap between supply and demand creates water scarcity. This provides added insight into the decline of human population, cropping, and urbanization with aridity.

However, the most pronounced decrease of population and cropland occur from the semiarid to arid drylands. This may be partly due to the larger spatial extent of the global semiarid dryland compared with other subtypes. On the other hand, use of rangeland peaks in the arid subtype; drier areas are not attractive to livestock, and in areas with higher productivity pastoralism gives way to farming. Thus other than urban areas (2%), most of the world's dryland area is divided by land cover and land use between rangelands (65%) and croplands (25%), although some of these are actually interwoven rangeland and croplands, supporting a mixed, integrated agropastoral livelihood. Both pastoralism and farming and their combination are often implicated as drivers of degradation.

It is likely that the sensitivity of dryland ecosystems to human impact increases with aridity—a little human pressure may not destabilize a dry subhumid ecosystem, but it will degrade the productivity of a semiarid one. And even less pressure will destabilize an arid dryland, in which the capacity of the inherent resilience mechanisms is lower than in less arid drylands. On the other hand, human population pressures and the associated pressure of livestock decrease with aridity, as Figure 22.8 indicates.

Much of the drylands have traditionally been used as rangelands, but with the increase in dryland human populations, a gradual transformation of rangelands to croplands has occurred. Although a large proportion of the hyper-arid dryland is used as range, the value of this range is low and so is livestock density. In the dry-subhumid, the extent of rangeland is low since much of it has been converted to cropland, but grazing pressure is reduced, possibly due to the higher potential profitability of croplands. (Note that human density is greater than livestock density only in this subtype).

Unlike sensitivity to human pressure, which increases with aridity, and human pressure, which decreases with aridity (from 70.7 persons per square kilometer in the dry subhumid to 10.4 persons in the hyper-arid drylands), land degradation—at least as presented by GLASOD—follows a hump-shaped curve, with a maximum in the arid and semiarid drylands. (See Figure 22.9.)

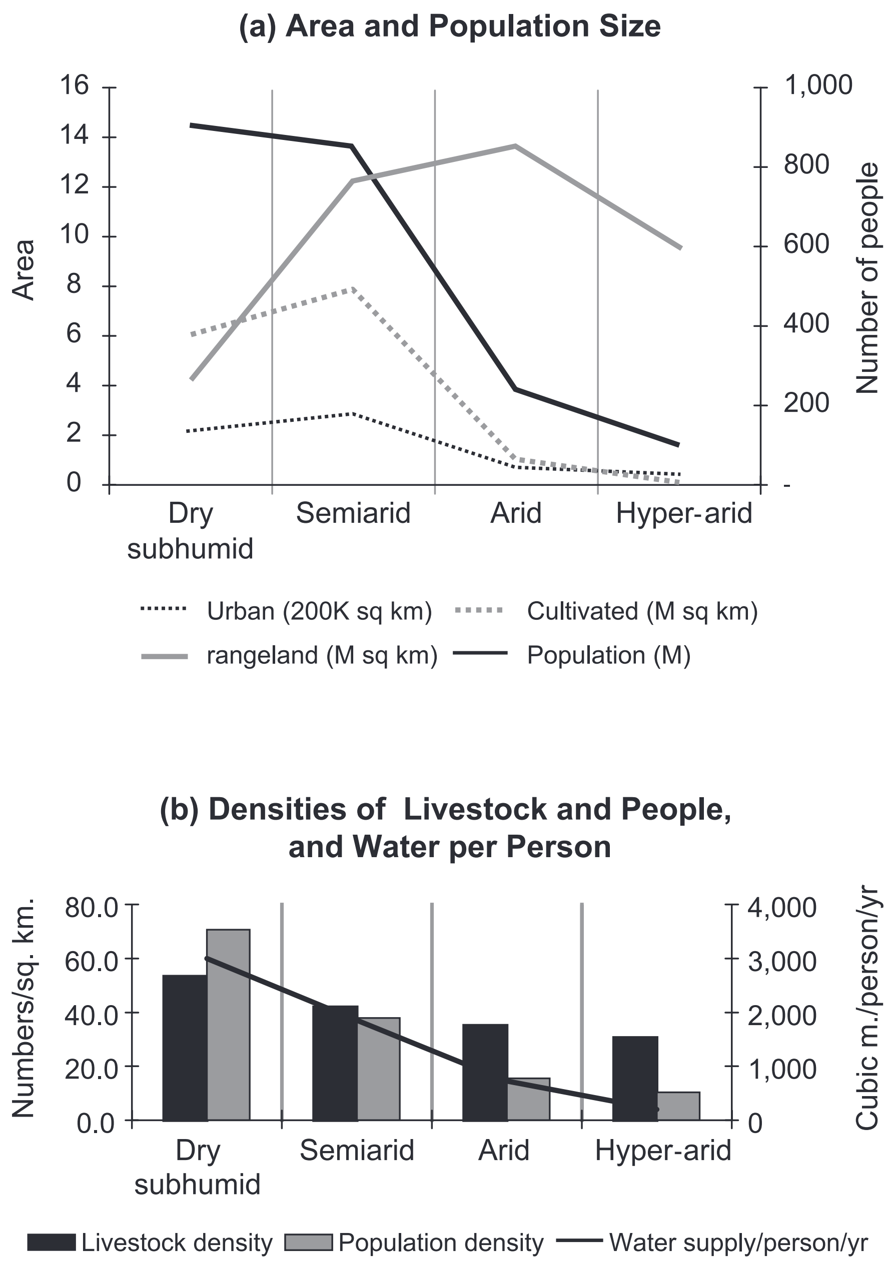

Figure 22.8. Land Use, Human and Livestock Populations, and Water Availability across the Aridity Gradient. Land use and human population size (a) note the different scale for size of urban area). Rangeland figures are based on available data on rangelands in drylands of developing countries (Reid et al. 2004; Thornton et al. 2002) and estimates of rangeland areas in the remaining drylands based on the assumption of uniformity in the rangeland's share of each dryland subtype. Human population densities (b) (CIESIN 2004) and livestock averages of mean densities for developing countries only (Thornton et al. 2002). Line-water supply per person: total runoff generated by a dryland subtype and augmented by inflows (e.g., rivers) from other subtypes or other MA systems, divided by the number of people living in the subtype but taking into account the position of humans along river corridors, in areas of higher (or lower) runoff, etc. Thus, the points represent population-weighted means in terms of the flows per person based on the populations served. (Fekete et al. 2002; Vörösmarty et al. 2005)

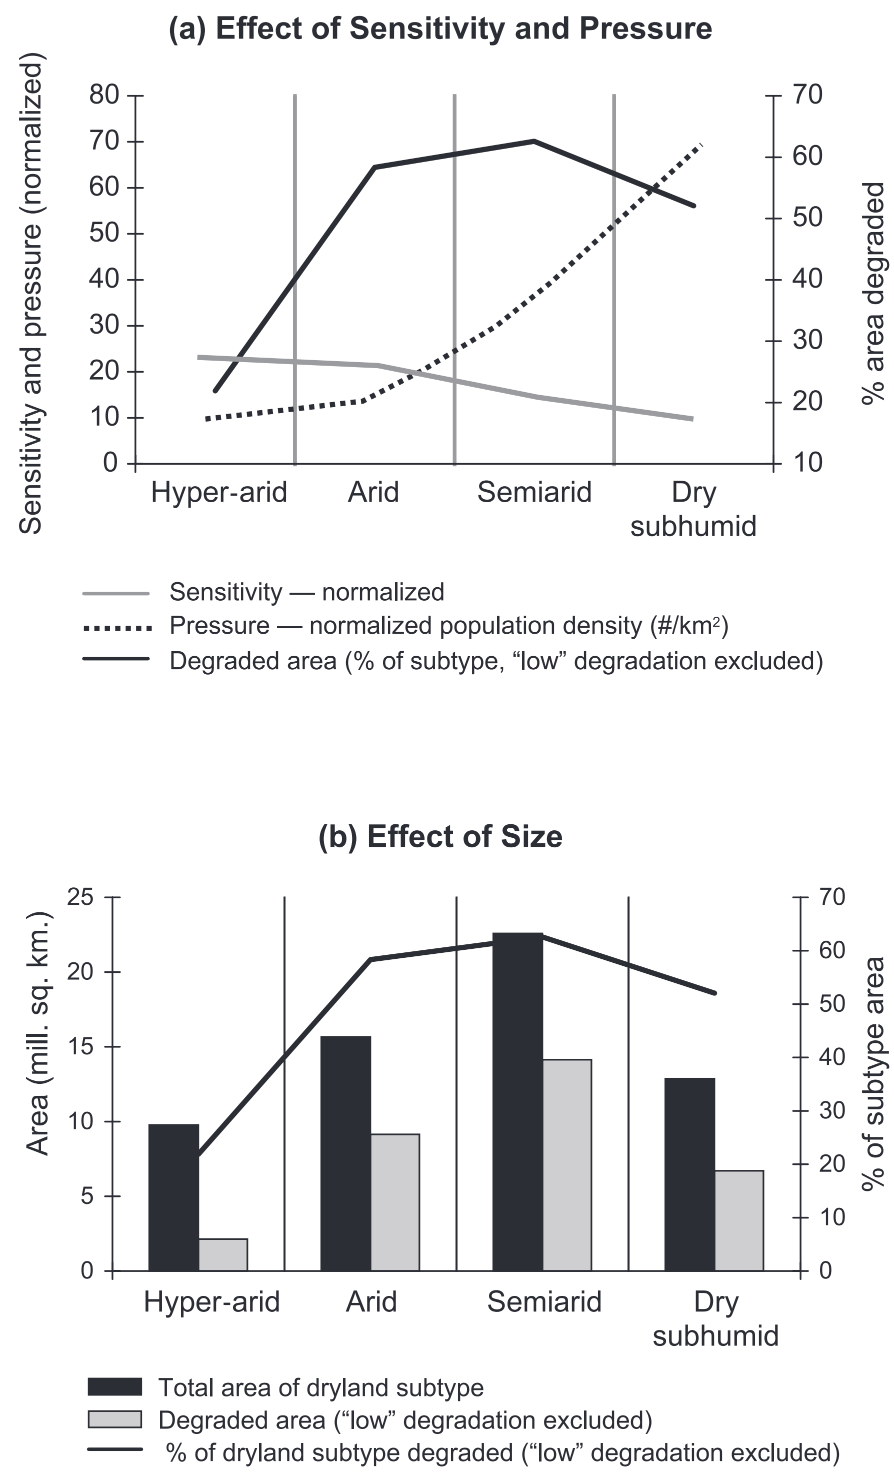

Figure 22.9. Dryland Degradation across the Aridity Gradient. Effect of aridity (a) and effect of subtype global size (b). Sensitivity to human pressure is 1-median of Aridity Index; sensitivity and pressure are normalized, lowest values set to 10; land degradation is from GLASOD (1990), excluding "low" degradation category, which may be hard to distinguish from "no degradation." (Population density data from CIESIN 2004)

This distribution of land degradation fits a model in which degradation is a function of the product of sensitivity and pressure: when sensitivity is linear but pressure increases exponentially with aridity, the degradation curve is biased to the lower aridity section. The peak is closer to the semiarid than to the arid section of the gradient, and the value for the dry-subhumid subtype is higher than that for the hyper-arid subtype.

These relationships between degradation, sensitivity, and pressure emerge when sensitivity is expressed as an inverse function of aridity and when pressure is a function of population density. The peak in percentage degradation coincides with the peak in global dryland size, however—the semiarid dryland has the largest global extent and the highest degradation percentage. Thus the most extensive degradation occurs in the central section of Figure 22.9, which also happens to be the most extensive global dryland subtype—the semiarid drylands. This subtype and the arid ecosystems subtype—and especially the transition between the two—have medium sensitivity and are driven by a medium anthropogenic pressure, a combination that generates the highest vulnerability and may result in desertification.

22.3.2 Condition and Trends of Rangelands

Dryland rangelands support approximately 50% of the world's livestock and also provide forage for wildlife (Allen-Diaz et al. 1996). Global data on the extent of rangelands within drylands are available only for developing countries. Based on Reid et al. (2004), rangelands occupy 69% of the drylands of the developing world. Their greatest extent is in the semiarid subtype (14 million square kilometers) and the proportion of dryland they occupy increases with aridity—from 34% in the dry-subhumid subtype to 54% in the semiarid, 87% in the arid, and up to 97% in the hyper-arid subtype. Data on livestock numbers in drylands are available only for industrial countries, where densities are calculated according to land units, mostly administrative units (Thornton et al. 2002).

Combining data from Reid et al. (2004) and Thornton et al. (2002), it is possible to estimate livestock densities per dryland sub-type as well as for just the rangelands within those dryland subtypes. Livestock densities for rangelands within the subhumid, semiarid, and arid subtypes are relatively uniform (32–35 animals per square kilometer of rangeland) but drop to a low 15 animals in rangelands within the hyper-arid subtype. The combined densities of sheep, goats, and cattle per dryland subtype area unit steadily decline with aridity (53 animals per square kilometer in dry subhumid to 31 animals in the hyper-arid subtype). The number of animals per unit area of a dryland subtype is greater than those per rangeland unit area, especially in the hyper-arid and the dry subhumid subtypes. This suggests that many animals (especially cattle) do not range freely in the dry subhumid areas, probably due to competition with cultivation, and are kept in fertile areas within the low-productivity hyper-arid rangelands, such as desert oases and along desert rivers—areas not classified as pastures.

22.3.2.1 Semiarid Rangelands

Most of the arid drylands are used as rangeland, but during the second half of the nineteenth century large-scale commercial stockbreeding spread over the semiarid drylands of North and South America, South Africa, and Australia. Both the type of herbivore and the grazing management applied (including fire prevention) were new to these semiarid ecosystems. The resulting disturbance created a ''transition trigger'' that, combined with drought events, led to a progressive dominance of shrubs over grass (Scholes and Hall 1996), a process that may have been facilitated by increasing atmospheric CO_2 levels that differentially favored C3 shrubs over C4 grasses (Archer et al. 1995; Biggs et al. 2002). The transition of grasslands to shrublands (see Figure 22.10) is widely reported around the world. This transition generated a mosaic of plant clumps within a ''matrix'' devoid of much vegetation, which encourages surface runoff, topsoil erosion, and exposure of rocky surfaces (Abrahams et al. 1995; Safriel 1999).

Eventually, the degradation due to overstocking and range mismanagement led to a decline in livestock numbers after peaking at the beginning of the twentieth century—40% loss in New Mexico (Fredrickson et al. 1998), 45% loss in western New South Wales (Mitchell 1991) and 60% loss in Prince Albert District *karoo* (Milton and Dean 1996)—and to substitution of sheep for cows, as they are better adapted to graze on tussock grasses.

22.3.2.2 Dry Subhumid Rangelands

Two opposing trends in the global area of temperate grasslands are evident: expansion at the expense of woodland and contraction due to the encroachment of cultivation. Examples of the first process are the expansion at the expense of forests in North America following European colonization (Walter 1968) and, in the Caucasus, a 27% increase in the last century at the expense of oak forest (Krenke et al. 1991). Grasslands' natural primary production generates high biomass of many species of herbaceous forage plants, and the second transformation involved redirecting the grasslands' primary production service for maximizing the production of seeds of a few species of domesticated grasses. The conversion of grasslands to grain crops occurred some millennia ago in the loess region of north-central China, in the last three centuries in the Russian Federation (162 million hectares), and during the last century in the United States (121 million hectares) (Ramankutty and Foley 1999). However, though temperate grasslands are fairly resilient to grazing, fire, and tillage that maintains the topsoil (Lavrenko and Karamysheva 1992), more-intensive cultivation dramatically reduces the provision of supporting services.

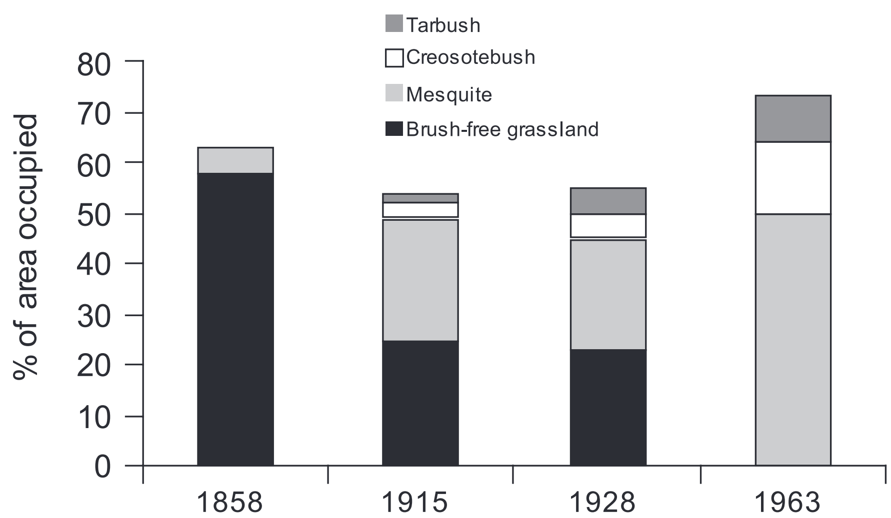

Figure 22.10. Transition of Grassland to Shrubland due to Stockbreeding in Semiarid Rangelands. The figure shows the percent of area occupied by dense (≧55% of perennial plant composition) brush cover of the major shrubs at various dates on the Jornada Plain of the Jornada Experimental Range in New Mexico. (USDA-ARS 2003)

Population increase is the main driver of the tropical savanna-cropland transition, and the dry subhumid African savannas north of the equator represent barely 14% of the original cover and are retreating at an estimated rate of 0.15% (or 340 square kilometers) per year (WRI 2004). Where human population in tropical savanna is relatively low but soil fertility high, fire is excluded, and grazing is heavy, however, range degradation occurs due to topsoil erosion driven by bush encroachment (Scholes and Hall 1996).

Rangelands of the Mediterranean xerophytic shrubland and woodland are relatively resilient to human impact. The Mediterranean landscape is of a fine-grained spatial heterogeneity, with mosaics of cultivated fields and stands of different vegetation succession stages that result from the combined effect of fire, grazing, and cropping. This dynamic mosaic of land uses maintains the soil conservation service, though frequent and extensive alterations may reduce it (Naveh 1991).

22.3.3 Condition and Trends of Cultivated Drylands

22.3.3.1 Oases in Hyper-arid and Arid Drylands

In the hyper-arid and arid drylands (the desert biome), most cultivation is either in oases or in croplands, where crops are irrigated by fluvial, ground, or local water sources or by a combination of these. Traditionally, oases were carefully managed by combining crops and water regulations. Since the middle of the twentieth century, oases have borne increasing demographic and investment pressures resulting in larger water abstraction, which has led to soil salinization and huge loss of surrounding vegetation through overgrazing and fuelwood exploitation followed by soil erosion.

Two examples are indicative of these trends. Recent indirect drivers of change in the Maghrebian oasis (northern border of the

Sahara) have been population increase, policies to settle nomadic populations, investments generated by migrants working abroad, and transformation of self-sufficiency to open-market economies in countries of the Maghreb. The expansion of cultivated areas irrigated by water from deep aquifers and a lack of drainage (de Haas et al. 2001) led to spreading shallow water tables and subsequent soil salinization (Mtimet and Hachicha 1995). In the Nile delta, traditional water management of the summer flood kept the water table at 5–7 meters below the surface during the low flow season. But nineteenth- and twentieth-century water management policies and practices, including construction of the Aswan dam, enabled year-round irrigation and the growth of out-of-season crops, such as cotton. These reduced the water table depth, however, resulting in soil salinization and a dramatic decline in crop yield (Ruf 1995).

22.3.3.2 Semiarid and Dry Subhumid Agriculture

Where massive agricultural encroachment into temperate grasslands has occurred, and where drylands are exposed to freezing and thawing and suffer a relatively high recurrence of drought and strong winds, topsoil is at risk of being lost and with it all the provisioning services. This happened in the Chinese loess plateau south of the Yellow River bend millennia ago and in North American central plains in the first quarter of the twentieth century. Once the topsoil is lost to wind, the underlying layers—rich in calcium carbonate and poor in organic matter—develop crusts that impede infiltration and foster further soil loss through gully erosion (Mainguet 1996). In the United States, temperate grassland soils can lose up to 50% of their original carbon within the first 50 years of cultivation (Conner et al. 2002). In parallel to carbon loss, conversion of grasslands to croplands can result in loss of fertility, increased soil erosion, and decreased water quality through larger sedimentation and non-point chemical pollution by salts, nutrients, and pesticides.

When agricultural encroachment of tropical savannas occurs, there is a risk of soil impoverishment through erosion and nutrient depletion (Stoorvogel and Smaling 1990; Drechsel et al. 2001) unless nutrients and water are carefully managed. Subsequent erosion may leave the subsurface soil horizon with its limited water infiltration capacity exposed, resulting in further soil loss by gully erosion. However, if land husbandry practices are properly adjusted, the increased crop production required to meet a growing population does not necessarily have to lead to nutrient depletion (Scoones 2001; Niemeijer and Mazzucato 2002; Mortimore and Harris 2004).

The long, traditional agricultural use of Mediterranean shrublands and woodlands in the Mediterranean basin has prevented soil loss through sophisticated terrace systems used across hill slopes. But the pulse of rural population increase that started at the end of the nineteenth century occurred too fast to allow widespread land conditioning, and it triggered extensive soil losses. The outcome was large upstream areas of exposed rock (Roquero 1990) and accretion pulses in river deltas (Hoffmann 1988).

22.3.4 Condition and Trends of Alternative Livelihoods

Rather than grappling with drylands' low biological productivity, dryland peoples have explored ways to exploit other ecosystem functions that can serve them better, even better than if they exploited the same functions in non-drylands. Such emerging ''alternative livelihoods'' do not depend on traditional land uses and are generally undemanding on land and natural resource use. Alternative livelihoods have minimal dependence on land primary productivity for producing subsistence products; do not impair the provision of other services of dryland ecosystems; generate more income per investment from local dryland resources, compared with the traditional, land biological production-dependent livelihoods; and provide people with a competitive edge over others who follow the same practices outside drylands. Five major alternative livelihoods are discussed, in order of decreasing dependence on land primary productivity and hence decreasing desertification risk and increasing likelihood of sustainability.

22.3.4.1 Dryland Afforestation

Silviculture and rain-fed horticulture are not very common in drylands and depend on labor-intensive construction and maintenance of runoff-harvesting structures (Evenari et al. 1982; Droppelmann et al. 2000). However, dryland silviculture and horticulture provide better soil protection than agriculture because tree canopies are denser and tree root system deeper and more extensive than those of agricultural crops and because trees continue to provide soil conservation after harvest, unlike agricultural crops, where very little is left to cover the soil after harvest.

Dryland afforestation for firewood production is a livelihood that depends on the biological production service. Unlike grazing or cropping, afforestation provides a superb soil conservation service for an area greater than that occupied by the forest itself since flashfloods are not generated by dryland forests. Dryland afforestation will qualify as an alternative livelihood if it generates more income than a traditional dryland land use and, even better, if it can generate more income than non-dryland silviculture.

Carbon sequestration by forests and their contribution to above- and belowground carbon reserves and the recent emergence of ''carbon trading'' under the Clean Development Mechanism may make the required difference. This is because most non-dryland ecosystems with good provision of the biological productivity service are already either cultivated or afforested. On the other hand, though the global drylands are less efficient than non-drylands in carbon sequestration, their potential for further carbon sequestration is high and has not yet been developed, while non-dryland capacity is already close to the maximum. Experiences in Israel have shown that a mean annual addition to the carbon reserve of drylands of 150 grams of carbon per square meter per year is possible, generated mainly during winter (rather than during summer in non-drylands), thus storing twice as much carbon as the adjacent nonforested rangeland (Gruenzweig et al. 2003).

Dryland afforestation only counters desertification in those cases where it is used as an alternative for unsustainable cropping and grazing practices. It is not a suitable alternative for rangelands, agroforestry systems, and areas under natural plant cover, as these offer equal or better protection against desertification. Also, in the case of degraded croplands, the benefits are quickly lost if trees are watered through irrigation (with its potential for salinization and water resource depletion) rather than through runoff harvesting.

22.3.4.2 Controlled Environment's Cash Crop Agriculture

There are dryland agriculture practices that can qualify as alternative livelihoods by employing plastic covers in agrotechnology. The plastic cover allows nearly full light penetration and at the same time offers options for locally manipulating many other crop-relevant environmental factors (Arbel et al. 1990). This practice ranges from covering individual rows of low-stature crops, with no additional intervention and for only a part of the growing season (mainly in the least dry drylands), to covering plots within "growth houses" or "greenhouses," within which several of the internal environmental conditions are artificially manipulated to the extent that the crop is virtually separated from the outer dryland environment (mainly in the driest drylands). The plastic enclosure reduces evapotranspiration and thus maximizes water use efficiency (Pohoryles 2000); it reduces insecticide use and makes CO_2 fertilization feasible.

Often the crops are grown on artificial substrates, with nutrients supplied and water provided by irrigation that incorporates fertilizer application ("fertigation"), and pollination may be provided by commercially raised and marketed pollinators (BioBee 2000). Together these enable intensification of biological productivity while economizing on land resources. This approach uses the dryland's abundant incident light and winter warmth, but it is otherwise nearly independent of local ecosystem services. Provided that it does not deplete local water resources and that salinity is controlled and not allowed to leach into groundwater, this practice does not generate desertification.

However, this livelihood requires investment in infrastructure, such as energy for ventilation and cooling, making it more suitable for industrial countries. The intensification of crop growth generates more yield per unit of investment, but the crops need to have high market value—namely, cash crops. The production of cash crops in drylands may be more profitable than in the non-drylands, on account of two physical/climatic features of most (but not all) drylands: high irradiation due to relatively infrequent cloud cover and higher ambient winter temperatures relative to those in the nearest non-dryland areas. Indeed, the gross value added and the cash generated per unit area from that part of the hyper-arid dryland of Israel in which intensive greenhouse agriculture is widely practiced is higher than those of all other types of Israeli agriculture, including those of the least dry areas of the country (Portnov and Safriel 2004).

22.3.4.3 Aquaculture in Drylands

Dryland aquaculture is inherently advantageous to dryland agriculture because although aquatic organisms live in water they do not transpire it, so water losses from aquaculture are predominately from evaporation rather than raised evapotranspiration. Furthermore, many more aquatic species than terrestrial crop species are tolerant of salinity and even thrive in it. Thus, dryland aquaculture can prosper on fossil aquifers (quite common in drylands) whose high salinity greatly curtails their use by dryland agriculture.

When dryland aquaculture borrows the technology of dryland greenhouses (as just described), water conservation is even greater than it is in agricultural greenhouses due to zero transpiration of aquatic organisms. At the same time, dryland aquaculture does not compete for water with dryland agriculture due to the divergent salinity tolerances of terrestrial plants and aquatic organisms (Kolkovsky et al. 2003). Since dryland aquaculture is always more economic on land than dryland agriculture, land use as well as water use efficiencies are high. Thus dryland aquaculture, like dryland controlled-environment cash crop agriculture, does not depend on local ecosystem services and need not cause desertification.

Dryland aquaculture is based on aquatic animals and plants (mostly micro-algae) or some combination of these. The productivity of aquatic animals is not light- and CO_2-dependent, hence the costs of feeding the animals are greater than those of fertilizing the plants. There is, however, an added cost of water filtration due to the enrichment of the water by the surplus organic load of animal feed and animal excretions. This cost can be reduced by integrating animal and plant aquaculture, in which algae thrive on the animal waste-enriched water, or the enriched water can be used for irrigation of crops. Plant aquaculture is advantageous on animal aquaculture in that feeding is not required and organic load is not a problem. Also, given that most aquatic plants are either very small or unicellular, their growth is much faster than that of terrestrial plant crops, and the ratio of harvested to nonharvested biomass of the crop is much higher than that of terrestrial plants.

Dryland aquaculture of both plants and animals is more advantageous than aquaculture elsewhere due to the abundance of light for aquatic plants (Richmond 1986) and of winter warmth for both plants and animals (Kolkovsky et al. 2003). An added benefit is the higher availability and hence the lower price of land in drylands than in non-drylands and the reduced competition with agriculture on land in the drylands. Most of the products of dryland aquaculture are cash crops, such as ornamental fish, high-quality edible fish and crustaceans, and industrially valuable biochemicals produced by micro-algae, such as pigments, food additives, health food supplements, and pharmaceutical products.

22.3.4.4 Urban Livelihoods

Though "dryland development" and "rural development" are often used synonymously, dryland cities as an alternative to dryland villages may be a sustainable option for settling more people in drylands because the cities consume, and hence affect, fewer land resources than dryland farming and pastoral livelihoods do. However, this depends on the potential of dryland cities to provide livelihoods as well as living conditions that are advantageous compared with those provided by other cities.

A combination of appropriate building materials, architectural design (Etzion et al. 1999), and urban planning (Pearlmutter and Berliner 1999) can provide living conditions in drylands that are as comfortable as and much cheaper than those provided by non-dryland cities. This is because drylands are endowed with two climatic features that are highly conducive to "passive" (energy-saving) climate control. The very low air humidity in the driest drylands makes summer evaporative cooling very efficient and cost-effective, and the low dryland cloud overcast means that solar radiation (aided by appropriate positioning, dimensions, and technological design of glass windows) provides efficient and cost-effective winter warming (Etzion and Erell 2000).

Thus the use of fossil fuels for cooling, and of fossil or biomass fuels for warming, can be much lower in driest dryland cities than elsewhere. Furthermore, fossil fuels can be nearly completely replaced by solar energy-generated power (Faiman 1998) due to the high year-round intense solar radiation coupled with the low overcast of many drylands. Given the potential (though rarely realized) advantages of living in dryland cities and their relatively low impact on dryland services, a policy of encouraging urban livelihoods in appropriately designed and functioning dryland cities could significantly contribute to sustainable dryland management. Dryland tourism may be one such livelihood.

22.3.4.5 Dryland Tourism

Dryland tourism is driven by the increasing affluence, free time, and mobility of a relatively large segment of the global population coupled with the growing craving for uncongested, unpolluted, pastoral, pristine landscapes. Drylands offer many unique scenic, wildlife, biodiversity, historical, cultural, and spiritual services. Hence employment in the tourist industry may become an increasingly important alternative dryland livelihood for both rural and urban dryland people.

Though urban and tourism-related dryland livelihoods are economic on land use, their impact on dryland water resources requires attention. Given the large water demand of dryland agriculture, the per capita water demand of a dryland city is likely to be lower than that of a rural dryland village. However, the tourist industry is a significant consumer of water. Irrespective of dryland urban versus dryland rural development, the growing demand versus the diminishing supply of renewable water in drylands has catalyzed the improvement of technologies for recycling and reuse of wastewater and for water desalination in drylands (NRC 1999). These are also helping to address the water demand incurred by the dryland tourist industry.

22.3.5 Condition and Trends of Dryland Biodiversity

22.3.5.1 Species Endangerment and Extinction in the Drylands

Most available information on species threat status and extinctions is listed by country, and no assessment has been made on overall species status for drylands, let alone for specific dryland subtypes. However, to gain some insight on the situation we selected three relatively large countries (each more than half a million square kilometers in size) that are virtually 100% drylands and are geographically isolated from each other as to minimize species identity: Kazakhstan in Central Asia (semiarid and arid), Mali in north equatorial Africa (arid and hyper-arid), and Botswana in south of equatorial Africa (semiarid and dry subhumid). The combined number of terrestrial threatened and non-threatened vertebrate species for these countries totals 1,593 species (IUCN 2004), occurring over an area of more than 4.5 million square kilometers. Only one species is known to be globally extinct (a mammal in Kazakhstan), and 69 species (4.3%) are threatened (see Table 22.5), which appears to be much lower than global species endangerment (12–53% for different groups; see Chapter 4).

No correlation exists between the species richness of each group and its proportion of threatened species, and it is likely that threat status is more related to body size. The dryland birds and mammals of these countries are more prone to extinction than amphibians and reptiles are, and though there are many more bird than mammal species, the highest proportion of threatened species is among mammals. It is likely that this is because, on average, mammals are larger than other vertebrates, have larger home ranges, and hence are more affected by habitat loss or are subject to greater hunting pressure or persecution by humans.

Analyzing a single country—Israel—by dryland subtype reveals 3% of the desert biome vertebrate and plant species (hyper-arid and arid subtypes combined) are threatened, compared with 7.7% of the Mediterranean biome species (semiarid and dry subhumid subtypes), which suggests that, at least in Israel, threats decline with aridity. These figures also include locally and globally extinct species: five freshwater fish and one amphibian species lost in Israel are globally extinct. Furthermore, 57% of the breeding birds associated with wetlands and inland waters in Israel have become locally extinct or are threatened (compared with only 27% of non-wetland birds) (Nathan et al. 1996). This is in agreement with the global situation, whereby species of freshwater habitats are at greatest risk of extinction (see Chapter 4), and it demonstrates the intense pressures on wetlands in drylands.

22.3.5.2 Conservation of Biodiversity in Drylands

Protected areas occupy 8% of global drylands, which is close to the global average for all systems (10.6%). The fraction of each subtype area within protected areas declines with aridity: 9% of dry subhumid drylands, 8% of the semiarid drylands, and 7% of arid drylands, although the figure for the hyper-arid subtype is the highest at 11%, just above the global average. The high degree of protection provided in the dry subhumid subtype has two explanations. First, greater political attention is focused on the conservation of less-arid areas and, second, due to the high population pressure in dry subhumid areas, there is a greater awareness of conservation needs there. At the same time, the negligible population pressure and low competition for dryland services make hyper-arid drylands ideal for designation of protected areas, which explains the high degree of protection there. Protected areas in drylands are managed for three different reasons: to support biodiversity, to promote the provision of their cultural services, and to promote biodiversity's role in provisioning all other services.

Of the 25 global "biodiversity hotspots"—terrestrial areas where at least 0.5% or 1,500 of the world's 300,000 plant species are endemics and with habitat loss expressed in the decimation of 70% or more of their primary vegetation (Myers et al. 2000)—8 are in drylands. These are the Succulent Karoo and Cape Floristic Province, both in southwestern Africa; the Brazilian Cerrado; Central Chile; the California Floristic Province; the Mediterranean Basin; the Caucasus; and parts of southwest Australia. (Note, however, that most of these hotspots represent the Mediterranean type biome only.) Of the 134 terrestrial "ecoregions" (200 global ecoregions defined by Olson and Dinerstein 1998) identified as priority conservation targets, 24 are within drylands. Almost 30% of the global Centers of Plant Diversity (WWF/IUCN 1994) contain, at least partially, drylands. Using the IUCN Protected Area classification, dryland protected areas that are managed to support biodiversity, and with the highest degree of protection and least access to people, occur mainly in the semiarid drylands and occupy 11.4% of all dryland protected areas.

Table 22.5. Endangerment of Vertebrate Species in Three Dryland Countries. Data for all IUCN categories of endangerment combined. (Data from IUCN 2004)

	All Species		Amphibians	Reptiles	Birds	Mammals
	Total	Threatened	Threatened within Each Group			
	(number)	*(number and percent)*	*(percent)*			
Mali	340	20 (6)	0	1	3	9
Kazakhstan	462	35 (8)	7	4	4	10
Botswana	349	14 (4)	0	0	4	4
Total	**1,593**	**69 (4)**	**2**	**1**	**3**	**8**

In protected areas maintained primarily for the provision of cultural services, human exploitation and occupation are restricted, but visitors are welcome and tourism is encouraged and hence they offer potential economic benefits to local people. In total, these account for 44.7% of all dryland protected areas combined and are most common in the arid subtype. Many of these are national parks or (officially non-protected) private game farms, which provide many of the same cultural services. In many of the national and private parks, especially in Africa, management is geared to maximizing the number of large game species for visitors, which may lead to trampling and overgrazing due to overpopulation of game.

It is increasingly difficult to set aside formally protected areas that largely exclude human populations, especially in dryland countries with high poverty levels. In some regions, historically protected areas have been associated with oppressive political regimes and the exclusion of local inhabitants, where wildlife conservation goals have been put ahead of human needs. This image of protected area use has been challenged over the past decade, especially through increased efforts to promote community-based natural resource management. Protected areas managed for their provisioning services, which allow for controlled exploitation of ecosystem goods, account for 43.9% of dryland protected areas and are most common in the semiarid drylands.

22.4 Drivers of Change

22.4.1 Conceptual Framework of Dryland Drivers: The Desertification Paradigm and Its Counterpart

The overarching change in drylands is land degradation defined as a persistent decrease in provisioning of ecosystem services—also frequently termed desertification, as described earlier. A number of phenomena are tied in through various links, interactions, and feedbacks, which jointly make up the ''desertification paradigm.'' This section assesses the validity of the desertification paradigm by presenting the relevant direct and indirect drivers, including both biophysical and socioeconomic drivers. More-recent research has led to the development of an alternative ''counter-paradigm'' concerning drylands processes; this approach identifies interventions that prevent the occurrence of desertification. Between the two paradigms there is general agreement on the role of the direct biophysical drivers discussed in the next section. Where the common ''desertification paradigm'' and the emerging ''counter-paradigm'' differ is in the proposed role of indirect drivers. This is the subject of the subsequent two sections.

22.4.1.1 Direct Bioclimatic Drivers

The relatively low productivity and low soil moisture content of drylands are often exacerbated by the uni-modal pattern of rainfall, resulting in a long period during which soil moisture falls. Low and infrequent precipitation patterns and radiation-induced evaporation jointly and directly drive a linear sequence of biophysical processes. In this cycle, low soil moisture leads to low plant productivity, poor soil development, and high runoff, resulting in a high susceptibility of drylands to soil erosion.

The same two bioclimatic factors that are drivers of vulnerability to erosion are also drivers of vulnerability to salinization. Low rainfall does not leach the surface salts into deeper soil layers, down below the root zone of plants, hence the dryland topsoil is vulnerable to salinization. These natural conditions make dryland ecosystems vulnerable to land degradation, while both drought and human activities can further exacerbate existing vulnerabilities.

22.4.1.2 The Desertification Paradigm

The desertification paradigm holds that bioclimatic drivers and anthropogenic drivers that traditionally maintain dryland ecosystems in a stable state become drivers of change, pushing the transition from sustainable exploitation of ecosystem goods and services to a new ecosystem state of much lower level of service provision. Extremes of direct bioclimatic drivers, rainfall fluctuations leading to droughts, and extensive, intensive, and frequent fires, when coupled with indirect anthropogenic drivers, jointly become drivers of change that through an intricate chain of processes lead to a downward spiral of productivity ending in irreversible land degradation—that is, desertification.

Human population growth in drylands, which increased 18.5% between 1990 and 2000, has been the highest of any MA system (CIESIN 2004). Increased aspirations for raised standards of living are driving an increase in the exploitation of ecosystem services, often accompanied by an increased use of labor and new technologies. This is expressed as a proliferation of livestock and expansion of agriculture and through the adoption of intensive farming practices. The adverse impacts are further amplified when intensification of human activities coincides with droughts, which temporarily but drastically reduce soil and plant productivity.

Cropland in drylands has lower productivity than ''wetter'' croplands. Farmers attempt to address this through supplements such as additional water, fertilizers, and pesticides. If they cannot afford these, rain-fed dryland croplands are left fallow, but land shortages reduce fallow length, often leaving the land insufficient time to recover. Irrigation increases productivity, maintains vegetation cover, and helps protect soil from erosion. However, dryland irrigation accelerates soil salinization due to the often high salinity of available irrigation water and high evaporation. Salinization in croplands directly affects plant growth, dramatically impairing the provision of the soil's productivity service. Over time, soil erosion and salinization reduce productivity to the point where cropland has to be abandoned. In a similar way, rangelands may be degraded due to overgrazing.

The indirect anthropogenic drivers of change in drylands are diverse and act on several scales. They include demographic drivers, such as local population growth or immigration resulting from regional population growth; economic drivers, such as local and global market trends; and sociopolitical drivers, such as local and regional land tenure policies as well as scientific and technological innovations and transfer. According to the desertification paradigm, these combined drivers intensify pressure on drylands (in areas already in use and ''virgin'' territory) in anticipation of increased provision of ecosystem services. However, this pressure for increased productivity frequently fails and, worse, can lead to decreased productivity.

The impact of reduced land productivity is manifest through reduced income, malnutrition, and poor health, culminating in famine and increased mortality rates. People frequently abandon degraded land in order to avoid this impact and either intensify the use of other intact but lower-quality land or transform more rangeland to cropland, practices that may delay but not avoid further land degradation. Since alternative livelihood opportunities are few, migration from rural to urban areas and transfrontier migration often follows. These migrations often create environmental refugees, a situation that exacerbates poverty and urban sprawl and can bring about internal and transboundary social, ethnic, and political strife. These may encourage foreign intervention, which has the potential for destabilizing local, regional, and even global political and economic systems. This chain of processes driven by anthropogenic drivers of change leads to a downward spiral of productivity loss and increasing poverty.

Furthermore, the paradigm implies that since soil degradation and vegetation degradation are linked to increased aridity as part of a negative feedback loop, desertification is practically irreversible, and its inevitability increases with aridity (Cleaver and Schreiber 1994). And since desertification takes place mainly where agriculture is the major source of local livelihoods, agricultural practices are often blamed for desertification and the associated decline in the provision of ecosystem services and rise of poverty. Finally, the paradigm claims that investments are usually required to make dryland agriculture sustainable, but these are generally in short supply due to poverty. Thus poverty is not only a result of desertification but a cause of it.

22.4.1.3 The Counter-paradigm

According to the counter-paradigm, the drivers, processes, and events described in the desertification paradigm do exist, but the chain of events that leads to desertification and the chain-reaction cycle of reduced ecosystem productivity and poverty are far from inevitable. This section identifies the conceptual weaknesses of the desertification paradigm and presents the counter-paradigm approach.

The "desertification narrative" dates back to the 1920s and 1930s, when concerns about a presumed extension of the Sahara began to be raised and when claims of harmful African farming practices coincided with reports about the American "Dust Bowl" experience (Anderson 1984; Swift 1996). So even before the term "desertification" was coined, the narrative or paradigm already existed (Swift 1996). Although large-scale drought-related famines in drylands are not a new phenomenon (Nicholson 1979), however, there has always been a recovery after each drought rather than the irreversible collapse implied by the desertification paradigm. This suggests that the desertification paradigm does not fully describe what is happening on the ground. In particular, as described in this section, there are problems with the knowledge and understanding of dryland systems that form the basis for the theoretical foundation of the paradigm; the evidence for degradation on which the paradigm builds; and its assumptions about human response to changes in the natural and socioeconomic environment.

22.4.1.3.1 Inherent instability of drylands

The desertification paradigm assumes that natural dryland ecosystems are in a stable state that can be disrupted by population growth induced by overcultivation and overgrazing leading to a degraded condition of the service of primary production. Based on this assumption, measured deviations from a theoretical natural stable state are considered degradation, so human and livestock populations above calculated carrying capacities indicate degradation (Leach et al. 1999).

The notion of this "balance of nature" has been increasingly challenged by twentieth century ecologists, however, and an increasing number of studies in the last two decades have shown that dryland systems exhibit large variability in space and time and that many of them are far better described in terms of non-equilibrium systems (Ellis and Swift 1988; Behnke et al. 1993; Leach et al. 1999). A lot of this work has focused on African savanna systems, but the principles are likely to apply to other dryland regions. The basic premise is that irregular droughts prevent the establishment of a stable equilibrium between plants and livestock (Ellis and Swift 1988). Droughts, disease, and social upheaval have had similar disruptive impacts on many dryland farming systems, introducing elements of non-equilibrium systems there as well. Misinterpreting these systems as in equilibrium leads to an overestimation of land degradation because each (temporary) shift in the balance of vegetation versus human and livestock populations is interpreted as a sign of degradation.

22.4.1.3.2 Problems defining and detecting degradation of an unstable system

Recent remote sensing studies (see Box 22.4), using multiyear analyses of rain-use efficiencies and vegetation indices, have revealed that the widely claimed land degradation in the Sahel may have been a temporary phenomenon caused by the droughts of the 1980s (Nicholson et al. 1998; Prince et al. 1998; Eklundh and Olsson 2003). In contrast, traditional desertification assessments have tended to be simple snapshots in time that have extrapolated observations and measured rates of change linearly into the future. To some extent that may be appropriate for equilibrium systems undergoing a transition, but such linear extrapolations are not justifiable for non-equilibrium systems that undergo continuous change (Niemeijer 1996).

While the understanding of the basic principles of the individual biophysical processes underlying the desertification paradigm is essentially correct, the methods of assessing and quantifying the processes have been problematic. Evidence for degradation has been based on the assessment of vulnerabilities using national, regional, and continental soil surveys and models of carrying capacity, as well as experimental plot studies, expert opinion, and nutrient balance models. While each method is sound in its own right, findings cannot simply be extrapolated in time and space to map out an essentially dynamic and spatially heterogeneous phenomenon such as desertification (Stocking 1987; Mazzucato and Niemeijer 2000b; Scoones 2001). To take just one example, erosion, which is rightfully a major concern in the desertification paradigm, is extremely difficult to measure accurately, let alone to extrapolate to large areas given the high spatial variability of rainfall, geomorphology, and soils in most dryland environments. Due to difficulties in measuring and extrapolating wind and water erosion accurately, landscape-level erosion figures based on plot measurements can lead to overestimation of the actual erosion by a factor of 10 to 100 times (Stocking 1987, 1996; Warren et al. 2001).

22.4.1.3.3 Responses to keep ahead of degradation

The desertification paradigm is grounded in simplistic, mechanistic thinking about human responses to the dryland environment and the processes of desertification. This section presents the crux of the counter-paradigm. An understanding of the dynamism of human responses helps explain why degradation estimates based on carrying capacity concepts of the desertification paradigm can be somewhat misleading.

It is important to note that the paradigm has its root in the environmental sciences (soil science, agronomy, and to a lesser degree forestry) and is strongly influenced by Malthusian thinking on the population-environment nexus. The sciences that deal with human behavior have been largely ignored; as Swift (1999) noted: "Soil science has been brilliantly informed by reductionist physics and chemistry, poorly informed by biology, ecology and geography and largely uninformed by the social sciences." The premise of the desertification paradigm is that land users, in response to their needs, increase pressure on the land in unsustainable ways, leading to decreasing productivity and a downward spiral of poverty and further degradation.

However, there is increasing evidence that these negative feedback loops need not occur. Rather, dryland populations, building on long-term experience with their dynamic environments as well as active innovation, can stay ahead of degradation

BOX 22.4

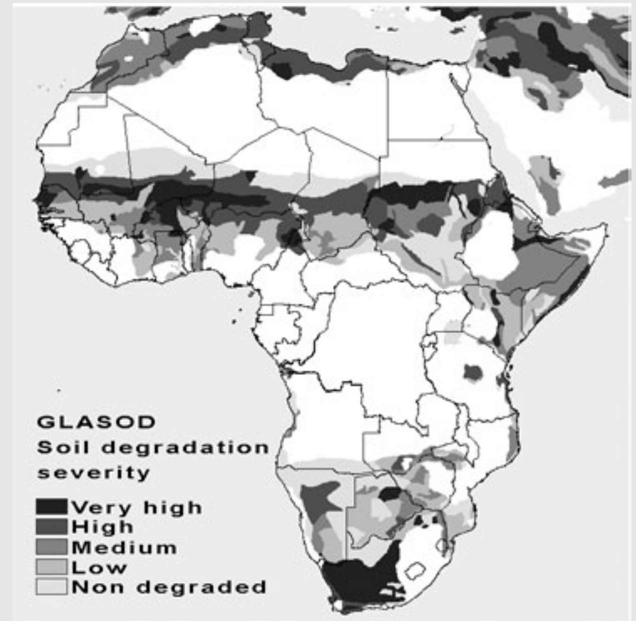
How Much of the Dryland Is Degraded?

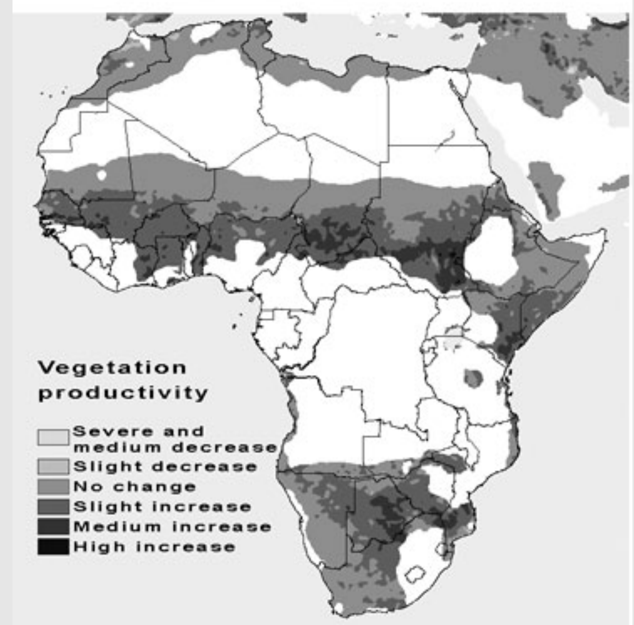
The top Figure shows the severity of soil degradation as it was reported in the late 1980s by experts for the Global Assessment of Soil Degradation (Oldeman et al. 1991). Darker tones indicated more severe land degradation. A band of high to very high soil degradation severity can be seen across the Sahel, as well as similar degradation severity in northern and southern Africa.

The bottom Figure shows a map of the trend in primary production between 1982 and 2000. It was based on temporal analysis of satellite imagery (as described below). Dark tones indicate an increase in vegetation productivity, medium tones a no-change situation, light tones a decrease in productivity over time, and white areas are non-drylands and hyper-arid areas left out of the analysis. This Figure suggests a vegetation recovery since the Sahelian droughts of the 1970s and 1980s. Such a recovery would not be expected in areas of severe soil degradation, because soil degradation reduces the capacity of the soil to absorb and store rainwater, reduces soil nutrients for plant growth, and creates less suitable conditions for seed germination.

It is difficult to reconcile the "greening" of Africa (bottom Figure) in often the very same parts of dryland Africa reported as severely degraded in the 1980s (top Figure). What is more, areas of high degradation in the top Figure do not necessarily coincide with similarly located and shaped areas of decreasing vegetation productivity in the bottom Figure. While these Africa-wide results are preliminary, they are corroborated by more detailed studies for the Sahel region (Nicholson et al. 1998; Prince et al. 1998; Eklundh and Olsson 2003). These results suggest that desertification may be much less pronounced than the GLASOD map suggests, but more detailed analysis of the remote sensing material will be needed, especially in relation to the correlation between rainfall dynamics and vegetation cover response.

Methods: For the bottom Figure, 18 years of continental normalized difference vegetation index data (1982–2000, 1994 excluded) from the NOAA Pathfinder program were analyzed and compiled into a single image. Yearly vegetation productivity (calculated as the sum of NDVI values across the year: iNDVI) was calculated, resulting in a temporal linear regression of productivity over time for each pixel. The result was subsequently smoothed to improve legibility. Hence the image illustrates the general trend in vegetation productivity. Assuming that many areas in the drylands of Africa in the analyzed period experienced an increase in rainfall, some of the slightly darker tones may indicate a no-change situation, and medium-toned areas may indicate a decrease in vegetative response to rainfall. (Nielsen and Adriansen 2005; Nielsen in prep)





by intensifying their agricultural practices and enhancing pastoral mobility in a sustainable way (Prain et al. 1999; Niemeijer and Mazzucato 2002; Mortimore and Harris 2004). In these scenarios, population growth does not lead to degradation and poverty but to a Boserupian-style intensification and improved environmental management. (Esther Boserup (1965) analyzed different trends of technological development of countries and continents over centuries and concluded that population growth provides the impetus for technological change. She found that the increased need for food and land scarcity caused by population growth was commonly countered by an intensified use of technologies in which more labor was used in conjunction with land improvement technologies.)

There is, for example, a mounting body of evidence that in the African Sahel region, once considered the centerpiece of the desertification paradigm, land users are achieving higher productivity by both intensifying and improving their land management practices—capitalizing on improved organization of labor, more extensive soil and water conservation, increased use of mineral fertilizer and manure, and new market opportunities (Scoones 2001; Niemeijer and Mazzucato 2002; Tiffen and Mortimore 2002; Mortimore and Harris 2004).

These studies have shown that yields per hectare and food output per capita and livestock sales are largely determined by policies and market opportunities within the constraints posed by the natural environment. It is also argued that population growth is not the overriding driver of either desertification or sustainable land management, but that the impact of population growth is largely determined by the rate of change and the way in which people adjust to their increasing numbers, mediating the effect on the environment and their own well-being through adaptations of local informal institutions, technological innovations, income diversification, and livelihood options and strategies (Mazzucato and Niemeijer 2002; Mortimore and Harris 2004).

The message of the counter-paradigm is that the interacting direct and indirect drivers combined with the local situation can create a range of different outcomes and that raising a general alarm based on questionable scientific evidence in the end is much less effective than identifying individual problem areas where large influxes of refugees or other complicating factors have led to an unsustainable local response. It is also crucial to distinguish between problems originating from the natural harsh and unpredictable conditions of dryland ecosystems and problems caused by unsustainable management of the environment, since the remedies will often be different.

Figure 22.11 shows the interrelationship between the two paradigms. The desertification paradigm focuses only on the negative interactions (left side of figure), whereas the counter-paradigm allows for both negative (left side of figure) and positive interactions (right side), depending on how humans respond to the direct and indirect biophysical and anthropogenic drivers. The counter-paradigm offers a much more flexible approach in

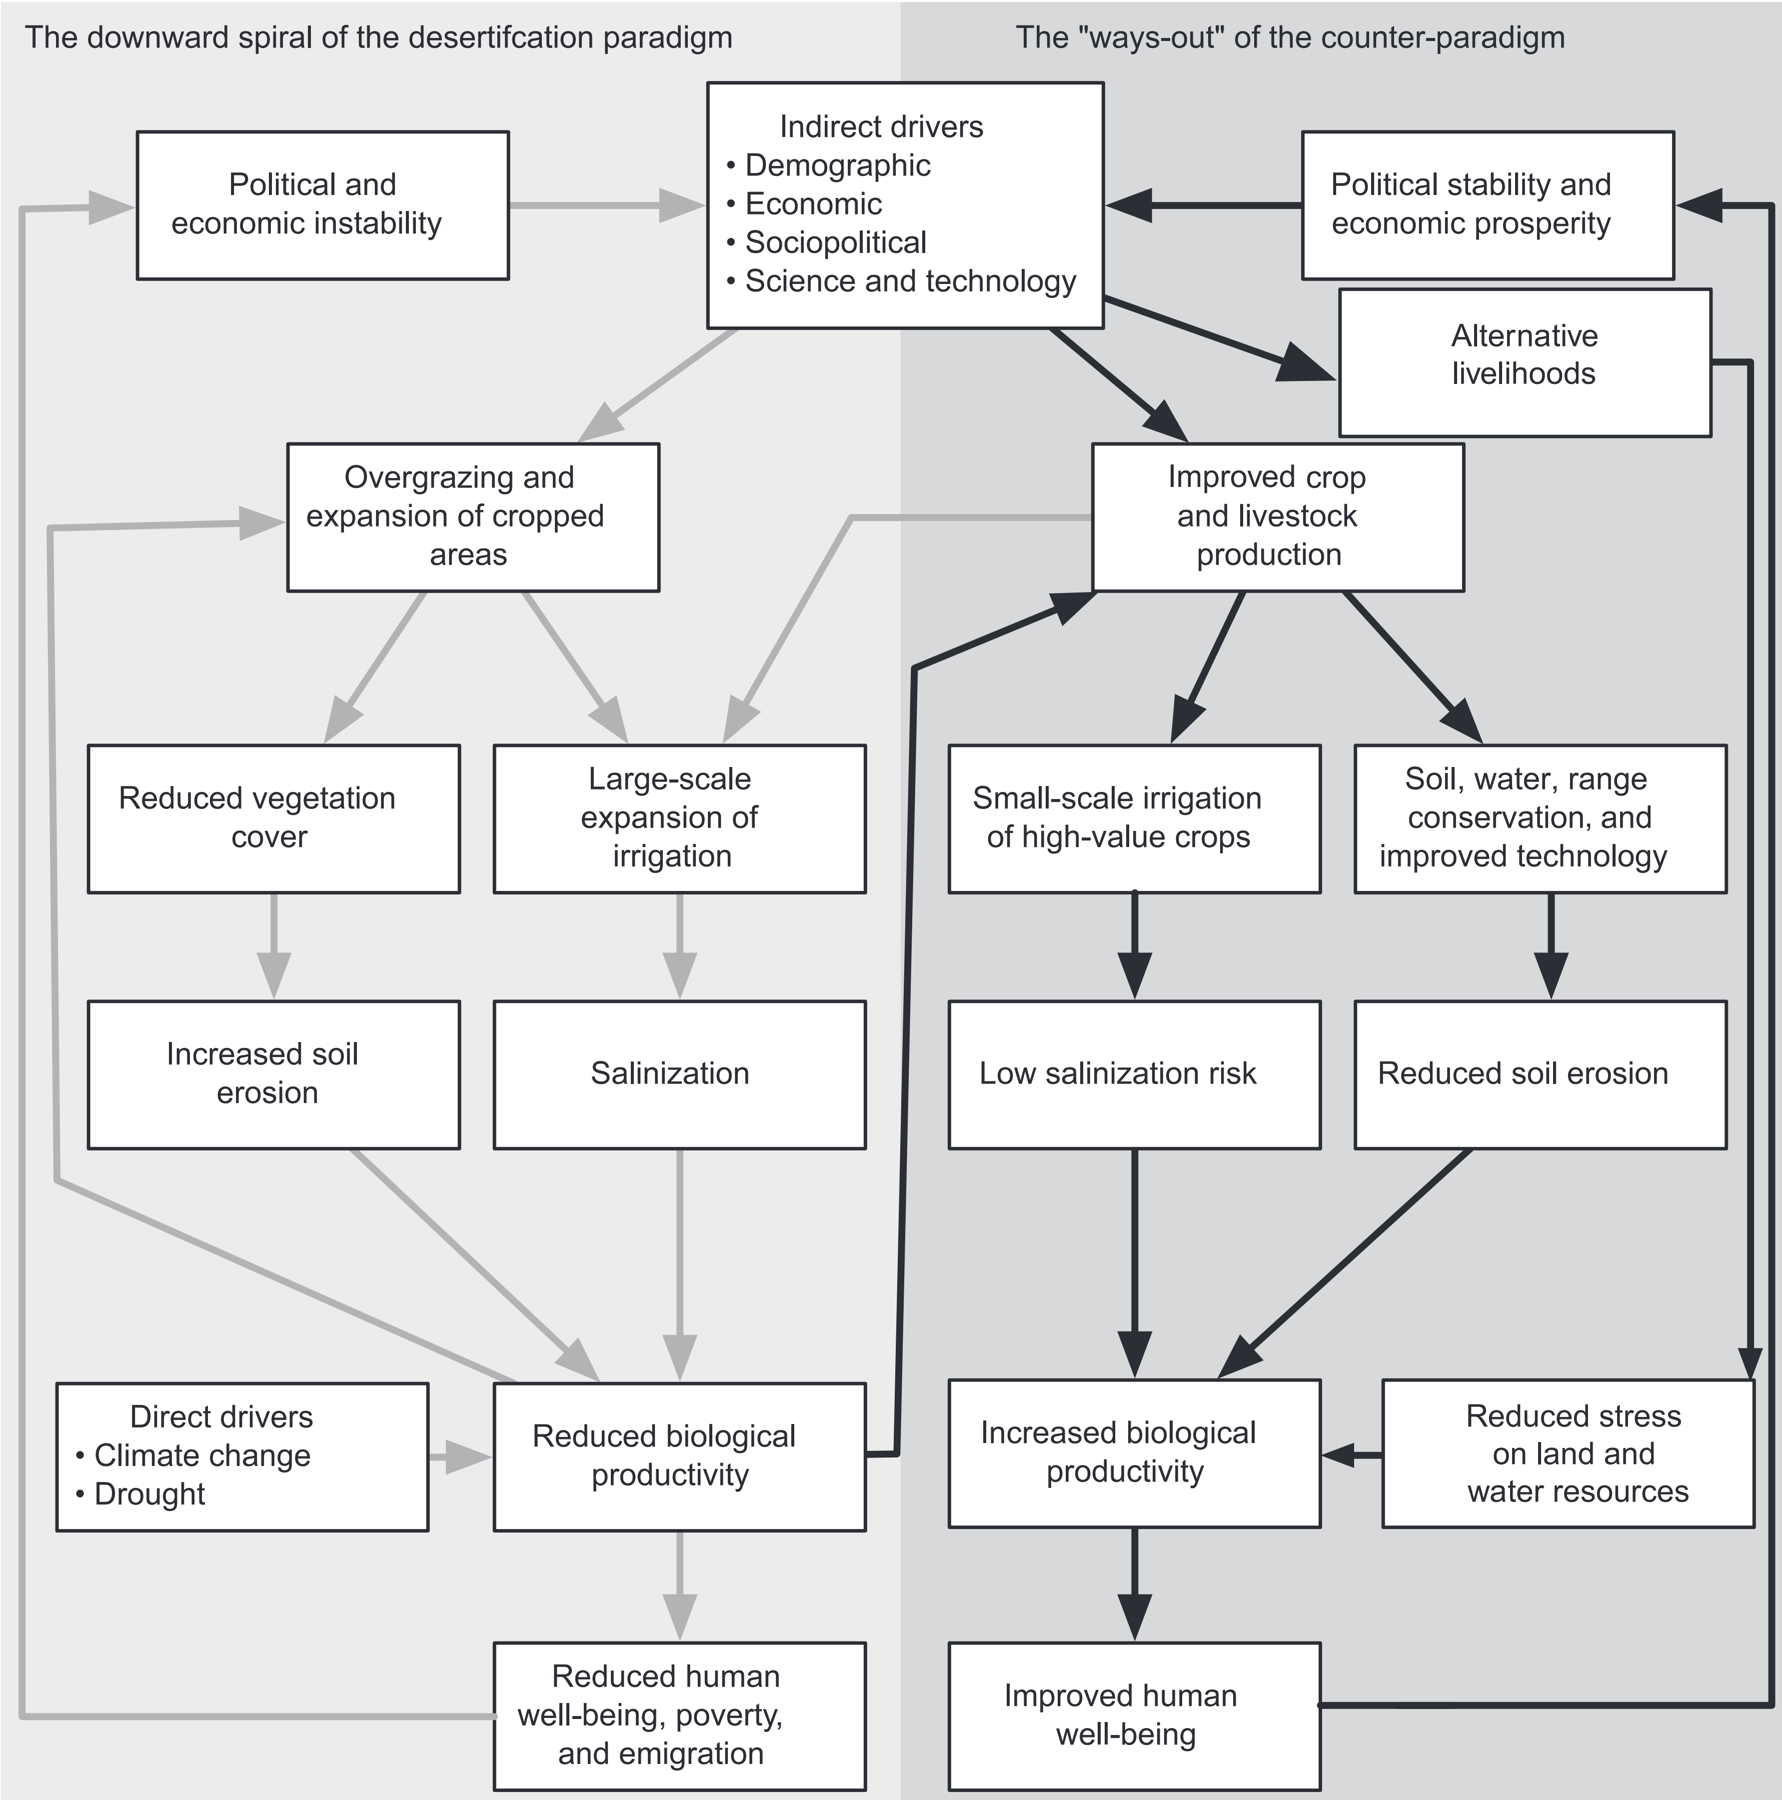


Figure 22.11. Desertification Paradigm and Counter-paradigm. The schematic shows the inter-relationships between the two paradigms: The desertification paradigm focuses only on the negative interactions (left side of figure), leading to a downward spiral of desertification. The right side shows the counter-paradigm, which entails developments that can help avoid or reduce desertification. In the counter-paradigm, land users respond to stresses by improving their agricultural practices on currently used land. Both development pathways occur today in various dryland areas.

that it allows for multiple sustainable development pathways and does not impose a single, intervention-based development model as the only way out.

22.4.2 Socioeconomic and Policy Drivers

22.4.2.1 Policy Drivers—Successes and Failures

Top-down policies with minimal participation of local communities often lead to land degradation, whereas policies encouraging participation and local institutions can induce a sustainable intensification of primary production. For example, a study of eight countries in West Asia and North Africa (Hazell et al. 2002) revealed that past agricultural policies favoring only rich farmers promoted agricultural growth that led to environmental degradation. On the other hand, policies that emphasize risk-reducing strategies, that secure property rights, and that take into account both technical and socioeconomic constraints do ensure adequate incentives for participation in resource management and can thus avoid degradation (Sanders et al. 1996; Pender et al. 2001; Hazell et al. 2002). Community-based land use decision-making and social networks also contribute to the success of non-degrading agriculture in drylands (Mazzucato et al. 2001).

There are also examples for the Boserupian ''induced innovation'' triggered by increasing needs and sustained by the community's investments in agricultural infrastructure, markets, and conservation practices; in the Machakos (dry subhumid Kenya), demand from the nearby growing city of Nairobi since the 1930s has motivated farmers to restore degraded lands by terracing, penning, and feeding livestock; manuring croplands; planting high-value trees; adopting labor-saving plows and new maize varieties; and creating small-scale water harvesting and irrigation structures. In Gombe (semiarid to dry subhumid north-central Nigeria), farmers repeatedly changed their livelihoods base from livestock to sorghum/groundnut, to cotton, and to maize as market access and prices shifted and as fertilizer and new cultivation technologies became available through government programs since the 1940s (Tiffen and Mortimore 2002). In these two cases, market demand increased returns on agricultural production, which stimulated development toward a more labor-intensive system in which labor-intensive soil and water conservation practices paid off through higher yields and better prices at the market.

However, there are other situations where induced innovation has not occurred and higher population has increased pressure on the land, which has not been compensated for by more investment in soil and water conservation measures (Lopez 1998; Kates and Haarmann 1992). A comparison of these successes and failures suggests that critical drivers for successful indigenous dryland rehabilitation include access to technologies that can increase labor and land productivity faster than population growth and access to markets (Pender and Kerr 1998; Pender et al. 2001).

Next to intensification, diversification away from a small list of regular crops or mono-cropping systems provides economic sustainability as well as maintenance of service provision. Trees interspersed with crops provide year-round ground cover and livestock feed, protecting soils from the degradation spiral. A greater diversity of crops also provides a more consistent stream of employment and income to the farm year-round, reducing the incentive for out-migration and hedging against short-term drought risk. Higher-value products provide farmers with the income needed to reinvest in soil nutrient replacement, in turn building soil organic matter. In some areas, such practices have traditionally been an integral part of the system; in other areas, they are currently being stimulated through development interventions.

22.4.2.2 Demographic Drivers

Population is an important driver; however, population growth projections for drylands can be confounded by the impact of socioeconomic and health problems, like HIV/AIDS. For example, in Botswana, which is mostly semiarid and where one in three adults is reported to be HIV-positive, a 20% decline in population is predicted between 2000 and 2050 (UNFPA 2003). This situation could also apply to other dryland countries in Africa. Rapid demographic changes—increases or decreases—make planning resource management more problematic.

Migrating populations can be a source of additional pressure on dryland environments and on resource management when livestock temporarily concentrate at key resources such as water points. Under these circumstances, conflicts over water often arise between nomads and farmers (as in the dry subhumid part of Tanzania) (Mbonile 2005). A transition between migration as a temporary livelihood strategy to permanent migration creates additional pressure on drylands, as described later.

Nomadism can be described as a rangeland management practice that over the centuries has proved to be sustainable and within the carrying capacity of drylands. Sedentarisation of nomads and other policies and infrastructure that promote farming in rangelands at the lower limit of cropping viability can act as drivers of land degradation. The concentration of human and livestock populations in particular areas can reduce the ability of nomads to adjust their socioeconomic activities in the face of stresses such as droughts, and a Convention on Nomadic Pastoralism to protect pastoralists' rights and empower them economically, socially, and politically has been suggested (CENESTA 2002). Sedentarization under the Tribal Grazing Land Policy in Botswana has not yet caused large-scale environmental degradation, but it has reduced the resource base and options for both environmental and societal resilience to natural environmental variability (Thomas et al. 2000). Similarly, in Kenya's semiarid Laikipia District, sedentarization of the previously nomadic population in a dryland wetland placed the people in an escalating human-wildlife conflict (Thenya 2001).

22.4.2.3 Land Tenure Policies

Land tenure practices and policies in drylands can also act as indirect drivers of land degradation. When farmers and herders lose control or long-term security over the land they use, the incentives for maintaining environmentally sustainable practices are lost. Problems of water scarcity, groundwater depletion, sedimentation, and salinity can all be symptoms of deeper policy and institutional failures, including a lack of well-defined, secure, tradable property rights (Ahmad 2000). According to this argument, it is essential that people perceive that they have secure ownership over local natural resources for management to be effective. However, security of tenure need not imply systems of private property rights. For instance, long-established collective and community-based management of village tank systems has been more effective than the current proliferation of privately owned boreholes (Gunnell and Krishnamurthy 2003).

22.4.2.4 Water Policies

Water policies are relevant to many provisioning and supporting services in dryland areas. These policies include allocation systems, pricing, government investments in water resource development, and priorities in conservation measures. Water allocation for irrigation has caused degradation in some dryland areas where flows in semiarid rivers used for irrigation, such as the River Ord in Western Australia, are highly variable and unpredictable. Therefore the proportionate water release strategies have been found to be unsuitable and to cause detrimental effects to the riverine ecosystem (Dupe and Pettit 2002). Irrigation policy decisions also depend on other factors, such as water availability and pricing and anticipated crop prices (Norwood and Dumler 2002).

Increasing water scarcity and degradation of quality are also linked to water sharing between upstream-downstream riparian users (Lundqvist 1999). A frequent policy focus on the aggregate availability of water—more specifically, the ratio between the number of people in a country or region and the amount of water that is naturally available—hides how much of that water can and is withdrawn and used by different people (Lundqvist 1999). Therefore, a shift from the mindset of resource development to one of resource management and conflict resolution is more useful (Shah et al. 2001).

Institutional reforms such as pricing of water have been slow to materialize due in part to strong political interest groups resisting policy changes in the water sector (Ahmad 2000). The National Water Act of South Africa is an example of legislative innovation attempting to address these issues (Kamara and Sally 2003).

22.4.2.5 Governance Approaches

Central or local government investments in infrastructure and accessibility to credit can also influence sustainability or vulnerability of dryland livelihoods as well as determine human well-being in these areas. Large-scale government-driven projects can facilitate the sustainable development of drylands, as seen in developed dryland areas in Israel, California, and Australia. But if inappropriately designed, implemented or managed, they can lead to desertification, as in the Aral Sea region. Around the Mongolian-Chinese borderland, increasing cooperation with the Chinese government through development projects has led to both economic benefits for the Mongol population and to changes and homogenization of land forms, increasing sand dune encroachment and vulnerability (Jiang 2004; Brogaard and Zhao 2002).

The failure of African governments to devolve power to affected people and to link environmental degradation to economic policy has been seen by some as a significant drawback in combating desertification and drought (Darkoh 1998). As a result of these failings, many programs lack local support or are undermined by conflicting trade and agricultural policies pursued by governments.

22.4.2.6 Economic Drivers: Local Markets and Globalization

International, national, and local market dynamics and private and public-sector financial flows are treated as indirect drivers of pastoral and agricultural practices of dryland people, driving either sustainable use of dryland natural resources or desertification. Regarding globalization, the increasing focus on raising production for exports in Ghana (mostly semiarid) and Mexico (more than half of the country arid to dry subhumid), for instance, has led to increasing degradation (Barbier 2000). The negative impacts from increased access to markets challenge the conclusion of Zaal and Oostendorp (2002) that much of the explanation for the successful intensification in the Kenyan Machakos may be attributed to access to enlarged markets.

As far as local markets are concerned, these drive livestock management decisions and determine the effects that land degradation and droughts have on human well-being (Turner and Williams 2002). Local markets for off-farm labor also influence farm-level resources and resource management decisions, particularly regarding the use of fertilizers and land improvements (Lamb 2003; Pender and Kerr 1998).

22.4.3 Biophysical Indirect and Direct Drivers

22.4.3.1 Water Use

Freshwater resources like lakes, rivers, and aquifers are essential to the transition of rangelands to croplands by providing fresh water for irrigation. The intensity of this driver decreases with distance of the dryland from the source. The proximity of fresh water generates interventions in water transportation infrastructure, which accelerate the use of the provisioning services. These interventions can cause a degradation of several dryland services.

22.4.3.2 Global Climate Change

Anthropogenically induced global warming has been detected in the last 50 years (IPCC 2001). Dryland-specific and comprehensive information and predictions for the dryland system are not readily available, but it can be inferred that global warming has driven climate changes that have also affected many drylands. These may include the 0.3% rainfall decrease per decade during the twentieth century between 10° N to 30° N; the 2–4% increase in the frequency of heavy precipitation events in mid-latitudes of the Northern Hemisphere over the latter half of the last century; the more frequent, persistent, and intense warm episodes of the El Niño-Southern Oscillation phenomenon since the mid-1970s; and the increased frequency and intensity of droughts in parts of Asia and Africa in recent decades. These trends are expected to continue, whereas precipitation will either decrease or increase in different regions (IPCC 2001).

The combination of global climate change induced by anthropogenic emissions of greenhouse gases and the fact that carbon dioxide is both the most significant greenhouse gas and an important ingredient for primary production constitutes a potential driver of dryland services. The service of biological productivity, on which so many dryland peoples directly depend, is most sensitive to this combined driver.

The water deficit by which dryland primary production is constrained is caused by low precipitation but also high evaporative demand of the dryland atmosphere, which makes plants lose water each time they open their stomata to let in carbon dioxide, a raw material for primary production. With increased CO_2 concentration in the air, plants shorten the time of stomatal opening, thus reducing water losses, or they maintain transpiration rate but increase overall production, made possible by the increased CO_2 concentration. Furthermore, rainfall may locally increase due to climate change, which too may promote primary production. However, increased temperatures may be above the optimum for dryland plants and may also increase evaporation from soil surfaces, hence reducing soil moisture and even negating possible increases in rainfall. Should plant cover decline, the service of water regulation and hence also primary production will be disrupted. Modeling projects decreases in grain and forage quality in the drylands (IPCC 2001).

Climate change is also likely to drive changes in the water provision service through reduction of water quality and due to increased solubility of minerals with the temperature increase. Since global climate change is expected to increase the intensity of rainstorms, this together with the reduced plant cover will increase the incidence of flashfloods. These increased freshwater flows (Mirza et al. 1998) may offset the water quality degradation but increase soil erosion. Also, the projected higher frequency of dry spells might encourage dryland farmers to increase water withdrawals for irrigation. Since sea level rise induced by global warming will affect coastal drylands through salt-water intrusion into coastal groundwater, the reduced water quality in already overpumped aquifers will further impair primary production of irrigated croplands.

Rangelands will be affected too, by projected changes in grassland/shrubland boundaries due to climate change driving changes in plant community composition (Sala et al. 2000). On the other hand, dryland scrublands and woodlands, used mostly for livestock grazing, will be affected by a greater frequency and extent of fire (Howden et al. 1999). Climate change will also increase habitat fragmentation and thus detrimentally affect dryland biodiversity (Neilson et al. 1998).

Overall, climate change is expected to exacerbate desertification (Schlesinger et al. 1990). Furthermore, it is conceivable that it might amplify the potential negative effects of an existing management regime on the services of interest, increase the risks of land degradation, and raise the cost of intervention and reversal

(Fernandez et al. 2002). However, climate change is expected to have different effects on the various dryland subtypes; Canziani et al. (1998) suggested that since plants and animals of fluctuating environments are better adapted to environmental change, the adaptability of biodiversity to climate change will increase with aridity, since the drier dryland subtypes are also environmentally less stable than the less dry subtypes.

22.4.3.3 Floods

Drylands are characterized by low, unpredictable, and erratic precipitation. The expected annual rainfall typically occurs in a limited number of intensive, highly erosive storms. This produces overland flows that usually develop into violent floods. These floods can be a major driver of soil erosion and soil loss, and the dry spells between storms increase the risk of crop failure. However, these floodwaters can also replenish freshwater resources, deposit fertile minerals and organic debris, and recharge groundwater or the soil profile.

The prevalence of flash floods in drylands typically leads to a number of responses from farmers directed at storage of runoff and flood water, mainly for increasing crops and forage. These include using catchments of up to several hectares (Pacey and Cullis 1986) with or without mechanical or chemical treatment to reduce infiltrability (UNEP 1983); creating micro-catchments of several square meters around a single bush or tree; cultivating wadis that are naturally flooded following rainstorms; spreading the water over extensive tracts to reduce the kinetic energy and enhance infiltration; constructing diversion channels, stone or earth bunds, and even wood bunds to irrigate farmlands of hundreds or even a few thousands hectares; and combinations of several of these techniques (Reij et al. 1988; van Dijk 1995; Niemeijer 1999). Runoff farming is suitable in arid and semiarid areas where direct rainfall is too low for cropping, but in dry subhumid areas it would lead to extensive periods of waterlogging, causing yield reduction. In many of the drier areas floodwaters are also used to recharge wells and fill basins used for drinking water for livestock and humans or for some dry season gardening.

22.4.3.4 Fires

Natural and induced fires are drivers of land cover, soil condition, and biodiversity, especially in the dry subhumid and semiarid dryland subtype. With respect to soil condition, nitrogen and organic carbon are largely lost to the atmosphere or converted to inert forms (charcoal) by fire, while soil erodibility increases for a period after the event. Thus highly recurrent fires can lead to soil degradation.

Historically, land use and management changes have modified the temporal and spatial patterns of fire occurrence and intensity, with strong consequences on soil fertility and the composition of the vegetation it supports. In general, traditional land users maintained a fine-grained spatial pattern of small fires with low on-site recurrence, such as the aboriginal fire management in Australia (Griffin and Friedel, 1984a, 1984b, 1985), which could be extrapolated to other semiarid and dry subhumid dryland.

Dryland fires are often controlled by grazing and browsing of either wild herbivores or livestock. The twentieth-century commercial agricultural and stock breeding systems as well as wildlife management regulations led to widespread fire prevention together with overstocking of rangelands. The outcome has been a new pattern of larger patches of higher-intensity fires, which is claimed to be one of the triggers for grass-shrub transition (Scholes and Hall 1996). World carbon emissions from savanna burning are estimated at 0.87 billion tons of carbon per year (Scholes and Hall 1996). In the northern Mediterranean basin, the burned area has been increasing at an annual rate of 4.7% since 1960 due to vegetation regrowth after agricultural abandonment (Le Houerou 1992).

22.5 Trade-offs, Synergies, and Interventions

This section compares and contrasts the major options available for drylands management. Each category of options is assessed in terms of trade-offs, as far as gains and losses of services with regard to their impact on human well-being; synergies, where one type of management option leads to multiple benefits; and vulnerability (losses greater than gains and no synergies) and sustainability (losses are equal to or smaller than gains).

22.5.1 Traditional Dryland Livelihoods

22.5.1.1 Woodland-Rangeland-Cropland Trade-offs and Synergies

Historically, dryland livelihoods have been based on a flexible combination of hunting, gathering, cropping, animal husbandry, and fishing. Archeological records and anthropological studies have revealed shifts in livelihood strategies over time in the same location and often involving the same cultures. As a consequence, land use changes both in time and space as an adaptation to new economic possibilities, in response to environmental or climatic changes, or as a result of war or drought-induced migration (Robbins 1984; Berry 1993; Niemeijer 1996). Land use changes are thus both responses to changes in the provision of ecosystem goods and services and drivers of changes in this provision.

Population increase drives a growing tension between pastoral rangeland and cultivated land use. This can lead to intercultural conflicts and service degradation as herders and farmers claim access to and use of the same land (van Driel 2001). Depending on annual rainfall, supplemental or full irrigation may be introduced for conversion to cultivated systems, often requiring capital investment by governments or farmers. In the long run, trade-offs between the two land uses can also lead to a tighter cultural and economic integration, with herders cultivating more land, farmers holding more livestock, and an increased exchange of services (Breusers et al. 1998; Mazzucato and Niemeijer 2003).

Woodlands are a source of wild fruits, edible plants, and wildlife that can be important sources of food and off-farm income—vital during years of drought. Woodlands also often have cultural and religious significance for the local population, which protects them to some degree against overexploitation. When woodlands are transformed to croplands, the tree volume decreases. In many traditional systems, however, certain trees and shrubs are not removed because their fruits, leaves, or other products are used for consumption or medication or are traded, as described earlier. The species composition changes and the soil cover decreases following clearance, especially during the dry season, when no crops are grown. The transformation negatively affects regulation and cultural services and reduces biodiversity, but at the same time it increases food production and creates multiple livelihood opportunities.

Woodlands that are increasingly used by livestock (and often managed with fire) may develop into rangelands with a reduced tree cover and increased grass or shrub cover. Over time, the species composition changes as a result of grazing, browsing, and fire (more fire-resistant species become dominant, for instance). For herders, economic productivity increases, but for hunters and gatherers the changes in species composition and the reduced habitat for wildlife negatively affects their livelihood. On a larger scale, the disappearance or transformation of woodlands reduces the service of supporting biodiversity by eliminating corridors for migration and refuge from predation and disturbances.

In semiarid and dry-subhumid areas, different land uses meet and there is the greatest potential for both trade-offs and synergies. Afforestation, silvipastoral, and agropastoral systems develop in response to population growth, environmental changes, and economic and political developments. Natural biodiversity is replaced by agrobiodiversity, where different species and landraces of livestock and crops are introduced. Synergies are found in mixed farming practices, where a single farm household combines livestock rearing and cropping (Slingerland 2000).

Synergies are also found where different households or communities engage in either livestock herding or farming and trade food and services. Such interactions can decrease livestock pressure on rangelands through fodder cultivation and provision of stubble to supplement livestock feed during forage scarcity. At the same time, cultivated systems benefit from manure provided by livestock. Many West African farming systems are based on this kind of integration of pastures and farmland (Prudencio 1993; Steenhuijsen 1995; Mazzucato and Niemeijer 2000a; van Driel 2001). Growing crops in the most fertile areas and grazing livestock on the less fertile land can optimally exploit spatial and temporal variability in service provision.

When used infrequently and controlled, fire plays an important role in the management of most pastoral and cropping systems. Pastoralists use controlled fire to get fresh shoots that are more digestible for their livestock. Farmers use fire to clear new land or old fallows for cultivation and in some cases also to remove the remaining crop residue at the onset of the wet season. In both cases, the use of fire promotes nutrient cycling essential for maintaining the productivity of rangeland and cultivated land. Although fire provides a temporary boost to the provisioning services, carbon and nitrogen are lost to the atmosphere, and the excessive and improper use of fire can also lead to land degradation.

22.5.1.2 Use of Water Resource for Cultivated Drylands

The relative scarcity of dryland water dictates trade-offs in land use and often creates competition and conflicts between different riparian users, as well as upstream-downstream conflicts. For example, dryland-crossing rivers provide drinking water, irrigation, and navigational uses for multiple countries. Water abstracted for irrigation often conflicts with the downstream needs of wetland areas of coastal or inland deltas. On a more local scale, farmers and pastoralists may compete for use of water between irrigation and livestock use. These competitive uses of water resources pose political, economic, and ecological conflicts and trade-offs that sometimes go back to ancient time.

Effective water harvesting and water conservation practices reduce runoff and erosion and increase crop performance, but they also reduce downstream water supply. This reduction in runoff and erosion generally reduces flooding and siltation of fields and water ways. More significant trade-offs need to be considered when runoff farming and water harvesting include intentional clearing of the catchment areas, by removing vegetation and sometimes using artificial coatings to seal the soil. This helps increase the amount of runoff that can be harvested from the catchment, thereby increasing water availability in the run-on area for crop production or livestock watering. However it leads to a loss of ecosystem services for the catchment area itself. Such catchment clearing is labor-intensive and not common in traditional runoff farming and soil and water conservation practices, except in the arid and hyper-arid regions (Pacey and Cullis 1986; Reij et al. 1996; Bruins et al. 1987).

22.5.2 Drylands and Other Systems

Six MA-defined systems overlap with the dryland system, some of which overlap with each other. Cultivated systems (44% of dryland area), inland water systems (rivers and wetlands, 28%), coastal systems (9%), mountain systems (32%), forests (12%), and urban systems (2%) are all embedded in drylands. These systems generate services for the drylands in which they are embedded, and often feedback loops and even synergies develop between the drylands and the systems embedded in them. The trade-offs and synergies between cultivated systems in drylands and other land uses are discussed in previous sections. The linkages of dryland systems with coastal and mountain systems are important and are discussed in the related chapters. Inland waters and urban systems are assessed in this section.

22.5.2.1 Inland Waters and Wetlands

Inland water systems—rivers, canals, lakes, and wetlands—are an integral component of the dryland system and relate to provision of many services, including freshwater provision and supporting biodiversity. Rivers in drylands often feed dryland freshwater lakes (such as the Aral Sea and Lake Chad), landlocked salty lakes (the Dead Sea and Salt Lake in Utah), or end up in dryland deltaic (such as the Mesopotamian marshlands) or landlocked marshes (the Okavango, for example). There is a major trade-off and potential for conflict here: increasing abstraction of water from rivers is essential for agricultural production but it reduces the quantity and quality of water reaching lakes and marshes, leading to reduction in surface area and increase in water salinity.

For example, the Aral Sea lost about 60% of its 68,000 square kilometers between 1960 and 1998, a figure expected to rise to about 70% by 2010, and its salinity increased from 10 to 45 grams per liter (DFD 1996). This resulted in the total collapse of the 44,000 annual tonnage of the lake-based fishing industry and in wind transport of the salt and pesticide-laden soil particles to other parts of the Aral Sea basin, with severe health effects on the population (DFD 1996).

The large-scale abstraction of water for irrigation is directly expressed in shrinkage of wetlands; for example, the Mesopotamian marshlands lost 89% of 20,000 square kilometers between 1970 and 2000, which also affected fisheries of the Persian Gulf (UNEP 2001). Similarly, Lake Chad lost 95% of its 25,000-square-kilometer area from 1963 to 1997 due to irrigation appropriation and climate (USAID/FEWS 1997; ITAP 2003). Such changes could have a significant impact on the 180 fish species in Lake Chad, which are the second most important source of household income in the Nigerian drylands (Sarch and Birkett 2000).

Water abstraction also affects the provision of other services of dryland wetlands, including nutrient cycling, primary production, soil formation away from wetlands, provision of food (both animal and wild food plants) (Brouwer and Mullié 1994), provision of fuelwood and biochemicals, climate regulation through evaporative cooling, and removal of several pollutants from water. Many dryland wetlands are critical for survival of cross-desert migratory birds. Wetlands also provide cultural services (spiritual services and tourism, for instance, as described earlier).

22.5.2.2 Urban Systems

The proportion of the global population living in urban areas is expected to increase following a historical trend, with the urban fraction increasing to around 52% by 2010 (see Chapter 27) and to 60% by 2030 (UN 2002). This projection implies that nearly all the population growth over the next three decades will occur in urban areas. Such growth has consequences for drylands, depending on whether it is undertaken with proper planning and provision of services, infrastructure, and facilities. In hyper-arid drylands, a much larger fraction of the population is urbanized. (See Figure 22.12.) This may be a result of concentration of livelihood opportunities and better living conditions in otherwise harsh settings (CIESIN 2004). Overall urban population density increases with decreasing aridity, accompanied by a decreasing per capita income (expressed by GNP, calculated as dollars per capita). Such correlations with aridity can be linked to the reduction of provision of services with increasing aridity. On the other hand, the ''ecological footprint'' or impacts of dryland urban centers on adjoining rangelands and cultivated systems cannot yet be assessed.

22.5.2.3 Systems Away from Drylands—Dryland Dust

Drylands also affect non-dryland areas, indirectly at the sociopolitical level (through environmental refugees, for example, or immigration), and in various direct ways, such as the dust particles carried by winds from the drylands. Dust from the Gobi desert is carried to the Pacific coasts of America, and Saharan dust is carried to the Caribbean islands (Prospero and Nees 1986) and the Amazon basin (Swap et al. 1992). Chemical contaminants and bacterial and fungal spores adhere to the surface of these dust particles, which can be hazardous to people and are suspected to have already affected organisms of the Caribbean coral reefs (Smith et al. 1996). It is hypothesized that this and other recently emerging coral reef degradation episodes are coincidental with the desertification-driven increased frequencies of Saharan dust storms (Shinn et al. 2000).

22.5.3 Climate Change and Carbon Sequestration

During the last century, global drylands have experienced anthropogenically induced climate changes that are predicted to continue and even to accelerate during the present century, as noted earlier. Drylands ecosystems contribute carbon emissions to the atmosphere (0.23–0.29 billion tons of carbon a year) as a result of desertification and related vegetation destruction, through increased soil erosion and a reduced carbon sink (Lal 2001b). This latter effect is expected to intensify with climate change, but if they are properly managed, dryland systems have the potential to function as a carbon sink.

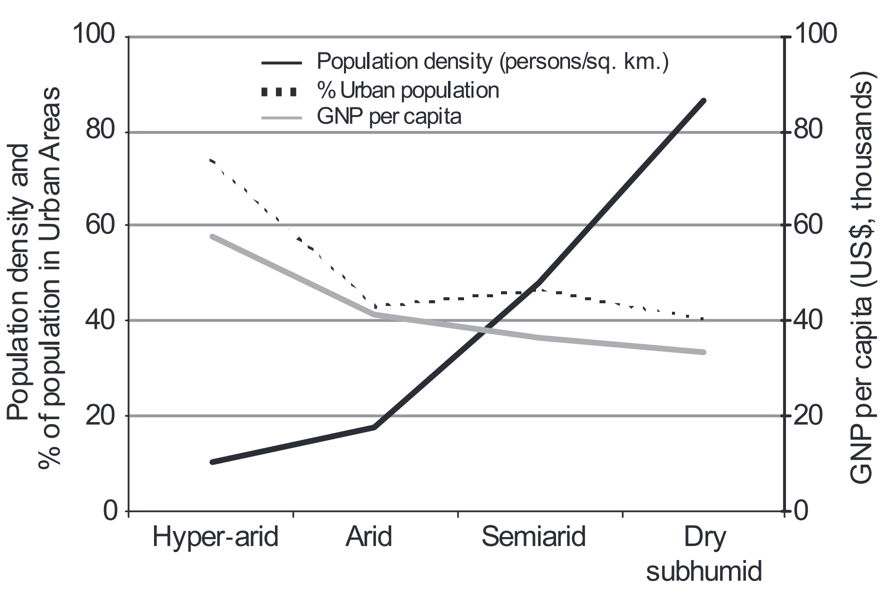

Figure 22.12. Impacts of Urbanization and Population Density on Income Levels in Drylands (CIESIN 2004)

Lal (2001b) estimated the potential of dryland ecosystems to sequester up to 0.4–0.6 billion tons of carbon a year if eroded and degraded dryland soils were restored and their further degradation were arrested. Furthermore, Lal also pointed out that through active ecosystem management, such as reclamation of saline soils and formation of secondary carbonates, carbon sequestration can be further enhanced. This will add sequestration of 0.5–1.3 billion tons of carbon a year; similar magnitudes of potential carbon sink capacity of dryland ecosystems have been estimated by Squires et al. (1995) on a global scale. This restoration and enhancement of dryland condition, if undertaken at a global scale, could have a major impact on the global climate change patterns.

A significant change in the direction of national and local policies would be needed to implement such restoration and enhancement in the carbon sequestration service. Knowledge gaps also need to be filled by collecting information on credible rates of the extent and severity of soil degradation at different spatial scales; biotic and soil carbon pools and fluxes; the impact of land use changes and desertification on the carbon sequestration dynamics; and the cost-benefit ratio of soil improvement and carbon sequestration practices for small landholders and subsistence farmers in dryland ecosystems.

However, there are also numerous hidden costs of enhanced soil carbon sequestration that must be considered (Schlesinger 1999). Such enhancements require the addition of mineral or organic fertilizer (especially nitrogen and phosphorus) and water, which would need significant capital investment. An incentive to further enhance the natural condition of the service even with the costs involved and at the expense of other services is that drylands can be instrumental in counter balancing the increased anthropogenic emissions of carbon dioxide to the atmosphere. In the context of the Clean Development Mechanism proposed by the Kyoto Protocol, developing countries can attract investments from industrial countries and multinational industries. Such projects are expected to generate income through emerging international carbon trading (World Bank 2003a, 2003b), which may offset the expenses. The long-term impact of such projects in developing countries depends on the future of the Kyoto Protocol and the Clean Development Mechanism.

22.6 Human Well-being in Dryland Systems

22.6.1 Indicators of Human Well-being in Drylands

In general, the human well-being of dryland peoples is lower than that of people in other MA systems (see Chapter 5). Dryland peoples have the highest infant mortality rates, and their economic condition (as expressed by the GNP per capita) is the lowest. (See Figure 22.13.) Though the two factors may be linked, the question remains as to what drives the relative and absolute low human well-being in drylands.

The MA defines human well-being as a composite of the basic materials for a good life, freedom and choice, health, good social relations, and security (MA 2003) and implies that these are directly or indirectly linked to the availability of ecosystem services. One hypothesis is therefore that HWB in drylands is low because the natural rate of provision of ecosystem services is inherently low. Hence, the relatively low rate of water provision not only reduces biological productivity on which most dryland peoples depend, it also restricts people's access to clean drinking water and adequate sanitation, thus worsening their health.

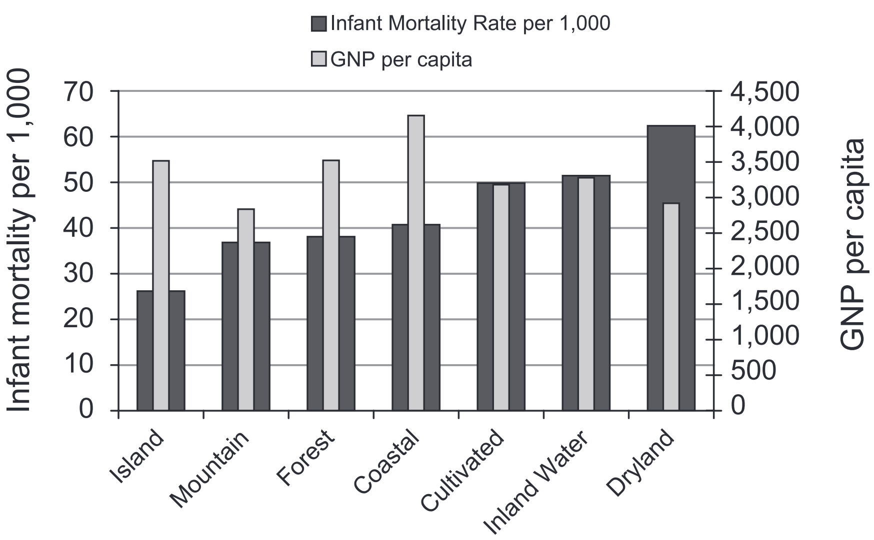

Figure 22.13. Comparison of Infant Mortality Rates and GNP per Capita across the MA Systems in Asia (CIESIN 2004)

Another hypothesis is that land degradation in drylands further reduces the natural rate of service provision, which either drives or exacerbates HWB in the drylands. The degree to which these dryland communities are reliant on dryland ecosystems to sustain them (Webb and Harinarayan 1999; Nyariki et al. 2002) and the extent to which their relatively low HWB is linked to services' failure can be assessed by extending the analysis to subtypes of drylands, with the underlying assumption that the level of aridity is associated with the quality of ecosystem services as well as to the level of stress or degradations observed in drylands. (See Figure 22.14.)

This correlation manifests itself when observable well-being indicators are measured. The hunger rate in children under the age of five and infant mortality rates in drylands demonstrate a clear linkage to the level of aridity. It can be argued that semiarid areas are worse off in terms of human well-being as a result of a high degree of sensitivity and high degree of pressure, which also generate the highest degree of land degradation. The region-to-region variability is also significant, with drylands in sub-Saharan Africa and Asia lagging well behind drylands in the rest of the world, whereas the GNP per capita in OECD dryland countries exceeds that of dryland countries in other regions almost by an order of magnitude. This is not surprising, considering that economic performance relates to many other governance and macro- and microeconomic factors. Thus the economic status of dryland societies is not entirely linked to the low availability of basic ecosystem services such as water and biological productivity. This section assesses the contribution of ecosystem services versus socioeconomic factor to components of HWB in the drylands.

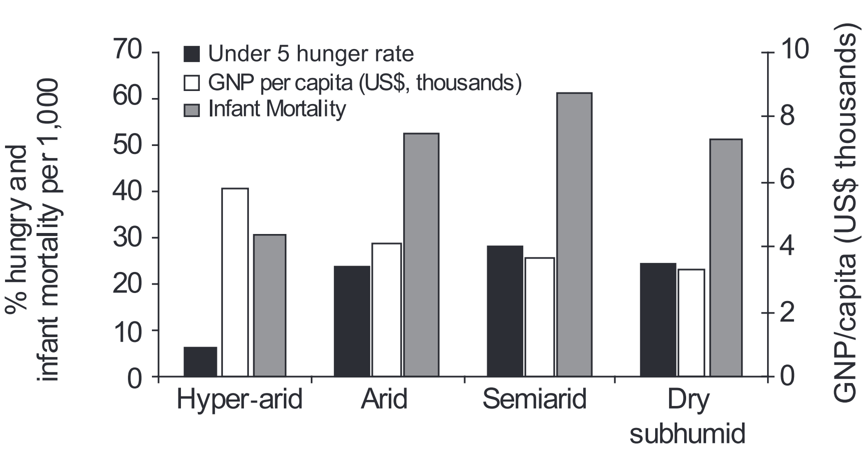

Figure 22.14. Human Well-being Statistics by Dryland Subtypes (OECD countries excluded)

22.6.2 Human Well-being Components in Drylands

The MA conceptual framework (MA 2003) broadly identifies five key components of human well-being.

- *Basic materials for a good life.* The low biological production of drylands, constrained by water, is the ecosystem condition that limits the provision of basic materials for a good standard of living. This also limits the livelihood opportunities in drylands and often leads to practices, such as intensified cultivation, that cannot be serviced due to low and further impaired nutrient cycling and water regulation and provision, requiring adjustments in management practices or the import of nutrients and water provided by services of other ecosystems.
- *Health.* The two key factors contributing to poor health in drylands are malnutrition and limited access to clean drinking water, again reflecting their low biological production and water provision. In Asia, for example, the fraction of children under the age of five facing hunger is 36% in drylands compared with 15% in the forest and woodland system (averaged for the different subtypes of each of these systems) (WHO 2004). However, poor health is also exacerbated by poor health-related infrastructures.
- *Good social relations.* The quality of social relations can be gauged in terms of social strife (wars and political upheavals) and refugees. Environmental refugees leave their homes due to environmental degradation and lack of viable livelihoods. And the sale of stock, wage labor, borrowing of cash for food, and the sale of valuables all precede their migration (Black 2001). Other categories include people displaced for political reasons that may affect the availability of services in drylands to which they have been relocated. Thus demography and sociopolitical drivers, more than the direct condition of ecosystem services, contribute to the quality of social relations.
- *Security.* Food security is an essential element of human well-being in drylands and is related to socioeconomic marginalization, lack of proper infrastructure and social amenities, and often the lack of societal resilience. Climatic events like prolonged droughts and excessive floods also drive insecurity in drylands. But sociopolitical drivers like land tenure practices that relate to sharing and conservation of natural resources or that generate land cover change that may limit traditional pastoral livelihood opportunities can greatly affect food security. Snel and Bot (2002) proposed a list of socioeconomic indicators of land degradation, including indicators to reflect insecurity caused by land degradation. Other security attributes, however, can be only indirectly related to the condition of the ecosystem.
- *Freedom and choice.* Dryland people are not affected just by the unique condition of the ecosystem but are also further restricted by local and global political and economic factors, which can exert major limitations on their freedom and life choices. With the exception of OECD countries, dryland peoples are mostly politically marginalized; that is, their role in political decision-making processes is perceived as being insignificant. Consequently, market factors that determine dryland farmers' decision-making and the effects on their well-being are often critical (Turner and Williams 2002).

This discussion demonstrates that provisioning of ecosystem services is not the only driver of low HWB in drylands. The lack of a strong HWB-service correlation can be attributed to a number of exogenous factors, including political marginality, slow growth of health and education infrastructure, facilities and services, and so on. What needs to be assessed, though, is whether or not there are thresholds in the provision of services that either independently or together with the exogenous factors cause human well-being to drop to a level that crosses the poverty threshold.

22.6.3 The Relative Dependence of Human Well-being on Ecosystems and Socioeconomic Drivers

Natural climatic fluctuations can move the level of service provision to the point of crossing a threshold from a relatively high, stable rate of provision to a lower yet relatively stable state of provision. This can be a temporary transition, but a prolonged drought or overexploitation can exert a persistent impact, resulting in a permanently reduced rate of service provision that does not regain the previous level even when the impact is removed (e.g., Puigdefabregas 1998).

The grassland/scrubland transition is an example of a dryland ecosystem that moves from one relatively stable state with a high provision of forage to a different relatively stable state with a lower provision of forage due to human impact. Even when the impact is removed, the lower-service state persists, as described earlier. Whether such a threshold is associated with a threshold in socioeconomic and political drivers and a resulting significant change in human well-being is not certain. The Sahel drought of the 1980s, for example, produced a devastating reduction in HWB, yet the region reverted to its former state once the prolonged drought terminated. Thus it is likely that the issue of concern is not that of thresholds but of vulnerability to a persistent ecosystem change, coupled with concomitant, resultant, or driving socioeconomic and political changes.

The relative contribution of the condition of the dryland ecosystem and of socioeconomic drivers to poverty attributes—such as per capita rural cereal production, the time spent by household members collecting water and fuelwood, the quantity of annual household consumption that is derived from common lands, the percent of children under five who are underweight, wasted, or stunted, and the percent of the rural population below the poverty line (Shyamsundar 2002)—has not yet been adequately assessed.

22.6.4 Responses to Improve Human Well-being in Drylands

The section explores the response interventions that can mitigate or reverse the effect of degraded ecosystem and service condition on the well-being of dryland people. Experience has shown that locally appropriate interventions can introduce dynamics of sustainability and can improve human well-being by interrupting the vicious circle of poverty leading to overexploitation of services and to environmental degradation and desertification.

Traditionally, dryland societies have been able to cope with their harsh environment through livelihood adaptations over extended periods. A number of commentators have explored the ''failure'' of dryland farmers in sub-Saharan Africa and elsewhere to develop as quickly as farmers in non-dryland regions during the Green Revolution (Singh 2004). Analyses conducted at the smallholder level have concluded that while overall progress has been compromised by widespread insecurity, significant achievements have been made by dryland farmers due to social resilience, the evolution of knowledge over time, and successful farmer adaptation (Bird and Shepherd 2003; Mortimore 2003). These achievements are contrasted with the failures of non-dryland farmers at comparable poverty levels (Mehta and Shah 2003). This section assesses the relative role of traditional practices and modern technologies in building capacities and public participation for improving HWB in the drylands.

22.6.4.1 Traditional Knowledge

Traditional response options combine tested approaches for resource management based on insights into the local natural and socioeconomic environment with continuous experimentation to deal with changes in that environment (Prain et al. 1999). Such approaches have enabled communities to live in the harsh dryland environments for millennia. In oases, for example, traditional management approaches are based on the appropriate usage of the physical and geomorphological factors. These include production and distribution systems for water management, architectures that regulate micro-climate, cultivation of salinity-tolerant fruit species such as the date palm, waste recycling systems, and sand dune stabilization techniques.

Traditional methods of water harvesting allow the replenishment of the resource and its long-term availability. They make effective use of local topographic and soil characteristics. In some cases, horizontal underground tunnels drain water from the surface of the groundwater table. Vertical ventilation shafts augment supplies by capturing night-time humidity. Locally adapted architectural innovations are also used to facilitate water conservation by condensing atmospheric water, including stone heaps, dry walls, little cavities, and depressions in the soil, thus allowing the plants to overcome periods of high drought.

Contrary to the literal implication of the term, however, ''traditional'' knowledge is not static but evolves over time, incorporating elements of local experimentation and integrating new ideas and technologies brought from outside or observed during seasonal or temporary migrations (Mazzucato and Niemeijer 2000b). Local knowledge can significantly contribute to human well-being because it has the benefit of integrating the multiple constraints posed by the natural and social environment in ways that are often lacking with introduced technologies. Where local approaches are failing, it is important to distinguish cases where the technologies themselves are fine but need a more enabling political or socioeconomic environment from those cases where a technological solution is needed in the form of improved local technologies or the introduction of new technologies.

22.6.4.2 Adaptation of New Technologies

The gradual introduction, trial, and development of new technologies have allowed considerable progress to be made in some dryland farming communities (Chapman et al. 1996). The adaptation of new techniques is entirely dependent upon the skill and environmental awareness of dryland farmers (Twomlow et al. 1999). Integration of new technologies with tested management approaches is a measure that can improve human well-being at various levels. Three such examples are:

- Integrated water resource management approaches include consideration of the full extent of water resources available within a catchment. Even in hyper-arid areas, opportunities can often be identified to use additional water sources, such as rainwater, seasonal floodwaters, and wastewaters, to supplement over-reliance on groundwater or variable rainfalls. Cumulative uses of water in a catchment are also considered in order to prevent overuse of water by multiple users over time and the resulting depletion of aquifers.
- Integrated water and farming approaches highlight the importance of considering water management in relation to other factors in the dryland production system. For example, the potential to economically irrigate a crop of turnips to provide

an additional source of nutritional value for lactating dairy cows is considerably affected by sowing dates, soil type, and insect damage (Jacobs et al. 2004).
- Farming systems approaches (e.g., Singh 1998) look into the whole production and farming system for synergies among its components, such as arable cropping, livestock management, alternative land use systems, and management of village commons or degraded lands.

22.6.4.3 Capacity Building and Public Participation

Dynamically evolving local and ''traditional'' practices into which adapted new technologies are integrated have the potential to build capacity for improving HWB in drylands. However, this potential is not always realized. For example, the Indian National Demonstration Programme, which was coupled to training and visiting system (beginning in the 1960s), was unsuccessful in the drylands of India (Singh 1998). This was in contrast to the Green Revolution that occurred elsewhere, with the instant adoption of the technology package over large areas in high-capacity irrigated regions. Singh (1998) concludes that this was because the dryland farmers were less willing to take risks and invest in the new technologies since they were poorer to start with and suffered from water-related constraints and uncertainties in the production process and because the demonstration approach could not convince them that the technologies were appropriate to their needs. Following such experiences, more-recent approaches to capacity development in drylands have adopted a more participatory approach to capacity development, working with farmers as they develop their knowledge, according to their needs and perceptions, rather than demonstrating to them what they could or should do.

Similarly, participatory learning approaches have been used to facilitate the transfer of technologies. In Australia, for example, increasing use is being made of on-farm experiments for capacity development (e.g., Foale et al. 2004; Lawrence et al. 2000). Public participation in resource-use decision-making in drylands is increasingly seen as a key to demand-management for scarce water resources (Kulkarni et al. 2004) and biodiversity conservation (Solh et al. 2003). Participation in dryland decision-making is generally structured according to the prevailing system of land and water rights. For instance, ''community-based'' projects in Sudano-Sahelian West Africa have often attempted to improve resource management by spatially delimiting appropriate land uses, strengthening the community's exclusionary powers, and clarifying specific claims to village resources. However, such moves can also increase social conflicts (Turner 1999). Thus, further experimentation and experience in merging ''traditional'' with advanced knowledge as a tool for capacity building for increasing HWB in the drylands may still be required.

22.6.5 Services, Degradation, and Human Well-being

This chapter is an attempt to present ''drylands'' and ''dryland peoples'' not as homogenous entities but as a continuum of ecosystems and their human inhabitants arranged along a global aridity gradient in which life and livelihoods are constrained by water. The magnitude of this constraint determines the makeup of the suite of services provided by the ecosystems and, accordingly, the land uses by people and their respective livelihoods. The chapter also examines the mutual interactions between ecosystems and people across this gradient and explores the degree to which the services provided by the ecosystems are used sustainably or are overexploited.

The findings are that both sustainable use and overexploitation occur, but they depend more on socioeconomic drivers than on the degree of water constraint and the resulting dimensions and qualities of the provided ecosystem services. Thus the greatest pressure on ecosystem services takes place at intermediate aridity and not, as might be expected, in the least arid drylands where population density is highest, or in the most arid areas, where population is lowest. The high overexploitation of services is inferred by physical, biological, and social phenomena—soil erosion and salinization, reduced biodiversity and biological productivity, and reduced income expressed by reduced human well-being—and it is reflected by the highest rate of infant mortality and hunger among children. It can therefore be suggested that where aridity is intermediate, on average, there is a mismatch between the rate of service provision and the intensity of exploitation. But there are deviations from this average, expressed in sustainable use of the ecosystems.

Two interlinked drivers are involved in generating this sustainability. The first one is a selective use of services depending on their divergent condition in different areas. For example, in areas where the quality and provision of cultural services are high, local people choose livelihoods served by cultural services (such as ecotourism in the African savanna). And in areas where the quality of provisioning services is high, people choose livelihoods served by these services (such as food crops in natural or managed desert oases). The second factor that promotes sustainability is the adaptation of sociocultural institutions and practices to the prevailing natural condition of the services and the implementation of policies that recognize the natural constraints and create economic instruments that provide for sustainability of the use of services, combined with the promotion of good human well-being.

This assessment also highlights the significance of dryland biodiversity as a whole rather than just individual, selected species in the provision of every single dryland service. It is therefore implied that livelihoods and human well-being depend on biodiversity just as they depend on services. Thus in addition to protected areas, most dryland management, land uses, and livelihoods that maintain biodiversity in drylands will contribute significantly to the well-being of dryland peoples. Also, the chapter suggests that some natural attributes of the drylands have the potential, already realized in some places, to provide dryland peoples with a competitive edge economically (through ''alternative livelihoods,'' for example). Together with policies based on sociocultural and socioeconomic considerations, all dryland livelihoods—pastoral, farming, and ''alternative''—can contribute to alleviation of the current high relative poverty and low human-well being of dryland peoples.

Main Messages

The coastal, marine, and inland ecosystems of islands provide valuable regulating, provisioning, and cultural services to more than 500 million people. Many small islands have a strong traditional dependence on marine and coastal biodiversity for their food, tools, industry, medicine, transport, and waste disposal. With increasing human population pressures through high migration and reproductive rates, island systems face several serious issues both in the immediate and the near future.

Islands systems, in spite of size, category, climate, and social conditions, share a commonality, identified here as the ''isola effect.'' This represents the physical seclusion of islands as isolated pieces of land exposed to different kinds of marine and climatic disturbances and with a more limited access to space, products, and services when compared with most continental landmasses. In addition, subjective issues such as the perceptions and attitudes of islanders themselves on their conditions and their future on the island are incorporated into the ''isola effect.''

Coastal fisheries, a particularly important and traditional source of food, protein, and employment on many islands, are seriously depleted. Overfishing has already deprived island communities of subsistence fishing and caused conflicts in many tropical islands across Asia. Island states and their exclusive economic zones comprise 40% of the world's oceans and earn significant foreign exchange from the sale of offshore fishery licenses, but this situation cannot last forever.

Watershed modification on islands has had a negative impact on water resources in terms of water quality and quantity as well as flow regime. Despite limited coverage on some islands, forested watersheds are critical regulators of island hydrology. Without adequate freshwater resources, small islands depend on desalinated or imported water. Island water supply is often threatened by pollution, particularly from poorly treated sewage.

The natural land cover of island systems has changed drastically under the pressure of growing human populations and consequent exploitation of the landmass. On some islands, the impact has exceeded critical thresholds, particularly along the coastal fringe. Anthropogenic changes range from deforestation for cropland to urbanization and the abandonment of degraded land. All these have immediate repercussions on habitat destruction and loss of biodiversity. One conspicuous effect of natural and anthropogenic actions in the coastal zone threatening islands systems is the erosion of soft coastlines (sandy and muddy beaches).

Island systems are highly dependent on outside sources for food, fuel, and even employment, which together increase the economic fragility of many islands. At the same time, island resources are increasingly affected by globalization and trade liberalization. It is questionable whether regional or international groupings of islands, such as the small island developing states, can respond adequately to such pressures.

Energy constraints are particularly critical in island systems. The usually limited size of islands, their constrained capacity to provide ecosystem services (in spite of type or size), and often their distance from large-scale energy supply systems are key factors to explain why energy issues are an important factor in island systems. However, oceans—through currents, tides, waves, and thermal and salinity gradients—offer a source of new renewable forms of energy that remain underexplored.

Low-lying island systems are under threat from climate change and predicted sea level rise. These in turn are expected to have serious consequences on flooding, coastal erosion, water supply, food production, health, tourism, and habitat depletion. The sea level rise would be severe or devastating to millions of people living on low-lying islands and atolls. The projected changes in temperature and rainfall could disrupt terrestrial and marine ecosystems on most islands, especially small ones. Increased flooding and coastal erosion will have serious consequences for the tourism industry. The incidence of dengue fever has been correlated to the Southern Oscillation Index, and extremes in rainfall are likely to exacerbate diarrheal illnesses. Islands need to develop appropriate coastal assessments and management so as to adapt to these changes in a sustainable manner.

The coastal systems of islands, such as coastal forests, dunes, mangroves, coral reefs, and seagrass meadows, are being altered through agriculture, aquaculture, coastal urban sprawl, industrialization, and resort development. In addition, these changes produce further stresses on the island systems, such as the production of sewage, solid waste, and water pollution. These alterations exacerbate the fragility of island systems.

23.1 Introduction

This chapter presents an overview of the status of and trends in island ecosystem services. Its aim is to recognize the services that islands, as a composite of ecosystems, provide to human well-being, to discuss the drivers of change on island systems, and to offer a critical assessment of these drivers in light of the trade-offs between change and ecosystem services.

23.1.1 Overview

Islands differ in their geological and geomorphologic settings and geography, in their physical, biological, climatic, social, political, cultural, and ethnic characteristics, and in their stage of economic development. Yet they share several characteristics that not only unify them as a distinct category but underscore their overall vulnerability in the context of sustainable development (Maul 1993; Leatherman 1997).

As islands and island chains are associated with specific geophysical settings, they are strongly influenced by the surrounding ocean and atmosphere. Their geophysical conditions may result in economic strength for some, but they can pose hazards that threaten the economic viability of others. Some islands are densely populated, and islanders rely on the sea for sustenance and economic viability, but many islands do not have the material or human resources to address the issues that are central to human well-being.

Islands generally have a distinct character or uniqueness, though these component characteristics are difficult to define (Granger 1993). One prevalent idea is that many islands can be defined by their small size and isolation in relation to the mainland, thus justifying a special and differential treatment to small island countries. On the other hand, Srinivasan (1986) has presented an alternate view that ''many of the alleged problems of small economies are either not peculiar to small economies or can be addressed through suitable policy measures'' and that ''causes of economic and social stagnation in some of these economies cannot be attributed to their smallness.''

This chapter addresses the environmental issues relevant to the ecosystem services that fit the technical and legal descriptions pertaining to islands and that are unique to these island systems. This uniqueness is here called the ''isola effect,'' which takes into account the particular physical seclusion of islands as isolated pieces of land exposed to different kinds of marine and climatic disturbances and with a more limited access to space, products, and services when compared with most continental landmasses. In addition, subjective issues such as the perceptions and attitudes of islanders themselves on their conditions and on their future on the island are incorporated into the ''isola effect.''

Some emphasis is placed on small island developing states, as they are most at risk from projected global changes. Like other small islands, SIDS share limited physical size; generally limited natural resources; high susceptibility to climatic changes and natural hazards such as tropical cyclones (hurricanes) and associated storm surges, droughts, tsunamis, and volcanic eruptions; and relatively thin fresh water supplies that are highly sensitive to sea level changes. The vulnerability of islands or island economies can be attributed not only to smallness itself but also to the disproportionate impacts of natural disasters. Smaller island systems tend to have limited fertile soils and an unreliable water supply, and natural hazards can seriously affect their economic base. Ecological constraints such as sea level rise, salinization of coastal aquifers, and changes in rainfall distribution are exacerbated in such systems and are expected to increase with climate change and its anticipated oceanic impacts.

Small island developing states, in particular, experience even more specific challenges and vulnerabilities arising from the interplay of socioeconomic and environmental factors, such as small populations and economies, weak public- and private-sector institutional capacities, remoteness from and dependence on international markets, high cost of transportation, limited diversification in production and exports, export concentration, and income volatility and vulnerability due to exogenous economic shocks, leading to greater volatility than in other countries (Nurse et al. 2001; CBD 2004).

23.1.2 Definitions and Categorization

Islands can be defined and categorized in a number of ways, each useful for some purposes, but no single definition or categorization fits all needs. Most available definitions on islands tend to incorporate the size factor (Granger 1993). Additional threshold criteria include remoteness and morphology, population size, and gross domestic product, but their validity remains questionable.

Islands are usually defined as pieces of land surrounded by water, formally smaller than Greenland, which has 2.2 million square kilometers (Gorman 1979). As such, they can include independent island states, archipelagic states, and islands associated with large countries.

Combinations of area and population have been proposed to define islands, such as 13,000–20,000 square kilometers with fewer than 1.0–1.2 million people. The UNESCO Man and the Biosphere Programme consider ''small islands'' to be 10,000 square kilometers or less in surface area and to have 500,000 or fewer residents (Hess 1990). Additional criteria, including surface area, GNP, and population size, were used to define Pacific island systems as ''small,'' ''very small,'' and ''micro'' (Lillis 1993). The Commonwealth Secretariat uses a threshold of 1.5 million people to define ''smallness,'' which is accepted by UNESCO. Of the developing countries and territories with populations below 1 million, 60 are islands and only 16 are not (UN 2002).

From a biological perspective, many islands are small biotopes, with terrestrial (nonmigratory) fauna that have been sufficiently isolated from continents that there have been little if any movements or genetic exchanges with continental populations, leading to local adaptation and endemism (Rosenzweig 1995; Vicente 1999). For migratory species, however, island landmasses are not difficult to reach, and island ecosystems can provide critical habitat for species that are not genetically unique to that island (such as breeding beaches for marine turtles and stopover sites for migrant birds).

Islands can be categorized by physical aspects such as latitude (tropical, temperate, or Arctic), underlying geology or island structure (continental islands and oceanic islands, with the latter subdivided into volcanic islands and carbonate islands), hydrology (a runoff basin area), altitude (high versus low islands) and habitat (suitable habitats for an organism that are surrounded by unsuitable areas, such as mountaintops, lakes, caves, or host plants), land area, or human population or by some political (such as former colonial affiliation) or economic index (GDP). Islands can also be grouped by sociocultural categories—either at the centre or at the periphery of a culture, an economy, or some other national or regional designation. Human colonization patterns provide another distinction. In the Caribbean, for instance, few of the original peoples remain, whereas the peoples of Pacific have been there for at least 2,000 years.

According to Article 121 of Part VII of the International Convention on the Law of the Sea, an island is a naturally formed piece of land surrounded by water on all sides, emerging above the surface of the sea at the highest tide, capable of sustaining human habitation or economic life on its own, and with dimensions that are smaller than that of a continent.

Conceptually, the MA defines islands as lands isolated by surrounding water and with a high proportion of coast to hinterland. The degree of isolation of an island from the mainland in terms of natural and social aspects leads to the ''isola effect.''

For mapping and statistical purposes, the MA uses the ESRI ArcWorld Country Boundary dataset, which contains nearly 12,000 islands, including islands belonging to the Association of Small Island States and in the Small Island Developing States Network. In this chapter, populated islands with more than 0.15 square kilometers of surface area, up to the size of Greenland, are considered islands. In addition, islands had to be separated from the mainland by at least a distance of 2 kilometers, and only when the isolation or the perceptions of the islanders could be verified.

23.1.3 Insularity

Insularity is a distinguishing feature of islands and is influenced by their size to some extent. For example, islands cannot materially modify their macro-climate because of their size, with the exception of the largest, such as Greenland, New Guinea, Borneo, Sumatra, Hispaniola, Madagascar, and Sri Lanka (Granger 1993). Island systems have highly coupled terrestrial and marine ecosystems due to their large ratios of coastline lengths to land area. In such contexts, the impacts of natural or anthropogenic changes are much more immediately visible than for larger continental systems (Brookfield 1990). Moreover, islands with limited areas have limited capacity to buffer or trade off natural hazards or anthropogenic disturbance.

Although insularity is clearly increased by geographic, socioeconomic, and political isolation (Granger 1993), sociocultural factors are probably more important in defining the insular characteristics of islands. The more powerful the links with the outside world, the less pronounced will be insularity, no matter the size of the island.

The perception that islanders have of themselves can be explored further to refine the uniqueness and peculiarities of islands. Human sciences consider ''islands'' as places where the inhabitants see themselves as islanders. The German Brockhaus Encyclopedia's definition of islands includes not only the conventional idea of a piece of land surrounded by water on all sides, but also the idea that water, and especially the sea, permeates the whole of the island—physically and culturally—and that the island is submitted to some kind of insular marine condition leading to the ''isola effect.''

23.2 Condition and Trends in Island Ecosystem Services

Island systems provide important ecosystem services, such as biodiversity, fisheries, energy, fresh water, vegetation cover, traditional ecological knowledge, and tourism. Insularity leads to an obvious strengthening of the linkages between island ecosystem services and people. Over time, these linkages have been further affected by human pressure, which has contributed to an increase in the vulnerability of island ecosystems and to a reduction of species diversity (Baldacchino 2004).

23.2.1 Island Biodiversity

23.2.1.1 Isolation

Surrounded by water, which functions as a barrier to terrestrial animal and plant dispersion, islands provide a clear example of ecological isolation where biodiversity issues assume critical importance through endemism. (See also Chapter 4.) The size, distance, and period of isolation from large landmasses often culminate in high levels of adaptive specialization and thus high levels of endemism. Isolation, as a by-product of biogeographic insulation, is a key factor of evolutionary change, for it allows the genetic reservoir of a population to become distinct from that of other populations. Island isolation has usually led to a high level of plant and animal specializations associated with high endemism, and this is especially true for small isolated oceanic islands (Whittaker 1998; Dullo et al. 2002).

The very nature of isolation is, however, important to humans and biodiversity, for it is their isolation that has often excluded threatening processes from causing the extinction of many species. For example, the red fox in continental Australia has had a devastating impact on native mammals, yet its absence from many of Australia's offshore islands allows mammals that are endangered or extinct on the adjacent mainland to persist (Algar et al. 2002).

23.2.1.2 Dispersal, Speciation, and Extinction in Islands

The isolation of oceanic islands lends itself to another important phenomenon for nonmigratory species: low or no dispersal. Island species, particularly those on small islands, evolved in competition with a relatively low number of other species under the influence of natural selective forces peculiar to insular conditions (CBD 2004). Therefore, the flora and fauna have reduced competitive ability, small populations, and narrow distributional ranges compared with continental areas (Dullo et al. 2002). This is not necessarily true for continental islands (that is, within the influence of continents or large landmasses), which have a more complete fauna that fills the available habitats and closely resembles that of the adjacent mainland portion of the continent (Gibbons 1990). This is the case, for instance, for recently formed forests in Puerto Rico, which are composed of both native and alien species (Lugo and Helmer 2004).

The difficulties in dispersal and the isolation of populations in small isolated islands is due to the barrier that the sea presents to the dispersal of terrestrial species. The number of species on an island is therefore a consequence of area, the distance from continental landmasses, impoverishment, and in some cases competition with species that have become established earlier. The surface of a given region allows us to predict, with a high level of certainty, the number of present species based on the species-area relationship of MacArthur and Wilson (1967). Nevertheless, other authors, having analyzed the influence of constraints other than area, have found alternative variables that help to explain regional predictions of the number or richness of species for particular taxonomic groups, such as the number of vascular plants, vegetation height, or number of soil types (Case 1975; Dueser and Brown 1980).

Rapid speciation is frequent, and morphological and physiological change and adaptation are inevitable in many insular taxa. Adaptive radiation will proceed to the extent that new niches become available, particularly following disturbance events, such as land clearing. General mechanisms that promote population ''smallness'' (*sensu* Caughley 1994) include local catastrophes such as fire, anthropogenic change, direct or indirect killing, introduced predators and competitors, and introduced diseases. Each of these parameters will affect the biota that has become specialized to an insular ecosystem, increasing the probabilities of extinction. Island ecosystems are especially sensitive to disturbances and vulnerable to extinction, which can occur at rates that often exceed those of continental systems. As such, islands have been sites of concentrated extinction: of the 724 known animal extinctions in the last 400 years, about half were of island species, and at least 90% of bird species that became extinct in that period were island dwellers (CBD 2004).

23.2.1.3 Islands as Biodiversity Hotspots

Since island species tend to be concentrated in small areas, the contribution of islands to biodiversity is out of proportion to their land area, and many of them are considered biodiversity ''hot spots'' in global terms (Mittermeier et al. 1998). Although islands constitute less than 7% of the land surface of the world, one in six of Earth's known plant species occur on oceanic islands (Fisher 2004). In addition, endemism is typically high on islands. For instance, more than 80% of vascular plants of Saint Helena and the Hawaiian Islands are endemic (Rosabal 2004). High altitudinal ranges coupled with aridity (among Mediterranean islands) or tropical climes (among equatorial islands) further encourage endemism.

23.2.1.4 Island Biodiversity and Human Well-being

The health and wealth of island ecosystems and the conservation of biodiversity have important implications for the ecological, social, and economic well-being of island populations. Island systems provide habitats for plant, animal, and microbial species inhabiting both marine and terrestrial environments. Together with geological features, these habitats have particular value due to their high endemism or their absence on nearby mainland areas, making islands important refuges for many species.

Marine and coastal biodiversity still remain essential for many islanders, particularly those living in traditional societies, to meet their daily needs for food, tools, industry, medicine, transport, and waste disposal, in spite of new technologies and lifestyles. This is the case for many of the Pacific islands, including the Marshall Islands, Kiribati, and Tuvalu, which together contain some of the highest coastal biodiversity in the world (UNEP 2004c). Biodiversity is a particularly essential component of food security in small, isolated islands.

23.2.2 Fisheries

For many islands, and especially small oceanic islands and island states, fish provide an almost indispensable source of animal protein. In the Philippines, some 1,500 coastal communities (70% of the population) account for 40–60% of the national fish capture (www.oneocean.org). Traditional methods do not generally deplete the fish stocks. However, modern fishing methods, pollution, and the impacts of natural hazards have meant that the limits of sustainable fishing have been reached on many small islands or areas of larger islands. (See also Chapter 18.)

The small islands of the Pacific, Caribbean, and Indian oceans have narrow coastal shelves surrounded by deep waters. A simple fishing pressure index based on estimates of the number of people actively fishing (according to FAO) per kilometer of coastline suggests that fishing pressure is greatest in the China-Philippines area. (See Figure 23.1 in Appendix A.) Overfishing in the near shore of these islands has led artisanal fishers to venture further offshore for access to pelagic resources such as the large tunas. This has led to encounters and conflict with the already well established industrial factory ships of more industrialized countries or other island states fishing in these waters using longlines or purse seines. These conflicts over marine resources are increasingly being arbitrated through the provisions of the United Nations Convention on the Law of the Sea.

The importance of fisheries can be illustrated by reference to the Caribbean, though there are similarities with other regions. The FAO database shows that in both Central America and the Caribbean, about 500,000 people were actively fishing in the 1990s (or less than 0.1% of a total the population of 145 million), with fish protein contributing about 7% of total protein consumption. The export value of fish and fisheries products increased from $400.6 million in 1976 to $1.6 billion in 2000. Per capita annual consumption of fish in the Caribbean is approximately 15 kilograms, which is approximately three times as much as in the United States.

Consumption in several SIDS in the Caribbean is higher than local production and has to be satisfied by imports. These are very high in the insular states and account for the majority of the fish supplied for human consumption—such as in Haiti (70%), Jamaica (78%), and Martinique (80%). The composition of imports in the small island states is dominated by dried, salted, and smoked fish but fresh, chilled, and frozen products are also imported, mainly by countries with a tourism industry. The FAO database shows that exports of fish from the Caribbean (mostly for the U.S. market) have also been growing steadily and in 2000 were valued at approximately $1.2 billion. Export products are dominated by high-value commodities such as shrimp *Penaeus* sp., spiny lobster (*Panulirus* sp.), tunas (*Thunnus* sp.), snappers (Lutjanidae), and queen conch (*Strombus gigas*), which command premium prices on the international market.

Perhaps one of the most important roles of fisheries is the employment opportunities they offer for thousands of people in a region where the high levels of unemployment continue to be a major concern. The fisheries sector provides stable full-time and part-time direct employment for more than 200,000 people and indirect employment for another approximately 100,000 in the secondary sector (processing and marketing), boat building, net making, and other support industries. In addition, it is estimated that each person in the fisheries industry has five dependents, making the total number of people who depend on fisheries for their livelihood approximately 1.5 million. Those engaged in fishing often have low levels of formal education, limited access to capital, and limited occupational and geographical mobility.

Further information on fisheries can be found in Chapter 18.

23.2.3 Fresh Water

The issue of freshwater resources on islands involves many of the same problems facing developing countries in general, including inadequate human and financial resources. However, islands also have unique physical, demographic, and economic features, including relatively limited surface areas and natural resource bases (arable land, fresh water, mineral resources, conventional energy sources), greater sensitivity to natural disasters (typhoons, hurricanes, cyclones, earthquakes, volcanoes), and an isolation from mainland systems—all of which contribute to the vulnerability of their water resources. These all lead to the impact of the surrounding sea being more pronounced for small islands than for large islands and mainland areas.

23.2.3.1 Physical Conditions

Fresh water is scarce in many small islands, which mainly rely on rainfall harvesting, surface reservoirs and flows, or groundwater lens floating on top of the salt water for the majority of their resources. Severe water shortages are often experienced on atolls and raised limestone islands where there are no rivers. The amount of fresh water available on islands is dependant on rainfall, and this varies according to the geographic location of the island and its climate conditions. Natural events, such as El Niño, can result in a shift of expected rainfall patterns so that islands that normally have abundant rain, such as some of the central Pacific islands, may also experience periods of drought.

Vanuatu, for instance, experienced major droughts in 1978 and 1983; Samoa had the same experience in 1971 and 1989; and Fiji in 1987, 1992, and 1997. The 1987 Fiji drought was one of the worst in a century, beginning in the 1986 dry season and extending through the 1986/87 wet season.

The El Niño event in 1997/98 brought some of the worst droughts on record to the Northern Mariana Islands, Guam, the Marshall Islands, Nauru, Papua New Guinea, Fiji, Tonga, Samoa, and American Samoa. The Marshall Islands received slightly over two inches of rain from January to March 1998, just 8% of the norm. After more than four months of the El Niño–caused drought, the Marshall Islands government declared the country a disaster area. Desalination plants were sent to Majuro and Ebeye, the two main urban centers, while smaller water makers were installed on ships to provide fresh water to the outer islands. From August 1997 to March 1998, the highlands of PNG experienced one of the worst droughts on record, creating a national crisis and the need for an airlift of emergency food and water supplies (Lean 2004).

One of the main natural sources of fresh water on islands and in coastal areas is groundwater reservoirs. Water balance is not easy to determine, and average groundwater recharge normally requires in the region of 20–25% of rainfall, which is not easily retained on islands. Although there are several technologies available, islands cannot expect to develop their groundwater resources easily. Overpumping of groundwater through bore holes can lead to salination problems, which can have serious consequences for food production and human well-being. Also, salination may be enhanced by natural hazards, such as sea level rise, that cause higher penetration of sea water into the freshwater aquifers.

In several SIDS, freshwater shortage is amplified by the lack of effective water delivery systems and waste treatment, coupled with increasing human populations and expanding tourism, both of which may result in the overabstraction of water, contamination through poor sanitation and leaching from solid waste, and the use of pesticides and fertilizers (Bridgewater 2004).

23.2.3.2 Desalination

Desalination of the surrounding seawater to provide a source of fresh water is an option that has been explored by a number of islands, but expensive existing technologies mean this it is still a very costly way of supplementing the freshwater supply. Technology to implement reverse osmosis that leads to seawater desalination is proving a useful alternative to improving freshwater supply (Veza 2001). Ocean thermal energy conversion plants are also being proposed for island states not only to generate energy from thermal gradients but to help with the desalination process. (See Chapter 7 of MA *Policy Responses* for more on desalination).

23.2.3.3 Water Quality

Lack of safe drinking water and sanitation is one of the major causes of disease and death worldwide (WHO 2001). On islands, particularly small islands with rugged interiors (such as islands off the east coast of Peninsular Malaysia), people tend to be concentrated on the more gently sloping lands along a coastline. The resulting high population densities can cause problems for the safety of water supplies, which can easily become polluted by poor sanitation facilities or by facilities that are sited too close to the source. Also, the increased use of pesticides and fertilizers and leaching from solid waste disposal sites pose additional pollution hazards to ground and surface water on many islands. (See also Chapter 15.)

23.2.4 Forestry and Vegetation Cover

The extent of forest cover varies greatly among islands (Dulloo et al. 2002; CBD 2004). The forest cover of SIDS represents less than 1% of the forest area of the world. Insular Africa has 0.006%, insular Asia 4%, insular Caribbean 0.15%, and insular Oceania 0.9% of the total forest surface of the world (FAO 2001). In spite of the relatively small area of forest cover in global terms, some tropical and sub-tropical islands have significant forest cover and are characterized by comparatively short distances between upland and coastal forest areas.

Forest is estimated to cover a total of 75 million hectares, or about 63% of the combined land area of 41 SIDS, compared with the world average of 29.6% (CBD 2004). Under such conditions, island forests are critical regulators of freshwater supply for consumption, irrigation, and industrial uses. Forests also contribute directly to food security through the provision of food and animal products. Also on many tropical islands, mangroves are an important source of fuelwood and household products, provide a nursery for many marine fish and invertebrate species, and protect the coast from erosion.

For many of the larger islands, such as Borneo, forests also contribute significantly to the national economy and to the international trade in wood and non-timber forest products (Wilkie et al. 2002). In addition, forest cover buffers against natural hazards and anthropogenic disturbance. The prevention of erosion by forest cover has a direct impact on the health of coastal and marine systems by reducing the sediment load. Forests also play a buffering role, particularly in small tropical islands, against the impacts of tropical storms, hurricanes, and cyclones combined with high rainfall levels (Wilkie et al. 2002). On Hainan Island, where rubber plantations have replaced the local forests, it has been found that the plantations can still have an important hydrological ecoservice function (Jiang and Wang 2003).

Although the overall rate of island deforestation appears to have slowed down in the last decade, annual deforestation on islands is almost three times the world average rate (0.8% compared with 0.3%) (FAO 1999). The main causes of deforestation include conversion for agricultural use and for infrastructure development such as roads, ports, housing, and tourism development (CBD 2004).

Regarding global biodiversity, loss of forests in island systems often has more serious impacts than forest loss in continents due to intensified interactions of various activities within a limited geographic space and to the loss of endemic species and rare ecosystems (FAO 1999).

23.2.5 Cultural Services

23.2.5.1 Traditional Ecological Knowledge

The term traditional ecological knowledge commonly refers to the knowledge that indigenous peoples have about their environment, which is used to sustain themselves and to maintain their cultural identity. TEK covers a wide range of subjects, from agriculture, fishing, plants, and forests to general aspects of culture. (See Box 23.1 and Chapter 17.) Local cultivators, fishers, and other resource users often have a profound knowledge of the highly varied environments that could be better tapped in assessing the potential use of locally available resources and the sustainable development opportunities of their environments.

TEK is an integral part of the dynamics of island systems and the islanders who live there. For example, Indonesia has strong traditional medicine and many varieties are practiced, the oldest being the *Jamu* system of herbal medicine (Erdelen et al. 1999). Some 10% of Indonesia's total flora is estimated to have a medical value, and some 40 million Indonesians depend directly on biodiversity (Erdelen et al. 1999).

In addition, many stories and beliefs of islanders show the role of traditional villages and communities in improving the marine environment. For example, the Balinese believe in the harmony between God, communities, and nature for coastal management, and the traditional village has many roles, including protecting the coastal region from destruction by outsiders, promoting availability of knowledge to communities, assessing problems caused by populations, and maintaining healthy natural resources for the next generation (sustainable development) (Sudji 2003).

The greatest use of TEK on islands relates to sustainable use and management within customary inshore fishing grounds, for example in Fiji (Veitayaki 2004), in the customary prohibition on the use of resources (*ra'ui*) in Rarotonga in the Cook Islands, and in the village reserves in Samoa in the Pacific (MacKay 2001). Traditional ecological knowledge and customary sea tenure are also integrated into the conservation management of bumphead parrotfish (*Bolbometopon muricatum*) in Roviana Lagoon in the Solomon Islands (Aswani and Hamilton 2004).

TEK has also been of direct benefit in the protection of reefs from adverse impacts from commercial and recreational fisheries, scuba diving, snorkeling, aquarium fish collection, and onshore development (Calamia 1996). It has helped ensure sustainable development of the intertidal zone, with a focus on shellfish gathering and marine tenure in the atoll communities of western Kiribati, Micronesia, which are under pressure from population growth, urbanization, extractive technologies, and expanding market opportunities (Thomas 2001). While it is possible to integrate local and scientific knowledge in fisheries (Mackinson 2001), policy-makers and managers find TEK generally unsystematic and its generally unstructured nature makes its difficult to use in regional and national decision-making.

Traditional ecological knowledge has also served as a foundation for the conservation of trees outside forests in small island states of the Pacific Ocean (Thaman 2002). In addition, the knowledge of traditional agroforestry systems and associated traditional knowledge can serve as basis for addressing deforestation, forest degradation, agro-deforestation, and loss of diversity. In Pagbilao, Philippines, ecological knowledge has been shown to

BOX 23.1

Traditional Knowledge That Is Important to Environmental Management (Unit B5 1998)

Agriculture
- The many different varieties of crop plants and their utilization
- The best places, conditions, and times for planting, caring for, and harvesting crops
- Food storage techniques
- Control of crop sicknesses, insects, and other pests
- Management of agricultural land, both seasonally and from year to year; planting sequences or rotations; periods of fallow to allow the land to recover; techniques for soil improvement
- Control of erosion and wind damage
- Identification or classification of soils
- Water management and irrigation, including complex systems of aqueducts and irrigated terraces
- Controls on land use and access to land

Fishing
- Fishing methods and materials
- Knowledge of fish species and their behavior, migration, and reproduction
- Best fishing locations, times, and techniques for each species
- Controls on fishing: limited access to fishing areas, taboo areas or seasons, catch restrictions
- Changes in fishing resources, effects of overfishing, "how things used to be"

Animals and Hunting
- Behavior of species and hunting or trapping methods
- Controls or limitations on hunting: taboo areas, special times for hunting and restrictions to special occasions or special ranks

Plants and the Forest
- Useful trees and the qualities and uses of their woods
- Techniques for cutting and hauling trees from the forest
- Edible plants and plant parts (nuts, leaves, bark, roots, and so on)
- Medicinal plants and their uses
- Genetic resources, varieties, or special features of plants; loss of varieties
- Changes in the forest, loss of forest cover (where the forest used to be)

General
- Traditional names for and classifications of species and communities
- Calendars related to the weather, to celestial bodies (solar and lunar cycles, appearance or movement of stars), or to association with natural events such as the flowering or fruiting of trees or the migration of birds
- Weather patterns and prediction, cycles of rain and drought, changes in climate
- Natural catastrophes, cyclones, tsunamis, floods; signs and warnings; effects and areas affected
- Changes in the environment, past extent of the forest and agricultural areas, former locations and populations of villages
- Environmental knowledge: who possessed it, how it was used and transmitted

improve economic assessment of the mangroves (Ronnback and Primavera 2000), and in the Marshall Islands and atolls, traditional knowledge of medicinal plants serves as an inexpensive way to maintain human health (Nandwani and Dasilva 2003).

TEK has provided new biological and ecological insights, is useful in resource management and environmental assessment, has been used for protected areas and conservation education, and benefits development agencies by providing a more realistic evaluation of the environment in development planning (Berkes 1993; Calamia 1996).

UNESCO's work on the TEK of islands has emphasized that recording and applying traditional ecological knowledge provides one approach to making more effective use of global biological wealth, particularly as a starting point for strategies of integrated conservation and sustainable development. It also recognized that there may be considerable scope for information on techniques and practices refined over generations in one part of a particular geographical ecological region, to be tested and adapted to other localities.

On some tourist islands, the commercial value of traditional knowledge and cultural property is already well recognized through its contribution to income from tourism, arts, and crafts. However, many islanders are justly concerned about the unauthorized and uncompensated use of their heritage, including the appropriation of indigenous arts and cultural expression, similar to the ongoing appropriation of indigenous biodiversity material or knowledge by industrial-world companies and researchers (so-called biopiracy). They are also concerned about the introduction of "modern" agricultural, fishing, and medicinal practices that threaten to replace traditional ways. Biopiracy has been recorded in areas used for ecotourism, and the Maldives and Pacific Island states have been particularly vulnerable to such thefts (GRAIN and Kalpavriksh 2002). UNESCO has recognized that much of the TEK and cultural knowledge is unrecorded and unexploited, and every year part of this knowledge is lost through the loss of natural habitats and transformation of local cultures. (See also Chapter 17.)

Much of the traditional island cultures and environmental knowledge has already been lost in recent decades. For instance, in Pohnpei information on components of Micronesian life—such as planting taro, the use of plants to stun and capture fish, fermentation methods for breadfruits, and construction of outrigger canoes—has been lost as older generations have died (Lee et al. 2001). Traditional knowledge on canoe making and turtle catching are under the greatest risk of loss (Balick 2003).

23.2.5.2 Tourism

Globally, tourist arrivals increased from 25 million in 1950 to 700 million in 2003 and are expected to double by 2020 (Christ et al. 2003). Despite multiple international crises (economic recession, SARS, terrorist attacks, and the war on terrorism), international tourism has grown 4–5% in the past decade (WTO 2001). Tourism is an important contributor to or dominates the economies of many small island states. (See Table 23.1.) The Caribbean is the most tourism-dependent region in the world and accounts for about 50% of world cruise tourism berths, while the Maldives is the most tourism-dependent country.

Tourism based on the natural environment is a fast-growing component of the tourism industry. In the last decade, nature (or eco-) tourism, which can be defined as travel to unspoiled places to enjoy nature, has emerged as the fastest growing segment of the industry, with an estimated growth rate of 10–30% annually

Table 23.1. Tourist Arrivals and Tourism Expenditures as Share of GNP, 2001 (Scott 2003; WTO 2003)

Country	Tourists	Tourism Expenditure
	(thousand)	*(percent)*
Anguilla	47.9	65.1[a]
Antigua and Barbuda	93.1	43.8
Aruba	691.4	42.7[a]
Bahamas	1,428.2	40.0[b]
Bahrain	2420	8.3[a]
Barbados	507.0	28.8[b]
Bermuda	274.9	23.0[a]
British Virgin Islands	296.0	41.3[c]
Cape Verde	115	4.0[a]
Cayman Islands	334	71.7[c]
Comoros	24[b]	7.0[b]
Cyprus	2697	20.2[b]
Dominica	67.9	20.2[b]
Dominican Republic	2,868.9	14.2

Trinidad and Tobago	383	2.8
United Kingdom	22,833	1.1
Vanuatu	53.2	21.7

[a]1999 [b]2000 [c]1998 [d]1997

(Conservation International 2002). Of the various forms of nature tourism, coastal/marine tourism, including islands, is the largest component. Biodiversity plays a key role in the nature tourism development of many islands and is the major tourism attraction for islands such as Madagascar and Borneo (Christ et al. 2003). Ecotourism extends as far as the subantarctic islands, where special voyages give tourists the experience of a variety of marine and pelagic fauna, using the islands as a base.

There is a great potential in many SIDS for the further development of ecotourism, which is often a small but rapidly growing share of their market economy. Ecotourism can provide employment and generate income while helping to protect and conserve natural resources and contributing to the implementation of national biodiversity action plans (ECOSOC 2004).

Tourism has a great potential for biodiversity conservation and the promotion of the sustainable use of natural resources. In the Seychelles, for instance, tourism has been a major force and source of funding for biodiversity management and conservation, as well as ecosystem rehabilitation. In many cases, tourism is the only means by which a management infrastructure can be put in place on isolated islands to enable conservation activities. Indeed, well-informed tourists are increasingly the driving force behind the tourism industry's involvement in biodiversity management (Chafe 2004).

Rapid and uncontrolled tourism growth can be a major cause of ecosystem degradation and destruction, however, and can lead to the loss of cultural diversity. Often, such destructive development paths start with tourists discovering a destination that rapidly develops beyond its carrying capacity and eventually fails to meet tourism demands and expectations. Such developments have been spontaneous or frequently without adequate enforcement of planning laws and guidelines. Alternatively, tourism can be developed in a more careful, planned manner, with government input and a more responsible approach by developers. Smaller resorts, such as the island resorts in the Maldives (Domroes 2001) and other small tourist enterprises on many islands, have been developed successfully. Large integrated developments, such as Nusa Dua in Bali and Bintan Beach International Resort on Bintan, both in Indonesia, require large investments, depend on large tourist flows, and are more difficult to implement.

Tourism development without proper planning and management standards and guidelines poses a threat to biodiversity (Christ et al. 2003). This is compounded by the fact that environmental impacts are often not clearly visible until their cumulative effects have destroyed or severely degraded the natural resources that attract tourists in the first place, and some destinations have only recognized the costs of environmental damage after significant and often irreversible damage has been done. As a consequence, many SIDS have embarked on initiatives aimed at building a wider, more sustainable support base for the tourism industry among the local population, promoting participatory action and a sense of ownership in order to ensure the success of the industry (ECOSOC 2004). Key measures suggested include ensuring that integrated planning policies and implementation plans provide for environmental impact assessments for all tourism projects and cultural impact assessments for all large tourism operations (ECOSOC 2004).

Within the Caribbean region, fisheries are important not only as a source of food and employment for commercial and subsistence fishers but also for a growing population of recreational fishers—those fishing for pleasure and relaxation rather than for commercial gain or subsistence. Dozens of international, regional, and national fishing tournaments are held each year throughout the region. In most Caribbean countries sport fishing is promoted by tourism interests and is neither monitored nor regulated by the national fisheries administrations. In addition, watching coral reef fishes and other marine life has always been an important leisure activity of thousands of locals and tourists, and skin divers and scuba divers in the Caribbean. Over the past two decades, several countries have established marine parks and aquaria to use these resources and to promote education and conservation of their marine resource systems.

23.3 Drivers of Change in Island Systems

The stresses imposed on island systems are the result of the interplay of environmental and sociocultural factors that together have the potential to increase the impact and reduce the resilience or ability of the islands to cope with changes relative to mainland ecosystems. Like continental populations, people on islands must be able to survive the stochastic variations in their environment. However, natural hazards and anthropogenic disturbance, such as deforestation, unsustainable agricultural practices, mariculture, habitat loss, and biodiversity loss, may assume a disproportionate importance in island systems for several reasons, often depending on the latitude.

For example, some equatorial islands (such as those in the Caribbean) can have rapid rates of vegetation regeneration, as evidenced after cyclones, whereas many arid islands (such as those in the Mediterranean) do not. These differences in responses to change reflect rainfall patterns and the degree of isolation. Contrary to what happens on continents, where species immigration generally occurs rapidly, leading to recolonization, catastrophic events on some islands can have long-term effects because extinction rates are higher and rates of recolonization are much lower (Vitousek et al. 1997; Courchamp et al. 2003). Small populations are also far more prone to random nonadaptive changes in their genetic pool and consequently to chance extinction. The main drivers of island ecosystems are both natural and anthropogenically induced, and both are addressed in this section.

23.3.1 Population Issues

It is estimated that by 2025, 75% of the world's population will live within 60 kilometers of the sea, which can be considered ''the global coastal zone,'' where more than 70% of the world's metropolises are located (UN 2002). A high proportion of this occupancy will be on islands of developing countries. (See also Chapter 19.)

Population growth in cities contributes to urbanization, and this is a serious and growing problem for some islands, particularly among those in Asia, such as Java and Luzon. Many cities on these highly populated islands cannot currently provide the basic resources for the well-being of the inhabitants. Among the Pacific islands, populations are small, but growth and rapid urbanization are also putting pressure on limited resources (Zann et al. 2000)

For many islands in the tropics, the traditional activities of the coastal population have been subsistence production, such as fishing and agriculture. With rising numbers of people moving to coastal areas and islands, conflicts over coastal resources and human values and expectations will increase in the years to come. These are further accelerated by the sociopolitical, cultural, and economic differences between the traditional inhabitants and the newly arrived populations. These differences are more evident among developing countries (where most of the tropical islands occur), which may be subject to huge and rapid internal migrations.

23.3.1.1 Outmigration

Outmigration has been a familiar process for many islands and affects the population balance beyond those related to natural birth and death rates. Outmigration may be due to the impact of outside forces or internal drivers, as when an island's economy is based on a single specialized crop that fails due to disease or market changes. For example, the Asian economic crisis of 1997–98 influenced the extent and nature of population movement between Java and the Outer Islands of Indonesia (Hugo 2000). It may in part be a response to environmental constraints at home and perceived opportunities elsewhere. For instance, migrations from many of the small island states of the South Pacific and the Caribbean have been to metropolitan countries (Connell and Conway 2000).

On many small islands dependent on fisheries, the combination of overfishing and environmental stress has led to outmigration, mainly of young adults. This can alter the size of an island's population, leading to a shift in age groups toward an older society (Hamilton et al. 2004).

However, the benefits of out-migration have also been recorded. One study on the Samoan Islands in the Pacific suggests that out-migration from rural regions generally tends to preserve the local natural environment, leading not only to a more satisfactory use of agricultural and grazing land but also to a greater retention of native species diversity (Baker and Hanna 1986). Yet people who migrate from developing rural societies to urban societies generally suffer a decline in many physical and psychological aspects of health, even though life expectancy may rise.

23.3.1.2 Role of Gender

Gender issues have not been clearly identified as affecting island societies, but this does not mean that islands have no problems related to gender inequality. Indeed, they exist and seem to be related to the same kind of issues that promote gender inequalities in continental societies. Nevertheless, the ''isola effect'' could increase the problems. For example, in some islands matriarchal societies appear to be driven by isolation together with other factors (such as out-migration by males). Gender inequalities are most clearly related to socioeconomic underdevelopment, a common condition of many island populations (Browne 2001; Lewis 1998).

23.3.2 Energy Issues

Although ecosystem services provide low amounts of energy nowadays (wood, biomass, and so on), energy issues are critical for islands, as unanimously recognized at the SIDS conference in Mauritius in January 2005. The availability, constraints, or scarcity of energy sources are important drivers of changes for island ecosystems and human well-being, particularly enhanced under the ''isola effect.'' Some islands have developed around the fossil fuel industry, but in many islands the import bill for fuel alone exceeds earnings from exports (Roper 2005), lowering the capacity of improving human well-being and, consequently, increasing the pressure over natural ecosystems. Also, the potential hazard to islands linked with the operation of power plants not based on renewable sources (fossil fuels and nuclear power), where size is a factor, could outweigh the benefits of these sources to the island's people and ecosystems.

With imported petroleum being the main source of primary commercial energy (ECOSOC 2004), developing further renewable and unconventional energy sources for islands is a key issue. Islands are usually well suited to use combinations of modern renewable energy technologies and energy efficiency due to the availability of renewable energy resources and current energy consumption patterns (Roper 2005). New technologies have been developed (Cavanagh et al. 1993) that harness the energy of the sun, the wind, the earth, and the ocean, and these can be specifically targeted for usage among island systems.

The world's oceans, where islands are interspersed, represent an enormous and virtually untapped source of clean, non-polluting renewable energy (see Table 23.2). Among the facilities that the ocean offers to islanders, renewable sources of energy can be listed at the top, including the capacity of ocean tides, waves, and currents to generate energy and the extraction of power from the thermal gradient of sea water (Penny and Bharatan 1987; Sanders 1991). Technological breakthroughs, standardized plant designs, increased fossil fuel prices, market instabilities, and increased world concern over environmental issues such as climate change will increase the pace at which ocean biomass, wave, tides, the current, and ocean thermal energy conversion systems are tapped.

In a number of SIDS, small-scale solar photovoltaic power systems have been used to provide electricity in rural areas on a pilot scale, but more work on financing and institutional arrangements is needed to realize their full potential. Moreover, there is a need for technology transfer and national and regional capacity building in renewable energy and energy efficiency (ECOSOC 2004).

23.3.3 Invasive Alien Species

A major threat to oceanic island biota today is the increasing breakdown of the insularization of their habitats (Whittaker 1998). Invasive alien species are one of the primary threats to biodiversity on most islands and have caused serious ecological and economic damage and high social costs (e.g., Courchamp et al. 2003; Veitch and Clout 2002). Invasive plant and animal species often outcompete native insular species directly or indirectly for common resources and can alter the ecosystem processes of an island.

Overgrazing by introduced stock, for example, has had an adverse impact on Mediterranean islands because of the aridness of the land. The introduction of the brush-tail possum (*Trichosurus vulpecula*) to New Zealand and its offshore islands has had devastating impacts on forest systems (Atkinson 1992). Sub-Antarctic Macquarie Island, 1,500 kilometers south of Australia, has seen a host of exotic species (particularly cats, rats, rabbits, and mice) introduced either directly or indirectly by sealers (Cumpston 1968), and the impacts of these species on endemic birds and flora has been significant (Taylor 1979; Copson and Whinam 1998). Another example of the impact of invasive species is the introduction of the brown snake (*Bioga irregularis*) into the formerly snake-free island of Guam in the 1940s. This led to the loss of 10–13 species of native forest birds and several lizard species, and power outages occur frequently as the snakes contact electrical lines and generation facilities. The cost to the island's economy from the establishment of this single invasive alien species is estimated at $5 million a year (Fritts 2002).

Table 23.2. Potential Energy Outcomes from Ocean Sources (POEMS 2004)

Resource	Power *(terawatts)*	Energy Density[a] *(meters)*
Ocean currents	0.05	0.05
Ocean waves	2.7	1.5
Tides	.03	10
Thermal gradient	2.0	210
Salinity gradient	2.6	240

[a] Expressed as proportional to the length of the water column.

The invasion of exotic species onto islands is a worldwide phenomenon, but it is uncertain whether islands are more susceptible to invasion than mainland sites (e.g. Sol 2000). The level of invasion depends on how and to what degree the native biotic community is disrupted and on the resilience of an island's ecosystems. In theory, the ecological impacts of invasive alien species on islands can occur in the same manner as on mainland ecosystems. However, these impacts are usually more rapid and more pronounced on islands due to their vulnerabilities (CBD 2004). Approximately 80% of documented introductions (planned or unplanned) of birds and mammals have been to islands (Ebenhard 1988). The effects of such introductions have often been so devastating on the native flora and fauna that it is claimed that invasive alien species are among the main environmental hazards to island systems (Vitousek et al. 1997) and have an ability to create an ecological homogenization of the island's ecosystem in addition to influencing other agents of global change (Mack et al. 2000).

Diseases and their impact on native flora and fauna have often been associated with recent island invasions, yet they remain understudied in insular environments. Avian malaria, introduced into Hawaii in exotic birds by settlers, spread through the endemic bird populations following the introduction of the southern house mosquito (*Culex quinquefasciatus*), which acted as vectors for the waterborne parasite (Van Riper et al. 1986). Similarly, the invasion of black rats (*Rattus rattus*) onto Christmas Island is believed to be responsible for the extinction of the bulldog rat *R. nativitatis* (Day 1981). The speed of introduction and spread is increasing. On the Galapagos Islands, the number of introduced plants has doubled since 1990 from 240 species to 483, now representing 45% of the total flora. In Hawaii, naturalized species account for about 47% of the flowering plant flora (CBD 2004).

There is a realization that invasions of alien species can sometimes be managed with adequate human intervention through good planning, adequate techniques, and sustained effort (Clout and Veitch 2002). However, the feasibility of eradications of invasive aliens on islands will depend on the size of the island, available resources, the public will to undertake control programs and ensure effective quarantine, and the secondary effects of the eradication action on non-target species and other benign alien species on the island. For example, ecological release may allow one alien species to become invasive following the removal of another invasive species, with no net benefit to native populations (Zavaleta 2002).

Three main issues have been identified that can help assess whether islands are subject to a higher risk of invasion than mainland areas: the opportunities for exotic species to reach islands, whether exotic species are more likely to establish on islands, and whether exotic species have a greater impact on island systems (D'Antonio and Dudley 1995). An analysis of those criteria suggests that some island systems are more likely to be invaded by alien species than similar mainland systems because there are fewer resources to deal with risk management (D'Antonio and Dudley 1995). However, it has also been argued that not all islands show evidence of higher invasion than mainland sites (Sol 2000).

Response measures needed to prevent and minimize the impacts of invasive alien species are generally known, though many island nations and territories lack material or human resources to prevent the introduction of or to control or eradicate alien species that threaten ecosystems, habitats, or other species (Veitch and

Clout 2002). The key to quarantine of invasive species is to use early detection mechanisms together with rapid-response mechanisms that can be managed with sufficient funds and powers to see eradication campaigns through to completion (Simberloff 2000).

23.3.4 Habitat Loss, Pollution, and Land Degradation

Island biodiversity has unique biological characteristics, since isolated islands provide ideal conditions for the development of new species with specialized traits. Habitat loss, through pollution, land clearing, and natural hazards, is clearly associated with biodiversity loss, expressed either as population declines or species extinctions.

Chemicals imported for agriculture, industry, transportation, health services, and households are a growing source of pollution among populated islands. Poorly treated sewage emptying into coastal areas is the major chronic pollutant and contributes to coastal nitrogen and phosphorus eutrophication and harmful algal blooms. On islands, the cumulative impact of household runoff from baths and sinks that eventually drains into the sea is also a major contributor to ecosystem decline but is frequently overlooked. This condition occurs because most people living within the coastal zone and the majority of the hinterland population in most island developing states are not connected to centralized sewage treatment facilities. A complementary problem is widespread bacteriological contamination of groundwater from soak-a-way septic systems. Added to this severe nutrient and bacterial pollutant load in coastal areas and groundwater is the addition of fertilizers and pesticides from industrial and agricultural activities.

Due to the short-term nature of the numerous pollution studies carried out on islands, it is difficult to assess the overall pollution condition or trend. However, a proxy indicator may be used, such as a simple sewage pollution index based on the number of people without access to safe sanitation per kilometer of coastline (equivalent to the density of a population living within 100 kilometers of the coast without access to safe sanitation divided by the length of coast).

Because of the complexity of initial attempts to use topography to define the extent of the coastal zone, this study assessed the level of direct human modification of the coastal zone by examining the population within 100 kilometers of the coast. The estimate was derived for the World Resources Institute using a spatially explicit database reflecting global human population (CIESIN et al. 2000). Figure 23.2 (in Appendix A) suggests that coastal sewage pollution is a ubiquitous problem around the world except for industrial countries in North America, Australia, and Europe. Regionally, the Philippines, Latin American, Caribbean, and African and Asian islands stand out as having significant problems.

Although the deleterious effects of pollution are generally recognized, the focus of attention is usually on the immediate aesthetic affects of very visible pollutants, such as garbage and oil spills, or on the human health effects of bathing in contaminated marine waters rather than the long-term deleterious effects of the decline in the ability of an ecosystem to sustainably provide services such as fish or coastal protection. Yet in the long term it is the chronic rather than episodic pollution that has the greatest impact on the limited ecosystem services of islands (Mohammed 2002; Burke et al. 2001).

Increased amounts of hazardous waste are often associated with limited facilities for waste disposal in island systems. As such, many inhabited and uninhabited islands face increasing problems of coastal pollution of land origin, as well as external pollution threats, which may include hydrocarbon pollution originating from local and international shipping and offshore activities and the fast-growing threat of disposal of the toxic wastes of industrial nations in the exclusive economic zones of developing islands and at land sites from which coastal waters can become contaminated. Incidents of dangerous and illegal pollutants being discharged into streams and oceans have increased on islands, with growing urbanization and establishment of manufacturing industries, as a result of, among other factors, inappropriately sited and poorly managed garbage dumps, poorly planned development, inadequate disposal methods, and destruction of and encroachment onto coastal habitats (UNEP 2004a, 2004c). Moreover, the use of agrochemicals has become standard practice in the agricultural production systems in SIDS to respond to export requirements (CBD 2004). The fertilizers, pesticides, and herbicides required to maintain high crop yields contaminate aquifers and affect the biology of sensitive riverine and coastal ecosystems (UNEP 2004b).

Islands are also facing increased problems of coastal and beach erosion due to inappropriate forms of coastline engineering and tourism development that often use coral and beach sand as building material. The degradation of critical ecosystems like coral reefs, mangrove forests, and seagrass meadows reduces the natural defenses of the coast, increasing the potential of erosion from hurricanes and storms. Coastal problems are aggravated by the vulnerability to environmental change of many coastal habitats, such as coral reefs, seagrass beds, and mangroves. Deterioration in coral reefs, for example, is caused by sewage discharge, often aggravated by tourism, and by land runoff in the form of erosion products and chemical fertilizers and pesticides. (See Chapter 19.)

23.3.5 Economic Changes

The issues and priorities relating to economic development differ from one island group to another and reflect the nature of the island systems and the extent of use of island resources. For many small island states, constraints to economic development include a small population size, with limitations in terms of trained and skilled personnel; limited exploitable land; an often weak infrastructure (transport, energy, communications and the basic service sectors, and health and education); distance from foreign markets; a restricted and undiversified natural resource base; heavy dependence on international trade; and often amorphous exclusive economic zones with little or no protection from poaching by foreign fishing or from mineral exploration interests.

23.3.5.1 Land Ownership

Land ownership can be an important driver of island ecosystem change. For example, customary land tenure in island countries such as Samoa, Papua New Guinea, or the Solomon Islands makes it difficult to lease land for tourism, forestry, mining, or extensive farming. Within the Pacific, land is a particularly sensitive issue, especially in the tourism sector (Samoa 2003).

23.3.5.2 Access and Transportation

The geographical isolation of an island has a number of implications for its economy. The sourcing of raw materials and inputs from overseas markets can be costly when minimum volumes are required for orders. Due to this isolation from major markets, downstream processing of local products—such as agricultural produce and the drying, salting, and smoking of fish—is necessary. Increased isolation for many islands has meant more reliance on the local environment and resources.

For some remote islands, the provision of transport service by ferries and other forms of communication is expected to play a crucial role in influencing island population levels, economy, and quality of life (Cross and Nutley 1999).

23.3.5.3 Economic Diversification

Many island states have attempted to diversify their economies. One approach adopted has been the development of island ecotourism, which currently has a small share of the global tourism market but is growing rapidly, as noted earlier. The development of offshore financial services sectors as a means to diversify island economies has also occurred in a number of islands. This is not an easy measure, however, as experienced by the Seychelles, where substantial and complex levels of legislation and reporting mechanisms have to be in place before an offshore center is deemed internationally acceptable (Seychelles 2003).

Despite their geographical isolation, some islanders have migrated to other islands or countries. Contrary to early conceptions, research has shown remittances and associated spending by returning islanders are not unproductive expenditure but can be a significant form of private transfer of capital. Returning migrants represent people endowed with capital and new skills, which can enrich the economic, social, and cultural capital stocks of island communities, offering better prospects for development than those offered solely by domestic economic opportunities (Connell and Conway 2000). Compared with purely foreign investors, capital from return migrants can be channeled into projects that rehabilitate the island systems, such as capacity building, reforestation, integrated coastal management, policies and programs to address beach erosion, sand mining, and coral reef conservation and protection.

23.3.5.4 Globalization and International Trade

Globalization presents both difficulties and opportunities and has direct and indirect impacts on the biodiversity of islands. Various forms or types of globalization have distinct consequences for island systems (Read 2004).

With increasing globalization, many SIDS are concerned with their growing vulnerability as a whole. This is the result of their size and persistent economic structural weaknesses, as small islands face enormous difficulties integrating into the global economy. Trade liberalization accompanied by the progressive removal of trade preferences (tariffs) has severe impacts. SIDS can be marginalized in a world economy, as they are unable to compete due to high costs arising from their small size and geographical isolation.

For some islands with natural and primary resources, globalization presents an opportunity to gain access to new markets, facilitate the transfer of new technologies, and increase productivity. Their development is therefore dependent on the country's capacity to participate in a world economy, especially in agriculture and tourism. For economic development in many small islands, the choice is to be part of the global economy (Prasad 2001). Their governments encourage investments through transnational firms and policies, but these are sometimes influenced by international agencies such as the International Monetary Fund and the World Bank (Prasad 2001).

Globalization has had negative impacts on many island resources, however, particularly fisheries and agriculture. For example, longline fishery operations opened to foreign investors have negative impacts on migratory species, such as tuna. Increasing fishing efforts and new technology have depleted many local fisheries (Hunt 2003). This is compounded by often-illegal access to and overexploitation of the marine resources in the exclusive economic zones of many island states.

The global agro-food complex has increasingly embraced the most isolated and peripheral small island nations in the Pacific since the 1980s. This has had a negative impact on the environment. In Tonga, for instance, foreign investment has boosted the commercial production of squash pumpkin for Japan, with dire environmental consequences through the excess use of pesticides. And on Niue, taro production for the New Zealand market has destroyed biodiversity, disturbed animal habitats, and depleted soil nutrients, while fertilizers and insecticides have had an enormous impact on the water resource of the atolls (Murray 2001).

Globalization has implications for both individual and groups of island nations. Both have to restructure their economies to tackle mounting globalization, and one way is through the creation of regional markets or partnerships (Read 2004). CARICOM is one example of a successful association of small states.

23.3.6 Short-term Disturbances and Natural Events

Natural hazards, as extreme events such as earthquakes, droughts, floods, volcanic eruptions, hurricanes, and their follow-on effects such as storm surges or tsunamis, have a major impact on natural environments and human well-being at a global scale. The consequences of those same hazards are enhanced by the "isola effect," and they can have an even more critical impact on an island's systems and the well-being of its inhabitants.

Those islands located barely above sea level, such as the Maldives, are among the most vulnerable to the effects of extreme weather conditions and other natural hazards. The limited area of islands and their isolation due to the surrounding sea further increases their vulnerability to natural hazards. The changes in temperature and rainfall projected by the IPCC, for instance, could disrupt terrestrial and marine ecosystems of most islands, especially small ones (Lal et al. 2002).

The low coastal elevations also make the populations vulnerable to vector-borne diseases associated with waterlogged conditions, such as dengue and malaria. For instance, positive correlations between the El Niño/Southern Oscillation Index and dengue fever have been reported in 10 island countries of the South Pacific (Hales et al. 1999). In addition, global changes resulting in extremes of rainfall seem likely to have exacerbated diarrhea illness in many Pacific islands (Singh et al. 2001).

The impacts of cyclones on native wildlife include, among other things, high mortality due to the cyclone itself, starvation as a result of the disappearance of food and feed for long periods after the cyclone, predation of grounded wildlife by domestic animals, hunting by humans, failure to breed, and degraded health of habitats and ecosystems (UNEP 2004a).

Many islands situated near geological subduction zones, such as the islands of Indonesia and the Philippines, are prone to disasters associated with earthquakes and volcanic eruptions. Others, such as islands in the Pacific and Caribbean, are in regions that are subject to tsunamis. Low-lying islands are especially vulnerable to climate-induced hazards from sea level rise and tropical storm surge because of their high coastal-zone-to-land ratio, thereby reducing environmental security.

In general, nature and society are adapted to local climatic conditions. While climate is often considered in terms of averages, the extremes are at least as important in determining a region's climate. For instance, it is becoming clear that a warmer atmosphere will result in a greater number of extreme heat waves. In addition, a warmer atmosphere can hold more moisture, so changes in the hydrological cycle could alter flood and drought patterns at all scales, including islands of any size.

It is already known that tropical cyclones are the major cause of storm surges that affect small islands in the Atlantic, Pacific, and Indian Oceans. The devastating effects of recent hurricanes have received extensive coverage by the media. As mean sea level rises, present extreme levels will be attained more frequently, and new higher levels will result in significant increases in the area threatened with flooding. This will be especially true in areas where the height between sea surge and populated areas is low—in other words, there is a small surge envelope, which is typical for most small islands. Under such circumstances, even incrementally small elevations in sea level would have severely negative effects on atolls and low islands (Forbes and Solomon 1997; Nicholls et al. 1999).

23.3.7 Climate Change and Sea Level Rise

Many islands are likely to be among the communities most adversely affected by climate change as a result of their small size, their economic dependence on a limited number of natural resource–based sectors (particularly agriculture, tourism, and extractive industries), and their limited human and financial capacities (IPCC 2001). Although the full impact of climate change on islands is far from certain, adverse consequences are predicted under probable scenarios for several systems (IPCC 2001). One of the most significant impacts of current climate change is sea level rise. This is predicted to lead to inundation of coastal areas and islands; shoreline erosion and the destruction of important island ecosystems such as coral reefs, wetlands, and mangroves; soil salinization; and the intrusion of saltwater into groundwater aquifers.

The IPCC Third Assessment Report indicated a sea level rise of as little as 1 millimeter a year during the twentieth century (IPCC 2001). During the last hundred years, the sea level has risen 100–150 millimeters, and a further rise in global sea level in the range of 350–1,100 millimeters between 1990 and 2100 is predicted, although local rates may vary from negative to positive values, depending on other localized effects (IPCC 2001). The "best estimate" in this range results in a 660-millimeter rise by 2100. This is mainly attributed to thermal expansion of the upper ocean layers and to melting of glaciers and small ice caps. There are, however, many uncertainties in identifying and assessing the causes of sea level trends. (See Figure 23.3.)

As most islands belong to developing countries, they are especially vulnerable to sea level rise due to their limited financial resources to respond to this and other natural hazards. Several small islands, such as the Maldives in the Indian Ocean and the Marshall Islands and Tuvalu in the Pacific, could face total inundation within this century if rates of sea level rise accelerate. This impact is also predicted for archipelagos such as the Philippines and Indonesia, where millions of inhabitants face displacement from their homes from sea level rise. Most of their populations live very close to the sea, and a rise of as little as a meter could prove devastating. Before their lands are lost underwater, some will face loss of their freshwater supply due to saltwater intrusion, contributing to an increasing shortage of the water supply. Sea level rise will also cause increased pressure on forest reserves due to loss of coastal agricultural land by salination and will lead to migration or loss of wildlife species.

Projected global temperature increases are not expected to have widespread adverse consequences on the terrestrial ecosystems in tropical SIDS (IPCC 2001). Some changes are likely to occur, however, especially alteration of species ranges, an increase in forest pest and diseases, reduction of food and water available for wildlife, and an increase in forest fire frequency, especially where precipitation remains the same or is reduced. The quantity and quality of available water supplies can affect agricultural production and human health. Similarly, changes in sea surface temperature, ocean circulation, and upwellings could affect coastal organisms such as corals, mangroves, seagrasses, and fish stocks. Tourism could also be affected through beach erosion, loss of land, and degraded reef ecosystems, as well as changes in seasonal patterns of rainfall (Nurse et al. 2001).

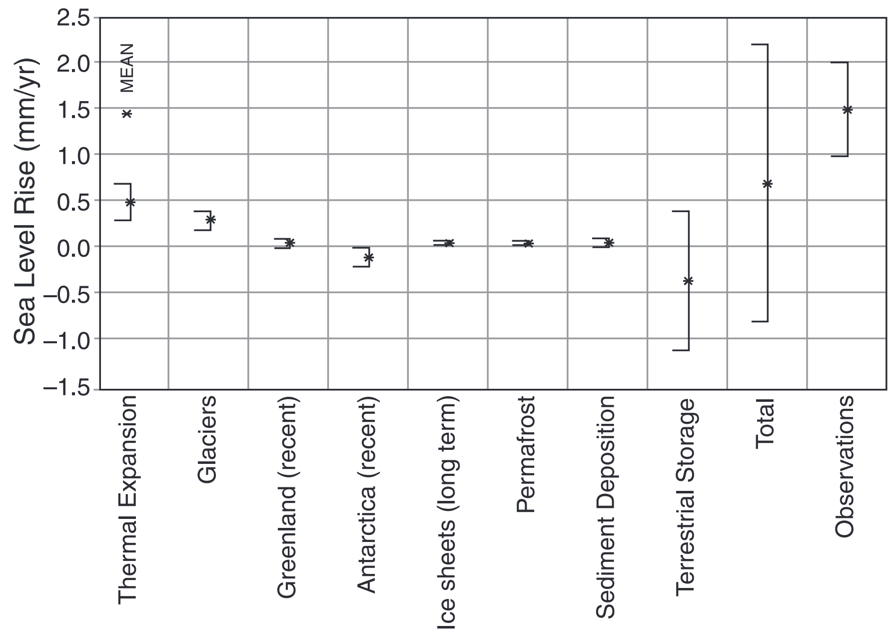

Figure 23.3. Ranges of Uncertainty for the Average Rate of Sea Level Rise and Estimated Contributions from Different Processes, 1910–90 (IPPC 2001)

The SIDS account for less than 1% of global greenhouse gas emissions but are among the most vulnerable of all areas to the potential adverse effects of climate change and sea level rise (Jones 1998; Nurse et al. 1998).

Among many relevant examples, Pacific islands provide a clear case study on the issue of climate change and sea level rise. Despite having persistent trade winds and convergence zones, the climate of the Pacific Islands region continues to be dominated by interannual variability associated with El Niño/Southern Oscillation events and by extreme events such as tropical cyclones, floods, and drought. Due to the enhanced greenhouse effect, the region will likely warm by 0.6–3.5° Celsius and the climate may become a more El Niño–type, with the central and eastern equatorial Pacific warming more than the western Pacific and with a corresponding mean eastward shift of precipitation.

Future ENSO events are likely to result in anomalously wet areas becoming even wetter and unusually dry areas becoming even drier (Hay et al. 2003). Also a general increase in tropical cyclone intensity is likely with an eastward extension of their area of formation. With climate change, the Pacific will also experience a rising sea level. However, interannual variations in sea level associated with ENSO and storm surges associated with tropical storms are likely to be of greater significance than a longer-term sea level rise over decades. (See also Chapter 19.)

23.4 Human Well-being in Island Systems

Islands are not being treated here as one global ecosystem. Islands are recognized as systems each with a variety of ecosystems, and thus of ecosystem services. Combining islands of similar geographic latitudes allows for recognition of similarities in ecosystems on islands. But as there is no global "island ecosystem," common conditions as well as common trends cannot be presented at a global scale.

Another issue faced in the assessment of conditions and trends in this chapter is that only a few examples have been selected from particular islands and island groups. It was impossible to include all global islands in this assessment. However, an assessment of certain groups of islands—such as small islands off California, Mexico, and Australia as well as Pacific tropical islands (the Philippines and Indonesia) or subantarctic islands—does allow for general conclusions to be drawn. As people are a major presence in the coastal zones of islands, see also the information on coastal communities and human well-being in Chapter 19.

23.4.1 Vulnerability and Adaptation

The small size of many islands makes the people living there generally more vulnerable environmentally, economically, and socially. Their vulnerability arises from islands' limited resources, export concentration, high dependence on strategic imports, remoteness and high transportation costs, external shocks beyond their control, structural handicaps, and susceptibility to natural disasters exacerbated by climate change and sea level rise.

23.4.1.1 Adaptation to Sea Level Rise

Owing to their high vulnerability and low adaptive capacity to climate change, island communities have legitimate concerns about their future on the basis of the past and present climate model projections. Economic development, quality of life, and alleviation of poverty presently constitute the most pressing concerns of many small island states. Thus, with limited resources and low adaptive capacity, these islands face the considerable challenge of charting development paths that are sustainable and that control greenhouse gas emissions, without jeopardizing prospects for economic development and improvements in human welfare (Munasinghe 2000; Toth 2000). At the same time, islands are forced to find resources to implement strategies to adapt to increasing threats resulting from climate change, a process to which they contribute very little (Hay and Sem 1999; Sachs 2000). Consequently, the already meager resources of these island states will be placed under further pressure.

One of the most serious considerations for some small islands is whether they will have adequate potential to adapt to sea level rise within their own national boundaries (Nurse 1992; IPCC 1998). For islands where physical space is already very scarce, adaptation measures such as retreat to higher ground or a set distance separating structures from the shore would appear to have little practical utility. In extreme circumstances, sea level rise and its associated consequences could trigger abandonment and significant out-migration at great economic and social costs (Leatherman 1997; Nicholls and Mimura 1998).

23.4.1.2 Island Vulnerability

Many studies have tried to assess the ecological and economic vulnerability of island systems along different spatial scales (e.g. Sax 2001; Courchamp et al. 2003). The results of such exercises are somewhat contradictory. Many authors have suggested that the main issues are not isolation and smallness themselves, but development problems, which may be proportionately larger for island systems. According to Farrell (1991), essential problems of small island states have little to do with their smallness and may be more a matter of degree, although he admits that smallness may exacerbate the problem and its effects. An alternative view on the viability-size issue was presented by Dommen (1980), who compared a sample of small island countries with a similar set of continental countries with respect to a number of social and natural characteristics and concluded that size was an important factor.

While all developing countries face challenges in addition to the general problems of development, such as political interference, requirements for environmental friendliness, and sustainability, island nations experience specific problems arising from their limited area of land and thus have a higher exposure to interactions and exchanges of materials and energy flows than continental nations do. This vulnerability is presumed to be negatively correlated with size but is also affected by a suite of other factors: remoteness, geographical dispersion, proneness to natural disasters, the vulnerability of ecosystems to disturbance and human effects, constraints on transport and communication, isolation from markets, exposure to exogenous economic and financial shocks, a highly limited internal market, lack of land natural resources, limited freshwater supplies, heavy dependence on imports and limited commodities, depletion of nonrenewable resources, migration (particularly of skilled personnel), and a limited ability to diversify and to reap the benefits of economies of scale.

Recently, economic hegemony and new communications technology are seriously challenging these concepts of insularity. In economic terms, island-based societies like Aruba, Iceland, Bermuda, and French Polynesia are counted among the world's richest people, while those of São Tomé and Principe, Vanuatu, and the Maldives are counted amongst the poorest (Baldacchino 2004). In short, some islands with a large area but sparse human population and a limited economy that may be classified as small, while others, small in area, have gross disposable products as large as or larger than some continental economies.

There are exceptions to the typical pattern of island vulnerability as defined in terms of size, population, or GDP. For example, Singapore and Barbados have demonstrated that being physically small and lacking significant natural resources are not necessarily limitations to economic growth and prosperity. Also, some of the richest islands are heavily dependent on one or two exports such as tourism and financial services to generate considerable growth. However, all remain vulnerable to external shocks (Clayton 2004; Crowards 2004).

There have been efforts to develop a vulnerability index for small islands for a number of years, as a relatively high GNP per capita gives the impression of economic strength when in reality island economies depend on and are determined by external forces (Briguglio 1995; UWICED 2002). All SIDS have favored the development of appropriate vulnerability sub-indices as measures of the new index. Currently, the vulnerability index has yet to be accepted as an alternative to the dominant GDP per capita measure (Seychelles 2004).

Among some islands, exposure to natural hazards reflects the degree of their vulnerability to change; on others, however, this relationship is not applicable because vulnerability can be reduced through appropriate planning and preparation—as illustrated by reduced casualties from hurricanes in Cuba, which has a high level of planning and state-led provision for cyclones (Clayton 2004).

Some island states have argued for a more positive approach to the concept of vulnerability of island systems through advocating the concept of resilience—that is, increased resilience means decreased vulnerability, and vice versa (Barnett 2001). By recognizing their vulnerability, communities can build their resilience through appropriate actions and programs. Many instances of successful resilience could be emulated; they arise from a combination of factors from good governance, sound macroeconomic framework, market reform, labor productivity, social cohesion, and protection and sustainable management of the environment, including increased energy efficiency, promotion of waste management, improvement of freshwater resources management, and promotion of sustainable use of biodiversity and natural resources (Report 2004).

23.4.2 Integrated Island Systems Management

For island States, the island systems management approach, as a multidisciplinary, integrated mechanism, offers an adaptive management strategy that both addresses the issue of resource-use conflict and provides the necessary policy orientation to control the impacts of human intervention on the physical environment of islands. It was developed by the Organization of the Eastern Caribbean States and adopted by the First Ministerial Meeting on the Implementation of the Barbados Programme of Action (held in Barbados in November 1997). However, its effectiveness depends on an institutional and legal framework that coordinates the initiatives of all sectors, both public and private, to ensure the achievement of common goals through a unified approach.

The long-term development objectives of islands also need to be considered. Despite physical and natural resource limitations, important consideration will need to be given to integrated planning, social cohesion, increased attention to managing biodiversity (in particular, invasive species), and a strengthening of territorial planning if islands are to become economically, socially, and ecologically resilient and self-sufficient.

*This appears in Appendix A at the end of this volume.

Main Messages

Half of the human population depends on mountains. Defined by elevation above sea level (minimum between 300 and 1000 meters, depending on latitude), steepness of slope (at least 2° over 25 kilometers, on the 30 arc-second grid), and excluding large plateaus, mountains occupy about one fifth of the terrestrial surface. Twenty percent (1.2 billion) of the world's human population lives in mountains or at their edges, and half of humankind depends in one way or the other on mountain resources (largely water).

Mountains are characterized by high biodiversity. Because of the compression of climatic life zones with altitude and small-scale habitat diversity caused by different topoclimates, mountain regions are commonly more diverse than lowlands and are thus of prime conservation value. They support about one quarter of terrestrial biodiversity, with nearly half of the world's biodiversity hot spots concentrated in mountains. Geographically fragmented mountains support a high ethnocultural diversity. For many societies, mountains have spiritual significance, and scenic landscapes and clean air make mountains target regions for recreation and tourism. Thirty-two percent of protected areas are in mountains (9,345 mountain protected areas covering about 1.7 million square kilometers).

Mountain ecosystems are exceptionally fragile. Mountains are subject to both natural and anthropogenic drivers of change. These range from volcanic and seismic events and flooding to global climate change and the loss of vegetation and soils because of inappropriate agricultural and forestry practices and extractive industries. Mountain biota are adapted to relatively narrow ranges of temperature (and hence altitude) and precipitation. Because of the sloping terrain and the relatively thin soils, the recovery of mountain ecosystems from disturbances is typically slow or does not occur.

Human well-being depends on mountain resources. These ecosystems are particularly important for the provision of clean water, and their ecological integrity is key to the safety of settlements and transport routes. They harbor rich biodiversity and contribute substantially to global plant and animal production. All these services depend on slope stability and erosion control provided by a healthy vegetative cover. As "water towers," mountains supply water to nearly half the human population, including some regions far from mountains, and mountain agriculture provides subsistence for about half a billion people. Key mountain resources and services include water for hydroelectricity, flood control, mineral resources, timber, and medicinal plants. Mountain populations have evolved a high diversity of cultures, including languages, and traditional agricultural knowledge commonly promotes sustainable production systems. In many mountain areas, tourism is a special form of highland-lowland interaction and forms the backbone of regional as well as national economies.

In general, both poverty and ethnic diversity are higher in mountain regions, and people are often more vulnerable than people elsewhere. Ninety percent of the global mountain population of about 1.2 billion people lives in developing countries and countries in transition—with one third of these in China and half in the Asia-Pacific region. Some 90 million mountain people—and almost everyone living above 2500 meters—live in poverty and are considered especially vulnerable to food insecurity. Land use pressure puts mountain ecosystem integrity at risk in many parts of the world. Industrial use, forest destruction, overgrazing, and inappropriate cropping practices lead to irreversible losses of soil and ecosystem function, with increased environmental risks in both mountains and adjacent lowland areas.

Mountains often represent political borders, restrict transport to narrow corridors, and are refuges for minorities and political opposition. As such they are often focal areas of armed conflicts. Further conflicts arise from the commercial exploitation of natural resources, usually by outside interests, and from ambiguity regarding traditional land use rights. Profits from extractive industries in mountains are not systematically reinvested either in the management of upland resources or the provision of benefits to mountain communities. Both poverty and remoteness are responsible for poor medical care and education systems in many mountain regions.

Strengthened highland-lowland linkages improve sustainability for both upstream and downstream populations. Lowland-highland relationships, whether formal or informal, have the potential to pay for investments in protection and sustainable use of mountain resources. When full costs are taken into account, stewardship of upland resources generally yields greater and more sustainable economic returns both to the people living in the mountain areas and to the immediate downstream economies when compared with extractive activities. In many cases, the focal point of such interactions has been based on providing a sustainable and clean supply of water, the most important and increasingly limiting mountain resource. In steep terrain, more than anywhere else, catchment quality is intimately linked to ecosystem integrity and functioning. Thus environmental conservation and sustainable land use in the world's mountains are not only a necessary condition for sustainable local livelihoods, they are also key to human well-being for nearly half the world's population who live downstream and depend on mountain resources.

24.1 Introduction and Scope of Global Mountain Systems

Since its existence, the surface of Earth has always been subject to tectonic forces that with the action of gravity and the erosive power of water have shaped landscapes into mountains, hills, lowland forelands, and old tableland. (See Figures 24.1–24.4.) Mountains are very attractive to outsiders, but the physical conditions challenge those living in these regions. Of the approximately 1.2 billion mountain people worldwide (20% of world population), only 8% inhabit places above 2,500 meters elevation. The key functions of mountains for humanity are frequently overlooked, such as the headwaters of river systems that supply nearly half of humanity with water. This chapter assesses the available knowledge on physical, biological, economic, and social conditions in the world's mountain areas and describes their likely future.

24.1.1 Definitions of Mountains and Altitude Belts

Since the transition from lowland plains to mountain terrain is usually gradual, the definition of mountains is based on convention. For the purpose of this assessment, inclusive rather than selective criteria were adopted to define the mountain system. The three major problems that needed to be resolved were latitudinal differences in climate from the equator to the poles and thus the variable altitude of different life zones (hill, montane, alpine, nival); the relative importance of elevation versus slope (high altitude plains versus steep slopes of lowland hills, for example); and, tied to both these, the definition of the lower limit for mountain terrain. For practical reasons, local climatic and topographic peculiarities could not be accommodated.

One common definition (and the one adopted by the United Nations Environment Programme World Conservation Monitoring Centre) is a lower limit of 300 meters (Kapos et al. 2000). (See Box 24.1 here and Figure 24.5 in Appendix A.) Alternatively, the lower limit has been set at 1,000 meters at the equator (the upper limit of many tropical plant species including the coconut palm), gradually decreasing to about 300 meters at the 65° northern and 55° southern latitude, reaching sea level at a short distance beyond

Figures 24.1–4. Mountains of the World. From top to bottom: Cradle Mountains, Tasmania, at 1,100 meters; Monte Rosa Glacier near Matterhorn, Switzerland, in the Central Alps at 3,000 meters; World Heritage Site Sichuan, Northwest China; Paddy field slope agriculture and deciduous montane forest (background) near Kathmandu, Nepal, at 1,200 meters.

BOX 24.1

Defining Mountains by Topography Only

Kapos et al. (2000) used criteria based on altitude and slope in combination to represent the world's mountain environments. Topographical data from the GTOPO30 global digital elevation model (USGS EROS Data Centre 1996) were used to generate slope and local elevation range on a 30 arc-second (about 1 kilometer) grid of the world. These parameters were combined with elevation to arrive at empirically derived definitions of six elevation classes. To reduce projection distortion in the original data set, analysis was based on continental subsets in equidistant conic projection. The global mountain area thus defined is almost 40 million square kilometers, or 27% of Earth's surface. Assuming a lower mountain boundary of 1,000 meters at the equator and a linear reduction of this boundary to 300 meters at 67°N and 55°S reduced the total "mountain" land area by 5.4 million square kilometers or 3.7 % of the global land.

Class 1, elevation $>$ 4,500 meters
Class 2, elevation 3,500–4,500 meters
Class 3, elevation 2,500–3,500 meters
Class 4, elevation 1,500–2,500 meters and slope $\geqq$ 2
Class 5, elevation 1,000–1,500 meters and slope $\geqq$ 5 or local elevation range (7 kilometer radius) $>$300 meters
Class 6, elevation 300–1,000 meters and local elevation range (7 kilometer radius) $>$300 meters outside 23°N—19°S
Class 7, isolated inner basins and plateaus less than 25 square kilometers in extent that are surrounded by mountains but do not themselves meet criteria 1–6 (this seventh class was introduced in the 2002 revision of the original 2000 system)

these latitudes, where the alpine merges with the polar life zones. Ideally, however, the lower mountain limit should be defined climatically, irrespective of latitude. But this would require a world topoclimate map, which is currently not available.

The choice of convention is important because it has a large influence on the global mountain area. The UNEP-WCMC definition gives the global mountain area at about 23%, whereas under the second definition it accounts for about 19% of the global land area. For this review, flat terrain (basins or plateaus) below 2,500 meters elevation was excluded if the aerial extent of such plains exceeded 25 square kilometers. In essence, the definition used here followed that by Kapos et al. (2000).

In this global assessment, three belts were distinguished for mountain regions where precipitation regimes allow forest growth. In treeless arid or semiarid regions, analogues to these belts can be defined. (See Figure 24.6.)

- *The montane belt* (see Figure 24.7) extends from the lower mountain limit to the upper thermal limit of forest (irrespective of whether forest is present or not). This limit has a mean growing season temperature of 6.7 + 0.8°C globally, but is closer to 5.5°C near the equator and to 7.5°C at temperate latitudes. Between 40°N and 30° S, this belt covers a range of 2,000–3,000 meters of elevation. Note the difference between *mountain* and *montane*.
- *The alpine belt* (see Figure 24.8) is the treeless region between the natural climatic forest limit and the snow line. The term "alpine" has many meanings, but here it refers strictly to a temperature-driven treeless high-altitude life zone that occurs worldwide and not solely in the European Alps (the term "alp" is of pre-Indo Germanic origin). Some synonyms such

as "andean" and "afro-alpine" are in common scientific use. Land cover is dominated by grassland or low stature shrubland. Outside subpolar regions (<60°N, <50°S), the alpine belt extends over an elevation range of 800–1,200 meters, with its lower boundary varying from about 500–4,000 meters above sea level, depending on latitude.

- *The nival belt* (see Figure 24.9) is the terrain above the snowline, which is defined as the lowest elevation where snow is commonly present all year round (though not necessarily with full cover). While the lower part of the nival belt is still rich in living organisms, usually very little plant and animal life is found beyond 1,000–2,000 meters above the tree line, although animals and flowering plants can be found up to around 6,000 meters in some parts of the world.

The critical bioclimatic reference line that permits global comparison and "calibration" is the high elevation tree line. The thermal limit for forest growth is surprisingly consistent worldwide and holds as a reference for all mountains where moisture permits tree growth. It is important to note that this may not be a visible line in many mountains, because forests have been re-

Figure 24.8. Alpine Grassland in the North Argentinean Andes at 4,100 Meters

Figure 24.9. Snow and Rock Fields in the Nival Zone in the Swiss Alps at 2,700 Meters

placed by pastures or cropland. These alternative land cover types are still categorized as ''montane'' when they occur below the thermal forest limit. Within the montane belt, different altitude-specific forest belts can be distinguished at lower latitudes, and the number of belts decreases toward higher latitudes. These belts are often referred to as lower-, mid-, and upper-montane.

24.1.2 Aerial Extent and Main Mountain Ranges

The Eurasian landmass has by far the largest mountain area of all continents; all of the world's mountains above 7,000 meters are in Asia, and all peaks above 8,000 meters are situated in the Greater Himalaya range. The Tibet (Qing Zang) Plateau is the most extensive inhabited land area above 2,500 meters elevation. Excluding Antarctica, South America has the second most extensive area of high elevation land, and the world's highest point outside Asia (Aconcagua, at 6,962 meters). Antarctica and Greenland also figure prominently, in part due to the extent and thickness of their icecaps.

Most of the world's mountain areas are found in the Northern Hemisphere and in temperate–sub-tropical latitudes (the Eurasian ranges and the North American cordilleras). (See Tables 24.1 and 24.2.) In addition, there are extensive mountain systems in the boreal (for example, Altai) and the subpolar (northeast Siberia, for instance) zones. In the Southern Hemisphere, the largest mountain systems are the Andes and the mountains of the Southeast Asian archipelago (such as New Guinea). Important but comparatively smaller mountain systems are also found in Africa, Australia, and New Zealand. More than a third of the montane belt is covered by forest, and perhaps as much as half could be potentially be covered by forest—that is, the cover is not limited by climate (see Table 24.3)—but has been converted to more open vegetation and agricultural lands by logging, fire, and grazing.

Slope, aspect, and altitude determine many of the fundamental characteristics of mountain environments. Gravity-driven topographic diversity adds significantly to the small-scale variation in life conditions. Geographic position such as latitude and distance from oceans affects climate and local weather patterns, making some mountains almost permanently wet, others dry, and some highly seasonal. Geological substratum adds a further dimension of geo-diversity and influences soil type and development, erosion processes, and vegetation cover.

Mountain climate shows a number of common features globally, but it can vary greatly regionally and locally. Several factors relevant to life processes change predictably with altitude and underlie the marked environmental gradients typical of high mountains. The most important common components are reduced pressure and reduced air temperature, with the associated reduction of water vapor pressure deficit. On average, temperature declines by 5.5 K per kilometer of elevation (but differs diurnally, seasonally, latitudinally, and from region to region), and air pressure (and with it, the partial pressures of oxygen and carbon dioxide) decreases by about 10% for every kilometer of elevation. Clear sky solar radiation increases with altitude, and higher maximum radiation and a greater short wave radiation (UV) are typical for higher elevations. However, clouds and fog may reverse altitudinal trends in solar radiation (Yoshino 1975; Barry 1992; Körner 2003).

Physical processes, in large part related to gravity, include erosion, landslides, mud flows, avalanches, and rockfall, and these determine life conditions in many parts of the world's mountains. At a more regional scale, volcanism and the associated sedimentation and slope processes affect biota and can have dramatic impact on people's life conditions. These physical phenomena of the mountain environment become enhanced when seismic activity comes into play, which is particularly the case in geologically

young and thus steep mountains. Economic consequences and the death toll can be dramatic, as exemplified by catastrophic events in the recent history of Rwanda, the Philippines, Nepal, India, Italy, and the United States.

24.1.3 Biota

Vegetation on lower mountain slopes may be broadly similar to that of surrounding lowlands. However, environmental gradients linked with elevation typically lead to marked zonation. In less humid regions, the availability of moisture may at first increase with elevation. In drylands, this can allow tree growth on mountains that emerge from treeless semi-desert plains. In humid regions, epiphyte-rich evergreen cloud forest may occur above more seasonal forest. With further elevation, temperature decreases to a point where tree growth cannot be sustained. There is no common altitudinal trend of precipitation. In the temperate zone it commonly increases with altitude, but in the tropics it often decreases beyond a montane maximum, often leading to semi-deserts above 4,000 meters (such as in the altiplano in the Andes or the semiarid top of Kilimanjaro).

The altitudinal temperature gradient in mountains is about 600–1,000 times higher than the corresponding latitudinal gradient. Discernible vegetation belts on mountains may commonly span an elevation range of 1,000 meters. Over such a range, the temperature change is about 5–6 K, enough to cause a full bioclimatic vegetation belt to be replaced by another (alpine by montane forest, for example). The latitudinal increase in seasonality and the annual temperature amplitude are mainly due to decreasing winter temperature, which limits the poleward extension of lower latitude species. Similarly, the colder climate of successive altitude belts restricts the growth of species from lower and warmer belts. One consequence of this is that ecosystems situated on mountain tops, with a species composition currently restricted by cold climate, are likely to disappear as a result of climate change.

Because of the compression of climatic zones along an elevation gradient, exposure effects, and large habitat diversity, species richness in mountains commonly exceeds that in the lowlands at small scales (such as hundred square meters). Within mountain regions, species richness decreases with increasing altitude, largely in proportion to the available land area (Körner 2000), but endemism often increases, due partly to topographic isolation (Gentry 1988; Peterson et al. 1993) and the often rapid formation and loss of links (corridors) in geological time.

Tree species diversity within a habitat commonly decreases with altitude; for example, in the tropical Andes there is an average decrease of nine species per 100 meters increase in altitude (Gentry 1988). Tropical mountain forests have 10 times higher species richness than temperate ones. Globally, there are some

10,000 species of flowering plants in the alpine belt alone—representing about 4% of all known species and covering about 3% of the vegetated land area (Körner 1995). Some groups of organisms (amphibia, for example, and bryophytes) may reach their highest taxonomic diversity in the montane belt. Two types of endemism can be prominent in mountain areas: palaeo-endemism (the survival of evolutionary old taxa in isolated refugia, exemplified by Tertiary relics of primitive angiosperms of the genera *Davidia, Tetracentron, Trochodendron* in Southeast Asia) and neo-endemism (more-recent speciation, for instance following the creation of new habitats due to volcanism or other major disturbances).

Thirty-two percent of all protected areas are located in mountainous regions, providing habitats for rare, relict, and endangered plants and animals (UNEP-WCMC 2002). Many species that survive in such refuges—pandas, tigers, takins, golden langurs, condors, and tapirs, for instance—are at risk from habitat fragmentation, however. Extended mountain ranges with continuous habitats provide a corridor for high altitude and cloud forest species, avoiding densely populated lowlands.

Ecological corridors that link isolated habitats are essential for many migrating species, which have extensive hunting or feeding territory requirements. Corridors can also facilitate species radiation, as shown for example in *Espeletia,* a giant rosette plant, in the Northern Cordilleras of the Andes (Cuatrecasas 1986). Connecting remote nature reserves, such corridors are effective tools to compensate for natural and human-induced fragmentation of habitats. Bhutan, for example, has nine protected areas covering 26% of the land (all in mountains), and all protected areas are linked by corridors, which cover another 9% of land area where land uses are compatible with conservation objectives (Dorji 2000).

24.1.4 Social and Economic Conditions

Twenty percent of the world's population—about 1.2 billion people—live in mountains. Most of them inhabit lower montane elevations, and almost half are concentrated in the Asia-Pacific region. Of the 8% living above 2,500 meters, almost all—about 90 million—live in poverty and are considered highly vulnerable to food insecurity. However, they have significant impact on larger populations living at lower elevations through their influence on catchments.

Low temperatures become prohibitive for people above 2,000 meters in temperate latitudes and above 3,500 meters in tropical latitudes (although there are exceptions up to 4,200 m), and human activities rarely occur above 4,500 meters. Special efforts and techniques are required to sustain agricultural production at altitudes close to the upper tree line level.

There are many historical examples of flourishing mountain economies based on mountain ecosystem services (including Berbers, Afghan and Caucasian tribes, Tibetans, Mongolians, Highland Papuas, Incas, and Aztecs), and many of these cultures still survive and in some cases even thrive. Lowland economies have generally dominated, however, because of intensive sedentary agriculture, manufacturing based on larger scales, easier transportation and trade, urbanization and associated better education, and the broader reach of common language and culture.

In most parts of the world, mountain areas are perceived as economically backward and culturally inferior. But there are some exceptions. In industrial countries, mountain areas have been rapidly transformed economically with improved access and the proliferation of recreational activities. In Africa, for instance, highland areas that grow tea and other high-value crops are more prosperous than lowlands. More often, however, mountain resources are extracted without benefit to local communities in order to support lowland economies, thereby contributing to the further marginalization of mountain people. Where extractive industries have been developed, mountain communities have often become dependent on wages for their livelihoods, and asset values and rents are usually allocated elsewhere.

With notable exceptions, particularly in areas where tourism and amenities migration (the movement of people because of a perceived high incidence of attractive or cultural resources) have created pockets of wealth, mountain communities suffer disproportionately from poverty and often lack even basic social services such as education and health care facilities. This, in part, has caused a counter movement in several mountain areas (the Andes and Himalayas) that is strongly linked to control over mountain resources (such as the movement of water in Bolivia).

Mountain communities are also insufficiently recognized as rich reservoirs of traditional knowledge and cultural and spiritual resources.

24.2 Mountain Ecosystem Services

For the purposes of this assessment, three main types of mountain ecosystem services are addressed:

- *Provisioning services*: extractive resources that primarily benefit lowland populations (water for drinking and irrigation, timber, and so on) and ecosystem production (agricultural production for local subsistence and for export; pharmaceuticals and medicinal plants; and non-timber forest products);
- *Regulating and supporting services,* such as biodiversity, watershed and hazard prevention, climate modulation, migration (transport barriers/routes), soil fertility, soil as storage reservoir for water and carbon, and so on; and
- *Cultural services*: spiritual role of mountains, biodiversity, recreation, and cultural and ethnological diversity.

Each of these mountain ecosystem services makes specific contributions to lowland and highland economies. Mountains play a key role in the water cycle, with feedback to the regional climate and by modulating the runoff regime. Tropical cloud forests are particularly significant in the latter respect. Mountain vegetation and soils play a significant role in reducing or mitigating risks from natural hazards. Mountain forests, for instance, protect from avalanches and rockfall; their waterholding capacity reduces peak stream flow; they are an important carbon pool; and they provide timber for fuelwood and non-timber products, including game and medicinal plants. Mountains are also used for grazing and subsistence farming. Mountain ecosystems are significant for global biodiversity, as noted earlier, and in addition they have intrinsic spiritual and aesthetic value (Bernbaum 1998; Daniggelis 1997).

Table 24.4 rates ecosystem services per unit of specific type of land area. This definition avoids a rating by the abundance of certain land types.

24.3 Condition and Trends of Mountain Systems

24.3.1 Atmospheric Conditions

Mountains extract moisture from the atmosphere through the orographic uplift of air masses that pass over mountain ranges. In this sense, mountains act as "water pumps" by pulling moisture from the atmosphere. Mountains also act as "water towers" by

Table 24.4. Ecosystem Services in Mountains

storing water in mountain glaciers, permafrost, snowpacks, soil, or groundwater.

There are conflicting predictions about the rate of tropospheric warming. General circulation models predict a warming in high northern latitudes and also in the mid to upper troposphere in the tropics and sub-tropics. Many tropical and sub-tropical mountain ranges reach the levels of the troposphere where the warming is predicted, and the retreat of many of the world's glaciers is consistent with warming at higher elevations. However, reliable assessments of the status of mountain atmospheric conditions are currently limited to relatively few high-elevation meteorological stations. For example, a transect along the Cordilleras of the Americas shows that there are currently no meteorological stations positioned at elevations high enough to address the issue of potential warming in the mid-troposphere in the tropics and sub-tropics.

24.3.1.1 Trends in Atmospheric Physics (Climate)

24.3.1.1.1 Temperature trends

Temperature changes in 1951–89 between 30° and 70° N show that mean maximum temperatures increased slightly between 500 and 1,500 meters, with minor changes at higher elevations, while mean minimum temperatures rose by about 0.2 K per decade from 500 meters to above 2,500 meters (Diaz and Bradley 1997). In the tropical and sub-tropical Andes, mean annual temperature trends for 268 stations between 1° N and 23° S during 1939–98 (Vuille and Bradley 2000) showed an overall warming of about 0.1 K per decade, but the rate has tripled over the last 25 years to 0.33 K per decade. The warming trend declined with elevation, especially on the Pacific slopes of the Andes, whereas in the central Himalaya the warming trend increased with altitude (Shrestha et al. 1999). In the Swiss Alps, temperatures increased by a total of 1 K during the twentieth century, and milder winters now occur (Beniston and Rebetez 1996). Temperature effects appear to be stronger at night than during the day.

In many locations for which high-elevation monitoring data are available, the rate at which the atmosphere cools with increasing altitude (lapse rates) has shown an increase because of faster warming at lower altitudes. However, there are exceptions. For example, in the Colorado Front Range of the Rocky Mountains there has been an overall cooling at 3,750 meters but warming between 2,500 and 3,100 meters since 1952 (Pepin 2000). Generally, the increase of air temperature lapse rate on mountains at the mid-latitudes is greater in winter than in summer (Yoshino 2002).

There have also been remarkable trends in permafrost temperatures. In the Swiss Alps, for example, permafrost warmed by about 1 K between 1880 and 1950, then stabilized, before warming accelerated between 1980 and 1994, followed by rapid cooling in 1994–96, which largely offset the previous warming (Vonder Mühll et al. 1998). Permafrost temperatures in the northern Tien Shan have risen by 0.2–0.3 K over the last 25 years (Gorbunov et al. 2000).

The position of the snow line has been similarly affected. The snowline in mountainous areas within 10° of the equator retreated by 100–150 meters between 1970 and 1986, which has been correlated with a warming of the sea surface over the eastern tropical Pacific (Diaz and Graham 1996). On the Quelccaya Ice Cap in Peru (14° S), meltwater penetration obliterated the uppermost part of an important climatic record provided by the ice core that Thompson et al. (1993) had collected only a few years earlier. Thus, some paleo records that are vital for our understanding of human-environment interactions are vanishing fast.

24.3.1.1.2 Precipitation and snowpack trends

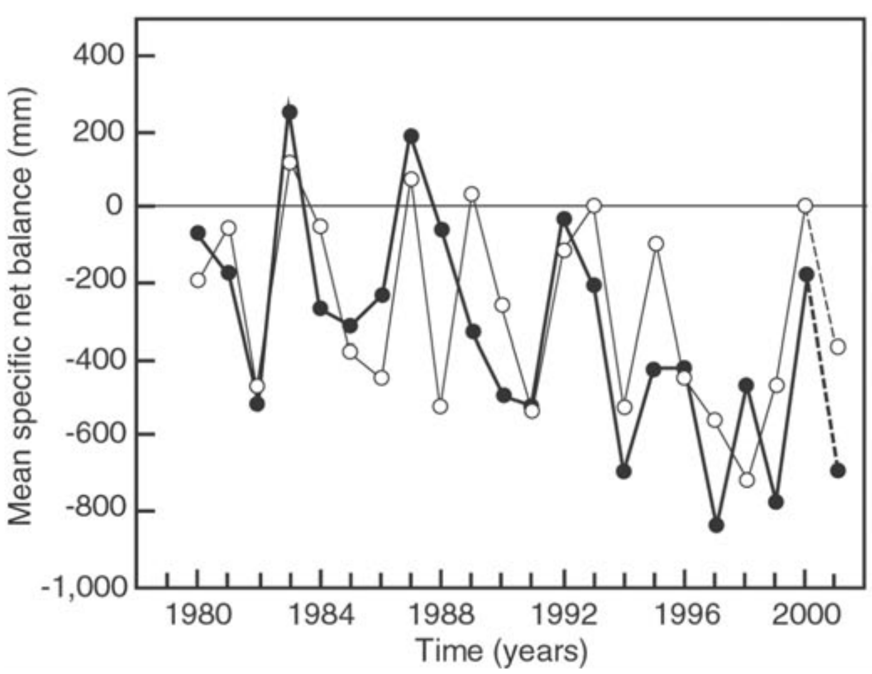
Precipitation in mountain regions is best assessed through hydrological budgets of catchments. This is because precipitation is highly variable and strongly influenced by dominant wind direction (slope/aspect effects) and because precipitation analysis is complicated by seasonality and the occurrence of extreme events whose statistics are difficult. Records for the Alps (Gurtz et al. 2003; Beniston et al. 2003) suggest a future trend toward higher winter and lower summer precipitation and an increase in the altitude at which freezing occurs, with largest relative changes occurring in alpine catchments. Less summer precipitation in combination with higher evapotranspiration rates will lead to a reduction in soil moisture and groundwater recharge.

Trends in snowpack and snow duration reflect the interplay between temperature and precipitation. Snowpack has already diminished in montane altitudes and is likely to continue to do so, while there may even be an increase in snowpack at upper alpine/nival elevations due to increased solid precipitations (Beniston 2003). On average, glaciers lost 6,000 to 7,000 millimeters of water from 1980 to 2000 (250–300 millimeters per year, based on the glacier area). (See Figure 24.10.) Unfortunately, few meteorological stations are situated at high altitudes that could address the extent to which the observed changes in mass balance represent increasing summer ablation of ice and snow or a decrease in the accumulation of solid precipitation.

24.3.1.2 Trends in Atmospheric Chemistry

24.3.1.2.1 Atmospheric deposition of nutrients and pollutants

Atmospheric processes control the deposition of long-distance pollutants in mountain environments (nutrient enrichment of



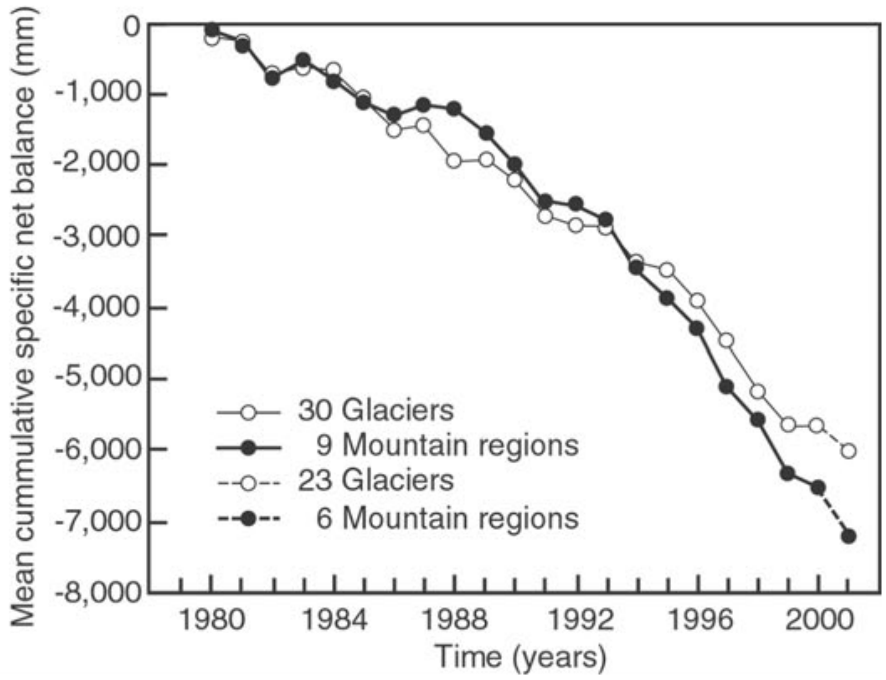


Figure 24.10. Mean Net Balance and Cumulative Mean Net Balance Continuously Measured for 1980–99 on 30 Glaciers in Nine Mountain Ranges. Data for 2000 are for 29 glaciers in eight mountain ranges and preliminary results for 2001 are for 23 glaciers in six mountain ranges. (World Glacier Monitoring Service, at http://www.geo.unizh.ch/wgms/)

mountain ecosystems and impacts on water quality). Atmospheric deposition of nitrogen and sulfur compounds, persistent organic pollutants, and metals such as mercury in mountainous areas is enhanced by proximity to anthropogenic sources and precipitation. For semi-volatile POPs, volatilization in warmer temperatures and condensation in colder temperatures results in increased deposition at high altitudes. For instance, semi-volatile organochlorine compound deposition increased 10- to 100-fold in snowpack with altitude (770–3,100 meters above sea level) in the Canadian Rockies (Blais et al. 1998).

Atmospheric deposition of acids, nutrients, organochlorines, and metals affect all components of mountain ecosystems. The loss of acid-neutralizing capacity in soils caused by the deposition of sulfur and nitrogen compounds reduces soil fertility and biodiversity and acidifies water bodies, leading to alterations in aquatic species composition. Excess nitrogen is undesirable because it induces changes in plant species composition and nutrient cycling, and it affects the ability of plants to withstand stress. Nitrogen enrichment can also increase non-native species invasions in mountainous aquatic or wetland habitats. On the other hand, nitrogen's fertilizing action can be a benefit in areas where enhanced productivity is desired, such as in commercial mountain forests. Rare or endemic species, often found in oligotrophic habitats, are likely to become suppressed by more vigorous species of wider distribution.

A preliminary examination indicates a pattern of biological accumulation of POPs in animals and foliage at high altitudes (Schindler 1999). The occurrence of the insecticide toxaphene in fish increased by 1,000-fold over a 1,500-meter elevation range in the Canadian Rockies, and similar patterns have been observed in the Alps for polychlorinated biphenyl concentrations (Grimalt et al. 2001). Organochlorines and metals are harmful to fish health and reproductive ability, and bioaccumulation transfers poisons to waterfowl, wildlife, and humans.

Atmospheric deposition in conjunction with other disturbances (such as unsuitable land use practices and floods) can create many problems, such as losses of soil nutrients or the accumulation of xenobiotic substances. For example, water from glacial catchments was recently shown to be the dominant sources of POPs in the mountain rivers of Alberta, Canada (Blais et al. 2001). At the same time, however, processes such as N enrichment may increase species invasions in mountainous aquatic or wetland habitats. Glacial runoff in summer becomes channelized on the glacier surface, funneling POPs rapidly to alpine and subalpine waters. Glacial meltwater also showed evidence of the accumulation of tritium in glacial ice during atmospheric nuclear tests in the 1960s and 1970s (Blais et al. 2001). There is a high probability that under a scenario of increasing global temperatures, glacial melt will lead to unexpectedly high concentrations of POPs in montane waters.

24.3.1.2.2 Carbon dioxide

Globally, mountain ecosystems at temperate latitudes are among the largest biotic carbon reserves because these mountains tend to be forested, accounting for, for instance, 25–50% of the contribution to the total U.S. carbon stock and up to 75% of the western U.S. carbon stock (Schimel et al. 2002). The effects of elevated CO_2 concentration on montane forests vary with nutrient availability and species. Haettenschwiler and Körner (1998) found no effect of elevated CO_2 on the growth of montane *Picea abies* (Norway spruce), and no effect was found in *Pinus uncinata* (mountain pine) after three years of in situ free air CO_2-enrichment (FACE) at the Swiss tree line. However, deciduous larch *Larix decidua* showed a continuous response, provided trees were not affected by larch bud moth. If this trend in differential growth continues over the long term, it would provide a clear example for CO_2-driven biodiversity effects (Handa et al. in press). Studies of ecosystem productivity in alpine grasslands in the Swiss Alps found no detectable increase after four years of double-ambient CO_2 concentration. However, higher CO_2 concentrations reduced forage quality, increased (compensatory) herbivory by grasshoppers during certain periods, and altered the plant community composition (Körner et al. 1997).

24.3.1.3 Consequences of Atmospheric Changes

Environmental conditions change rapidly with elevation because of the steep temperature and precipitation gradients. Thus, rapid changes in life zones occur over short vertical distances, and relatively small changes of the climate can induce large changes in the area available for a given life zone (cf. Theurillat and Guisan

2001). Because topographic effects have a greater influence than elevation effects over conditions for life above the tree line, biota do not necessarily occur at higher altitudes, but may form new mosaics, with the distribution of snow often being far more influential than temperature (Gottfried et al. 1999).

Climatic change may enhance or reduce precipitation, depending on the region. A reduction of moisture in already dry mountain regions (such as the upper *Erica* belt on Kilimanjaro) will enhance fire frequency. Some mountain forelands will receive less water, with disastrous consequences for marginal semiarid lowlands. Enhanced activities such as El Niño may in turn expose other tropical and sub-tropical regions to excessive precipitation followed by floods and mudslides, as occurred recently in Peru, Ecuador, and Colombia. In many cases, mountains are the primary source of fresh water in these regions.

The reduction in glacier volumes is expected to have a strong impact on dry-season river flows in rivers fed largely by ice melt (Haeberli and Beniston 1998). This will very likely affect the provision of downstream water for drinking, hydropower, and irrigation. Over 65 countries use more than 75% of their available fresh water for agriculture. These include countries with large populations such as Egypt, India, and China, which rely heavily on mountain discharge (Viviroli et al. 2003). Unfortunately, mitigation efforts such as constructing dams and reservoirs are problematic in tectonically active regions where slope stability is further compromised by glacier recession and melting permafrost (Haeberli and Beniston 1998). Conversely, it is likely that some maritime mountain regions may experience increased precipitation under warmer conditions, which may lead to slope instability, mass movement, and accelerated erosion.

In the Himalayas of Nepal and Bhutan, glacier lake outburst floods are increasing in frequency due to the rapid recession of glaciers. It is anticipated that such events could reach rates of one significant glacier outburst flood each year by 2010 (Kaeaeb et al. 2005), which will impose a substantial risk to downstream communities and hydroelectric power schemes.

Winter tourism is particularly vulnerable to climatic change in areas near the lower winter snowline. For example, it is likely that a number of winter resorts in the European Alps situated below 1,500 meters above sea level will be forced to close in the near future, which in turn will increase demand on high-elevation resorts.

24.3.2 Mountain Biota

24.3.2.1 Overview of Land Cover in Mountains

Table 24.5 provides a summary of land cover in mountain areas, obtained by overlaying the global land cover data set for 2000 (Bartholome and Belward 2004) with the modified mountain map of Kapos et al. (2000). Based on this data set, 13.3% of the mountain area is cultivated, while the urban (''artificial'') land area amounts to 0.05%, or 15,400 square kilometer, making it nearly negligible at the global scale.

Overall, it is very likely that about half of the global mountain area is under some sort of human land use (we assume that unvegetated or bare land and wetlands and other water bodies, which together amount to 14% of the global mountain area, are mostly unaffected by humans). A considerable proportion of forests, including plantation forests, woodlands, and shrubland as well as herbaceous vegetation in mountains are under various human land uses, such as silvicultural interventions and grazing. Probably half of all temperate/boreal forests and two thirds of all tropical mountain forests are under some sort of management (from selective logging and shifting cultivation to plantation forest).

Wildlife—and free-roaming domestic animals—can have a dramatic impact on land cover. For instance, much of the initial fragmentation of montane forest on Mt. Kenya was a consequence of free elephant access. By contrast, deep canyons prevent elephant access to much of the montane cloud forest on Kilimanjaro, which has remained largely intact. Through wildlife management, including hunting and the extensive use of fire, wildlife influences have been modified and have often become less important than those of domestic animals.

24.3.2.2 Mountain Forests

Mountain forests account for 26.5% or 9.5 x 10^6 square kilometer (using the 300 meters low elevation threshold in the tropics) of the global closed forest area (Kapos et al. 2000). (See Table 24.6.) The upper forest limit lies at around 4,000 meters in the tropics; it gradually decreases toward the poles and ends near sea level at the polar forest limit. On a large scale, both the mountain and polar tree lines are set by temperature during the growing season (Ohsawa 1990; Körner and Paulsen 2004).

In the Southern Hemisphere, current forests often do not reach the potential climatic limit for tree growth that is predicted for the Northern Hemisphere. (In the Southern Hemisphere, introduced northern temperate trees can grow even above the indigenous species (Nothofagus)'s upper limit (cf. Wardle 1971).) So native species do not always reach their life-form limit. Since there is no land in the extreme south, deciduous and coniferous boreal forests are absent in the Southern Hemisphere, and evergreen temperate trees form the southern forest limit.

A continuous zonation of humid forests from the equator to the poleward forest limit can be observed in the mountain chains from humid, monsoon Southeast Asia to East Asia, and from the Northern to Southern Andes. In the other parts of the world, the forest area is interrupted by drylands between the equatorial and the temperate mountains.

The number of distinct elevational belts within the montane forest belt decreases toward higher latitudes (Holdrige 1967; Brown et al. 1991). Humid tropical montane forests are dominated by evergreen broad-leaved trees, from the foothills to the upper forest limit. (See Figure 24.11.) In temperate mountains, a marked altitudinal sequence of evergreen, deciduous, and coniferous forests can be found, but this varies from continent to continent. In North America and Europe, the evergreen broad leaf component is missing, while New Zealand has no conifer or deciduous belt. The presence or absence of conifers and deciduous trees in tropical versus temperate mountains suggests large differences in ecosystem functioning (seasonality, water, and nutrient relations).

24.3.2.2.1 Natural, unmanaged forests

Natural, unmanaged mountain forests are becoming rare. They are often isolated or fragmented but host a rich and original flora and fauna. What is commonly termed ''natural'' may still include some human activities, but these do not normally alter the abundance and composition of forest species. Many of these forests are relicts with varied protection status. Nearly 10% of the global mountain forests are under some sort of protection (UNEP-WCMC 2002). Recent networks of protected areas in many parts of the world aim at establishing connections using ecological corridor systems (for example, Bhutan). These forests are essential to protect fragile mountain slopes from erosion and leaching processes and as reservoirs of species for resettlement of deforested, fragmented, or newly created habitats affected by anthropogenic or natural disturbances.

Table 24.5. Land Cover in Mountains. The share of different land use types in each biogeographical zone is provided in parentheses. (Bartholome and Belward 2004, UNEP-WCMC updated by Thonell using the formation categorization by Ohsawa (1995 modified)) The criteria for the humid life zones are as follows (WI is defined as the sum of monthly mean temperature above 5° Celsius (Kira 1948), CMT is defined as the coldest monthly mean temperature (Ohsawa, unpublished)):

– Tropical life zone (latitude below 20–30° N/S): WI $<$15 (CMT > -1°C) $=$ above limit of tropical forest; 15 $<$ WI $<$ 85 (CMT $>$ 6°C) $=$ tropical upper montane zone; 85 $<$ WI $<$240 (CMT $>$12°C) $=$ tropical lower montane zone; WI $>$ 240 (CMT $>$ 18°C) $=$ tropical hill zone if elevation is above 300 m, otherwise not mountainous.

– Sub-tropical/temperate life zone (latitude above ca. 30° N/S): WI$<$15 $=$ above limit of temperate forest; CMT < -7°C $=$ temperate upper montane zone; -1°C $>$ CMT > -7°C (WI $>$ 15) $=$ temperate lower montane zone; 6°C$>$ CMT > -1°C, 12°C $>$ CMT $>$ –1°C and WI $>$ 85 $=$ temperate hill zone.

– For dry life zones, the Holdridge life zone classes (scrub, steppe, woodlands, dry tundra, and desert vegetation) have been used. (Holdridge 1967)

Biogeographical Zone	Forest and Woodland Cover	Shrub, Herbaceous Cover	Cultivated	Wetlands (mires, swamps, river basins)	Bare Areas (rock, gravel, etc.)	Water Bodies (including snow and ice)	Artificial (urban, industrial, etc.)	No Data	Total

24.3.2.2.2 Semi-natural forests

Human use has turned most natural forests into semi-natural forests, a process often completed several centuries ago in Europe but still going on in other mountain areas of the world. Thus semi-natural forests have become part of ecosystems in many parts of the world and are essential for local people to obtain both timber and non-timber forest products.

Large-scale forest statistics (e.g., FAO 2001) do not differentiate between high and low human impacts on forests, however. Sustainably managed semi-natural forests provide many ecosystem services, including tradable products such as timber and various non-timber products, and at the same time retain high biodiversity (Peterken 1981). But heavily disturbed or damaged montane forests are often invaded by fast-growing, early successional tree or shrub species. These pioneers often endanger relic species of the Tertiary (e.g., the Dove tree *Tetracentron* in western China, cf. Tang and Ohsawa 2002). On the other hand, such species may be crucial for the conservation of disturbed mountain ecosystems through their role of covering and stabilizing steep slopes and facilitating forest regeneration (cf. Bormann and Likens 1979).

The invasion of unpalatable herbs into overgrazed pastures and of small trees/shrubs into clearings is often regarded as noxious, but, again, these species may reduce nutrient loss, enhance the resilience of the ecosystem, and facilitate restoration (Callaway et al. 2000). In some cases alien species even invade pristine forests once established in disturbed areas (e.g., exotic *Myrica faya* invades undisturbed *Metrosideros* forests in Hawaii). Shifting agriculture systems in areas of low population density can maintain ecosystem integrity similar to coppiced forest systems, provided the replenishment of soil nutrients is achieved by allowing sufficient fallow periods. Exploitative farming systems with too short a fallow period (as is the case in systems where human population density is increasing) are not sustainable.

Table 24.6. Areas of Different Forest Types Occurring in Each Mountain Class (UNEP-WCMC 2003; FAO 2003)

Elevation Class	Temperate and Boreal Evergreen Needleleaf Forests	Temperate and Boreal Deciduous Needleleaf Forests	Temperate and Boreal Deciduous Broadleaf and Mixed Forests	Tropical (and Sub-tropical) Dry Forests	Tropical (and Sub-tropical) Moist Forests	Total	Forest Area/ Mountain Area
	(thousand square kilometers)						*(percent)*
Above 3,500 meters	25.0		1.7	0.2	19.4	23.3	1.3
2,500–3,500 meters	151.8	1.2	122.9	35.3	138.8	450.8	6.5
1,500–2,500 meters	548.0	76.2	476.9	50.6	277.0	1,551.3	29.4
1,000–1,500 meters	788.7	313.9	441.1	107.3	545.7	2,133.0	34.6
300–1,000 meters	1,377.1	985.6	1,275.7	343.4	1,173.0	5,179.4	39.9
Total	**2,890.5**	**1,377.0**	**2,338.0**	**551.8**	**2,333.0**	**9,479.2**	**26.5**
	(percent)						
Share of total mountain forests	30.4	14.5	24.7	5.8	24.6	100.0	
Location	North America, Europe, Central Asia, Himalaya	Central Asia, Northeast Asia	North America, Southern Andes, Europe, Himalaya, Eastern Asia	South Africa, India	Trop. Andes, Central America, East Africa, Madagascar, Southeast Asia		

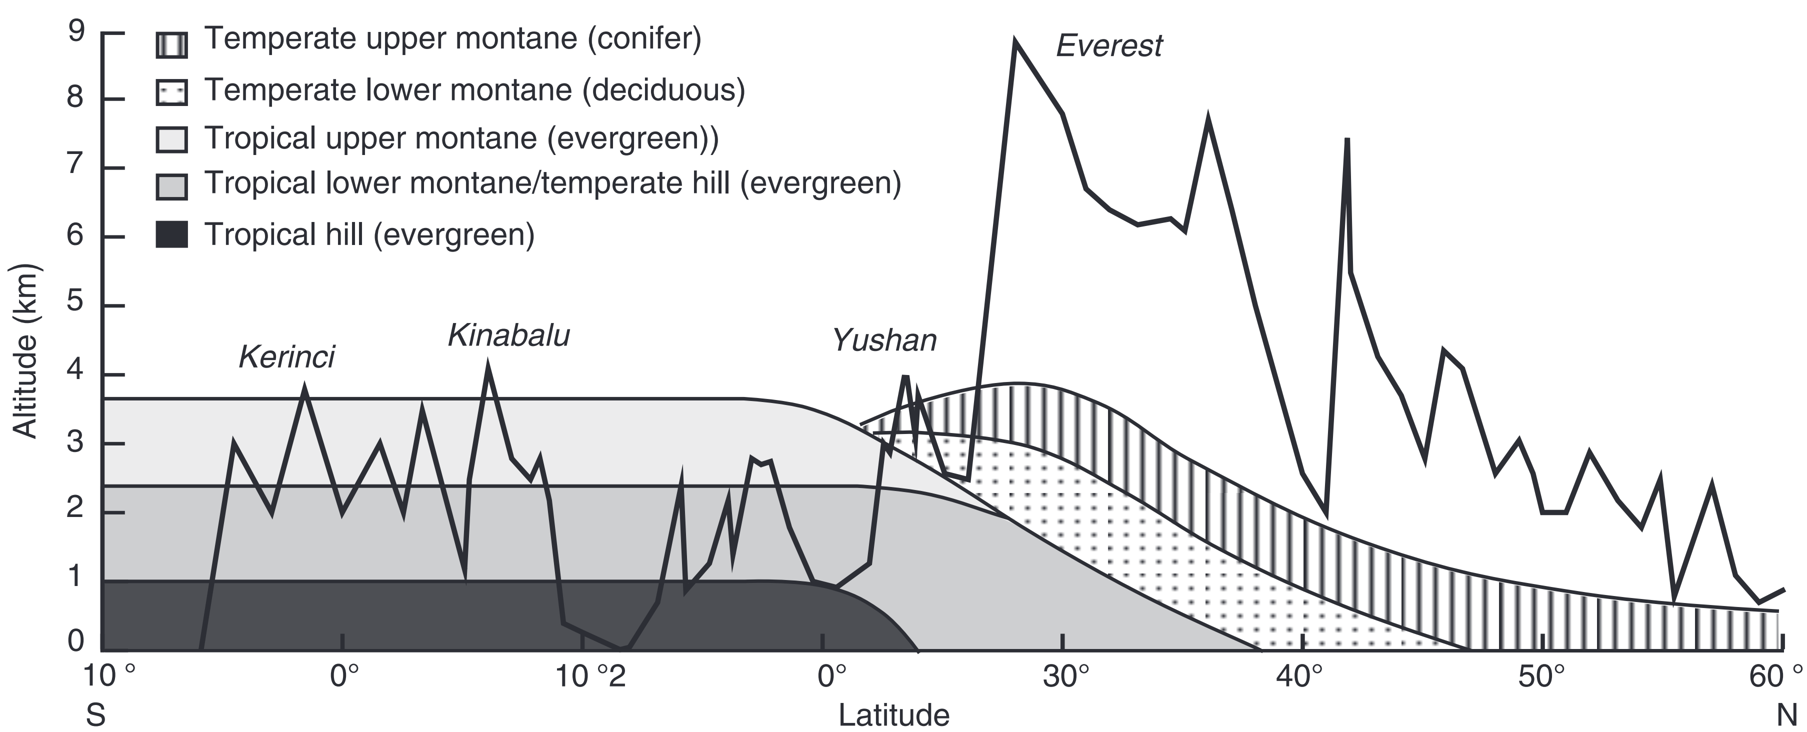

Figure 24.11. Potential Forest Life Zone Model Overlaid on Mountain Profile of Southeast to East Asia. (Ohsawa 1990, 1995) Note maximum of five sub-belts at 23°N and the latitudinal reduction of sub-belts to one at >47°N.

24.3.2.2.3 Plantations

Forest plantations occur mainly in temperate countries (75% of the global area of plantation forest); the rest are found in tropical countries. In sub-tropical and tropical humid mountains, the slow-growing natural hardwood forests are often replaced by fast-growing softwood species, and such plantations extract more water and reduce catchment yields, such as in South Africa, New Zealand, and some parts of the Andes (Hofstede et al. 2002; Morris 1997). In some cases, exotic plantations or ornamental trees introduce diseases and pests.

Large-scale monospecific plantations may exclude wild or domesticated herbivores and lead to a shift in their habitat selection toward the remaining natural or semi-natural forest fragments, thus causing excessive animal densities and deterioration in these more natural forests. When introduced species invade natural forests, they may suppress the regeneration of native species that protect soils from erosion and are important for biodiversity conservation. Recent trends in industrial countries suggest that productive exotic tree plantations can be converted back into less productive but lower risk systems dominated by native trees (FAO 2003). However, plantations can also have an important role in the process of restoring degraded land, as in Ethiopia (Yirdaw 2001), and act as catalysts for succession of native tree species at low population densities.

Recent changes in how forest services are valued, with a shift from simple timber production toward biodiversity, aesthetic, spiritual, and recreational aspects, may help change forest plantations to more natural forest in some cases.

24.3.2.2.4 Trends in mountain forests

Considerable changes are taking place in mountain forests as a result of overgrazing, pathogens, fire, and direct transformation of forest into other uses, such as plantations and agriculture. Development projects, such as dams, hydropower plants, roads, tourist infrastructure, and urbanization, also contribute to forest loss. In their global forest statistics, FAO (2003) distinguishes three types of new forest area: reforestation, afforestation, and natural expansion of forest. A comprehensive analysis of the change in forest area for the period 1990–2000 showed that natural forest area decreased by 6.8% in the tropics, while in temperate areas it expanded by 1.2%, mainly due to increases in forest cover in the mountainous countries of Europe (FAO 2001). (See also Chapter 21.)

24.3.2.3 Agricultural Systems

According to a recent FAO estimate, 78% of the world's mountain area is unsuitable or only marginally suitable for growing crops (Huddleston et al. 2003). Pastoralism and forestry are the predominant uses of mountain land in all regions. Nevertheless, agriculture remains important for a large number of people who will continue to depend on it as their main source of livelihood for the foreseeable future (see later sections on traditional use and vulnerability). Mountain livelihood systems are generally diverse within a variety of agricultural and nonagricultural activities. Typical mountain dwellers grow a wide range of crops and often multiple varieties of each crop. Small-scale livestock production, timber, hunting, fishing, and non-timber forest product collection complement food production. Nonagricultural activities frequently include seasonal migration of men to other areas and tourism, such as mountain guiding and nature conservation work.

In developing and transition countries, 7% of the total mountain area is currently classified as cropland; forest and grazing land cover about 25% each, and the rest is barren (33%) or within protected areas (10%) (Huddleston et al. 2003).

Above 2,500 meters, 88% of the total mountain area represents a mix of grazing land and sparsely vegetated or barren land. Sparsely vegetated high lands support about 5 million people; 29 million live off grazing land, interspersed with other land cover types; and 4 million live in protected areas. Forests above 2,500 meters provide home for another 2 million people. Mixed land use patterns—such as crop agriculture combined with exploitation of forest resources and herding of small livestock—are characteristic of some locations between 2,500 and 3,500 meters (mountain class 3) in Central and South America, in the East African and Ethiopian Highlands, and in Nepal. Although mountain people in these locations are increasingly vulnerable, their numbers are quite small. Two million people live in rural areas above 2,500 meters, which are mainly classified as cropland or mixed use. Cropland at higher elevations constitutes only 3% of the total mountain area.

Below 2,500 meters, grazing land interspersed with other land cover types accounts for 45% of the land, with a further 20% classified as mainly barren land. Around 300 million people, or two thirds of the rural mountain population below 2,500 meters, inhabit these areas and rely on livestock for income with some crop agriculture (Huddleston et al. 2003).

These findings confirm the importance of pastoralism for mountain people at all elevations. However, the loss of traditional trade routes and patterns of goods exchange, degradation of land resulting from population growth and increase in livestock numbers, and the impact of frequent, severe droughts in recent years have all greatly increased the vulnerability of this livelihood system, with mountaineering, tourism, or seasonal migration offering the only major alternatives for income generation. In the absence of men, women are forced back into crop agriculture, which is barely suited to the land.

FAO has identified 17 distinct farming systems that are significant in mountain areas at elevations above 1,000 meters. (See Table 24.7.) Together, these systems account for 67% of the total mountain area and include 82% of the total rural mountain population in developing and transition countries. The ''intensive mixed highland farming system,'' a livestock-dependent system, is by far the most important. Stretching from northern Africa to Southeast Asia and beyond, this system has many variants that are specific to local cultures and conditions. In the Ethiopian Highlands (1,800–3,000 meters), Near East and North Africa (300–2,000 meters), Hindu Kush–Himalaya (1,500–2,500 meters), and central Andes (1,500–3,000 meters), the main features of the system usually include cereals, legumes, potatoes, fodder trees and crops, ruminant livestock, coffee, and horticultural tree crops, with the sale of wool, meat, and tree fruits constituting the main sources of income. By contrast, in western China (500–1,500 meters) rice is important, and income is derived mainly from the sale of vegetables, fruits, pigs, and poultry.

24.3.2.3.1 Mountain crops

The major mountain crops grown at high elevation are potatoes and cereals (such as barley), in some tropical and sub-tropical regions grown up to 4,000 meters (and locally even higher). One cash crop of the high Andes is quinoa. At lower elevations, maize (corn), rice, beans, peas, and sweet potato as well as cabbage are important as staple foods globally. At the lowest tropical montane elevations, crops such as taro (*Xanthosoma, Colocasia*), yams (*Dioscorea*), cassava (*Manihot*), bananas, and papayas are grown. Various forms of millet and sorghum play a key role in African mountain agriculture.

Major plantation crops grown in the lower montane belt are tea and coffee: the latter at higher altitudes in Colombia and in montane regions of Brazil, Costa Rica, Guatemala, Viet Nam, and elsewhere, while tea is grown extensively in hill areas and the highlands of Africa and Asia. The presence of traditional crops, which can also be used to produce illegal crops (marijuana, coca, poppy) are a major socioeconomic and political problem in parts of the Andes, Atlas, Afghanistan, and Central and Southeast Asia. In some parts of the high Andes, industrial potato production is threatening the Parámo flora, which is rich in species and endemism.

24.3.2.3.2 Mountain rangeland

Mountain rangelands may be natural (vegetation above the tree line) or of anthropogenic origin (below the tree line). In the Alps, for example, a 60-kilometer North-South transect across the main divide revealed that 57% of the land is covered by meadows, pastures, and other types of palatable low-stature vegetation (Körner 1989). The vegetation of these rangelands is composed of species formerly found along rivers, in naturally disturbed areas and pockets grazed by wild herbivores. These species underwent selective pressure from human land use and assembled into highly adapted plant communities, which over millennia have formed closed and extensive ground cover on nonforested land.

Table 24.7. Main Mountain Farming Systems in Developing and Transition Countries: Location, Characteristics, Area, and Rural Population. Population numbers refer to number of people living in these areas. (Huddleston et al. 2003; definition of farming systems, Dixon et al. 2001)

Mountain Farming System Categories	Farming Systems	Area	Rural Population	Elevation and Geographical Location
		(mill. sq. km.)	*(million)*	
Other	not specified	7.4	88.2	Below 1,000 meters—all regions
Irrigated	irrigated rice	1.0	38.6	300–2,500 meters—Madagascar and some mountain riverbanks in Africa; coastal areas of Chile, Ecuador, and Peru and of Caspian and Aral Seas; terraced hills of Mexico, and South and Southeast Asia
Maize mixed	rice-tree crop	1.4	26.1	300–2,500 meters—uplands of Kenya, Lesotho, Malawi, South Africa, Swaziland, Tanzania, Zambia, and Zimbabwe; Central Mexico, Costa Rica, El Salvador, Guatemala, Honduras, Nicaragua, and Panama
Tree crop/sparse forest	maize mixed maize-bean	3.5	37.3	300–1,500 meters—hilly areas of West African coastal countries from Côte d'Ivoire to Angola; 500–3,000 meters—highlands of Burundi, Ethiopia, Rwanda, and Uganda; Indonesia, Malaysia, Mongolia, Myanmar, Pacific Islands, northern Argentina and southern Chile, western Chile
Pastoral	tree-crop highland perennial sparse (forest)	0.3	6.4	all elevations—semiarid and arid areas in all regions; important in Central Asian CIS countries and in Hindu Kush-Himalaya highlands and plateaus
Small-scale cereal-livestock	small-scale cereal livestock	3.5	224.3	300–2,500 meters—Turkey
Highland intensive mixed	highland temperate mixed highland mixed upland intensive mixed intensive highland mixed	2.0	50.7	300–3,000 meters—Ethiopian Highlands and small pockets in Angola, Cameroon, Eritrea, Lesotho, and Nigeria; Himalayan, South Asian, Near Eastern and North African hills; Indonesia, northern Thailand, Philippines, South China, and Viet Nam; Colombia, Ecuador, and Venezuela
Highland extensive mixed	upland extensive mixed high altitude mixed	2.3	11.1	800–4,500 meters and above—Cambodia, Indonesia, Laos, Myanmar, northern Thailand, Philippines, southeastern China, Viet Nam; Bolivia, northern Chile, northwestern Argentina, and Peru
Sparse	sparse (arid) sparse (mountain)	1.0	7.3	All elevations—arid areas throughout North Africa and Near East, and in China, Kazakhstan, Mongolia, Pakistan, Turkmenistan, and Uzbekistan; Above 3,000 meters—middle and upper Himalaya slopes
Total		**22.4**	**490.0**	

Present in the upper montane and alpine belt across the globe, these ecosystems reflect traditional, sustainable land use and represent biota of high ecological, conservation, and economic value. In many places they host unique and species rich assemblages of plants and wildlife and can often support 50 species or more of higher plants in a 100-square-meter area. The best examples of such rangeland assemblages are found in Europe, including the Caucasus, and across the Himalayas into western China. These high-altitude rangeland systems and their sustained productivity depend on appropriate land use (see vulnerability section later) and represent a cultural heritage that deserves protection. As with forests, increasingly intensive use is occurring over ever increasing areas in many parts of the world, causing loss of sustainability, land transformation with associated changes in ecosystem function, and, in extreme cases, a loss of ecosystem integrity and soils.

The general trends reflect the common economic, developmental, and demographic differences between industrial and developing countries. While abandonment of high-elevation rangelands is common in the former (in France, for instance), overexploitation has reached dramatic dimensions in many developing countries (Ethiopia and Nepal, to name two), a result of unprecedented population pressure. The long-term consequences will very likely be similar to those seen today in part of the Mediterranean coastal mountains, where overutilization has often been followed by catastrophic erosion, complete loss of soils, and conversion of flora and fauna (van der Knaap and van Leeuwen 1995).

The key to sustainable management of high-elevation rangeland has proved to be strict control of grazing. Prevention of loss of soil (productivity) has high potential as a policy-making intervention. In the Kosciusko National Park and Biosphere Reserve in the Snowy Mountains of Australia, for example, phasing out inappropriate grazing helped protect vegetation in an upland catchment, increasing the value for hydroelectric generation. In the absence of urgent measures, it is very likely that developing countries risk large-scale environmental degradation from overgrazing of mountain rangeland, with stark consequences for a large fraction of their current and future populations.

Through the abandonment of traditional grazing lands, industrial countries also risk a decrease in the landscape value of their mountains and the loss of a resource for quality food production.

In 30–50 years, abandoned pastures revert back, through scrub, to montane forest as long as seed sources are present. It is nearly impossible to reverse this process, because of both high costs and the loss of traditional knowledge. Abandonment of grazing management in mountain ecosystems that have a long history of grazing can also have adverse effects on the survival of some native plant species, many of which may be endemic. Traditional use is affordable only if all benefits are accounted for.

A remarkable secondary benefit of maintaining good quality grazing land is the benefit to hydro-schemes. The extra value in hydropower often exceeds the monetary value of the agricultural yield. In the Alps, and similarly for the Caucasus, the monetary value of an intact, high-elevation, short grass pasture in terms of hydroelectric yield was estimated to be about 150 Euro per hectare, higher than that of abandoned long grass turf or forest (Körner 1989).

24.3.2.4 Alpine Biota

The area of alpine land above the natural climatic tree line accounts for about 3% of the planet's land surface. Depending on region, most arctic-alpine vegetation north of 65–70° is probably better included in the term ''arctic.'' The alpine belt alone supports about 10,000 plant species worldwide (Körner 1995), corresponding to 4% of the total number of known species of flowering plants. Local flora of individual mountains (except for isolated volcanic peaks) throughout the world consist of 200–300 species, a surprisingly constant number (Körner 1995). The compression of climatic zones, high fragmentation and topographically diverse habitats, geographic isolation, glaciation, and varied history of species migration or evolution have led to high degrees of taxonomic richness (including endemism) in alpine biota (Nagy et al. 2003; Körner 2004).

Treeless by definition, the alpine belt is in large part composed of dwarf shrub heath and grassland, a vegetation that dominates the headwaters of most major river systems. In the tropics and sub-tropics, but also in the oceanic Southern Hemisphere temperate and subpolar zone, tall tussock grasses represent the dominant life form. In most parts of the world the wild ungulate grazers of this life zone have been replaced by domestic species. Animal trampling of fragile soils on steep terrain and fire management of tussock grasses are the major threats to the biota. In fact, the overdominance of tussocks versus more palatable low-stature grass cover has been interpreted as a consequence of excessive land use (Hofstede 1995). Inter-tussock surface erosion is a major problem associated with insufficient or weakened inter-tussock vegetation.

Since soil development is very slow at these elevations, revegetation after the loss of substrate is nearly impossible. In many parts of the world, alpine vegetation extends to below the climatic tree limit because of forest destruction. Together with forest preservation, the sustained integrity of these highland ecosystems is key to the quality and quantity of catchment discharge. Indeed, the ecosystem engineering role of species-rich alpine biota has become a focal area of internationally coordinated research (Körner and Spehn 2002; Spehn et al. 2005).

With respect to ecosystem productivity, neither atmospheric CO_2-enriched nor moderate climatic warming appear to exert significant effects on alpine systems. It seems that productivity is not limited by the availability of CO_2, and thermal conditions in the low stature ground cover are much more controlled by radiative solar heating than is the case in trees and forests, which are aerodynamically well coupled to atmospheric circulation (Körner 2003). At high latitudes, temporal and spatial patterns of alpine snow pack exert strong influences on vegetation, with patterns of precipitation, particularly during the cold season, being potentially more significant than summer temperatures. In addition to changes in precipitation and snow pack, major global threats in the alpine belt are regional nitrogen deposition and land use. Warming can open higher elevation habitats for organisms from lower altitudes, provided the summits are high enough (Grabherr et al. 1994).

24.3.2.5 Aquatic Biota

Mountain lakes, ponds, and streams provide important ecosystem services—including drinking water, fish, recreation, and aesthetic values. The productivity and diversity of algae, invertebrates, and fish decline significantly with increasing altitude because of the more extreme environmental conditions, such as low temperatures, short season, and low nutrient concentrations, and the isolation (Vinebrooke and Leavitt 1999), causing such biota to be more sensitive to any change in environmental conditions (Donald et al. 2001).Consequently, the migratory responses of mountain aquatic biota are closely tied to changes in the environment (e.g., Donald et al. 2001). Human actions, such as widespread introduction of exotic fish, led to significant biological impoverishment of montane and alpine lakes and streams during the twentieth century, which may require decades to recover from (Donald et al. 2001; Schindler and Parker 2002).

Oligotrophic aquatic ecosystems in mountains rely heavily on external inputs of nutrients (Vinebrooke and Leavitt 1998), which make them highly sensitive to human land use practices and air pollution. For example, nitrogen deposition impacts have been documented from oligotrophic mountain lakes in the western United States (Baron et al. 2000) and from streams in the Hindu-Kush Himalayas (Jenkins 2002). Cold climate aquatic biota also show pronounced accumulation of mercury and organochlorine compounds at higher elevations as a result of low temperature condensation of emissions originating from lower elevations and of release from melting glaciers in both North America (Blais et al. 2001) and Europe (Rognerud et al. 2002). However, the sensitivity of species-poor mountain aquatic ecosystems makes them excellent early indicators of environmental change.

Climate warming and drought have pronounced impacts on biota in non-glacial lakes and streams as they become clearer, warmer, less acidic, and more ephemeral because of reduced snowpack and increased mineralization rates (Sommaruga-Wögrath et al. 1997). Interactions between multiple environmental stressors, such as introduction of exotic species, air pollution, climate warming, and human land use, determine the cumulative impact of global change on aquatic mountain biota (Battarbee et al. 2002).

24.3.3 Mountain Watersheds

The relationship between vegetation, soil, and water is best expressed in the functioning of the hydrologic unit—the watershed. Watersheds integrate conditions and processes over large areas and determine the functionality of their ecosystems and the water yield for river systems, which provide essential fresh water for aquatic life (including fisheries), agriculture, hydropower generation, and industrial and domestic use for growing populations both in the mountains and in the lowlands. More than 3 billion people depend directly or indirectly on water from mountains.

24.3.3.1 The Hydrological Importance of Mountains

One of the most important services from mountain ecosystems is the provision of clean water. In 2000, the Second World Water Forum in The Hague declared that major challenges included:

- protecting the ecosystems that supply water—that is, the mountains, the water towers;
- managing the risks that have an impact on water supply and distribution—that is, the drivers of change; and
- increasing the valuation and improving the governance of water resources and watersheds.

Mountain areas typically produce about twice the discharge that could be expected from the land area they cover (Viviroli et al. 2003). Mountains account for 20–50% of the total discharge in humid areas, rising to 50–90% in semiarid and arid areas mountain watersheds (with extremes over 95% in the Nile, Colorado, Orange, Syr Darya, Amu Darya, and Rio Negro). (See also Box 24.2.) The drier the lowlands, the greater the importance of the linked and more humid mountain areas that supply them (Viviroli et al. 2003; Liniger et al. 1998). (See Figures 24.12 and 24.13.) Moreover, discharge from mountain areas greatly reduces the intra- and inter-annual variation in total discharge.

24.3.3.2 Hydrology and Forests

Natural forests are hydrologically the most effective land cover in mountain watersheds. They can reduce runoff peaks and local flooding, but this influence decreases with the increasing size of the watershed and distance from the headwaters (Hamilton with King 1983). On very shallow soil in mountains, however, runoff peaks may not be reduced. In monsoon climates, with very high amounts and intensity of precipitation, landslips and mass earth failures may occur even with full forest cover, although the incidence of landslips is greater with other types of land cover. Low-stature vegetation, such as lightly grazed grassland and well-constructed and maintained terraced cropland, is also effective in maintaining a good and balanced runoff regime.

While removal of forests may increase total water yield, such removal and subsequent land use commonly has a host of undesirable consequences that offset the additional water gain, and forest removal is not usually viewed as a sustainable management option. Because of lower evapotranspiration losses, well-maintained grazing lands can yield more total water than forested land. However, sustainable grazing regimes and well-constructed and maintained terraces are rare. Moreover, erosion can become a serious problem with other land uses.

Under most conditions, continued forest cover in watersheds is essential for the maintenance of hydrological integrity, although caution is needed with plantations of exotic fast-growing species, which often use more water than native forests. Many of the world's biggest cities, including New York, Jakarta, Tokyo, Mumbai, Rio de Janeiro, Los Angeles, Barcelona, Nairobi, Melbourne, Bogota, La Paz, and Mexico City rely on protected forests in catchment areas for much of their drinking water (e.g., Velázquez 2003). In fact, 33 of the world's 105 largest cities get their drinking water directly from formally protected areas (Dudley and Stolten 2003).

Montane cloud forests capture fog or cloud water (horizontal precipitation), which can add substantial amounts of water to the hydrologic system, especially for dry climates with dependable clouds intersecting the mountains (Bruijnzeel and Proctor 1995). This process is mimicked in some dry coastal ranges (in Peru and Chile, for example) where trees or artificial nets have been established to capture this otherwise unused and unavailable water from fog.

BOX 24.2

Overutilization of Water from Mountain Areas Leading to Desertification

The Aral Sea Basin is an example of the importance of mountain water resources and ice and snow storage (Spreafico 1997). The basin includes parts of Afghanistan, Kazakhstan, Kyrgyzstan, Tadjikistan, Turkmenistan, and Uzbekistan and has an area of about 690,000 square kilometers with a population of 32 million.

Home to many civilizations since 6,000 BC, irrigation agriculture has been practiced for millennia (today, it covers over 8 million hectares). In the high mountains of the Tien Shan and Pamir, the annual precipitation ranges from 600 to over 2,000 millimeters, with 30% falling as snow and 60% of the total precipitation falling between December and May. The lowland deserts that cover most of the basin and are characterized by low rainfall (less than 100 millimeters a year) and high evaporation (potential evaporation as much as 1,500 millimeters a year).

In the summer, snow and glacial melt contribute to the flow of the two main rivers—the Amu Darya in the south and the Syr Darya in the north. The total annual runoff of the rivers in the basin is about 120 cubic kilometers, of which approximately 116 cubic kilometers originate in mountain areas (about 77 cubic kilometers contributed by the Amu Darya, and 39 by the Syr Darya). Thus the mountains provide more than 95% of the basin's fresh water. More than half a century of overutilization and high evaporative losses have resulted in a massive shrinking of the Aral Sea and in large-scale desertification. (See also in Chapter 20.)

24.3.3.3 Erosion and Sediments

Leaf litter, understory vegetation, and forest debris protect the soil from splash erosion—reducing surface, rill, and gully erosion. Moreover the shear strength provided to the soil by tree roots protects against slumping and landslips (O'Loughlin and Ziemer 1982). Soil compaction is less under forest than under other kinds of land cover. Grasslands provide an excellent cover too, but poorly controlled grazing can impair watershed quality. The quality of water delivered from a watershed may also be adversely affected by surface erosion from cropland and by the use of fertilizers and pesticides. Sediments from eroded watersheds impair water quality for many uses, affect aquatic life, and reduce reservoirs' capacity for storage, flood control (see Box 24.3), hydropower generation, and low flow augmentation.

Conservative grazing, horticulture, and cropping, using well-tested soil conservation techniques such as terracing, can result in low surface erosion rates and reduced sediment production (Whiteman 1988). Agroforestry systems, fruit orchards, and coffee plantations can reduce shallow landslip incidence by increasing root shear strength. The impact of traditional shifting agriculture depends on the length of fallow periods (full forest recovery), the size of the areas cleared, and the pattern in the landscape (Hamilton with King 1983). Vegetated riparian buffer zones are especially important in mountain watersheds as they act as sediment/nutrient traps, stream bank stabilizers, and a good habitat for many species of wildlife (Hamilton and Bruijnzeel 1997).

24.3.3.4 Dams for Hydropower Production and Irrigation

The number of reservoirs in upper watersheds and river basins, built largely for the benefit of lowland dwellers, is still increasing, although in industrial countries most of the best sites have already been exploited. Dams change the hydrology of rivers, sediment loads, riparian vegetation, patterns of stream bank erosion, migration of fish, and water temperature and have a multitude of socio-economic impacts, often including the displacement of local inhabitants. Dams may reduce downstream flooding.

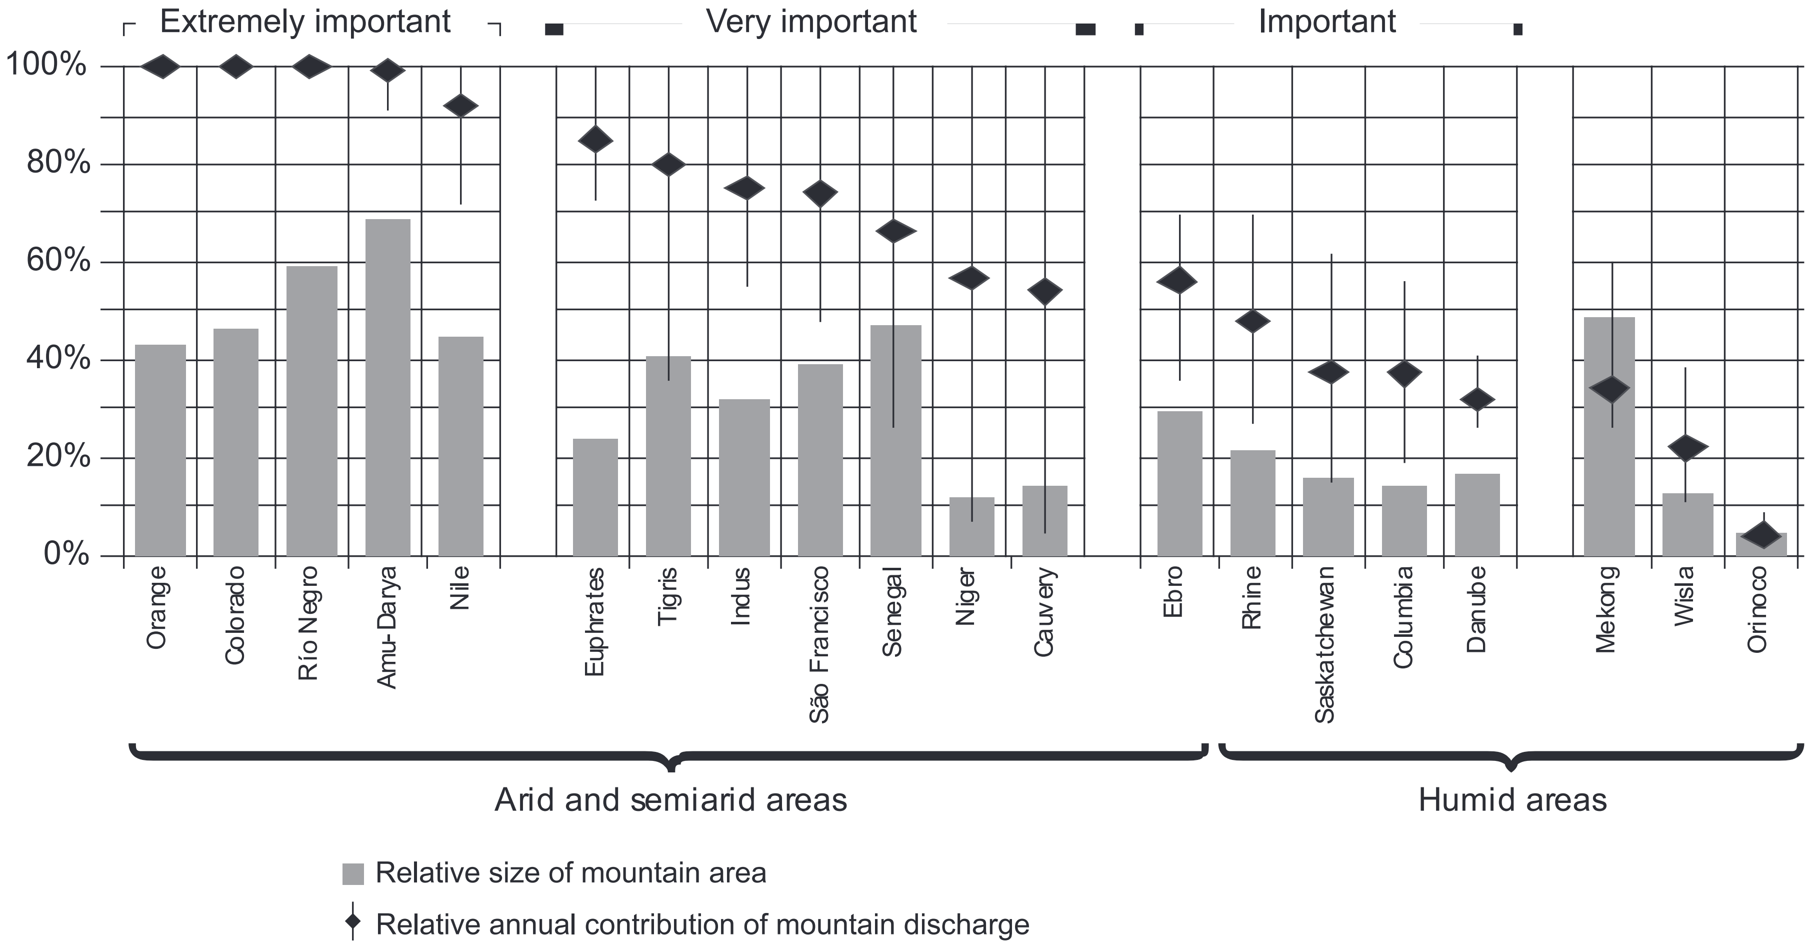

Figure 24.12. Mean Contribution (Importance) in Percent of Mountain Catchments to the Total Discharge per River System. The vertical lines denote the minimum and maximum contribution. Grey bars illustrate the areal contribution in percent of mountain area to the total area of the river system. Aridity declines from left to right. (Viviroli et al. 2003) Reprinted with the Permission of Mountain Research and Development.

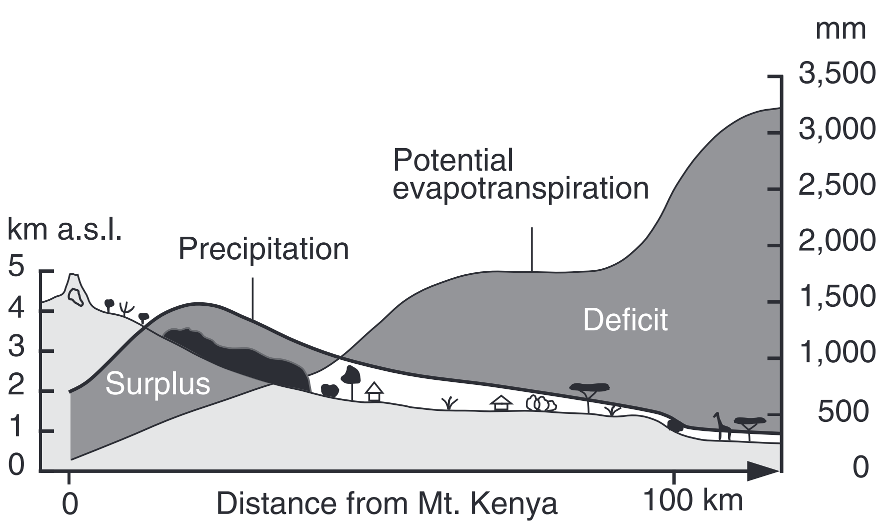

Figure 24.13. Example of the Ewaso Ng'iro River Catchment, Originating from the Slopes of Mount Kenya. Some 90% of the river flow comes from the upper montane zone (above 2,400 m) of Mount Kenya, supplying the semiarid plateau and the arid lowlands, where water resources are critically scarce during the dry season.

BOX 24.3

Floods, Landslides, and Reservoirs

On 19–20 July 1993, an extraordinary flood, which it was estimated would happen only once in 50–100 years, took place in eastern and central Nepal—with catastrophic effects (DHITAL et al. 1993). Several districts were affected by floods and landslides, a number of dams and roads were damaged, many people died, and many more became homeless. The high sedimentation during the flood halved the life span of the Kulekhani-Reservoir, which is located to the south of Kathmandu in the Bagmati watershed, cutting it from 50 to about 25 years.

Often, the lifespan of a dam is shorter than calculated, and the cost performance (if one includes all indirect costs) is rather low due to siltation. Policies that provide compensation for environmental services provided by mountain communities (through tariffs on the sale of water or of hydropower, for example) have been shown to have high economic benefits. The water bodies created behind dams can also benefit tourism enterprises or support a reservoir fishery.

24.3.3.5 Watershed Management

Watersheds are fragile environments that depend on a careful balance among many different elements, including soil, water, and both wild and agricultural plant and animal species. Population growth, particularly in cities, is increasing the pressure on watershed areas to provide water and food. As a result, nearly half of the world's population is affected by the degradation of watershed areas, which results from changes in water quantity and quality, sedimentation in lakes and reservoirs, loss of biodiversity, and ecological imbalances. Land abandonment following damming leaves behind complex environmental problems. In the developing world, degraded watersheds are among the most serious constraints to sustainable development.

Emigration has also played a crucial role in determining current watershed condition in developing countries. Demographic changes introduced by migrations strongly affect economic activities and trigger land use change processes that are most severe at upper watershed slopes (Li and Sun 1997).

While recognizing that watershed boundaries do not coincide with political units, there are nonetheless compelling reasons for planning and managing resources with due attention to this hydrologic unit. Easter and Hufschmidt (1985) provided this summary of the rational for a watershed approach to rural development:

- The watershed is a *functional region* defined by physical properties and boundaries.
- The watershed approach allows for evaluation of the biophysical interactions between upland and lowland activities that are linked through the hydrological cycle.
- The watershed approach is *holistic* and considers multiple facets of resource use and adopts an ecosystem view.
- Land use and natural phenomena in the highlands often result in a chain of *environmental reactions downstream* that can be readily examined in the watershed context.
- The watershed approach has a *strong economic logic.* Many of the externalities involved with alternative land management practices on an individual farm are internalized when the watershed is managed as a unit.
- The watershed provides a framework for analyzing interactions between people and the environment. Environmental impacts due to human activity within a watershed feed back to the socioeconomic system.
- The watershed approach can be *integrated with programs* of forest management, soil conservation, rural and community development, and farming systems.

As catchment limits rarely coincide with political boundaries, transboundary collaboration is normally required for sound catchment management. Effective watershed management requires accounting for interrelationships between highland and lowland areas and needs to involve local populations, as indicated in *Agenda 21* (UNCED 1992): ''Promoting integrated watershed development programmes through effective participation of local people is a key to preventing further ecological imbalance. An integrated approach is needed for conserving, upgrading and using the natural resource base of land, water, plant, animal and human resources.''

24.3.4 Socioeconomy in Mountains

24.3.4.1 Population

The global mountain population was estimated in 2000 to be 1.2 billion, or 20% of the total global population. (See Tables 24.8 and 24.9.) Nearly half (49%) of these people live in the Asia-Pacific region. About 30% of the mountain population occurs in each of two biogeographical zones—humid tropical lower montane and humid temperate hill and lower montane. Another 12% live in the dry cool temperate montane zone. (See Table 24.10.) Over 70% of the global mountain population lives below 1,500 meters, mainly in China. While just 8% live above 2,500 meters, this still amounts to about 90 million people, almost all considered extremely vulnerable. (See Figures 24.14–24.17 for photographs of mountain dwellers in various parts of the world.)

Table 24.8. Global Mountain Population Estimate and Share That Is Urban (CIESIN et al. 2004a, 2004b)

Mountain Area Class	Population	Urban
	(thousand)	*(percent)*
≥4,500 meters	5,405	4.6
3,500–4,500 meters	20,541	18.8
2,500–3,500 meters	63,373	27.7
1,500–2,500 meters	22,700	26.8
1,000–1,500 meters	226,292	30.3
300–1,000 meters	574,797	31.4
Total	**1,113,108**	**29.7**

Table 24.9. Mountain Population by Region and Average Mountain Population Density (CIESIN et al. 2004a)

Region	Population	Share of Total	Density
	(thousand)	*(percent)*	*(people/sq. km.)*
Asia	597,714	49	65.2
Former Soviet Union	34,851	3	6.4
Latin America	173,549	14	37.7
Northern Africa	141,113	12	52.3
OECD	119,559	10	18.3
Sub-Saharan Africa	152,613	13	43.1
World	**1,219,399**	**100**	**38.2**

Most mountain people are rural, particularly in the Asia-Pacific and sub-Saharan Africa regions. Globally, 30% of mountain people are urban, and settlements in and adjacent to mountain areas are expanding. The urban proportion is particularly high in the humid tropical upper montane, dry cool temperate montane, dry sub-tropical hill, and humid temperate lower-mid montane zones (52%, 43%, 39%, and 37%, respectively). The populations of the two zones with the greatest numbers of people are more than one quarter urban.

Mountain population density generally decreases with altitude. The total population at 1,500–2,500 meters is only slightly lower than that at 1,000–1,500 meters, however, reflecting more moderate climates and healthier environments above 1,500 meters in tropical mountains. Outside of urban areas, the highest overall density in mountains occurs in the humid temperate hill and lower montane biogoegraphical zone (96 people per square kilometer), which is also the zone with the greatest population. High densities (57–74 people) are also found in other humid zones, both temperate and tropical. The next highest densities occur in the widespread dry cool temperate montane zone (49 people per square kilometer), while the lowest densities (under 9 people) are found in alpine and nival zones.

Population growth rates vary considerably between biogeographical zones, with an average global rate of 16% from 1990 to 2000. The highest rates are generally in dry biogeographical zones (tropical hill, sub-tropical hill, warm temperate lower montane), which have population densities somewhat lower than the average of 38 people per square kilometer. Of the two zones with the highest populations, the growth rate in the humid tropical lower montane is above the average (22%), while that in the humid temperate hill and lower montane—the most densely populated—is below it (11%). Many of the zones with high population growth rates also have infant mortality rates above the global average for mountain populations (58 deaths per 1,000). Rates are also particularly high in the dry boreal subalpine and the humid tropical lower montane (respectively, 85 and 74 deaths per 1,000).

Migration has been characteristic for many mountain peoples since the earliest historical times. The numerous wars affecting mountain regions have led to massive movements of people. While comparison of data between censuses may show gross patterns of change, demographic flows are also often recorded within statistical reporting districts and within annual cycles. Consequently, although the spatial distribution of the population may

Table 24.10. Global Mountain Population, Share That Is Urban, Population Density, Population Growth, and Infant Mortality Rate by Biogeographical Zone (CIESIN et al. 2004a, 2004b)

Biogeographical Zone	Population	Urban	Density	Population Growth Rate 1990–2000	Infant Mortality Rate
	(thousand)	*(percent)*	*(people/sq. km.)*	*(percent)*	*(deaths/1,000)*
Humid tropical hill	53,940	18.2	60.2	18.6	55.4
Humid tropical lower montane	345,082	28.5	61.4	22.0	73.5
Humid tropical upper montane	12,130	52.0	74.4	22.2	35.1
Humid temperate hill and lower montane	349,308	26.4	95.9	11.2	42.8
Humid temperate lower–mid montane	79,949	37.1	57.3	5.4	29.8
Humid temperate upper montane and pan-mixed	49,947	22.2	10.4	7.7	39.1
Humid temperate alpine nival	4,426	4.7	2.8	17.4	51.1
Humid tropical alpine nival	1,103	18.5	8.8	14.4	39.7
Dry tropical hill	14,000	17.9	33.3	24.6	73.8
Dry sub-tropical hill	45,071	38.7	22.5	31.5	58.3
Dry warm temperate lower montane	43,575	35.6	33.1	24.8	60.5
Dry cool temperate montane	139,405	42.8	49.3	18.1	54.2

Polar nival	10,588	13.0	2.5	19.0	48.1
Total	**1,161,019**[a]	**30.0**[a]	**38.2**	**16.3**	**57.9**

[a] Difference from Tables 24.8 and 24.9 due to rounding errors.

change considerably, the level of data aggregation often hides these movements. Trends show both increased land use pressure at high elevation as well as increasing trends of urbanization (and a decrease in rural population) (Preston 1996).

In developing countries, mountain populations are generally growing, and some of the highest global rural population densities are found in tropical mountain areas (in Central American and Ethiopian highlands, for instance). This endogenous growth, complemented by immigration, has led to conflicts over land and other resources and the introduction of inappropriate land management practices and invasive alien species. In some mountain areas, such as in Latin America, there is increasing urbanization, with the total number of people in rural areas decreasing over the last two decades.

In industrial countries, one factor that stabilizes populations in mountain regions, or that encourages growth, is tourism, which is increasingly linked to amenity migration (Moss 1994). This phenomenon is becoming evident in many mountain regions. But amenity migrants and other immigrants may not spend all, or even much, of their working time in mountain communities. Indeed, the number of mountain commuters is also growing as travel times to urban and industrial centers decrease. These trends are leading to a blurring of rural/urban populations as mountain areas, and their inhabitants, become more integrated into the mainstream economy in many areas.

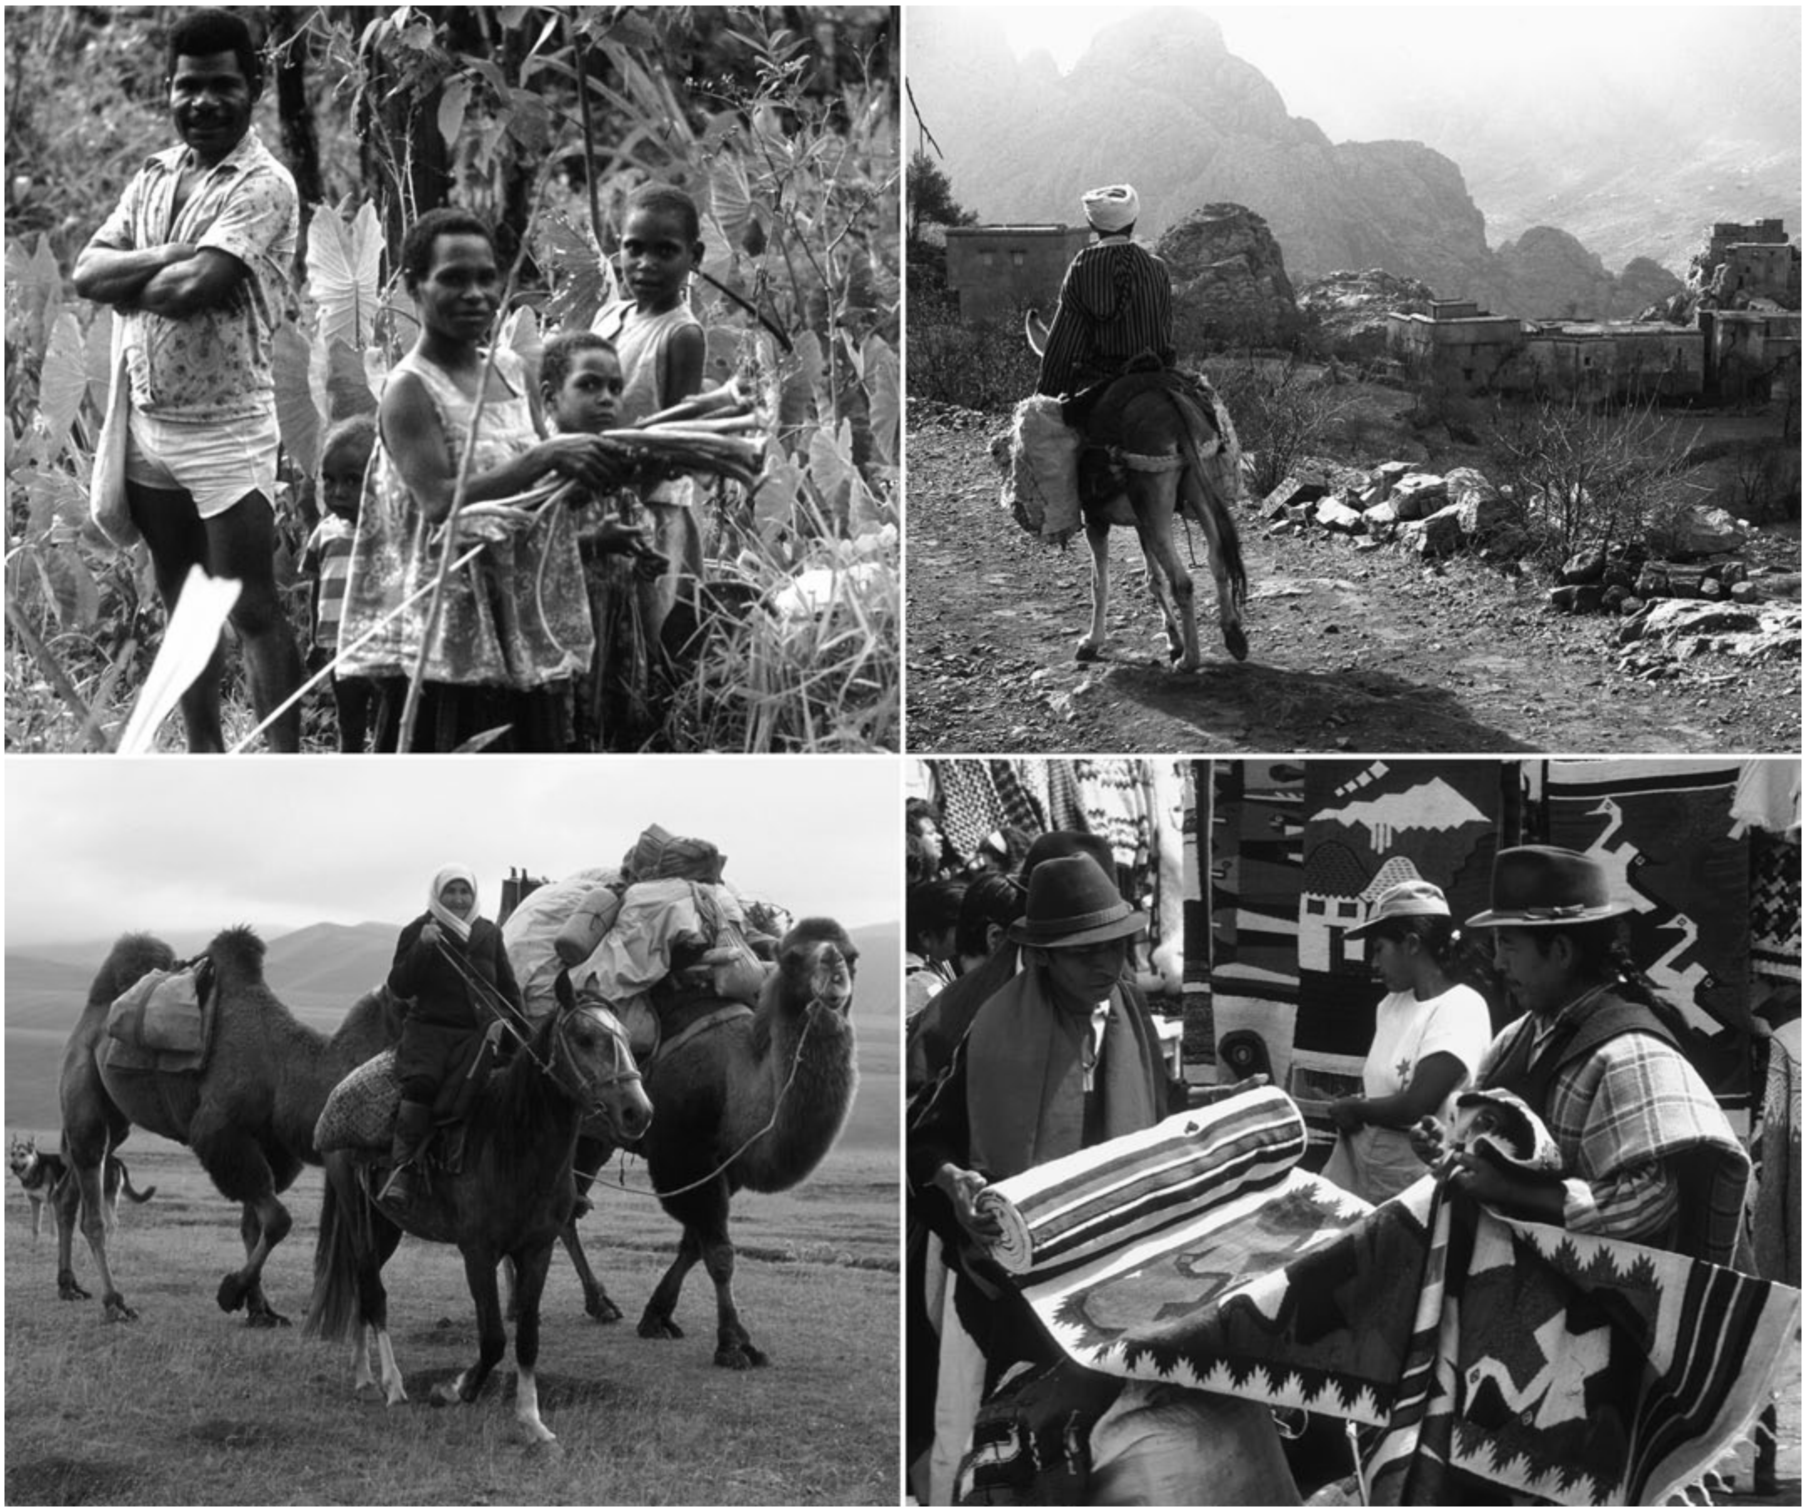
24.3.4.2 Economic Conditions

Of the main economic resources of mountains, extractive resources are generally thought to have the highest economic value. National economic policies therefore generally favor extractive industries over other resources and services in mountain areas.

Economic cost-benefit analyses of extractive resources are deficient, however, because they fail to take account of indirect costs or the distribution of benefits that largely accrue to firms and agents located far from the area of extractive activity. Indeed, the opportunities for local people to generate sustainable livelihoods are often restricted. Timber and mining in West Virginia in the United States are notable examples of this (U.S. Census Bureau and Lewis 1998, in Pratt and Shilling 2002). The Grasberg mine of PT-Freeport in Indonesia is a particularly egregious example (Kennedy et al. 1998, in Pratt and Shilling 2002).

Distortions in the distribution of benefits are evident in national accounts data. Foreign investment in Peru, for example, focuses mainly on the mining industry, with projected foreign investment of $9 billion for the period 1999–2007. This accounts for about 40–50% of exports, representing approximately 5.4% of the gross national product in 1998, and contributing 13% to government tax revenues (CONITE 1999). Little of this revenue, however, is redistributed to the mountain communities affected in the mining regions. Another example is Western New Guinea (Irian Jaya, Indonesia), a mountainous province rich in natural resources, particularly forests. On a provincial GDP basis, its per capita income is the highest in Indonesia, but its GNP per capita is the lowest. The nearly threefold difference between GDP and GNP clearly demonstrates the level of inequality between total production from the area and the proportion of goods and services that accrues to local residents.

These examples illustrate a general problem in assessing economic and social conditions in mountains: data collection is rarely undertaken on a spatial basis, and this represents a critical gap. Because mountain ecosystems and production systems are closely interrelated, geographically referenced data are essential to enable sound management. Most data linked solely to coordinates have proved to be insufficient for sound decision management. Natural entities, such as geomorphologic units as watersheds, are crucial to understanding processes in mountain regions and should form the basis for management decisions (Bocco et al. 2001).



Figures 24.14–17. Mountain People. Top left: Shifting agriculture in montane tropical forests, Papua New Guinea, at 1,200 meters. Top right: Mountain village in the Atlas Mountains, Morocco, at 1,400 meters. Bottom left: Pastoralism in the Tien Shan Mountains, South Kazakhstan, at 2,550 meters. Bottom right: A local market in Otavalo, Ecuador, at 2,000 meters.

Mountain areas tend to have greater poverty and lower levels of development than lowland areas. Starr (2004) noted that, "Poverty has long been a feature of life in many high altitude communities. But the poverty that prevails in many mountain areas today is of a peculiarly modern sort, in that it arises from a growing dependence on lowland metropolitan centers rather than from age-old self-sufficiency in a harsh environment."

Using standard economic criteria, relative poverty in many mountain areas is high—from the Appalachians in the United States to the Amerindians in the Andes and the inhabitants of the Pamirs and Caucasuses in Eurasia. Initial work by the International Livestock Research Institute in Kenya has suggested that mountain areas tend to have relatively high poverty, though the use of relatively low-resolution data does not allow strong conclusions.

The Aga Khan Rural Support Programme and the U.N. Food and Agriculture Organization have each begun to assess mountain poverty (Rasmussen and Parvez 2002; Huddleston et al. 2003). AKRSP found that the status of people in mountain areas reflects the overall level of income of the country in which they live. The higher the national income, the higher the income of mountain people. Yet most available intra-country studies indicate that mountain people do economically less well than lowland populations. There are notable exceptions, however. The mountain areas of the European Alps underwent a rapid economic transformation following improved accessibility. Similarly, traders involved in long-distance trade across some mountain barriers, such as the Himalayas, are quite rich compared with local subsistence farming communities. Noncommercial values such as better access to water, better air quality, and fewer pests such as malarial mosquitoes also add to the benefits of life in the mountains.

Traditionally, dispersion and fragmentation of mountain communities is associated with language differences (for instance, more than 800 different languages in the mountain areas of Papua New Guinea), which further inhibits cooperation on larger-scale activities that could help the improve living standards of mountain people. Mountain roads are expensive to build and maintain, and they generally serve few people per kilometer. A comparison of mountain and non-mountain areas in several countries confirms that mountain populations are more isolated, as measured by distance from roads (Huddleston et al. 2003).

Settlement fragmentation in mountain areas makes it difficult to provide basic social services, medical care, or schooling. There is evidence that malnutrition, particularly micronutrient deficiencies, is higher among mountain inhabitants than in lowland populations (Huddleston et al. 2003). Migration provides important—though often socially negative—connections between upland and lowland areas, and remittances constitute an important source of income for mountain families.

Mountain and lowland economies are interdependent today. Lowland populations depend on environmental services provided by mountain ecosystems and people, including watershed protection and recreation. Mountain populations in turn are increasingly affected by global markets, particularly where commodities are concerned—whether these be agricultural products (coffee, tea, medicinal plants), minerals, or hydropower. There is a high level of consensus that the key to achieving sustainable and acceptable standards of living in mountains has been to transfer to local people more control over mountain assets and the means to negotiate more equitable allocations of benefits. In part, this requires improving access to education and health services. This, in turn, depends on building more equitable relations with lowland political institutions and assuring a better distribution of public services. Enlightened self-interest on the part of lowland institutions and well-coordinated actions on the part of mountain people are required to achieve progress in this area.

24.3.4.2.1 Types of mountain economies

Almost all adverse environmental and social impacts of economic activities in lowlands have their mountain equivalent. What is different about mountain regions is that the constellation of adverse ecosystem and social impacts is characteristic, rather than exceptional. Anthropogenic impacts often result in permanent, or at least very long-lasting, destruction of biodiversity and productive potential. Given that every mountain range is different in the specificity, complexity, and economic potential of its ecosystem resources and services, methods that help assess the impacts of alternative management choices will need to be developed.

Forest management professionals, mining engineers, policymakers, and environmentalists often face conflicts about how to manage mountain resources. Separating economic values and environmental service values can help management choices. (See Figure 24.18.) In all but one of the cases that follow, actions needed to balance conservation and development interests are quite specific, both in nature and in terms of which actors have primary responsibility.

- *Low Export and Low In Situ Value.* The Ethiopian highlands, Tibetan plateau, and Andean altiplano exemplify the case of low export and low in situ value, where subsistence farmers have no access to markets and have poor soil and other resources. In such cases, some economic improvement is possible with appropriate technologies, when combined with some restoration of ecosystem functions. Ecosystem restoration is critical, as lowland economies simply cannot absorb the mountain populations that would be forced to migrate in the absence of a viable environment. Downstream populations benefit economically when mountain ecosystems and ecosystem services remain intact. In some cases, if transportation access is provided a region can even shift to high export value if it can find markets for its minerals, timber, or agricultural produce. Even the most minimal transportation access can help communities gain access to local markets. In extreme cases, however, subsidies continue to be justified on humanitarian grounds.
- *Low Export and High In Situ Value.* In some of the world's most scenic ranges, such as the Cascades Park in North America and Makalu Barun National Park in Nepal, the biodiversity, watershed protection, and recreational values are clear. Low export values may result from inaccessibility to markets, making resource extraction prohibitive; but at the same time the inaccessibility enhances scenic and recreational value. Tourism is a major resource for such mountain economies, and studies in many regions have shown that protection of watersheds provides greater economic value than resource extraction (The Mountain Institute 1998). Conservation is often compatible with tourism, and generates revenue for government in addition to local employment and income. Bhutan and Rwanda, for example, have established high fees, generating substantial funds for conservation and sustainable development. And Nepal and Peru have begun using community-based tourism to improve livelihoods of local people. However, conservation and the creation of parks and protected areas are not the only choice. Management for sustainable use in agro-forestry-grazing systems has been practiced in the Alps for at least eight centuries. Such systems, however, require strong links to downstream markets.
- *High Export and Low In Situ Value.* In areas with low biodiversity, where extractive potential is high (mineral resources or hydropower, for example, and managed timber), export of resources is appropriate, such as in the arid mountains of the Peruvian Andes. Adverse environmental impacts can be addressed in environmental impact assessments, provided that mitigating measures and social safeguards are implemented. In practice, however, indigenous communities receive an equitable share of revenues only in exceptional cases, either from corporations or through government programs funded by taxes from the extractive enterprise.
- *High Export and High In Situ Value.* Areas where extractive potential and environmental benefits are both high, such as in old-growth mountain forests, are classic examples of conflict, with mining in Papua New Guinea often singled out for particular attention. In such cases, decision-makers—corporate, governmental, and civil society—encounter expensive and extended negotiations with stakeholders and are faced with difficult trade-offs in the attempt to satisfy the needs and demands of all stakeholders.

24.3.4.2.2 Economic contribution of ecosystem services

Ecosystem services of mountains, often ignored, provide greater economic benefits than extractive resource use in most cases. Intact biodiversity protects watersheds and attracts tourism, as well as furnishing rich natural resources for key industries. When measured, watershed protection values have been found to significantly outweigh extractive resource use.

While mountain people play essential roles in maintaining cultural landscapes and traditions, they may not derive significant benefits from tourism, particularly when most investments come from outside and when revenues leave the area. Governments, nonprofit organizations, and private companies have the potential to ensure benefits to local communities through investments, subsidies, low-interest loans, or training to those involved in promoting tourism and maintaining cultural landscapes and traditions.

The concept of payment for ecosystem services has received much attention in various countries as an innovative tool for the

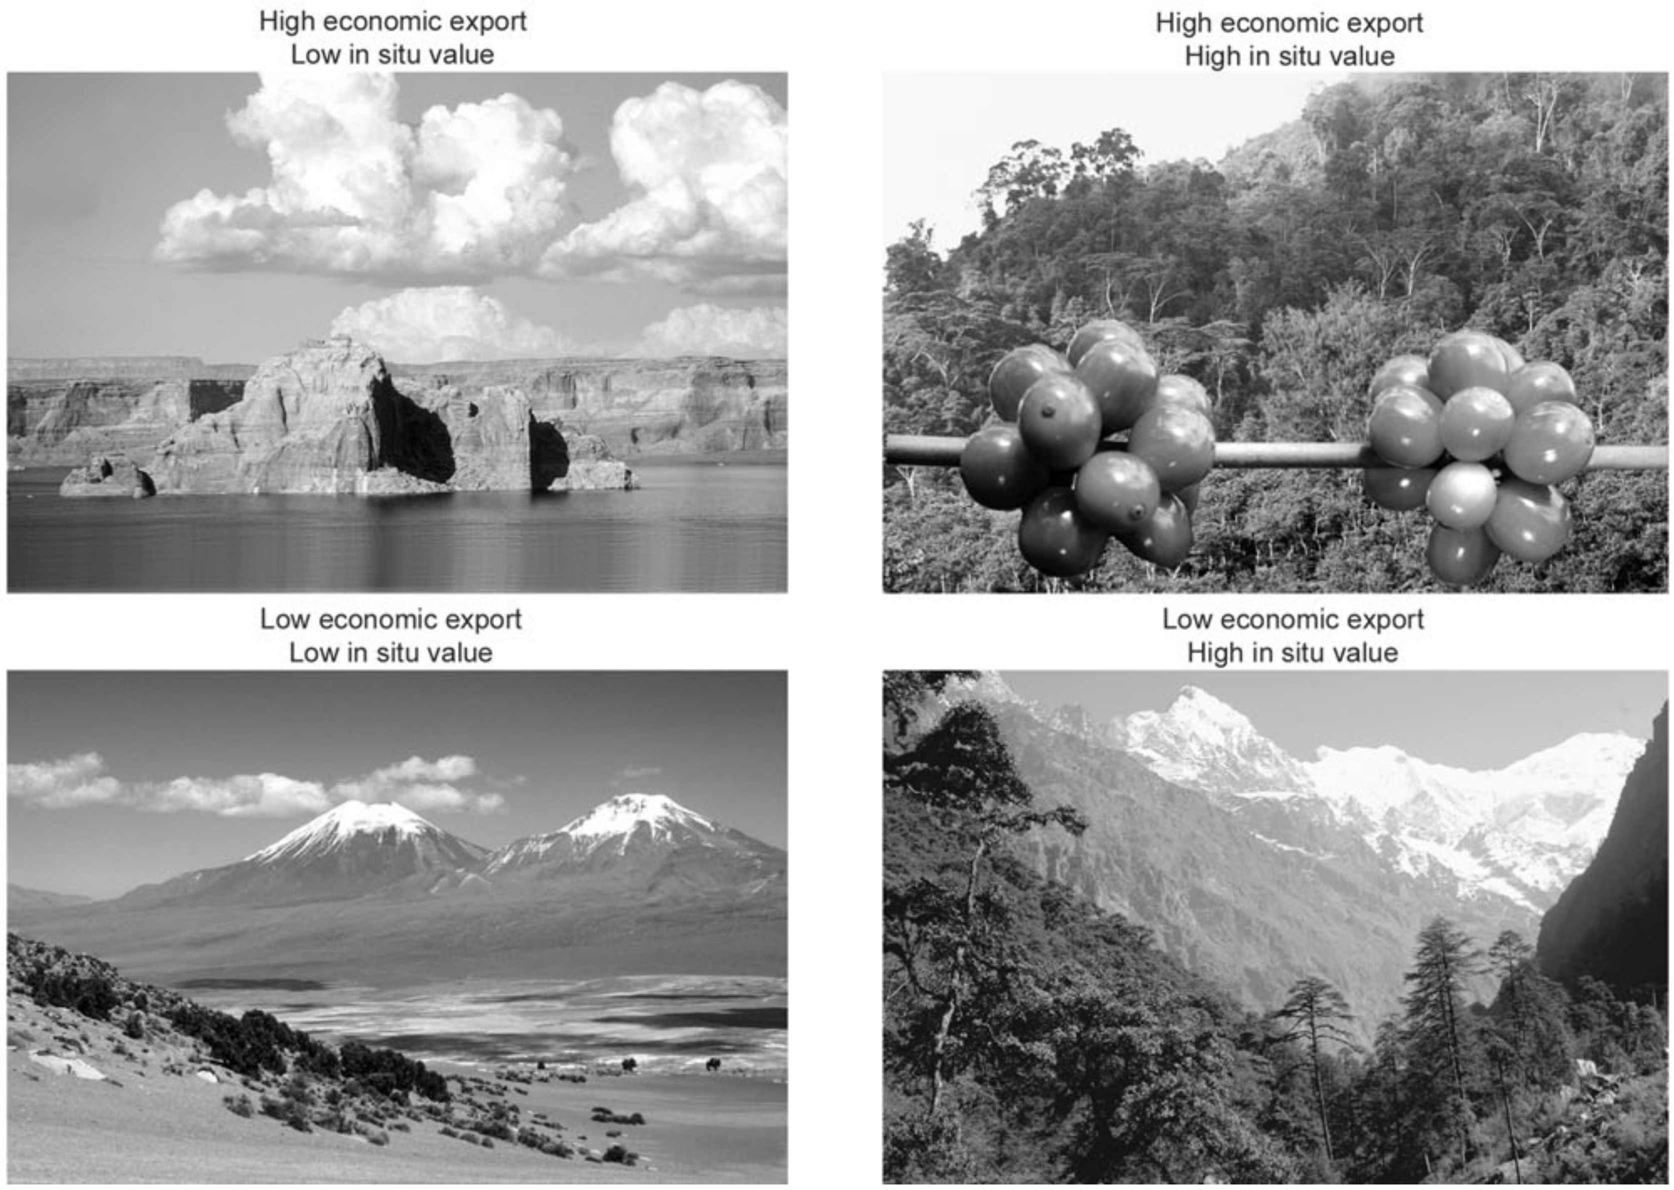


Figure 24.18. A Typology of Mountain Economies. In situ values are ecosystem services provided by the mountain environment in its natural state (such as flood mitigation, water purification, and carbon sequestration. The top left (Lake Powell Reservoir, Utah) represents an area where water existing at high altitudes could be tapped for hydropower or irrigation downstream, but where access problems make it all but impossible for humans to reap economic benefits in situ. The top right (a montane tropical forest in Wau, Papua New Guinea) indicated the main areas of conflict, as represented symbolically by a rich montane forest with shifting cultivation supplying all local needs coming in conflict with a major cash crop, coffee, and the need to clear the forest to grow it. The high, barren landscape in the bottom left (Bolivian Altiplano at 4,200 meters; no export of water, minerals, timber, etc., and marginal local pastoralism) shows that some mountain areas have few natural resources available to inhabitants, and fewer resources that could be profitably exported. A combination of high in situ value but low economic export (bottom right, Langtang valley, Nepal Himalaya; rich forest and gardens at lower montane altitudes, but little to no export) is generally found in areas where lack of access makes export of natural resources too difficult or expensive or where legal or regulatory restrictions have been established that prohibit export of resources, as in national parks.

financing of sustainable management of land and water resources in watersheds. PES schemes consist of a payment or direct compensation by the users to the providers of the service for the maintenance or provision of an environmental service. In watersheds, this usually relates to water supply, availability, or quality. Until now, PES systems in watersheds have been applied at very different stages of the process and for various reasons, from the micro-watershed level—focusing on a very specific service—and usually managed by an NGO or local government to national programs controlled by the State.

Recent reviews of PES experiences in Latin America (FAO 2004; FAO/REDLACH 2004) show that such schemes can be sustainable in the long term if they are funded by local resources and if the service as well as the users and providers are well defined. They can contribute to conflict-solving processes by providing platforms for negotiations. Furthermore, they may transfer resources to socially and economically vulnerable sectors in upper watersheds, which offer environmental services. Important limitations to the application of the PES concept include the high transaction costs during design and implementation of the scheme (biophysical studies, for instance, and assessment and system installation) and the significant uncertainties regarding the cause-effect relationships between land use and the environmental services, particularly forest-water linkages (FAO 2002b).

Modern transportation gives tourists access to almost all mountain regions. Mountain tourism is very unevenly distributed, however. For example, in the Alps 40% of communities have no tourism and only 10% have major tourist infrastructure. Generally, the former are losing population, while the latter have stable or growing populations. Mountain tourism is highly diverse, involving many often seasonal activities, and is highly competitive and sensitive to political tensions. Thus its benefits are unevenly distributed and unpredictable. Flexibility and strategic perspectives are essential, and where income from tourism is reinvested it provides livelihoods for mountain people and helps maintain environmental quality.

Finally, mountains help protect against hazards (erosion control, slope stability) and contribute to soil fertility (volcanic ashes, carbon fixation), as well as modulating climate through several mechanisms discussed earlier. The vertical upthrust of mountains captures precipitation, often creating rain shadows on one side of the range and wet areas on the other. Seasonal snowpack melting and mountain bog ecosystems are critical sources of water for agriculture as well as for drinking water.

The economic impact of these climate-modulating effects is taken for granted and implicitly factored into the costs and benefits of water use. Major changes in the ability of mountains to provide such environmental services, however, would create significant and potentially disastrous cost increases. For example, the retreat of glaciers caused by climate change is likely to cause short-term increases in water availability, leading to increased investments in irrigation and enabling the growth of downstream cities. In the medium term, however, the water supply from meltwater is likely to be markedly reduced if glaciers continue to recede, negating the value of massive infrastructure investments.

24.3.4.2.3 Extractive industries and public utilities

Mountains provide the largest share of resources for mining, forestry, water for drinking and irrigation, and hydropower, and they generate an increasing amount of wind power as well.

Water is becoming a limiting constraint to development in many parts of the world, and in some cases to life itself. The critical importance of mountain ecosystems in regulating water quality and quantity cannot be overstated. In addition, the specific economic value of hydropower depends largely on mountain water, which in turn depends on conserving mountain watersheds.

Some 6% of the world's energy and 15% of its electricity is produced from hydropower. Aside from a few hydropower projects built on swiftly flowing rivers that require no dams, most hydro projects inundate large areas for reservoirs. In mountains, the massive weight of such holdings creates a risk of induced seismic events and dam failure, sometimes resulting in catastrophic flooding. The benefits of hydropower—in terms of access to electricity and profits—accrue mostly to the lowlands. Those in mountains often suffer losses from inundation, diversion of water flows, and disruption of traditional production.

Yet mountain communities and downstream beneficiaries share a common interest in protecting upstream watersheds to assure continued productivity of both hydropower sites and upland production systems. This has proved to be one avenue to joint stewardship arrangements. Properly managed, water supply and hydropower can be a sustainable use of mountain resources. But extra efforts are usually needed to ensure that mountain people get a fair share of benefits and, in the case of hydropower projects, a connection to the power grid.

Globally, forests are probably the second most important economic resource provided by mountains, although this varies across mountain regions. Since most logging is done in pristine forests, little or nothing is paid for production costs. However, standing timber also provides valuable services—stabilization of water flow, protection of biodiversity, carbon sequestration, provision of amenities, and many non-timber products. Several studies have calculated that the economic value for such services exceeds that of the timber extracted. Harvesting primary forests is therefore like mining a resource without compensatory reinvestment. And as with hydropower and mining, many of the economic benefits do not remain in the region that provides the resource.

The loss of trees significantly alters the ecosystems of mountain areas and leads to the loss of alternative sources of income—non-timber forest products, biodiversity, tourism, and so on. Losses of ecosystem benefits are often hard to measure, however, as they are not priced or traded in markets. But some local studies have shown that such benefits often far outweigh the value of timber from logging. In Indonesia, for example, the value of alternative uses exceeds the value of logging by more than 50% (Conservation International 1999).

Communal forestry is a critical element in integrative participatory forest management in many regions. In large parts of mountainous areas in Latin America, Africa, and South and Southeast Asia, collective forest management has proved to be a successful alternative to government or commercial control. Policies that undermine these collective systems have promoted the abandonment of traditional farming systems, often with large, adverse environmental consequences.

Mineral extraction contributes a relatively small part of global GDP, but mineral revenues are often important in mountainous countries. Minerals account for 45% of Chile's exports, 49% of those from Peru, 64% of Zambian exports, and 62% of Papua New Guinea's. While some of the world's largest and most productive mines are found in low-lying areas, mines tend to cluster along mountain ranges. An exception is the Himalayan area, which is not yet cluttered with mines, where ruggedness and distance from markets—in addition to strong local opposition—makes it harder to justify mining operations. Cases in the Supreme Courts of India and Nepal against mining in the fragile Himalayan watersheds drew attention to the risks of mining in these areas (Bandyopadhyay and Shiva 1985). China is nevertheless expanding exploration in some areas on the northern side of the Himalaya.

Mines are nearly always highly destructive to the local environment and displace people living in the immediate area (Pratt 2001). More threatening still are the pollution and toxic wastes produced or accidentally released by mine operations. Toxic pollution from mines has often been recorded leaching out and contaminating large areas downstream, especially in developing countries.

There is a high level of consensus that significant benefits are obtained from better stewardship of upland resources and the appropriate reinvestment of profits from extractive industries into resource management in a way that benefits local communities. For instance, the Sierra Nevada in California produces some $2.2 billion per year in commodities and services. Water resources constitute 61% of the total, yet reinvestment in watershed management is basically zero, since water rights are not taxed as property, and commercial real estate assessments are low compared with revenues generated. In contrast, recreation and residential use provide 21%, timber 14%, and grazing 2% of total value, but reinvestment amounts to $10 million, $23 million, and $7 million (in the latter case, as subsidies) (The Mountain Institute, Investing in Mountains, 1997).

Mountain farming systems involve multiple land use activities and diversified production systems that adapt/amend the natural resources (such as through water harvesting or terracing). This has resulted in diversified and context-specific farming systems characterized by positive social system–ecosystem links. In nearly all mountain regions, non-timber forest products are an important adjunct to traditional agriculture, often providing the sole or major source of medicine for local people, as well as supplying key nutritional supplements. With globalization, the production of nuts, fruits, off-season vegetables, flowers, and cosmetic and medicinal plants has opened new economic opportunities for mountain communities. However, the value added by mountain dwellers will likely remain proportionally small unless local processing replaces the export of raw produce (Jodha 2002).

With closer integration of mountain and lowland economies, enhanced administrative interventions, and population growth, the connection of mountain communities to natural resources has declined (Berkes and Folke 2002). Increased poverty, inequity, and dependence on external support in most areas is a major consequence. Interventions to address such problems have not proved effective because they lack a mountain perspective—that is, sensitivity to mountain-specific conditions that take into account the fragility, marginality, limited accessibility, and diversity of mountain systems. Based on studies in developing countries, the International Centre for Integrated Mountain Development has identified over 50 indicators of unsustainable mountain agriculture and resource use that are emerging in these areas (Jodha 2001). These range from reduced crop productivity to a decline in the range and quality of sustenance options (excluding areas with better access and infrastructure, and where inaccessibility encourages cultivation of illicit crops). These trends are likely to accelerate as market forces gain primacy.

The rise in global demand for mountain herbs and other organic and non-timber forest products is leading to over-extraction. Disregard of customary rights, collective risk sharing arrangements, and reduced social transfers (subsidies) have increased vulnerabilities. While some mountain areas have benefited from the process, others have to face the deleterious effects of globalization (Jodha 2000). In general, agricultural production systems in mountain areas are likely to be driven and controlled by market forces rather than people's sustenance needs and preferences.

24.3.4.2.4 Relationships between drivers and changes in ecosystem condition

All the impacts just described are exacerbated by the development of modern economic infrastructures, such as highways and communications towers that interrupt conservation corridors, reduce scenic values, and contribute to erosion and pollution from traffic. Although roads reduce remoteness and inaccessibility of highland communities, inappropriate siting, construction, and maintenance often have serious adverse impacts in steep upper watersheds (Cassells 1996; Hamilton and Bruijnzeel 1997). Location in landslip- or landslide-prone environments creates both on-site and downstream sediment problems. Roads run the risk of crossing groundwater aquifers, altering hydrologic stability and interfering with water supply for both upstream and downstream watershed residents. Sealed surfaces enhance runoff, increasing the risk of flash flooding. Cut-and-fill situations are particularly erosion-prone. Soil erosion problems demand frequent and costly maintenance. To lessen hazards, the construction of underpasses and overpasses for road users and animals has proved effective. Construction or mining camps or towns for workers create environmental disturbances and also serve as a major vector for HIV/AIDS and other diseases.

24.3.4.2.5 Implications for human well-being

This assessment indicates that when full costs are taken into account, stewardship of upland resources generally yields greater and more sustainable economic returns both to the people living in the mountain areas and to the immediate downstream economies when compared with extractive activities, in cases where there is competition between the two. For mountain communities, protecting the ecosystem that they depend on requires interventions: regulatory protection has a high potential to ensure that full costs are included in project design and implementation, and promoting solid links between upstream and downstream markets creates economic opportunities that generate mutual benefits. In the long term, there is a consensus that upland and lowland ecosystems, and the economic resources and services they provide, depend on populations in both regions supporting stewardship of mountain environments. The challenge for investment and policy action has been to bridge short- and long-term interests.

The failure to protect and manage mountain resources sustainably has dire consequences that become visible only when it is already too late. Among the most important economic consequences are impacts on employment and sustainability. Conservation programs that protect environmental services have been shown to create employment for local people and, in the best cases, to strengthen cultural identity and security (for example, the UNESCO Biosphere Reserve concept). Mismanaged conservation programs can drive local people out by force or when competition for land and housing drives up prices. Those driven out tend to place burdens on nearby urban areas through unemployment and demands for public services. They are often considered ''different'' from local people, contributing to discrimination and ethnic violence.

Extractive industries are particularly problematic in mountains. Hydro projects frequently disrupt aquatic ecosystems but rarely offer long-term jobs for local people. Forestry provides greater local job opportunities, but mountain forests regenerate slowly or not at all, and employment disappears once the timber is gone. The loss of forest also eliminates traditional lifestyles that use hunting, fishing, and non-timber forest products to supplement farming. Mining has serious environmental consequences; but modern mining often provides scant local employment. Mining companies have shown increasing willingness to provide social services, but the benefits tend to last only until the mine is exhausted, while environmental damage is persistent.

Greater attention to conservation and to strengthening traditional production systems has the potential to generate greater economic value. Managing trade-offs among uses is often limited because most data on resource extraction and ecosystem production and services are not spatially referenced, masking the contributions of mountain regions, and leading to ecosystem degradation and economic inequities. The availability of spatially referenced data is thus a critical gap.

24.3.4.3 Cultural Issues

Many mountain communities are ethnically or culturally distinct from lowland populations, and local highland communities are often highly distinct from each other. The significance of mountains for human cultural diversity is demonstrated by the great ethnic and linguistic diversity of some mountain regions, such as the Caucasuses, the Himalaya, and the mountains of New Guinea (Association des populations des montagnes du monde 2003). Indigenous mountain populations often exhibit genotypic physiological adaptations to altitude (Beall 2002).

In mountain ranges throughout the world, traditional cultures and conservation have evolved together over the ages. Sustainable natural resource management is driven by the beliefs and behaviors of human communities, and local cultures are strengthened by their intimate connections to the natural environment that sustains them. Sacred and spiritual values are thus integral to mountain cultures; mountains are considered sacred by more than 1 billion people (Bernbaum 1998). (See also Chapter 17.)

The value of place-based mountain cultures today is in their continuing stewardship of watersheds and other mountain resources and in the wisdom they have to impart regarding the requirements for sustainability of mountain ecosystems (Pratt 1998). A major cultural element of life in the mountains is tied to animal husbandry, which also is by far the most influential form of land use (in terms of area). Quite often this involves the use of fire (Price 1999). The U.N. Commission on Sustainable Development has stated that ''support is needed to recover and foster the cultural expression of mountain populations because mountain cultural diversity is a strong and valid basis for sustainable use and conservation of mountain resources'' (Commission on Sustainable Development 1995). And the need to protect and support the cultural diversity of mountains has been emphasized in the declarations of numerous major international meetings (e.g., Association des populations des montagnes du monde 2003).

24.4 Drivers of Change in Mountain Systems

Environmental and economic change is a constant and familiar factor in mountains, but the magnitude and rate of change and its influence on social systems in recent times threatens to overwhelm mountain ecosystems—with serious consequences for the well-being of mountain communities as well as hundreds of millions of people downstream. Mountain systems are changing more rapidly than at any time in human history. The core issue is that more than half of humanity depends on mountains for water to drink, to grow food, to produce electricity, and to generate industry. In addition, mountain ranges represent important challenges for transportation, communications, and access.

Natural forces such as volcanic and seismic events, landslides, and flooding devastate large areas of mountainous ecosystems every year. Such changes, though vast and visible, are nevertheless dwarfed by deleterious anthropogenic changes, such as intensification of land use and overexploitation of natural resources (Messerli and Hurni 2000; FAO 2002a; Pratt and Shilling 2002).

24.4.1 Direct Drivers

Because mountains are formed by tectonic forces, it is not surprising that mountain regions are particularly susceptible to damage from earthquakes and volcanoes, which in many cases results in a significant loss of life and property. Climate change is another direct driver with special significance for mountains and serious implications for human well-being. Mountains are particularly susceptible to climate change because their biota are adapted to specific often narrow altitudinal zones, and diseases have proved to be able to move more quickly than plants and animals can adapt. Conversion of land in mountains, largely through pasture practices, the use of fire, and animal husbandry is another major driver.

Large-scale mining can massively overburden steep terrain, and often pollutes streams and damages aquatic and other wildlife. Construction of roads in mountain areas often leads to slope instability, land slides, and erosion. The large-scale building of vacation homes and resorts has had mixed impacts in mountains, while in many regions, out-migration of mountain farmers has led to reforestation and loss of alpine pastures. Elsewhere, forest is cleared for commercial timber. Such loss of vegetative cover—regardless of the cause—can have a significant adverse impact on water quality and quantity both in mountain regions and below. Threats to human well-being from these drivers range from increased risk of avalanche to loss of income from tourism.

These drivers of change are not new—there are historical accounts of human impacts on mountain environments, with drought and famine, dating back millennia (such as the felling of mountain cedar forests in Palestine and Lebanon 5,000 years ago). Forest destruction continues, however. Major drivers of the direct anthropogenic impacts are the lack of public awareness and knowledge and indirect socioeconomic forces.

24.4.2 Indirect Drivers

Indirect drivers affecting mountains can be complex. In mountain areas from Jamaica to Nepal, mountain forests are destroyed as population increases in the lowlands, forcing poorer people into the mountains, where they cultivate marginal land for subsistence. Economic development often results in land use changes such as those just described, with consequent degradation of ecosystem services. More difficult to measure, but nonetheless important, economic development in mountains usually leads to a weakening of traditional cultures and religions that have provided the underpinnings for local sustainability.

Science and technology, on the other hand, have frequently had positive impacts in mountain areas and have the potential to provide solutions to a number of critical problems. Solar and wind energy, and especially small-scale hydropower, have brought enormous benefits in regions where they have been introduced and where extension of transmission lines is otherwise prohibitively expensive. Information technology is perhaps the single most promising technology for mountain communities, with potential to overcome access barriers that currently limit educational opportunities for tens of millions of mountain families.

The sectorally based organization of governments hampers the implementation of more holistic or ecosystem-based approaches to mountain ecosystem management (Rodgers 2002; Pratt and Shilling 2002). Overall, flawed institutional responses (lack of mandates, policies, and political will) are pervasive indirect drivers of change in mountains. The lack of structural mechanisms that can deal holistically with mountain areas has made it difficult or impossible to prevent or mitigate adverse impacts of key drivers. This can be seen in the lessons from decades of mountain water conservation initiatives that have generally failed due to sectoral fragmentation of institutional responsibilities, political interference, over-reliance on technocrats at the planning stage, too little involvement of landowners and local communities, an overemphasis on maximal instead of sustainable resource use, and a lack of knowledge on adequate farming systems (many introduced systems were originally developed for lower altitudes).

Other indirect drivers are the lack of public awareness, lack of real valuation of resources and services, and lack of knowledge transfer. Empowered and well informed local communities have proved to be key to managing changes imposed from outside; in the case of biodiversity, a functional network of protected areas is an essential starting point for genetic reservoirs and monitoring stations (Dhar 1997).

For many drivers, indicators and monitoring programs are in place, like the recent worldwide installation of monitoring sites in mountain summit regions—the Global Observation Research Initiative in Alpine Environments (Pauli et al. 2004, 2005). What is missing is the sociopolitical and economic understanding of how scientific insights can be applied and how local stakeholders can be involved on a continuing basis.

24.4.3 Property Rights to Mountains

In most mountains outside Western Europe and the United States, legal ownership of the land is retained by the state. Mountain lands are also covered with customary use rights for members of local communities (de facto ownership). Major challenges for resource governance in many parts of the world include encouraging governments to recognize customary rights and finding ways of recording and enforcing such rights. (See Box 24.4.) Over a dozen countries have enacted specific legislation related to mountains (Lynch and Maggio 2000).

Property rights to mountains are often poorly defined because mountain areas for most of history have been seen to contain few resources. Now, however, market forces are reaching into remote mountain communities, and government interest in managing ecosystems and their services has increased. Indigenous (or non-capitalist) cultures have usually developed customary law similar to property rights for specific material resources. Property rights claimed by the state have led to discrimination against indigenous peoples in some parts of the world, making their customary rights harder to defend.

The early modern states tended to pursue a policy of bundling ''ground,'' ''remainder,'' and specific resources (see definitions in Box 24.5) into one owner unit in their legal systems. This ''dominium plenum'' position on ownership and its assumed beneficial economic consequences led to the processes of enclosure and land consolidation. Applied to mountains and other areas where local people were interested only in specific resources and socio-cultural symbols, this practice has tended to create conflicts, most notably for timber and other commercially valued resources.

Social and technological change creates new specific resources usually seen as belonging to the owner of the remainder (such as the generation of hydroelectric power), and this also leads to new regulation of ecosystem services. Such developments often conflict with customary use rights. Thus the potential for conflict is rising and is often precipitated by government interventions—for example, to protect mountain resources. Since states have made little or no effort to enforce their claims to property rights (except for timber, hydroelectric power, and mining rights), most customary uses have continued more or less uninterrupted. While the viability of local cultures depends on traditional resource use, it has often proved hard for mountain people to get recognition of their de facto and customary property rights. It should also be noted that customary systems of rights are vulnerable to the impact of market forces. For instance, the makers of local rules may respond too slowly to rapid changes in harvesting of local resources that have acquired market value.

Current trends in international law put greater emphasis on de facto rights as these are expressed in customary uses of an area (such as ILO Convention 169 concerning Indigenous and Tribal Peoples in Independent Countries). International conventions on human rights and indigenous peoples have sought to award property rights (by implication, probably in the dominium plenum tradition) to those who have, through traditional usages of an area, established use rights to specific resources.

Statistics on ownership of mountain resources do not yet exist for the world as a whole. Neither do available sub-regional figures conform to ecological boundaries or to social realities of mountain communities. Furthermore, publicly available statistics on property rights only report de jure rights. The plethora of de facto use rights is often found in separate records, if they are recorded at all.

Most land registers are based on the dominium plenum ownership concept and only register owners of the land itself (not its use). Even if approximate figures for de jure owners were collected (nations, local states, towns, collectives, or individuals), the lack of reliable information on de facto ownership of specific resources would make the presentation of de jure figures more misleading than helpful. Developments in international law, such as ILO convention 169, have tended to put emphasis on de facto possession rather on de jure claims. (See Box 24.6.) Theoretical developments in the management of complex resource systems tend to support the allocation of a high degree of autonomy to local user groups protected by property rules.

Starting with the Roman law assumption that all lands have a landlord, medieval states in Europe tried to gain control of nonarable lands. Unclaimed lands became crown lands. In many cases the early modern states (notably Sweden, Germany, and France) introduced state ownership of forestlands and strengthened the state control of the lands without owners. The result was often state ownership of mountains.

''New nations'' (including the United States) have at least since 1776 routinely claimed state ownership of unimproved lands. ''Improvement'' (such as industrial activity or agricultural use of arable land) was needed to justify privatization. This ''improvement'' policy for awarding title to land has in most cases led to state property rights to mountains. Socialist states in 1917–89 routinely nationalized land. In the restitution period after 1989, many of these states either neglected to include mountain areas (outside settlements) in the process or expressly reserved these areas for state control. Likewise, many new nations created through decolonization since 1945 have nationalized land, or at

BOX 24.4

An Institutional Definition of Property Rights

Property rights provide legitimate allocation to particular owners, with material or immaterial objects supplying income or satisfaction to the owner. They comprise a detailed specification of rights and duties, liberties, and immunities citizens have to observe. These are defined partly by law and partly by cultural conventions, and they are different for owners and non-owners. Property rights are ultimately guaranteed by the legitimate use of power.

The dynamics and performance of economic systems are intimately linked to the kind of property rights a state is able to enforce.

BOX 24.5

A Legal Definition of Resources (Black 1990)

The technical details in the specifications of property rights are many and are important to the dynamic of the economy. They are changing through time and across space and are in general moving toward greater diversity and more detail. For management purposes, legal reasoning will divide resources into 3 types:

- *the ground* (sometimes called the soil), meaning the abstract bounded area;
- *the specific material resources* embedded in the ground, attached to the ground, or flowing over the ground (in general there are limits on how far into the ground and how far above the ground the rights reach); and
- *the remainder,* meaning the future interest in resources not yet discovered or not yet capable of being exploited.

These three types of resources are usually included in discussions of who owns what and are routinely recognized by mature legal institutions. Landlords are, at a minimum, owners of the ground and are then entitled to the ground rent. It must be emphasized that in principle there may be different owners to the ground, to every single well-specified resource, and to the remainder.

BOX 24.6

Emerging Collectively Owned Resources

Environmental legislation is at the outset independent of ownership, but it is increasingly seen to change the meaning and content of ownership by defining and taking control over two additional types of resources that can be seen as emerging from the remainder:

- *ecosystem services,* such as water control, disaster mitigation, local climate control, biodiversity, and so on, and
- *sociocultural symbols* vested in a landscape (often attached to amenity and heritage sites).

Ecosystem services are usually managed through government regulations. Sociocultural symbols are created and sustained by the local culture but now increasingly taken over by national and international bureaucracies. (See Buck 1996 and Lowenthal 1985 for more about environmental management and sociocultural symbols.)

least unimproved lands. Mountains and less accessible land or lands assumed to be less valuable have tended to remain in state ownership even where other lands were privatized.

24.4.4 Wars and Other Conflicts

In 1999, 23 of the 27 major armed conflicts were in mountains (FAO 2002a). Due to their usual situation of relative inaccessibility and remoteness from centers of population and government, mountains are often used by those who wish to escape the established authority. In countries where there are guerrilla movements or rebels, it is the mountains that are often their sanctuary (as in Afghanistan, Chechnya, and Colombia), and many illegal drugs are produced from crops such as coca, poppy, and marijuana grown in highland regions.

For most of the past 500 years, the main source of conflict in mountainous countries was the effort of emerging states to extend their power over mountain peoples. Starr (2004) states ''Any government that thinks it can bludgeon mountain people into submission is engaging in a most destructive form of self-deception. The sense of territoriality, independence and cohesive social (often clan) relationships formed in isolated upland valleys are perfectly suited to sustain conflicts over the long haul.''

Mountain ranges are often borders between nations or other political jurisdictions. Tensions along borders are common, and in some cases the location of the border has been in dispute, such as in the Peru-Ecuador conflict of 1995 in the Cordillera del Condor (Peace Parks in this area are described in the next section). Many conflicts have also arisen over natural resources in mountains, often based on issues of property rights, such as over logging on customarily used lands. The Chipko forest conservation movement in the Himalayas is a good example of such a dispute (Bandyopadhyay 1997).

24.4.5 Mountain Protected Areas

24.4.5.1 Global Network

Biological diversity, water resources, soil, and geological, cultural, and spiritual values of mountains are all maintained best in some kind of protected area situation. Protected areas in this sense are those without unbridled exploitation, where some degree of restraint is required in human use in the interest of natural or metaphysical values. IUCN–the World Conservation Union defines protected areas as: ''Areas of land and/or sea especially dedicated to the protection and maintenance of biological diversity, and of natural and associated cultural resources, and managed through legal or other effective means'' (IUCN 2000). As of 2003, there are 102,000 of these sites, covering 18.8 million square kilometers, or roughly 11.5% of the world's terrestrial surface (Chape et al. 2003). They span many kinds of situations, with varying degrees of human intervention—from wilderness areas and national parks to multiple use areas and lived-in protected landscapes. The IUCN category system is shown in Table 24.11.

24.4.5.2 The Mountain PA Situation

Mountain PAs are well-represented in the global network, even though there is some ambiguity over what constitutes a ''mountain'' PA. The U.N. list for 2003 shows 9,345 mountain protected areas covering 1,735,828 square kilometers in the ''mixed mountain systems'' biome defined by Udvardy (1975); therefore about 16% of this biome is protected (Chape et al. 2003). Thorsell (1997) showed that the highest elevation Pas—based only on IUCN categories I-IV, minimum relative relief of 1,500 meters and minimum size of 10,000 hectares—had a good distribution throughout the biogeographic realms. (See Table 24.12.)

The Thorsell assessment covers ''high mountains'' and those with a minimum of human land use modification, though many of them do have quite intensive visitation by tourists, mountaineers, and hikers. They are most often in the ownership or under the control of some level of government.

The importance of the PAs in the remaining categories (V and VI, Table 24.11) must not be discounted. Grazing, forestry operations, and many kinds of agronomic use such as orchards, vineyards, and terraced annual crops can be conducted in non-destructive and non-resource-polluting ways. In addition, important cultural values are often maintained in mountainous protected landscapes. Agro-biodiversity, as well as much wild native biodiversity, can be conserved if sustainable land uses are in place.

Table 24.11. The Six IUCN Management Categories of Protected Areas (IUCN 2000)

Category	Name	Description
I a	Strict Nature Reserve	protected area managed mainly for science
I b	Wilderness Area	protected area managed mainly for wilderness protection
II	National Park	protected area managed mainly for ecosystem protection and recreation
III	Natural Monument	protected area managed mainly for conservation of specific natural features
IV	Habitat/Species Management Area	protected area managed mainly for conservation through management intervention
V	Protected Landscape/ Seascape	protected area managed mainly for landscape/seascape conservation and recreation
VI	Managed Resource Protected Area	protected area managed mainly for the sustainable use of natural ecosystems

Table 24.12. Mountain Parks (High Mountains)

Biogeographical Realm (Udvardy classification)	**Parks**	**Total Area**
	(number)	*(mill. hectares)*
Afrotropical	42	20.4
Antarctic	15	3.2
Australian	3	2.6
Indomalayan	42	7.2
Nearctic	96	153.8
Neotropical	103	34.5
Oceanian	8	3.6
Palearctic	164	39.1
Total	**473**	**264.5**

Water and soil resources can also be safeguarded by proper husbandry of forests and agricultural lands.

Most of this nature-friendly management will be carried out by private landowners or communities, often using traditional practices that have proved their sustainability over generations. Some are in national and state forest management areas or community forestry units. As wild areas, even in the mountains, succumb to development, much of the hope for maintaining biological and cultural diversity in mountain environments rests in proliferation of Category V and Vl areas of protection. And as secular forces erode ancient cultural belief systems, mountains once protected de facto by reverence, awe, or taboo need to come under formal secular protection in all kinds of PAs. Geological heritage is often protected in the Natural Monument Category, though ''geoheritage'' is under-represented in the world network.

24.4.5.3 International Designations

Many Protected Areas are also designated as UNESCO Biosphere Reserves, where core zones of more strict preservation are buffered by zones of conservation use, in which sustainable land uses are promoted. Scientific research on ecosystem functioning and human-environment interactions are carried out in these reserves. As of 2003, there were 436 Biosphere Reserves (Chape et al. 2003), at least 190 of which were in mountain areas (UNEP-WCMC 2002).

Some mountain PAs are of such global significance that they have been placed on the World Heritage List of UNESCO. This designation is reserved for areas of universal value. There are 88 natural World Heritage Sites and 16 mixed (natural and cultural) ones in mountain areas (UNEP-WCMC 2002). For high mountains, Thorsell and Hamilton (2004) reported on 57 existing World Heritage Sites and identified 28 other potential sites to help fill the gaps in coverage.

24.4.5.4 Weaknesses in Protected Area System

A major weakness in the mountain PA global system is that most of the units are discrete, covering single mountains. Connectivity between these ''sky-islands'' is badly needed along the ranges or in biogeographic clusters. Linkages through a landscape of conservation corridors can effectively enlarge the PA, providing better protection of the full suite of biodiversity, including ''umbrella'' species such as large wide-ranging carnivores. Moreover, such connectivity would provide greater insurance for migration of species and genes in the face of climate change. A number of these corridor initiatives are now in place, such as the 3,200-kilometer-long Yellowstone-to-Yukon corridor in the U.S. and Canadian Rockies and the Condor Bioreserve constellation in Ecuador.

Unfortunately, many mountain PAs were established to protect the scenic high peaks of local or national value as cultural icons or for mountaineering and tourism. Biodiversity values were not considered, and the PAs often conserve mostly rock, ice, and snow or upper montane forests and alpine meadows. Many are too small to accommodate serious natural or human disturbance or to embrace much mountain biodiversity.

The challenge is to enlarge these areas, in particular to extend them to lower elevations to achieve species, genetic, and community conservation and provide functional landscapes for wide-ranging species. Expansion and connection from summits to lowlands is also a ''must'' for climate change response—for instance, the corridor from the Royal Manas Tiger Reserve in the tropical lowlands of India through a series of parks and conservation areas in Bhutan up to the crest of the Himalaya in Jigme Dorji National Park, Bhutan. There are at least 36 such initiatives around the world in mountains areas.

24.4.5.5 Transborder Parks in Mountains

Since many national or sub-national borders follow mountain ranges, many mountain protected areas abut such borders and each other. There are approximately 169 complexes of internationally adjacent protected areas (Zbicz 2001). About 42 of these are in mountains. These offer good opportunities to carry out cooperative transborder planning and management to better conserve shared biodiversity and water resources and to fight fires, pests, and non-native species—none of which recognize political boundaries (Hamilton et al.1996). As indicated earlier, these offer opportunities to reduce tension and conflict between neighboring countries, as Peace Parks.

24.4.5.6 Effective Management and Monitoring of Protected Areas

The World Commission on Protected Areas of IUCN has an active Task Force on Management Effectiveness, and it has developed criteria and standards for more effective management of protected areas. Baseline data and monitoring are sorely needed as a basis for adaptive management. Far too many protected areas are ''paper parks'' without effective protection and little management. The IUCN World Commission on Protected Areas has recently produced a set of ''Guidelines for Planning and Managing Mountain Protected Areas'' (Hamilton and McMillan 2004) to help rectify this situation.

24.5 Trade-offs, Synergies, and Management Interventions in Mountain Systems

24.5.1 Highland-Lowland Interactions and Their Trade-offs

Until recently, the economic importance of mountains was generally ignored (with the exception of supplies of some minerals, timber, and water), and little attention was paid to local environmental, socioeconomic, and cultural issues. With the U.N. Conference on the Environment in 1972, changes in mountain landscapes—including deforestation, accelerating slope instability, earthquakes, landslides, and floods—began to be highlighted, but the focus was mainly on the potential destructive impacts on lowlands originating from the mountains.

These early and simplistic perceived linkages between highlands and lowlands fell into two categories: physical processes under the influence of gravity and the exploitation of mountain resources to satisfy the needs of lowland residents.

Highlands and lowlands have widely different resources and production opportunities. This forms a natural basis for complementary economic links between them. In practice, however, the relationship has been more often characterized by inequitable power relationships, although highland communities can have significant effects on the power structure and way of life of far distant lowlands.

There are often competitive demands on mountain resources—increased resource extraction reduces the extent and value of environmental services that ecosystems can provide. Conversely, preserving ecosystem services may reduce incomes for particular interest groups. Furthermore, the relative value placed on mountain resources depends on technological developments and shifts in the world economy. In developing countries, this often creates a bias for exports, and in most mountain regions it creates a bias for extraction rather than conservation of resources.

Several factors affect the highland-lowland links:

- limited accessibility, isolation, semi-closed situation created by slope, terrain conditions, and permanent underinvestment in addressing the problem, all of which adds to the cost of logistics and other support systems to harness production opportunities and their competitiveness and equitable trade, although in some cases limited accessibility can be tied to tourist attractions (in the Everest region, for example);
- fragility—a product of slope, soil factors, and so on—which not only prevents intensification of land resources use for high productivity but obstructs infrastructure development to improve accessibility to facilitate mobility and trade at lower or competitive costs;
- marginality of production—resource limitations caused by the factors just described and socioeconomic and geopolitical marginalization of mountain habitats;
- high levels of biological, cultural, climatic, and other diversity characteristic of mountains, which creates many special economic opportunities if properly harnessed and traded; and
- major known niche resources (hydropower, timber, NTFPs, minerals, eco-tourism, and so on) with comparative advantage to highlands.

The factors just outlined also help explain the persistence of poverty in many highland areas. Lowlands invest to harness highland opportunities largely for their own benefit. This has been helped by the unequal balance between highland and lowland people as trading partners and has resulted in generally unfavorable terms of trade for the highlands. Indeed, many export flows (both traded and non-traded) from mountains are neither appropriately priced nor fully compensated (Banskota and Sharma 1999).

The Earth Summit of 1992 in Rio de Janeiro signaled a new recognition of the critical importance of highland-lowland linkages and of the need for poverty and equity to be integrated in environmental management. The underpinnings of this increased awareness stem from four concerns regarding highland-lowland linkages: water shortages, together with growing demands for hydroelectricity in various parts of the world; warfare, which is disproportionately concentrated in mountain regions (Libiszewski and Bächler 1997); catastrophic events resulting from mismanagement of mountain resources (flash floods, massive flooding, and landslides); and climate change effects, including glacier retreat and loss of snowpack (Beniston 2000; Beniston et al. 1996).

Economic disparities between highland and lowland regions are closely related, either as cause or effect, to other key changes in mountain environments (described more fully in other sections), including migration, warfare, production of illegal drugs, risks and disasters, and climate change. These are noted here briefly, but only as related to the issue of linkages.

The problems of mountain-lowland population change are exemplified by trends in the Alps, where jobs and population are concentrating into a few favorable locations (transportation corridors and nodes). At the same time, the real alpine zone, with a few notable exceptions, is losing its productive potential (Bätzing et al. 1996) due to the loss of expert knowledge to manage landscapes in a traditional way. In terms of absolute numbers, however, out-migration is more than offset by amenity migration. This is causing problems in the mountains, where new migrants have different and often inappropriate land use practices, while migrants from mountains who settle in lowlands also face problems of adjustment and assimilation (Moss 1994; Price et al. 1997).

Armed conflict, guerrilla warfare, and extreme political unrest disproportionately affect mountain regions, both in terms of total surface area and in terms of populations. There is also widespread expression of political discontent among mountain (minority) peoples. Much of this conflict is attributed—either directly or indirectly—to the growing struggle for control of water (Libiszewski and Bächler 1997). Hewitt (1997) indicates that more than 70% of the almost 8 million war deaths in mountain lands since the end of World War II have been unarmed civilians. More recently, Starr (2004) supports this overall assessment, underscoring deeper linkages to poverty and inequity in mountains.

Mountain regions worldwide are frequently the source of illegal (and legal) narcotics: marijuana production in British Columbia in Canada; opium from the sizable remnant of the Golden Triangle, including Myanmar; hashish and heroin from Afghanistan; and cocaine from the central and northern Andean countries. These are effective cash crops for cultivators, and especially for the traders in the middle, because of the high market value and low weight. Some of the most dangerous places in the world for outsiders to visit are the drug-producing areas of the northern and central Andes. The level of hostile encounters there amounts to full-scale warfare; herbicide defoliation by military aircraft adds to the scale of environmental and human loss. The effects of downstream transfer of the toxic overflow are unknown. Certainly, the movement of the products takes on the guise of a singular highland-lowland interaction.

Mountain lands include regions of exceptional risk for human activities as well as some unique dangers. Earthquakes and volcanic eruptions are central to the processes of mountain building. Hewitt (1997) has argued that mountain peoples have experienced a pronounced disproportionate share of these disasters, whether this is calculated in terms of land area or population numbers. Mountain people also are deeply implicated in responsibility for some disasters as a result of their own management practices and are the disproportionate victims of inappropriate practices introduced by outsiders. Moreover, mountain regions lack access to emergency relief compared with lowland areas.

Climatological changes in mountain ranges are likely to have much more readily apparent impacts than in the surrounding lowlands. Winter recreation, availability of water, hydroelectricity, irrigation, and the sudden release of glacier lakes as glaciers continue to thin and retreat are all potential components.

Maximizing highland-lowland complementarities is crucial for both upstream and downstream communities. Healthy mountain communities require linkages to lowland markets, and lowland populations need mountain people to serve as stewards for upland resources and watersheds. Investments that favor such positive interactions are properly treated as transfer payments, not subsidies, and have a high potential to improve sustainability.

24.5.2 Management and Interventions

Chapter 13 of *Agenda 21,* adopted by governments in 1992, draws the attention of political authorities to the special issues facing mountain regions. Government structures to deal with mountain issues were called for, but as yet there are no government departments specifically for mountains, as there are for forestry or wildlife. Land, water, forest, environment, and development policies do not generally consider the challenges facing mountain regions, and organizational divisions make it particularly difficult to deal with the integrated, systems approaches needed. Nevertheless, with significant exceptions that are described here, existing management approaches have the potential to deal with most environmental problems specific to mountains.

Where biodiversity and scenic values are high and economically valuable commercial resources are inaccessible or limited (the ''high biodiversity and low extractive value'' situation described earlier), conservation interventions have proved valuable. Parks and protected areas help conserve water resources while providing scenic, aesthetic, and recreational value with considerable economic returns from tourism, as well as protection of investments in water supply for downstream populations. In some cases where formal conservation mechanisms are inappropriate (for example, due to high concentrations of upland settlements), interventions have nevertheless been designed to protect watersheds. Economic incentives for stewardship have potential for effective management, with transfer payments given in exchange for maintaining environmental services.

Where biotic resources are few, as in arid regions, and where commercial resources such as mineral ores are abundant (the ''low biodiversity, high extractive value'' case), regulatory approaches such as environmental impact assessments have been effective. However, successful interventions have been characterized by careful attention to implementing measures that avoid or mitigate adverse impacts and by social safety nets and revenue-sharing mechanisms designed and approved with active participation of local communities.

In a few regions, natural resources are so poor or degraded, and linkages to markets are so weak or nonexistent, that adequate management options have proved elusive. In these cases, downstream inhabitants receive few environmental services, but the size and cultural distinctness of mountain communities is such that it would be difficult to absorb any massive out-migrations. Here, governments have often justified welfare payments out of humanitarian concern, and such interventions have proved successful in achieving the limited goal of alleviating at least the extremes of hardship. More rarely, environmental restoration of such degraded lands has been attempted, albeit with varying results.

Management approaches have proved generally inadequate in two areas. The most important example is in mountain regions where both biological resources and commercially valuable extractive resources are significant and important. Standard management approaches, such as regulatory protections, have proved wholly inadequate, leaving almost all stakeholders frustrated. While environmental assessments are necessary, they are insufficient to deal with the complicated trade-offs involved, which require long time frames and mechanisms that permit continuing participation of all stakeholders. Such mechanisms and processes take more time than corporations and governments are generally comfortable with. And it has proved difficult to create ''level playing fields'' where local communities can negotiate on an equitable footing with national governments and private corporations. Nonetheless, providing the time and resources needed to address these highly complex situations is an urgent priority, as failure in such cases produces a disproportionate share of environmental damage in mountain regions.

A second area where interventions are lacking has to do with information for policy formulation and decision-making. In general, data are not currently collected on a spatial basis, making it difficult to ''see'' what needs to be done.

24.6 Mountain Systems and Human Well-being

24.6.1 Sustainability

This section is in part based on a background paper prepared for the *World Development Report 2002/2003* (Pratt and Shilling 2002), but see also the recent *Ambio* Special Report (Sonesson and Messerli 2002).

Sustainable development has been defined as ''development that meets the needs of the present without compromising the ability of future generations to meet their own needs'' (WCED 1987). The fragility of mountain ecosystems represents a considerable challenge to sustainable development due to the fact that the impacts of unsustainable development are more rapid, heavier, and more difficult to correct than in other ecosystems. Arriving at a comprehensive definition of sustainability in mountains, particularly one that is universally accepted, is itself a mountainous task—and not likely to be a productive effort. More useful is to identify areas that merit protection and the characteristics and attributes that contribute to the sustainable use of mountain resources for human needs, broadly defined, for the alleviation of poverty, and for a more equitable allocation of resources and power.

Human activity in mountains that is not in balance with the environment can have serious consequences, resulting, for example, in soil erosion, pollution of natural waters, disruption of water and energy balances, elimination of both animal and plant species, loss of soil productivity, increasing food deficits, malnutrition and poor standards of living. Some of these consequences can be irreversible, such as the extinction of species and the loss of soil and cultural diversity.

In looking at sustainability, it is important to recognize that there are several time spans to consider. Short-term impacts would occur over the coming 20 years, medium-term impacts over 20–50 years, and long-term impacts over a longer horizon, extending to centuries or geological time spans. Our concerns should extend over both short and long time spans: while fires, landslides, and erosion can wipe out large areas of forest and other ecosystems in a very short period of time, it takes 50–100 years for a forest to regrow in mountainous areas, if it does so at all. Roads, mines, and other constructions last 20–50 years and their impacts even longer, so decisions to undertake such activities have long-term implications.

Sustainability does not mean cessation of all change. Mountains are subject to continual natural change. They were created by massive geological forces and they are being torn down by natural forces of erosion and landslides. New species have evolved in mountains, and others have become extinct. The objective of promoting sustainability is therefore not to stop change in mountains but to manage resources in them in ways that provide livelihoods for people living there as well as the services valued in lowland areas—and to do so in ways that protect the long-term capacity of mountains to continue to provide such services.

In order to ensure sustainability in mountain areas it is necessary to reduce poverty, inequality, and marginality, to prevent deterioration of mountain natural resources and environments, and to improve the capabilities of institutions and organizations to promote conservation and sustainable mountain development. The goals are to:

- assure that people living in the mountains receive full benefit from their mountain resources so that poverty and inequity can be substantially reduced;
- preserve and enhance the long-term value of resources in mountains;
- eliminate or minimize disruptive, damaging, and polluting aspects of human interventions; and, most important,
- manage human-introduced change so that it generates benefits for current and future mountain inhabitants and for those living downstream.

Achieving environmental and human sustainability in mountains means finding ways to manage mountain resources and systems so that they can provide critical services indefinitely. While we cannot predict exactly what the future will look like or which services will be in demand, it is clear that mountains provide many essential services that will be valued for a long time and others that may increase in value (such as biological and cultural diversity, high-value forest products, and scenic beauty). Nearly all these values are tied to soil conservation—the alpha and omega of mountain integrity.

24.6.2 Vulnerability

This chapter has described how the vulnerability of mountain people has a variety of aspects and many different causes: availability of land; ownership of land; environmental constraints (climate, soils, slope, natural hazards); food insecurity; lack of access to markets, education, and health care; dependence on one single economic factor (such as only forests, livestock, or tourism); inappropriate governmental or industrial interventions; high specialization and interdependency of mountain social and land use systems; and globalization. Many elements of vulnerability are not well documented (but see Shrestha 2001 and Munir and Adhikari 2003), and there are few studies or statistics that quantify the number of mountain people vulnerable to these different elements. This discussion is based on a recent FAO study (Huddleston et al. 2003) and focuses on food insecurity, accessibility, and nutrient deficiencies.

Around 40% of mountain populations in developing and transition countries, or 271 million people, are estimated to be vulnerable to food insecurity, and of these, around half are likely to be chronically hungry. Most are rural people, with only 26 million of the vulnerable people living in mountain cities. An agriculture-based livelihoods approach has been used to locate and enumerate vulnerable people in rural mountain areas. Rural people living in areas where annual cereal production is less than 200 kilograms per capita and cattle numbers are small are considered vulnerable, as well as those living in closed forests. Work currently under way will extend the approach to cover other income sources in future vulnerability assessments. For instance, people living in protected areas can compensate through income from tourism if these monies are not channeled away to governmental agencies and operators, as is currently the case in most ''trekking'' destinations. However, they still remain very vulnerable in terms of food security, because tourism is unpredictable and may collapse over night.

Of the 245 million vulnerable mountain people living in rural areas, 87% live below 2,500 meters above sea level (classes 4, 5,

Table 24.13. Vulnerable Rural Mountain People in Developing and Transition Countries by Mountain Area Class.[a] Based on LandScan 2000 Global Population Database. (Huddleston et al. 2003; mountain area classes, see Box 24.1)

			(percent)				
Vulnerable in class as share of rural mountain population in class	48	55	43	57	87	82	
Vulnerable in class as share of total vulnerable	48	22	18	7	4	1	100

[a] Vulnerable rural mountain people are those living in rural areas where rain-fed cereal production is less than 20 kilograms per person per year and the bovine density index is medium to low, along with those living in closed forests of protected areas.

and 6), where they represent less than half of the mountain population at lower altitudes. (See Table 24.13.) With more than three quarters of mountain populations in developing and transition countries still classified as rural, the performance of agriculture is a crucial factor in determining the degree of their vulnerability to food insecurity. As described earlier in this chapter, pastoral systems are very important for mountain people at all elevations in developing and transition countries. At the present time, these systems are becoming increasingly vulnerable as populations grow, livestock numbers increase, the quality of pasture and browse declines, and the incidence of drought becomes more frequent and its impacts more severe.

In high mountain areas, the absolute number of vulnerable rural people is small, but they represent almost 70% of the population living above 2,500 meters, and many live in extreme poverty. The higher prevalence of vulnerability at higher elevations and the importance of these areas for the overall sustainability of mountain ecosystems warrant particular attention.

It is generally accepted that mountain people live in remote, isolated areas that are poorly served by physical infrastructure and social services. In Ethiopia, for instance, about half of the mountain population and 40% of the non-mountain population live more than 5 kilometers from roads. In Afghanistan and China, the figure for mountain people is around one third and for non-mountain people, about 20%. In Peru, however, just 20% of mountain people and 13% of non-mountain people live more than 5 kilometers from a road (Huddleston et al. 2003).

In 33 of the 40 mountainous developing countries covered by the FAO report (Huddleston et al. 2003), there has been an increase in malnutrition as the proportion of mountain people has increased, measured by the prevalence of vitamin A, iron, and iodine deficiencies (globally the most significant micronutrient deficiencies in children). There are also significant differences in the distribution of micronutrient deficiencies across regions. Vitamin A deficiency is particularly common in mountainous countries of eastern and southern Africa, where consumption of fruits and vegetables that are rich in vitamin A is low; iodine deficiency is particularly prevalent in the Himalaya, where the soils have been leached of their iodine-carrying salts; and iron deficiency is common across all regions, though with somewhat greater incidence in sub-Saharan Africa.

*This appears in Appendix A at the end of this volume.

Main Messages

Changes in polar community composition and biodiversity are affecting human well-being (*high certainty*). Important changes include the reduction of top predators in Antarctic marine food webs, altering food resources; increased shrub dominance in Arctic wetlands, which contributes to summer warming trends and alters forage available to caribou; changes in insect abundance that alter food availability to wetland birds, energy budgets of reindeer and caribou, or productivity of forests; increased abundance of snow geese, which are degrading Arctic wetlands; overgrazing by domestic reindeer in parts of Fennoscandia, Russia, and sub-Antarctic islands; and a rapid increase in the occurrence and impact of invasive alien species, particularly in previously isolated sub-Antarctic islands.

Climate change has substantially affected ecosystem services and human well-being in polar regions (*high certainty*). Warming has been regionally variable but, on average, temperatures are warmer now than at any time in the past 400 years. Warming-induced thaw of permafrost is becoming more widespread, causing threshold changes in ecosystem services, including subsistence resources, climate feedbacks (energy and trace gas fluxes), and support for industrial infrastructure. International conventions have established mechanisms to reverse human impacts on UV-B, but international efforts to reverse human impacts on climate change have been less successful.

Regional changes in atmospheric temperatures and sea-ice extent and duration are changing the functioning of Antarctic marine ecosystems (*high certainty*). The Antarctic Peninsula, with its neighboring oceanic sectors, is one of the most rapidly warming regions on the planet (*high certainty*). It is also the area where populations of higher predators are concentrated as a result of high primary and secondary production and where the majority of exploitation of living resources has been concentrated. Changes in ecosystem structure are already occurring.

Most changes in feedback processes that occur in polar regions magnify trace-gas-induced global warming trends and reduce the capacity of polar regions to act as a cooling system for planet Earth. These climate feedbacks result from changes in the physical system (increased moisture transport to the poles, declines in the areal extent of sea ice and glaciers, and earlier snowmelt) (*high certainty*). In addition, within the Arctic, most changes in vegetation (expansion of shrubs in North America) and trace gas fluxes (release of soil carbon to the atmosphere as carbon dioxide and methane) are amplifying regional warming, although the retreat of the tree line in Russia is leading to cooling (*medium certainty*).

In the Arctic, regional warming interacts with socioeconomic change to reduce subsistence activities by indigenous and other rural people, the segments of society with the greatest cultural and economic dependence on these resources. Warming has reduced access to marine mammals (less sea ice) and made the physical and biotic environment less predictable. Industrial development has reduced the capacity of ecosystems to support subsistence activities in some locations. Other animals, such as moose (*Alces alces*) in North America, have moved northward in response to warming.

There is *high certainty* that reductions in the summer extent of sea ice will increase shipping access along northern sea routes, fostering northern development, and—together with rising sea level—will increase coastal erosion that currently threatens many coastal villages. The net effect is generally to increase the economic disparity between rural subsistence users and urban residents.

Increases in persistent organic pollutants and radionuclides in subsistence foods have increased health risks in some regions, but diet changes associated with the decline in harvest of these foods are usually a greater health risk.

Mitigation of impacts (rather than reversing changes in drivers) is the most feasible short-term strategy for protecting polar ecosystem services and human well-being because the major causes of polar change are globally distributed. Direct impacts of human activities on polar regions have been modest, and nations with Arctic lands or Antarctic obligations have the economic resources to mitigate many current and expected problems if appropriate policies are applied. Consequently, many parts of polar regions have a high potential to continue providing key ecosystem services, particularly in polar oceans and wetlands where biodiversity and resource harvest are concentrated. However, the sensitivity of polar ecosystems to disturbances associated with resource extraction makes them vulnerable to future global increases in resource demand.

25.1 Introduction

The polar systems treated in this chapter are treeless lands at high latitudes. These systems merge in the north with boreal forest (see Chapter 21) and in the south with the Southern Ocean (see Chapter 18). This chapter emphasizes the ecological processes that most directly influence human well-being within and outside polar regions. The physical processes in polar regions that influence human well-being (such as ozone effects on UV-B and changes in glaciers and sea ice) are described briefly in this chapter and more fully in the Arctic Climate Impact Assessment and in assessments of the Intergovernmental Panel on Climate Change (Anisimov et al. 2001). Because of its greater area of ice-free land and larger human population, the Arctic figures more prominently than the Antarctic in this chapter, although both are equally important when physical processes and marine ecosystems are integrated with terrestrial ecological processes.

25.1.1 The Arctic

The basic characteristics of Arctic terrestrial ecosystems were recently summarized by the Arctic Climate Impact Assessment (Callaghan et al. in press). It is a 12-million-square-kilometer treeless zone between closed boreal forests and the ice-covered Arctic Ocean. Within the Arctic, there are northward gradients of shorter snow-free seasons (from three months to one month), lower temperatures (from 10–12° Celsius to 2° Celsius in July), and less precipitation (generally from about 250 to 45 millimeters per year) (Jonasson et al. 2000). Permafrost (permanently frozen ground) is nearly continuous in most of the Arctic but becomes less continuous to the south and in maritime regions such as Scandinavia. Regional variation in Arctic climate reflects the nature of adjacent oceans. Cold waters in ocean currents flowing southwards from the Arctic depress the temperatures in Greenland and the eastern Canadian Arctic, whereas the northeasterly flowing North Atlantic Current warms the northern landmasses of Europe.

The land cover of the Arctic includes ice, barrens (which in this chapter includes polar desert and prostrate shrub tundra with less than 50% plant cover), and tundra (which in this chapter includes treeless vegetation with nearly continuous plant cover). Tundra constitutes the largest natural wetland in the world (5 million square kilometers). (See Table 25.1.) The distribution of these major Arctic land cover types is well known, although their areal extent differs substantially among authors, depending on vegeta-

Table 25.1. Polar Subtypes and Their Areas. The area of the major subtypes of Arctic and Antarctic ecosystems was estimated from the maps in Figure 25.1. The Arctic includes only areas north of 55°N and excludes forests and woodlands in that zone. Barrens are lands with less than 50% vascular plant cover, and arctic tundra has >50% plant cover. Barrens include polar desert and prostrate shrub tundra; Arctic tundra includes graminoid tundra, erect shrub tundra, and wetlands. All Arctic tundra is classified as wetlands under the Ramsar Convention. (CAVM Team 2003)

Ecosystem type	Total	Canada	United States	Greenland	Eurasia
			(mill. sq. km.)		
Arctic	10.57	3.29	1.01	2.14	4.13
Ice	2.50	0.25	0.10	1.95	0.20
Barrens	3.01	1.90	0.11	0.12	0.88
Artic tundra	5.06	1.14	0.80	0.07	3.05
Antarctic ice	12.44				

tion classification (McGuire et al. 2002; CAVM Team 2003). (See Figure 25.1 in Appendix A.)

Only 3% of the global flora and 2% of the global fauna occur in the Arctic, and their numbers decrease toward the North (Chernov 1995; Matveyeva and Chernov 2000). However, the Arctic is an important global pool of some groups, such as mosses, lichens, and springtails. The proportions of species that occur in the Arctic differ among major groups—spiders at 1.2%, for instance, insects at 0.3%, fishes at 1.8%, reptiles at <0.1%, mammals at 2.8%, and birds at 2.8%. In general, primitive groups (such as springtails, up to 12%) are better represented in the Arctic than are advanced groups such as beetles (0.1%). Exceptions to the general gradient of declining terrestrial diversity at higher latitudes include sawflies and shorebirds (Kouki 1999; CAFF 2001).

Animal species decline with increasing latitude more strongly than do vascular plants (frequently by a factor of 2.5) (Callaghan et al. in press). There are about 1,800 species of vascular plant, 4,000 species of cryptogam, 75 species of terrestrial mammal, 240 species of terrestrial bird, 2,500 species of fungus, and 3,200 species of insect (Matveyeva and Chernov 2000). Because of the low species diversity, some ecologically important species—such as the sedge *Eriophorum vaginatum,* lemmings, reindeer and caribou, and mosquitoes—have large populations with broad geographic, often circumpolar, distributions. Terrestrial food webs are often simple, with few species at a particular level in the web. Consequently, changes in abundance of one species can have many direct and indirect ecosystem consequences (Blomqvist et al. 2002). A significant attribute of Arctic biodiversity is the importance of migratory species, including most birds and marine mammals, caribou, and many key fish species such as salmon. Many of these species are important subsistence foods for local residents, and their population dynamics can be strongly affected by processes outside the Arctic.

Terrestrial net primary production and decomposition rates are low and decrease from south to north. The stocks of soil carbon are high in boreal woodlands and Arctic tundra but low in barrens. (See Table 25.2.) Because of low productivity, revegetation after human disturbance can take centuries (Forbes et al. 2001).

The Arctic has been populated throughout the Holocene. Of the 3.8 million people who live there, about 8% (300,000) are indigenous. Population density ranges from near 8 persons per square kilometer in the Murmansk Region of Russia to fewer than 0.1 person per square kilometer in the Canadian Arctic (Knapp 2000). Most people in the Arctic live in urban areas, so population densities in rural areas are extremely low (typically fewer than 0.1 person per square kilometer). The percentage of indigenous peoples is greatest in Greenland and North America, intermediate in Scandinavia, and lowest in Russia.

25.1.2 The Antarctic

The Antarctic (12.4 million square kilometers) is similar in size to the Arctic but differs in being a largely ice-covered continent surrounded by a ring of sea ice and extensive cold oceans. It has no indigenous peoples, and use of the area for harvest of marine mammals, birds, and fish began less than 200 years ago. The northern boundary of the Antarctic region is the Antarctic Polar Frontal Zone linked with the Antarctic Circumpolar Current, where the southern cold surface waters sink below warmer southern temperate waters at about 58° S (Anisimov et al. 2001). The combination of the oceanic frontal zone and the circumpolar current and westerly atmospheric circulation provides a strong barrier to the movement of both terrestrial and marine biota into or out of the region (Clarke and Crame 1989; Barnes et al. submitted). Within the Antarctic region, three zones are frequently recognized (Smith 1984; Longton 1988): the sub-Antarctic (oceanic islands close to the Polar Frontal Zone), maritime Antarctic (Scotia Arc archipelagoes and west coast of Antarctic Peninsula to about 72° S), and continental Antarctic (the remainder of the peninsula and main continental mass).

The Antarctic and Arctic experience parallel latitudinal influences on seasonal climate (day length and insolation) but otherwise have quite different environmental patterns and extremes (Convey 1996; Danks 1999), largely driven by the contrasting geography of the two regions. Several sub-Antarctic islands encircle Antarctica close to the Polar Frontal Zone. These have cold, relatively stable temperatures, with thermal variation buffered by the surrounding ocean and with high precipitation and cloud cover. Mean monthly air temperatures for most islands are positive year-round (Doran et al. 2002a; Thost and Allison in press).

The maritime Antarctic also experiences a strong oceanic influence, effectively acting as a physical barrier to the circulation of moist air from the Pacific component of the Southern Ocean. Mean monthly air temperatures in the maritime Antarctic are positive (but less than 2° Celsius) for two to four months in summer and negative for the remainder of the year, although positive air temperature may occur in any month (Walton 1984; Smith et al. 2003).

Inland, the climate of the Antarctic continent is colder than the Arctic, with average annual temperatures of −20° Celsius or lower (Hempel 1994; Doran et al. 2002b). Large parts of continental Antarctica are classified as frigid or polar deserts, with extremely low precipitation. This, combined with low humidity and strong katabatic winds, can lead to rapid ablation and extensive ice-free areas (Doran et al. 2002a; Nylen et al. 2004). The largest of these, the McMurdo Dry Valleys (about 4,800 square kilometers), contains a mosaic of perennially ice-covered lakes, ephemeral streams, and arid soils (Fountain et al. 1999). Plant and animal biomass of these valleys is low, and microbes dominate biological productivity (Doran et al. 2002b).

The Southern Ocean is covered by an expanse of sea ice that varies seasonally from 3 million to 20 million square kilometers: about the size of North America. Sea ice contains within its matrix a microbial community of algae, bacteria, and small consum-

Table 25.2. Comparisons of Carbon Pools in Arctic-Alpine Tundra with the Boreal Zone and World Total. The soil pools do not include the most recalcitrant humic fractions. (McGuire et al. 1997)

	Area	Soil	Vegetation	Soil:Veg. ratio	Total carbon		
					Soil	Veg.	Soil+Veg.
	(mill. sq. km.)	*(grams per sq. meter)*			*(trillion kilograms)*		
Arctic and Alpine tundra	10.5	9,200	550	17.0	96	5.7	102
Boreal woodlands	6.5	11,750	4,150	2.8	76	27	103
Boreal forest	12.5	11,000	9,450	1.2	138	118	256
Terrestrial Total	130.3	5,900	7,150	0.8	772	930	1,702

ers (Arrigo et al. 1997; Brierley and Thomas 2002). It also serves as a refuge for juvenile krill that browse on the microbial community (Siegel et al. 1990) and as a feeding platform for penguins and seals (Fraser and Hofmann 2003). There are marked regional interannual variations in the extent and duration of sea ice that generate changes in the functioning of the whole ecosystem (Murphy et al. 1995, 1998; Loeb et al. 1997; Fraser and Hofmann 2003). The entire Antarctic marine ecosystem, from primary producers to whales, therefore depends on the extent and duration of sea-ice cover (Quetin and Ross 2001; Smith et al. 2003; Atkinson et al. in press).

The terrestrial biodiversity of Antarctica is much lower than that in the Arctic because of its geographic isolation, the relative youth of most terrestrial habitats (formed after the retreat of Pleistocene glaciers), and the extreme environmental conditions (Convey 2001b). There are no native terrestrial vertebrates, but large populations of marine birds (penguins, petrels, gulls, terns, skuas) and seals take advantage of the absence of land-based predators, relying on terrestrial sites to breed, molt, and rest. These provide considerable nutrient input to terrestrial habitats while also imposing physical damage through trampling and manuring.

Less than 1% of the continent is seasonally ice- or snow-free, providing rock and soil habitats for life (Block 1994). Vascular plants and higher insects are poorly represented on the Antarctic continent (two native species of each, both restricted to the maritime Antarctic). Mosses, liverworts, and lichens are frequent in coastal low-altitude areas but rapidly decrease with progression into the interior or the ice-free dry valley deserts. Likewise, the more primitive or lower groups of invertebrates (such as mites, springtails, nematodes, and other soil mesofauna) assume a dominant role in food webs rarely seen elsewhere. The simplest faunal assemblages found worldwide occur in the Dry Valleys and inland continental nunataks (Freckman and Virginia 1997; Convey and McInnes in press). Many of these groups show high levels of endemism. Biodiversity on the sub-Antarctic islands is considerably higher than on the continent, though lower than at comparable latitudes in the Arctic, and rates of endemism are again extremely high (Chown et al. 1998; Bergstrom and Chown 1999).

The only permanent human residents in Antarctica are scientists and support staff who live in 37 research stations and many temporary camps. They number about 4,000 in the three- to four-month summer and 1,000 in winter (Frenot et al. in press). Their research examines processes and patterns that can only be explored in extreme conditions, such as the record of Earth's climate history preserved in ice cores, physiology and organism adaptation in extreme conditions, and the functioning of highly simplified ecosystems (Weller et al. 1987). There is a rapidly growing tourist trade, with 14,000 people visiting the Antarctic in 1999–2000 (Frenot et al. in press). Tourists predominantly visit coastal areas to view marine birds and seals and to see historic huts and sites used by Antarctic explorers of the early twentieth century, spending most of their time on ships. Increased tourism has global causes. Economic prosperity provides individuals with the financial means to participate, while events such as the economic downturn in Russia resulted in the release of ice-strengthened research ships to support tourism.

25.2 Condition and Trends in Polar Ecosystem Services

The dramatic changes in many of the drivers that shape polar processes are having profound effects on ecosystems and the services they provide to society. This section describes the current condition and major trends in ecosystem services that are important to society, both within and beyond polar regions.

25.2.1 Climate Regulation

25.2.1.1 Physical Feedbacks

Polar regions play a key role in the global climate system and therefore influence human activities and well-being throughout the world. (See Chapter 13.) They act as an important cooling system for Earth by reflecting incoming radiation from ice, snow, and clouds and by radiating back to space the heat that is transported poleward by the atmosphere and oceans. The heat loss from polar regions (180 W m^{-2} annually), for example, is greater than solar input (80 W m^{-2}), with the imbalance (100 watts per square meter) coming from lower latitudes (Nakamura and Oort 1988).

The latitudinal temperature gradient is a major driving force for atmospheric and ocean circulation and therefore for heat transport from the equator to the poles. Ocean heat transport is driven both by surface winds and by the movement of cold saline surface water to depths around Antarctica and in the North Atlantic (Anisimov et al. 2001). Recent increases in Antarctic precipitation have caused a freshening of surface layers that weakens bottom-water formation (Anisimov et al. 2001). This bottom-water formation is sensitive to climate effects on sea-ice formation and decay and, in the Arctic, on freshwater discharge to the ocean. Polar ice sheets account for 68% of the fresh water on Earth, so changes in the mass balance of these ice sheets could alter sea level and the input of fresh water to zones of deepwater formation. Past variation in the strength of bottom-water formation has contributed substantially to Earth's long-term climate variation (Anisimov et al. 2001).

Until recently, the warming trend at high latitudes had little detectable effect on the mass balance of the Greenland and Antarctic ice sheets, because of measurement inaccuracy and because warming simultaneously increased inputs of snow (because the warmer atmosphere holds more water) and the melting of ice sheets (Anisimov et al. 2001). Since 1990, however, increased melting and water infiltration at the base have increased ice flows to the ocean (Krabill et al. 2000; Thomas 2004). The mass wastage in 1991–2000 was 80 cubic kilometers per year (Box et al. 2004). Mountain and subpolar glaciers have exhibited a negative mass balance of similar magnitude (90–120 cubic kilometers per year) for the past 40 years (see Figure 25.2), particularly in Alaska, Canada, high-mountain Asia, and Patagonia (Dowdeswell et al. 1997; Dyurgerov and Meier 1997; Arendt et al. 2002; Rignot et al. 2004). In contrast, the Antarctic ice sheet shows regional and temporal variation in mass balance but no overall directional trend (Rignot and Thomas 2002; Bentley 2004). Warming has been most pronounced on the Antarctic Peninsula, causing a 10,000-square-kilometer retreat of adjacent ice shelves (Anisimov et al. 2001).

There is enough ice on the Antarctic Peninsula to raise global sea level by 0.5 meters, but the time course of its melting is *speculative*. The rapid disintegration and collapse of the Larsen-B ice shelf in 2002 was unprecedented; grounded ice sheets serve as brakes on the glaciers behind them, and the glacier behind the (now absent) Larsen-B sheet has accelerated its seaward flow (Scambos et al. 2004). The total freshwater input from these ice sheets and glaciers has, however, had less effect on sea level than the thermal expansion of oceans resulting from recent climate warming has. Nonetheless, freshwater input from glacial melt has substantially increased since 1990.

The Southern Ocean has warmed faster than the global ocean at mid-depths (700–1,100 meters) has over the past 50 years (Gille 2002). In addition, the surface and shelf waters in the Ross Sea have warmed and become less saline over the past 40 years (Jacobs et al. 2002), owing to a combination of increased precipitation, a reduction of sea-ice production, and increased melting of the West Antarctic ice sheet (Jacobs et al. 2002). Ice dynamics are also sensitive to fluctuations in the Antarctic Circumpolar Current, regional warming, and ENSO-related variation in Southern Hemisphere atmospheric and oceanic conditions (Liu et al. 2002). The apparent precession around the Antarctic of anomalies in sea-ice conditions and the ocean temperatures associated with the Antarctic Circumpolar Current (termed the Antarctic Circumpolar Wave) (Murphy et al. 1995; White and Peterson 1996) are also related to ENSO and contribute to regional and interannual variation in ocean temperatures and ice conditions. Whaling records suggest a possible circumpolar retreat in Antarctic sea ice by 2.8 latitude between the mid-1950s and early 1970s, although this interpretation is debated (Anisimov et al. 2001). The sea ice then became more extensive from 1979 to 2002, but with high regional variability (Liu et al. 2004) and large impacts on ecosystem processes (Smith et al. 1998).

In contrast, Arctic sea ice continues to decrease in extent by 2.9% per decade (see Figure 25.3) and has become thinner over the past 40 years (Maslanik et al. 1996; Anisimov et al. 2001). The reductions in areal extent of sea ice, glaciers, and seasonal snow cover reduce high-latitude albedo (the reflectance of incoming solar radiation) and act as a positive feedback that has *medium certainty* of amplifying the rate of high-latitude warming at both poles (Serreze et al. 2000; Mitchell et al. 2001). Increases in clouds, as sea ice retreats, could dampen this polar amplification, however (Wang and Key 2003). The reduction in summer ice cover has a *high certainty* of making commercial shipping feasible in the Northern Sea Route, likely by 2020. The reduction in sea ice over the past 40 years has reduced available habitat and hunter access to many marine mammals, which are an important subsistence and cultural resource for many coastal indigenous peoples of the Arctic (Krupnik 2002). The modest sea level rise that has occurred to date, combined with reduction in sea ice and greater storm surges, has caused considerable coastal erosion, which endangers coastal communities and increases organic carbon input to coastal oceans.

25.2.1.2 Ecosystem Feedbacks

Ecosystem processes at high latitudes influence the climate system when they cause these regions to become net sources or sinks of greenhouse gases such as carbon dioxide and methane. In the Antarctic, oceans have the strongest influence on carbon flux through both physical processes that are driven by ocean circulation and biotic processes driven by photosynthesis and respiration. Photosynthesis (carbon uptake) by marine phytoplankton converts inorganic carbon into organic matter. When algae are eaten or die, some of this carbon is respired and returns to the atmosphere and some sinks to depth as dead cells or fecal pellets of their grazers, a biological pump that sequesters carbon in the deep ocean (Ducklow et al. 2001).

Many factors interact to control the productivity of phytoplankton, as described later in this section, and therefore the carbon export to depth in the oceans around Antarctica. Spatial variability in productivity and carbon export depends on vertical mixing, mixed layer depth, krill grazing, and micronutrient (iron, for example) limitation (Arrigo et al. 1999; Prezelin et al. 2000). Temporal variation correlates with sea-ice extent and timing, with

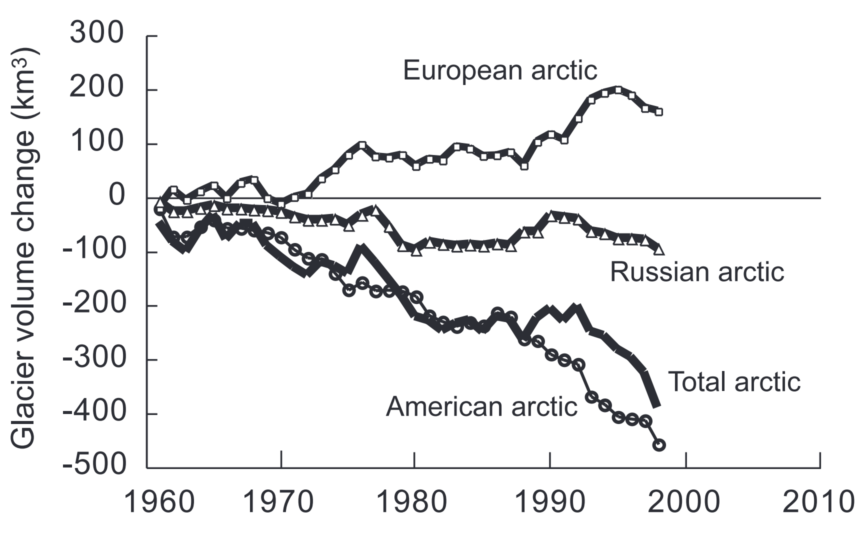

Figure 25.2. Trends in Glacier Volume for Different Arctic Regions, 1961–98 (Hinzman et al. in press)

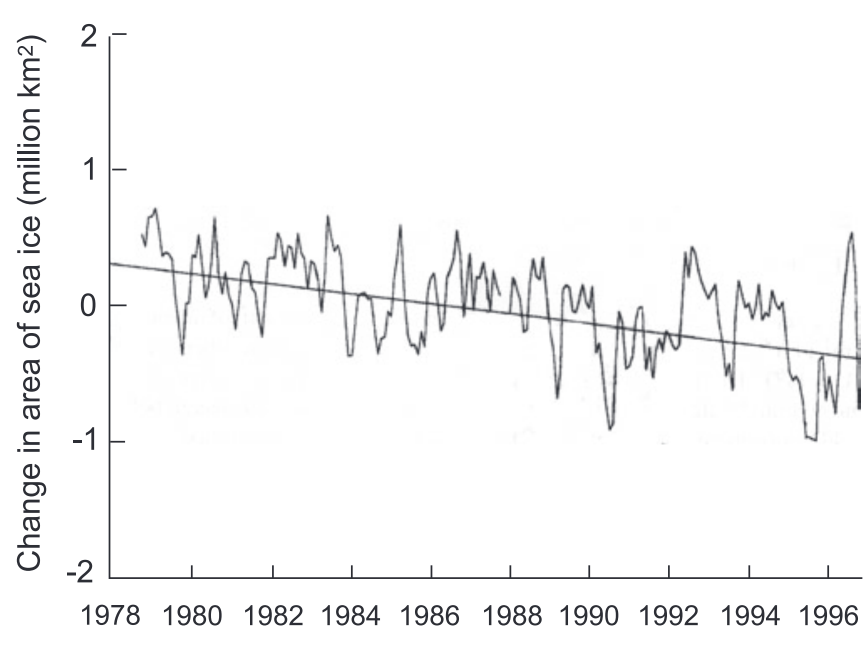

Figure 25.3. Trend in Arctic Sea Ice Extent, 1978–97 (Serreze et al. 2000)

extensive or late-melting ice favoring high productivity. Ice margins are highly productive because of high nutrient availability, whereas the productivity of the open ocean appears limited by iron availability (Boyd et al. 2000).

Warming has two counterbalancing effects on productivity and therefore on carbon export to depth. The more highly developed freshwater lens beneath melting ice enhances productivity, whereas the decreasing extent of sea ice reduces the areal extent of productive ocean. The Southern Ocean below 50°S is a net carbon sink, taking up about 0.5 petagrams of carbon annually, or about 20% of the total oceanic uptake, in 10% of its area (Takahashi et al. 2002). The intensity of uptake in the Southern Ocean highlights its role in the global carbon cycle. How it will respond to climate change remains *highly uncertain* (Sarmiento and Le Quere 1996; Sarmiento et al. 1998).

In the Arctic, terrestrial ecosystems are the major site of greenhouse gas exchange. Under current conditions, both direct measurements and global carbon models suggest that the circumpolar Arctic is neither a large source nor a large sink of carbon dioxide. Measurements suggest a modest source, whereas models suggest a small sink of 17 ± 40 grams of carbon per square meter per year (mean ± SD, spatial variance) (McGuire et al. 2000; Sitch et al. 2003; Callaghan et al. in press). Both estimates overlap zero, owing to *low certainty* and large interannual and regional variation.

Areas that have warmed and dried, such as Alaska and Eastern European Arctic, are generally a carbon source. For example, after a pattern of net carbon accumulation during most of the Holocene, Alaska became a net carbon source when regional warming began in the 1970s (Oechel et al. 1994). The strength of this source then declined as plant- and ecosystem-scale negative feedbacks increased carbon uptake by plants (Oechel et al. 2000). (See Figure 25.4.) This may reflect warming-induced nutrient release, which tends to enhance photosynthesis and net primary production (Shaver et al. 2000). Scandinavian and Siberian peatlands, which have become warmer and wetter, are a net carbon sink of 15–25 grams of carbon per square meter per year (Aurela et al. 2002; Smith et al. 2004). In Greenland, where there has been little warming (Chapman and Walsh 1993), net carbon exchange is close to zero, with sinks in wet fens balanced by carbon losses in dry heath (Christensen et al. 2000; Soegaard et al. 2000; Nordstrøm et al. 2001). Carbon fluxes in the high Arctic are extremely low—a net sink of about 1 gram of carbon per square meter per year (Lloyd 2001).

Taken together, Arctic flux measurements suggest that warming has substantially altered Arctic carbon balance but that the direction of this effect varies regionally, depending on hydrology, with wet areas tending to gain carbon and dry areas tending to lose carbon with warming. Remote sensing and indigenous observations suggest that drying trends predominate in the North American Arctic (Hinzman et al. in press). The greatest uncertainties in estimating recent and future trends in carbon exchange relate to changes in hydrology, nutrient dynamics associated with decomposition, and disturbance effects on vegetation (Chapin et al. 2000a; Oechel et al. 2000; Callaghan et al. in press). These processes have not yet been adequately incorporated into global carbon models. In summary, the short time period of record and the incomplete inclusion of key processes in global models result in *low certainty* of long-term trends, but the balance of evidence suggests a small trend toward carbon release in the short term, with long-term trends depending on the balance between increased production and uncertain trends in respiration.

High-latitude wetlands are one of the largest natural sources of atmospheric methane, about 70 teragrams per year (Cicerone and Oremland 1988; Schlesinger 1997). Methane fluxes are highly variable, both temporally and spatially. However, methane efflux responds positively to soil moisture, summer soil temperature, and the presence of oxygen-transporting vascular plants such as wetland sedges (Christensen et al. 2003). Warming and thawing of permafrost (see Figure 25.5) increase the area of wetlands and thaw lakes, further increasing methane efflux from the Arctic (Zimov et al. 1997; Christensen et al. 2004). There is *medium certainty* that warming enhances methane release, creating a positive feedback to climate change (Christensen et al. 2003).

Recent increases in length of the snow-free season (2.6 days per decade and similar increases in other northern regions) (Keyser et al. 2000; Walther et al. 2002) and the reduced albedo (reflectance) associated with shrub expansion (Eugster et al. 2000) both tend to increase annual energy absorption. This acts as a positive feedback to high-latitude warming (Betts and Ball 1997; Chapin et al. 2000b), but the magnitude of these effects has *low certainty*. Conversion of tundra to forest creates an even larger climate feedback by replacing a snow-covered surface with a dark, more absorptive surface. (See Chapter 13.) Model simulations suggest that conversion of tundra to forest accounted for half of the high-latitude mid-Holocene warming (Foley et al. 1994). Forest expansion generally lags behind regional warming because tree establishment is slow near the climatic limit of trees (Huntley 1996; Lloyd et al. 2003b).

Russian rivers have increased their discharge to the Arctic Ocean by 7% over the past 70 years, primarily due to increases in winter discharge (Peterson et al. 2002; Yang et al. 2002). (See Figure 25.6.) Changes in permafrost distribution associated with

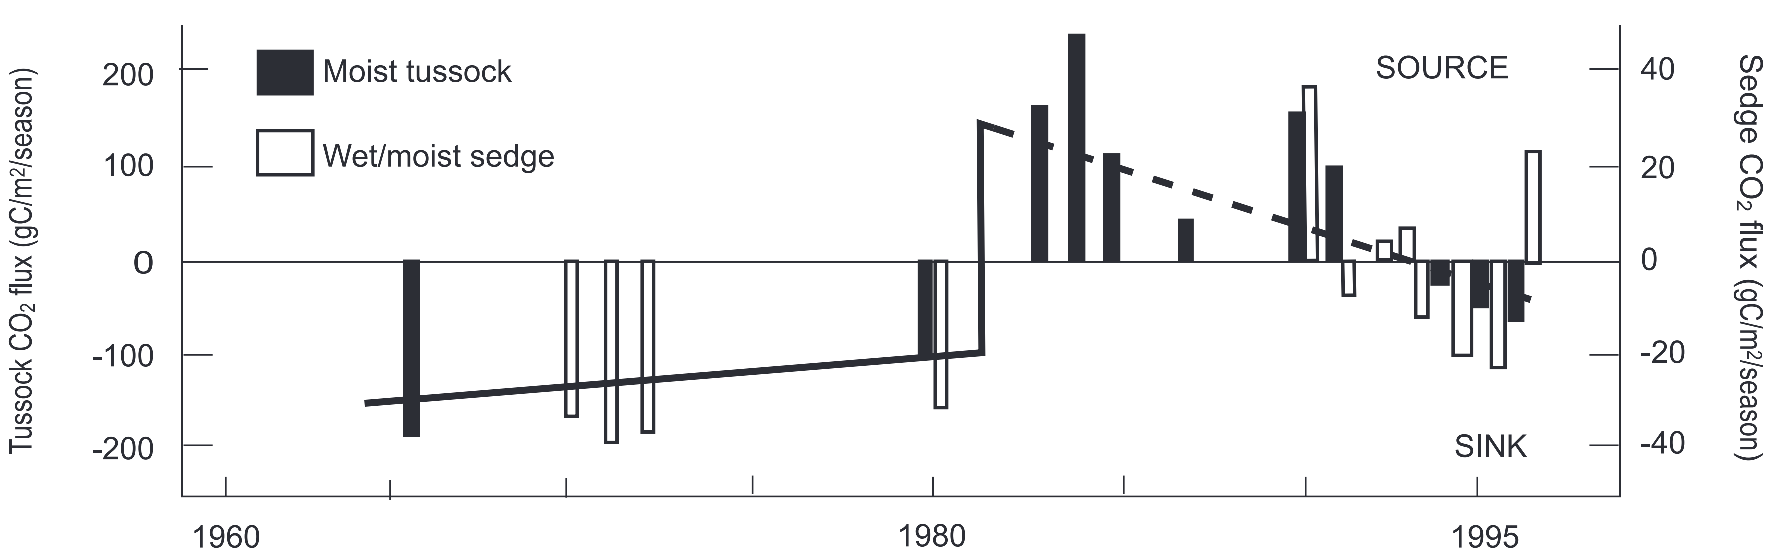

Figure 25.4. Trend in Net Annual Carbon Flux from Alaskan Arctic Tundra, 1960–95 (Oechel et al. 2000)

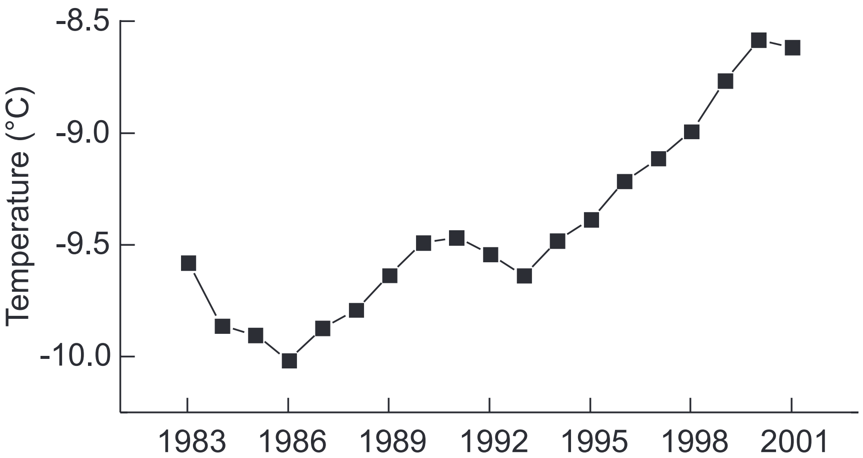

Figure 25.5. Trend in Permafrost Temperature at 20 m Depth at West Dock on the Coastal Plain of Northern Alaska, 1983–2001 (Osterkamp and Romanovsky 1999)

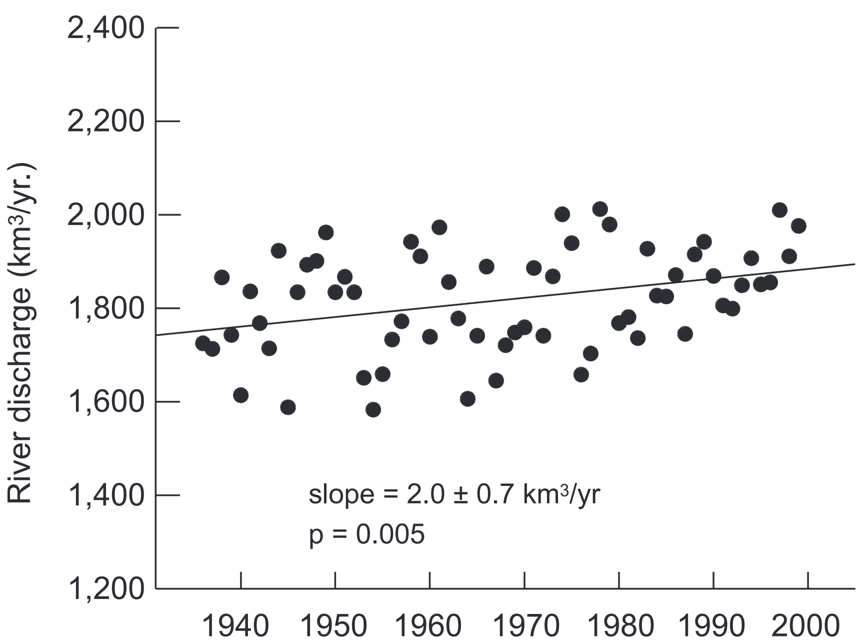

Figure 25.6. Trend in Discharge of the Six Largest Eurasian Arctic Rivers, 1935–2000 (Peterson et al. 2002)

wildfire or human-induced vegetation changes may have contributed to the increase in winter discharge (Serreze et al. 2003), although the causes are *speculative*. The discharge records for North American rivers are too short to detect long-term discharge trends. The Arctic Ocean is extremely sensitive to changes in discharge because it receives more discharge per unit ocean volume than any other ocean. Most river discharge into the Arctic Ocean eventually exits in the North Atlantic. Continued increase in the input of low-density fresh water could reduce North Atlantic bottom-water formation by the end of the twenty-first century if the discharge of Arctic rivers continues to increase at its current rate (Peterson et al. 2002). This potential change is *speculative,* but the climatic implications for Europe and the North Atlantic Region are enormous.

In the Southern Ocean, physical processes are entirely responsible for variation in bottom-water formation. Dense saline water is produced when sea ice forms beneath ice shelves and when polynyas (open water) or thin ice transfer heat rapidly from the ocean to the atmosphere. Antarctic surface waters have warmed since 1970 (Wong et al. 1999), a trend that would tend to reduce rates of bottom-water formation and thermohaline circulation. In summary, different processes at the two poles both tend to weaken bottom-water formation.

Less is known about carbon cycling in Antarctic terrestrial systems. Rates of CO_2 flux in Antarctic dry valley soils are exceedingly low, and the total volume of soil in the Antarctic is tiny in comparison with that of the Arctic (Parsons et al. 2004). The soil organic matter in some dry valleys appears to be a legacy of past climates when paleo-lake production enriched soils in carbon and nutrients (Burkins et al. 2001). It is not known whether these systems are net sources or sinks of carbon because interactions between abiotic and biological controls of CO_2 flux vary with soil environment and climate (Parsons et al. 2004).

25.2.2 Fresh Water

Antarctica is the driest continent on Earth, with nearly all water locked up in ice. Dependence on fuel to melt ice for usable water limits potential for human habitation, and low water availability limits many physical and biological processes across the continent (Kennedy 1993).

In contrast to Antarctica and much of the rest of the world, inhabited portions of the Arctic generally have abundant fresh water despite low precipitation. Water is important to Arctic residents as a source of hydropower and as a transportation corridor. (See Chapter 20.) Water quality in the Arctic is generally good except in areas of industrial development.

The net transport of contaminants (persistent organic pollutants, heavy metals, and radionuclides) to polar regions, however, produces a dilute source of pollutants that often become concentrated as they move through food webs and are a potential health risk to people, as described later in this chapter. Changes in water availability in the Arctic (for example, regional drying) are important primarily through effects on ecosystem services (such as habitat for fish and water birds, or trace gas emissions).

Arctic fresh water continues to receive attention from water-deficient regions of the world as a potential freshwater supply. Russian newspapers, for example, recently reported the reactivation of 1970s plans to divert the Ob and other northbound rivers toward water-starved regions in the south.

25.2.3 Biodiversity and Species Composition

25.2.3.1 Changes in Vegetation

Polar regions have historically experienced fewer invasions of exotic plant species than most biomes because climate is a severe physiological filter (Walther et al. 2002). However, recent climate warming has facilitated invasion of new species (Robinson et al. 2003; Frenot et al. in press). On some sub-Antarctic islands exotic species account for more than 50% of vascular plant diversity, and exotic grasses may outcompete native species (Smith 1994; Chown et al. 1998; Gremmen et al. 1998; Bergstrom and Chown 1999; Gremmen and Smith 1999; Frenot et al. in press). Exotic species also occur in maritime regions of the Arctic (such as Iceland) (Wiedema 2000) and inland areas with road and rail connections (in Canada and Russia, for example) (Forbes 1995), but the frequency of invasion is known with *low certainty.* Twenty species of Arctic plants are considered globally threatened—vulnerable, endangered, or critically endangered, according to IUCN Red List criteria (CAFF 2001).

Polar plant species have also changed in their relative abundance (Walther et al. 2002; Callaghan et al. in press). On the Antarctic continent, mosses have colonized previously bare ground, and the only two native vascular plant species have expanded their ranges (Smith 1994; Convey 2001a). Repeat aerial photography demonstrates that shrubs have increased in dominance in 70% of 200 sample locations in Arctic Alaska (Sturm et al. 2001), a change confirmed by indigenous observations across much of the North American Arctic (Nickels et al. 2002; Thorpe et al. 2002). NDVI, an index of vegetation greenness, has increased by 15% since 1981 in Arctic Alaska (Jia et al. 2003) (see Figure 25.7) and to a more variable extent in the circumpolar Arctic as a whole (Myneni et al. 1997).

In Alaska, the latitudinal tree line has moved northward, converting about 2% of tundra to forest in the past 50 years (Lloyd et al. 2003a), whereas in Russia the tree line has retreated southward as a result of forest harvest and anthropogenic burning, creating about 500,000 square kilometers of wetlands superficially resembling the tundra (Callaghan et al. 2002; Vlassova 2002). Thawing of permafrost has also converted large areas of well-drained lands to wetlands (Crawford et al. 2003; Hinzman et al. in press).

Experimental manipulations of climate, nutrients, and UV-B radiation in numerous studies throughout the Arctic suggest that mosses and lichens could become less abundant when vascular plants increase their growth (Van Wijk et al. 2004). Mosses and lichens are a large component of polar plant diversity and controllers of ecosystem processes: lichens are a key winter food for caribou and reindeer, and mosses insulate the soil. Similar manipulations on the Antarctic Peninsula indicate complex responses that could include a decline in density and diversity of soil invertebrates in response to warming (Convey et al. 2002) and a decline in nematodes in response to cooling in the McMurdo Dry Valleys (Doran et al. 2002b).

25.2.3.2 Changes in Caribou and Reindeer

Many of the North American barren-ground wild caribou (*Rangifer tarandus*) herds were at historic high levels at the end of the 1980s; several herds are currently in decline (Russell et al. 2002). Interannual variation in caribou calving success of several North American herds correlates with the rate of spring vegetation growth in calving grounds, as measured by satellite-derived NDVI (Griffith et al. 2002), although regional heterogeneity in other ecological conditions also affects reproductive success (Russell et al. 2002). The Peary caribou herd that occupies polar barrens in the Canadian Arctic islands has, in contrast to other North American herds, decreased to critically low levels and is currently on Canada's endangered species list. Potential causes of the decline include the impact of climate change on extreme weather events (such as autumnal ice storms), vegetation composition, insect harassment, animal energy demands, animal behavior, and shifts in animal distribution relative to human users' access.

In Fennoscandia, reindeer are intensively managed for meat, as a cultural resource, and for recreational harvest. Here reindeer herding is the subject of political conflicts owing to the degradation of pastures, protection of predators, and indigenous people's efforts to assert their access rights to traditional herding areas (covered later in this chapter).

In the Russian North, the collapse of the former state-supported supply and marketing system has led to a decline in domesticated reindeer stock over the past 10 years from 2 million to 1 million animals (Baskin 2000). This decrease was accompanied by increases in several large wild reindeer populations of Taimyr, Yakutia, and Chukotka, leading to serious impacts on pasturelands. Wild and domesticated reindeer are typically seen as ecological antagonists, because wild reindeer lead domesticated animals away, compete for (or damage) pastures, and are a reservoir of infectious diseases. On the Yamal Peninsula, in contrast, the population of semi-domesticated reindeer increased steadily in the post-Soviet period, in part because of the cultural role of reindeer herding among the Nenets people of that region.

Oil development has contributed to trends in caribou and reindeer populations in some areas. Caribou and reindeer are sensitive to disturbance during calving (Vistnes and Nellemann 2001; Griffith et al. 2002). In Alaska, for example, concentrated calving was displaced from industrialized areas to areas of lower forage richness, with caribou returning to industrialized areas during the post-calving period (Griffith et al. 2002). The effects on population dynamics of this herd displacement during calving are debated (NRC 2003). Development conflicts associated with potential habitat loss have been resolved in some areas through "calving group protection measures" (in the Northwest Territories of Canada, for instance), whereas in other areas (such as Alaska and Russia) calving grounds hold no special policy status.

Onshore oil and gas activities also impede access to traditional hunting and herding areas and thus disrupt community activities and traditional practices (Golovnev and Osherenko 1999). Pipelines and facilities create obstacles to free movement of reindeer herds. In the intensively developed Yamal Peninsula in Western Siberia, destruction of vegetation due to construction of facilities, roads, and pipelines and to off-road vehicle traffic exceeds 2,500 square kilometers and could more than double under current development plans. The resulting concentration of reindeer herds into an ever-decreasing undeveloped area has led to overgrazing,

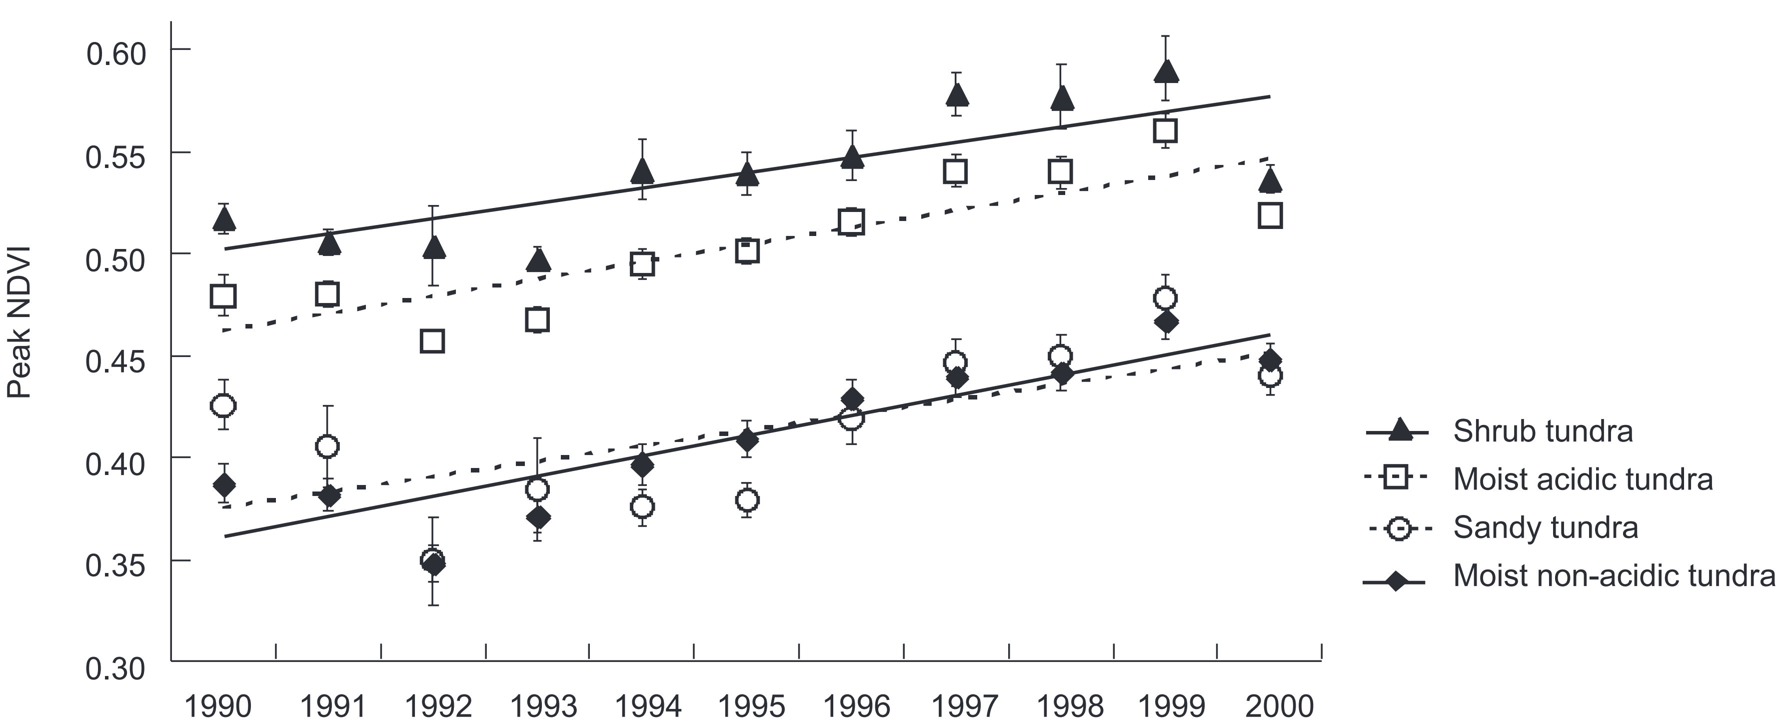

Figure 25.7. Trend in Normalized Difference Vegetation Index in Alaskan Arctic Tundra, 1990–2000 (Jia et al. 2003)

with potential long-term adverse effects on ecosystem productivity and local economies (Forbes 1999).

25.2.3.3 Changes in Other Terrestrial Mammals

Twenty-one species of Arctic mammal are considered globally threatened (CAFF 2001). However, it is difficult to assess recent population trends of polar mammals as a whole, because quantitative data are available for only a few species, mostly animals of economic importance or high conservation profile. (See Table 25.3.) Possibly in response to changes in climate or prey abundances, red fox (*Vulpes vulpes*) has expanded northward into habitats of the smaller Arctic fox (*Alopex lagopus*) in Fennoscandia and Canada, where it is thought to exploit the most productive habitats by interference competition (Hersteinsson and MacDonald 1992; Elmhagen et al. 2002). The observed expansion of shrubs favors the range expansion from adjacent biomes of some herbivore species with wide dietary flexibility (Klein 1999). Moose (*Alces alces*), for example, have expanded from the boreal forest to Arctic tundra in Alaska and eastern Canada but have declined in Siberia owing to increased hunting.

Deliberate introductions are modifying animal distributions. Musk oxen (*Ovibos moschatus*) have been introduced to new areas and to portions of their former ranges, after dramatic reductions in their numbers in the nineteenth century from many of these areas; they are expanding in population sizes and ranges in Alaska, Russia, west Greenland, Quebec, and Norway (CAFF 2001). Wood bison (*Bison bison athabascae*), the closest relative of the extinct Pleistocene bison, have also been reintroduced in several areas of Arctic Canada. Bison, like many animals, substantially disturb their habitat, so their reintroduction could lead to ecosystem changes that alter many species abundances and ecosystem processes (Zimov et al. 1995).

Fennoscandian lemmings and voles are changing in seasonal dynamics and losing the synchronous cyclic population fluctuations that characterize these species (Hanski et al. 2001), as occurred earlier in Alaska (Batzli et al. 1980). In Scandinavia, but not in Greenland, declines in lemming populations cause increased predation on water birds as an alternative prey, although changes in weather may contribute to these population changes (Summers and Underhill 1987; Soloviev et al. 1998; Yoccoz and

Table 25.3. Population Numbers and Trends of Some Key Arctic Animals. Population trends indicate moderate to high certainty that populations exhibit a directional trend. Where the trends differ regionally, the nature of these trends (increasing, decreasing, stable) is indicated. (Modified from CAFF 2001 with marine mammals from Marine Mammal Commission 2002)

Species	Total Arctic Population	Population Trend	Major Driver of Change
Birds			
Eiders (4 spp)	>3 million	declining/stable/increasing	unknown
Common murre/guillemot (*Uria aalge*)	8–11 million	declining/stable/increasing	unknown
Thick-billed murre (*U. lomvia*)	14 million	unknown	unknown
Gulls		increasing	garbage ??
Geese (15 spp)	11 million	40% of populations increasing 28% stable 18% declining 14% trend unknown	winter habitat, overharvesting
Shorebirds			
North America (21 spp)	14 million	decreasing	unknown
Eurasia (16 spp)	8 million	no clear trend; some declines	unknown
Terrestrial mammals			
Caribou/reindeer (*Rangifer tarandus*)	4.5 million	many herds increased until 1980s; Peary caribou declining	forage, weather
Muskoxen (*Ovibos moschatus*)	150,000	increasing/stable	reintroductions, weather
Brown bear (*Ursus arctos*)	170,000	declining/stable/increasing	habitat loss, poaching
Wolverine (*Gulo gulo*)	30,000	unknown/stable/increasing	unknown
Wolf (*Canis lupus*)	50,000	declining/stable/increasing	hunting, habitat loss
Marine mammals			
Right whale (*Eubalaena glacialis*)	<1,000	stable/uncertain	19th century harvest
Humpback whale (Megaptera novaeanglie)	thousands	increasing	19th century harvest
Gray whale (*Eschrichtius robustus*)	27,000	stable; near optimal	19th/20th century harvest
Killer whale (*Orcinus orca*)	few thousand	stable, not endangered	not widely harvested
Steller sea lion (*Eumatopius jubatus*)	30–40,000	declined 85% since 1970s	uncertain
Pacific walrus (*Odobaenus rosmarus divergens*)	230,000	trend uncertain	uncertain
Harbor seal (*Phoca vitulina richardsi*)	100,000	some populations declining	human and natural factors
Polar bear (*Ursus maritimus*)	25,000	unknown	sea ice decline
Sea otter (*Enhydra lutirs*)	100,000	decline since 1995	unknown

Ims 1999). Trends in mammalian predators (such as wolves (*Canis lupus*), bears (*Ursus* spp.), and wolverines (*Gulo gulo*)) have been regionally variable. In general, species interactions are complex and regionally variable (Blomqvist et al. 2002; Gilg 2002), making broad generalizations uncertain.

25.2.3.4 Changes in Marine Mammals

Hunting for marine mammals, especially whales, seals, and sea otters (*Enhydra lutris*), in the nineteenth century radically reduced many populations (Marine Mammal Commission 2002). The Steller sea cow (*Hydrodamalis gigas*) was hunted to extinction. The Southern right whale (*Eubalaena glacialis australis*) and Antarctic fur seal (*Arctocephalus gazella*) were almost extinct by 1830. Whaling proliferated in the nineteenth and first half of the twentieth centuries. Overexploitation led to the formation of the International Whaling Commission in 1949. There is now a moratorium on commercial whaling, although Iceland and Japan continue to harvest whales for research, and Norway, which objected to the moratorium on commercial whaling, continues commercial whaling, leading to an annual harvest of 400 ± 40 minke whales (*Balaenoptera acutorostrata*). Indigenous whaling in Greenland and North America has had no detectable effect on whale populations (Caulfield 1997).

Antarctic fur seal populations are growing as a result of decreased whale predation and are expanding their range to the south. In contrast, many whale populations have not fully recovered. The causes of recent declines in populations of southern elephant seal, Steller sea lion (*Eumatopius jubatus*), harbor seal (*Phoca vitulina richardsi*), sea otter (*E. lutris*), and other marine mammals are *speculative,* but in some cases appear to involve commercial fishing (of the southern elephant seal and sea otters, for example), reduced sea ice (for polar bears (*U. maritimus*) and walrus (*Odobaenus rosmarus divergens*)), or other changes in marine ecosystems (Estes et al. 1998).

Northern oil and gas development may also influence marine mammals. Noise from offshore oil exploration in the Beaufort Sea disturbs bowhead whales (*Balaena mysticetus*) and could deflect them from migration routes, making them less accessible to hunters. Autumn-migrating bowheads, for example, stay 20 kilometers from seismic vessels (NRC 2003). Oil spills from marine transportation or offshore oil platforms have the potential for widespread ecological damage, particularly in ice-covered Arctic waters. Spills from pipelines in temperate-zone oil basins in the headwaters of Arctic rivers such as the Ob, Pechora, and McKenzie could also contaminate Arctic waters.

25.2.3.5 Changes in Birds

There is extensive evidence of environmentally related changes in Antarctic seabird populations, although long-term exploitation of living resources may also be a contributing factor (Fraser et al. 1992). Among the most dramatic Antarctic changes have been local declines in Adélie penguins (*Pygoscelis adeliae*) combined with a southward reduction in range (Fraser et al. 1992). Chicks that fledge at a body mass of less than 2,850 grams have low survivorship. Most available penguin rookery habitat occurs in landscapes where snow deposition is enhanced during late winter and early spring storms. This causes chicks to hatch later and delays their key growth period until early February, when local krill (*Euphasia superba*) is less abundant and adults must forage greater distances for food. Adélie penguins have become locally extinct on some islands along the Antarctic Peninsula and are declining rapidly on other islands (Ainley et al. 2003). As the Adélie penguins decline, they are being replaced by a southward shift in distributions of chinstrap and gentoo penguins (*P. antarctica* and *P. papua*).

Adélie penguin populations in the Ross Sea sector appear to oscillate with a five-year lag to sea-ice extent, which in turn is related to ENSO conditions (Wilson et al. 2001). In the longer term, the southern limit to distribution of Adélie penguin breeding colonies is determined by changes in the pattern of year-round sea-ice presence (Baroni and Orombelli 1994; Emslie et al. 2003) Extensive sea ice during winter months appears to reduce sub-adult survival. Similarly, emperor penguins (*Aptenodytes forsteri*) decline with warmer temperatures and reduced sea-ice extent (Barbraud and Weimerskirch 2001), although they hatched fewer eggs when winter sea ice was extended (Barbraud and Weimerskirch 2001). These data indicate that penguins may be quite susceptible to climatic changes. In addition, there have been serious population declines in 16 of 24 species of albatrosses, primarily as a result of incidental catches in longline fishing (Crawford and Cooper 2003).

The Arctic is a breeding ground for many migratory wetland birds that overwinter throughout the world. Several hundred million birds, including swans, geese, and ducks, migrate from southern overwintering grounds to the Arctic to breed. These birds are indirectly affected by climate changes, habitat loss, and altered food abundance throughout their range (Lindström and Agrell 1999; Zöckler and Lysenko 2000). Critical coastal stopover sites are also threatened by human activities. The increases in Arctic plant biomass, height, and density caused by recent warming and eutrophication affect wetland birds negatively (Callaghan et al. in press). Twelve Arctic bird species are globally threatened (CAFF 2001). Climate change also fosters northern migration of more southerly bird species, including the common snipe (*Gallinago gallinago*), black-tailed godwit (*Limosa limosa*), and northern lapwing (*Vanellus vanellus*) in Russia (Lebedeva 1998; Morozov 1998), as well as American robins (*Turdus migratorius*) in the polar barrens of North America (Jolly et al. 2002). Ravens (*Corvus corax*) and some gulls have become more abundant near human settlements, acting as nest predators on other birds.

The greater snow goose (*Chen caerulescens atlantica*) increased twenty-five-fold, from 28,000 birds in 1965 to 700,000 in 1998 (CAFF 2001). The overall populations of "white" geese (greater and lesser snow goose and Ross's goose) increased from about 1 million to about 8.5 million over the same time period (Batt 1997). Changes in agricultural practices, which increased food availability, are probably the most important cause of these changes. The population increase has exceeded the threshold for persistence of salt-marsh vegetation, leading to catastrophic vegetation change and salinization of many coastal wetlands (Hik et al. 1992; Srivastava and Jefferies 1995).

25.2.3.6 Changes in Fish

The most dramatic changes in fish populations have occurred in Antarctic waters, where overfishing rapidly depleted stocks of marbled notothenia (*Notothenia rossii*), mackerel icefish (*Champsocephalus gunnari*), gray notothenia (*Lepidonotothen squamifrons*), and Patagonian toothfish (*Dissostichus eleginoides*). Some stocks recovered when conservation measures were instituted by the Convention on the Conservation of Antarctic Marine Living Resources, but others remain depressed by illegal, unregulated, and unreported fishing (CCAMLR 2002). (See Chapter 18.)

Overharvesting of whales and seals may have led to population increases of krill (*E. superba*), their major food source. Subsequent reductions in krill reflect some combination of commercial fishing, recent increases in fur seal and penguin populations, changes in sea-ice duration and extent, and, perhaps, increases in UV-B associated with ozone depletion (Naganobu et al. 2000). Krill are long-lived animals whose variation in growth and reproduction are sensitive to oceanic and sea-ice conditions; they comprise the main food source for fish in Antarctic waters (Murphy et al. 1998; Quetin and Ross 2001; Fraser and Hofmann 2003). Under conditions of increased sea-ice melt, cryptomonads expand at the expense of the diatoms, which are preferred by krill, potentially resulting in krill decline (Moline et al. 2000). This tight but complex linkage of krill population dynamics to sea ice suggests that any future changes in timing, duration, or extent of sea ice will strongly affect the community composition of phytoplankton, krill, and their predators. Because advection of biological material is important in maintaining Southern Ocean ecosystems, the potential impacts of regional changes may extend well to the north of the main sea-ice-covered regions.

In the Arctic, regional warming may have contributed to recent northward range extensions of anadromous fish such as salmon (*Oncorhynchus* spp and *Salmo* spp.) (Babaluk et al. 2000; Jolly et al. 2002) and to increased abundance of salmonid parasites in Alaskan rivers. Human activities have also altered fish distributions. For example, the salmonid parasite *Gyrodactylus salari* that is native in Central Asia spread naturally to the Baltic and then further to Scandinavia with the help of humans (Johnsen and Jensen 1991; CAFF 2001). This parasite feeds on young salmonids and causes major damages in Norwegian fish farms and rivers. Another example of human impacts on fish production involves introduction of the shrimp *Mysis relicta* to high-elevation Norwegian and Swedish lakes and rivers that are regulated for hydroelectric purposes. Initially the shrimp introduction had positive effects but over time feeding by *Mysis* on zooplankton reduced this food resource, leading to a decline in fish growth (Nesler and Bergersen 1991).

25.2.3.7 Changes in Insects

The introduction of alien insects on sub-Antarctic islands is threatening some native species and vegetation communities (Ernsting et al. 1995; Hanel and Chown 1998), and introduced flora is affecting soil faunal composition (Gremmen et al. 1998). The northern limit of Arctic insect species is usually determined by climatic factors (Strathdee and Bale 1998). For example, food plants probably determine distributions in less than 3% of the macrolepidopteran (butterfly) species of Finland (Virtanen and Neuvonen 1999). Species richness decreases by 65 species for each degree of latitude northward—that is, 93 species (12% of the total) per degree of mean summer temperature.

Lepidopteran species are usually good dispersers, so climate warming will likely promote increases in their richness as species move poleward. Conversely, the distribution of northern species (11% of the Finnish species) such as sawflies may shrink in a warmer climate (Kouki et al. 1994). Among bark beetles, *Ips amitinus* and *Xylechinus pilosus* have expanded their ranges in Fennoscandia (Heliövaara and Peltonen 1999), whereas other species (such as *Tomicus minor*) are retracting southwards.

A rise in winter temperature would favor species overwintering as eggs and may increase the frequency of insect outbreaks of those species (such as *Epirrita autumnata,* a geometrid defoliator of birch) (Nilsson and Tenow 1990; Neuvonen et al. 1999; Niemelä et al. 2001). Species overwintering as pupae will likely increase the number of generations per year (Virtanen and Neuvonen 1999). Summer warming will also increase the number of generations completed; this increase has been found in experimental field manipulations to increase the overwintering population of aphids on Svalbard by an order of magnitude (Strathdee et al. 1993).

In boreal Canada, pest-caused timber losses may be as much as 1.3–2.0 times the mean annual depletions due to fires (Volney and Fleming 2000). Global change will likely increase the frequency and intensity of outbreaks, particularly at the margins of host ranges. Changes in mosquito abundance in response to altered hydrology could strongly affect fish and waterfowl, for which they are an important food source, as well as caribou and reindeer, whose energy budgets are sensitive to insect harassment (Chernov 1985).

25.2.4 Food, Fuel, and Fiber

Documented changes in biodiversity have had negligible effects on the food supply of people in Antarctica, who bring their food, fuel, and fiber from lower latitudes. Marine harvests in Antarctic waters, however, provide food that is used globally. Fish and krill are now primary targets of human exploitation in the Southern Ocean. From 1970, when recordkeeping began, to 1998 a total of 8.7 million tons of krill and fish were harvested (CCAMLR 2000).

In contrast, indigenous peoples throughout the Arctic (and many nonindigenous residents as well) maintain strong social, cultural, and economic connections to the environment through traditional hunting, herding, fishing, trapping, and gathering of renewable resources. Local mixed economies of cash and subsistence depend strongly on household production involving harvest of local resources, food preparation and storage, distribution, consumption, and intergenerational transmission of knowledge and skills (Nuttall 1992; Caulfield 2000; Dahl 2000; Freese 2000; Nuttall et al. in press). Per capita consumption by rural Alaskans (indigenous and nonindigenous), for example, is 170 kilograms per year of wild foods (60% fish, 16% land mammals, 14% marine mammals, 10% plant products), valued at about $200 million. Urban Alaskans, in contrast, consume 22 kilograms of wild foods per capita per year. Cultivated crops are a smaller source of food except in maritime regions (such as Iceland and coastal Norway). Wood, sod, peat, and coal are used locally as fuels.

The subsistence resources used by Arctic peoples vary regionally. In the barrens, where terrestrial productivity is low, most communities are coastal and people depend primarily on fish and marine mammals (such as polar bears, seals, walrus, narwhals (*Monodon monoceros*), and beluga (*Delphinapterus leucas*), fin, and minke whales), although terrestrial mammals (such as caribou, reindeer, and musk ox), migratory birds and their eggs (such as ducks, geese, terns, and gulls), and plants and berries are seasonally important. In tundra, in contrast, people rely more heavily on fish—including salmon, Arctic char (*Salvelinus alpinus*), whitefish, and northern pike (*Esox lucius*)—migratory and sedentary birds, terrestrial mammals, and berries.

Caribou and reindeer, which include wild and domestic populations of North American barren-ground wild caribou, are arguably the most important terrestrial subsistence resource for Arctic indigenous peoples (Klein 1989; Paine 1994; Kofinas et al. 2000; Jernsletten and Klokov 2002). Many Arctic and sub-Arctic indigenous cultures co-evolved with reindeer or caribou, which provide food, shelter, clothing, tools, transportation, and other marketable goods. In North America, where indigenous subsistence hunting constitutes the primary use of caribou, there are approximately 3.2 million barren ground caribou and an estimated annual harvest of over 160,000 animals, equivalent to more than $30 million annually. In Russia, large-scale commercial hunting of wild reindeer, which began on the Taimyr in the

1970s, produced more meat than all reindeer husbandry of both Central Siberia and Yakutia but has not fulfilled the cultural role that reindeer play in reindeer-herding societies. The change from a migratory existence to permanent communities with schools, stores, and jobs alters traditional lifestyles.

25.2.5 Cultural Benefits

The numerous cultural groups in the Arctic (more than 50) reflect a diversity of historical roots and local ecological conditions provided by ecosystems. Subsistence activities, such as hunting, herding, fishing, trapping, and gathering, remain important for maintaining social relationships and cultural identity in these indigenous societies (Brody 1983; Nuttall 1992). These activities link people inextricably to their histories and their contemporary cultural settings and provide a context for thinking about sustainable livelihoods in the future (Nuttall et al. in press).

The Antarctic and Arctic provide important cultural benefits to non-Arctic residents as well. Some of these benefits are mediated by polar species that migrate to lower latitudes. In addition, non-polar residents value the near-pristine conditions of polar regions, motivating them to visit these lands (tourism) and to support legislation and lobbying efforts for their protection.

25.3 Drivers of Change in Polar Systems

The relative importance of drivers of change varies across the polar regions and depends on the stakeholders involved. For polar residents, the most important changes (in order of decreasing importance) are often climate change, industrial development, contaminants, marine fishing, and UV-B. For non-polar residents, the most important changes—again in order of importance—are often climate change, marine fishing, increased UV-B, industrial development, and introduction of exotic species. The shared concern by both polar and non-polar residents about many of the same drivers of change provides opportunities to develop agendas that enhance the well-being of residents both within and outside polar regions.

25.3.1 Climate and Hydrologic Change

Climate has warmed more dramatically in portions of the Arctic and Antarctic than in any other region on Earth, with substantial impacts on ecosystems, their services, and human well-being. The magnitude and global pattern of Arctic warming are known with *high certainty.* These warming trends are most pronounced in western North American Arctic and central Siberia (Kozhevnikov 2000; Serreze et al. 2000; Smith 2002; Convey et al. 2003). Warming has been negligible in parts of Scandinavia. (See Figure 25.8 in Appendix A.) Arctic warming results both from a general northern hemisphere warming and from a regime shift in hemispheric circulation (such as more-frequent positive phases of the North Atlantic and Arctic Oscillations) (Overland et al. 2004). Temperate air masses penetrate more frequently into the Arctic, causing increased climate variability (Overland et al. 2004) and conditions that are unfamiliar to local residents (Krupnik and Jolly 2002). Regions that previously exhibited a cooling trend (such as eastern North American Arctic and Chukotka from 1950 until 1990) are now warming.

Increases in precipitation during this time period are approximately balanced by increased evapotranspiration, suggesting only minor changes in terrestrial water balance (Serreze et al. 2000). Nonetheless, terrestrial studies suggest that changes in water balance are occurring but are regionally variable. These include increasing river runoff in Russia (Peterson et al. 2002) (as mentioned earlier), bog expansion in western Russia (Crawford et al. 2003), and drier soils in North America (Hinzman et al. in press) (perhaps explaining recent increases in area burned (Murphy et al. 2000)). The spatial pattern and magnitude of these changes in soil moisture are known with only a *low certainty.*

The Antarctic shows complex temporal and spatial patterns of both warming and cooling. Over the past 15–20 years, 60% of continental Antarctica has been thermally stable or cooling slightly (Doran et al. 2002b; Kwok and Comiso 2002; Thompson and Solomon 2002), although this trend is debated (Turner et al. 2002). In contrast, the McMurdo Dry Valleys show general twentieth-century warming but cooling since 1985 (Bomblies et al. 2001); the sub- and maritime Antarctic islands show consistent warming (Bergstrom and Chown 1999; Quayle et al. 2002; Convey submitted); and the Antarctic Peninsula has warmed as rapidly as any place on Earth (King et al. 2003; Smith et al. 2003; Vaughan et al. 2003). Increases and decreases in precipitation have also both been reported (Turner et al. 1997; Smith 2002; Quayle et al. 2003).

Temperature and precipitation changes show teleconnections with El Niño/Southern Oscillation events in the southern Pacific Ocean (Cullather et al. 1996; Harangozo 2000). Reported Antarctic cooling may result from increased strength of the Southern Hemispheric Annular Mode, which would cause the strong westerly winds around Antarctica to spend more time in the strong-wind phase (Thompson and Solomon 2002). Such an effect could also contribute to the warming seen along the Antarctic Peninsula, as fewer cold-air outbreaks would be seen with increased advection of warm moist air from the Southern Ocean.

25.3.2 Development of Extractive Industries

Extractive industries in the Antarctic are prohibited by the Protocol on Environmental Protection (the Madrid Protocol) to the Antarctic Treaty of 1959, which set aside Antarctica for peaceful purposes and international collaboration in science. In contrast, extractive industries have been a significant driving force for ecological and socioeconomic change in the Arctic for over a century. Gold mining has contaminated streams with mercury used to amalgamate gold dust and with increased sediment loads that damage downstream aquatic ecosystems. Industrial coal and base-metal mines have caused local surface contamination. However, the greatest local effects on ecosystem services derive from smelting non-ferrous metals. Emissions from smelters on the Kola Peninsula and in Norilsk, Russia have produced local concentrations of atmospheric heavy metals among the highest in the world, resulting in areas that are entirely devoid of vegetation from the combined effects of sulfur fumigation and acid and heavy-metal deposition (Doiban et al. 1992).

As petroleum and military development spread in the latter half of the twentieth century, transportation infrastructure (roads, pipelines, airstrips, ports) contributed significantly to surface disturbance and habitat fragmentation. Between 1900 and 1950, less than 5% of the Arctic was affected by infrastructure development (Nellemann et al. 2001; Ogden in press). By 2050, some 50–80% of the Arctic is projected to be disturbed, although this level of disturbance may occur by 2020 in Fennoscandia and some areas of Russia.

Changes in world energy markets and technology have led to a rapid expansion of oil and gas development in several regions of the Arctic during the past 30 years. Most activity to date involves oil onshore along the North Slope of Alaska and in western Siberia, and offshore in the Barents and Beaufort Seas. However, the Alaskan North Slope, the McKenzie Delta of Canada, the Yamal

Peninsula of Russia, and their adjacent offshore areas hold enormous natural gas deposits that are projected to be developed during the next decade (Forbes 2004a). These developments will likely continue expansion as reductions in sea ice open new sea and river routes and reduce development and transportation costs. In addition to direct effects on vegetation and hydrology, oil and gas developments have many cumulative effects on subsistence resources and on the economies and well-being of local peoples, including increased wages to local residents, the fragmentation of habitat, and increased access by nonresidents (Walker et al. 1987; NRC 2003).Global changes in politics, corporate structure, and resource demand strongly influence the patterns and rates of resource extraction at high latitudes (Whiteman et al. 2004).

25.3.3 Contaminants

Many environmental contaminants that are produced and released to the environment at low latitudes tend to accumulate in polar regions. Persistent organic pollutants, for example, are stable, fat-soluble, carbon-based compounds that volatilize at warm temperatures and are transported poleward by wind, water, and wildlife. Old and current research stations in the Antarctic and Distant Early Warning stations in the Arctic often constitute additional local sources of contaminants (MacDonald et al. 2002). Atmospheric transport is the most rapid pathway by which persistent organic pollutants, especially volatile or semi-volatile compounds, reach the poles. Once in polar regions, POPs are deposited on particles or exchanged with water, both processes that are enhanced by low temperature. Oceanic transport occurs more slowly but is an equally or more important pathway for compounds such as hexachlorocyclohexane or toxaphene that partition strongly into water (MacDonald et al. 2002).

Fish and migratory waterfowl, which winter in more-polluted regions of the world and come to polar regions to reproduce, constitute a third pathway for polar transport. Anadromous fish also transport POPs from the ocean to high-latitude lakes and streams (Ewald et al. 1998). Animals are particularly important vectors for highly fat-soluble compounds. Marine mammals, seabirds, top carnivores, and predatory fish accumulate the largest amounts of fat-soluble contaminants because of their high trophic position in complex marine food webs (AMAP 2003). These general contaminant patterns are known with *high certainty,* but the regional variation in contaminants is not well documented. Persistant organic pollutant concentrations in Antarctic pelagic food webs (Corsolini et al. 2003) and in the air (Kallenborn et al. 1998) are much lower than those found in the Arctic, but some forms may be increasing owing to greater usage of POPs in the Southern Hemisphere (Weber and Goerke 2003).

Limited evidence suggests a current decline in polar concentrations of POPs, such as dichlorodiphenyl-trichloroethane, or DDT, the use of which has declined globally. POPs that are increasing in their global use continue to accumulate in polar regions (AMAP 2003; Chiuchiolo et al. 2004), and brominated diphenyl ethers—flame retardants whose use is not banned—occur in high concentrations in Antarctic sea ice and juvenile krill (Chiuchiolo et al. 2004). Antarctic sea ice serves as a collector and focusing mechanism that injects accumulated POPs into the plankton system at its period of maximum biological activity. The effects of climate warming on persistant organic pollutant transport to polar regions have *low certainty.* Sources of uncertainty include the dynamics of adsorption to snow and the extent to which POPs currently trapped in sea and glacial ice will be released with warming.

Heavy metals, like POPs, are persistent compounds that can be globally transported, especially by wind. They differ from POPs, however, in that they occur naturally within and outside polar regions and exhibit areas of naturally high and low concentrations. Heavy metals bind to proteins, accumulate in organs (liver, kidney, brain), and are slowly excreted in hair, feathers, nails, and claws. With the exception of mercury, heavy metals tend not to biomagnify (concentrate as they move through food webs). Global sources of mercury pose the greatest threat in polar regions because the global combustion of coal, which is its major source, is expected to continue rising throughout the next century. There are trends of increasing mercury in some Arctic species (AMAP 2003).

In East Greenland, 100% of the human population has concentrations of mercury that are unacceptable, and health advisories have recommended reduced consumption of some locally harvested resources. Heavy metal pollution inputs have declined in those portions of the Russian North where cessation of subsidies caused many extractive operations to close. Even in these areas, however, pollutants released previously remain in high concentrations in ecosystems. In the Antarctic region, burning of fossil fuels (involving NO_x emissions) at research stations might affect local systems at decadal time scales (Lyons et al. 2000).

Radionuclides such as cesium-137 and strontium-90 are stable enough to be transported globally in the atmosphere and oceans. Radionuclide concentrations increased during atmospheric testing of nuclear weapons in the 1950s and, like other forms of air pollution, drifted to polar regions. Background levels of atmospheric fallout have declined markedly since the end of atmospheric testing in 1963, but a more recent release occurred during the Chernobyl accident in 1986. Anthropogenic radionuclides are locally abundant in sediments near sites of weapons testing, storage, and nuclear-powered electricity generation facilities. Lichens, which derive most of their mineral nutrition from the air, are particularly effective in accumulating radionuclides. Caribou and reindeer, which eat lichens in winter, are an avenue by which any future nuclear contamination might affect human health (Section 25.5.4).

25.3.4 Marine Fishing

Both climate variability and commercial fishing have caused significant variations in marine mammals and fish available for commercial and subsistence harvest (Finney et al. 2002; AHDR 2004). (See also Chapter 18.) For example, over half of the Northeast Atlantic regional stocks of cod (*Gadus morhua*), haddock (*Melanogrammus aeglefinus*), whiting (*Merluccius bilinearis*), and saithe (*Pollachius virens*) are depleted below safe biological limits and are therefore threatened with collapse. In Greenland, the collapse of the cod fishery occurred when overfishing coincided with climatic deterioration (Hamilton et al. 2000). In the North Pacific, the decline in bottom fish has contributed to drops in populations of Steller sea lions, causing killer whales to shift to sea otters for food and reducing the availability of marine mammals for human harvest (Estes et al. 1998). Commercial fishing has reduced fish runs in major rivers such as the Yukon in North America, reducing their availability as a subsistence resource. As sea ice continues to decline, commercial fishing may expand northward, reducing stocks that have previously had limited human harvest. These changes have, in many cases, had dramatic socioeconomic effects, as small Arctic communities adapt to the combined effects of climate change, changing fish stocks, and emergent markets (Hamilton et al. 2000).

In Antarctica, exploitation in the nineteenth and early twentieth centuries reduced seal and whale populations almost to extinction, but the consequences have *low certainty* (May et al. 1979; Murphy et al. 1995). Stocks of krill, the major food source of whales, may have increased, but this assumes that their abundance was under top-down control by predator demand. Fishing for krill has occurred over the past 20 years, but the fishery has operated at very low levels relative to the estimated stock sizes, and there is no evidence that fishing has significantly affected local abundance and availability to predators.

Fishing in Antarctic waters, particularly by Russia, expanded rapidly in the 1960s, leading to depletion of several fin-fish stocks by the 1990s. (See Chapter 18.) The Convention on the Conservation of Antarctic Marine Living Resources limits catch sizes, but continued illegal, unregulated, and unreported high-seas fishing threatens major fish stocks and makes effective monitoring and management difficult.

25.3.5 Increased UV-B

Anthropogenic destruction of Earth's protective stratospheric ozone layer gives rise to an ''ozone hole'' that allows UV-B radiation to penetrate to the surface (Farman et al. 1985). The boundaries of the ozone hole that forms over Antarctica each austral spring are dynamic and can extend to southern South America, New Zealand, and southern Australia. Although the Montreal Protocol curbs emissions of the causal chlorofluorocarbons, there is still no reduction in intensity of the annual ozone hole, although recovery is predicted within about a century (Shindell et al. 1998).

The most intensively studied biological impacts of UV-B are the effects on human health (described later in the chapter) and the reduction of phytoplankton production and plankton biodiversity (Smith et al. 1992; Quartino et al. 2001; Vernet and Kozlowski 2001). On land, UV-B reduces plant height and shoot mass (Day et al. 2001; Robinson et al. 2003) and induces the formation of protective pigments (Newsham et al. 2002; Newsham 2003) that may also alter palatability to herbivores (Hessen 2002). The impacts of UV-B in the Arctic are less dramatic than in the Antarctic and potentially include decreased marine primary production, increased mortality of fish larvae of some species, increased mortality of freshwater invertebrates, reduced growth of some plant species, and changes in microbial biodiversity and biogeochemical cycling (Vernet and Kozlowski 2001; Callaghan et al. in press). The net impact of increased polar UV-B on the ecological determinants of human well-being has *low certainty,* but its effects on Antarctic marine plankton assemblages and production have *high certainty* (Weiler and Penhale 1994; Meador et al. 2002).

25.3.6 Introduction of Exotic Species

Despite Annex II of the Protocol on Environmental Protection to the Antarctic Treaty, which prohibits introduction of exotic species to Antarctica, human introductions of exotic species (including rats, slugs, reindeer, cats, temperate grasses, and other plants) are problematic on most sub-Antarctic islands, although they have not yet significantly affected the Antarctic continent (Chown et al. 1998; Vidal et al. 2003; Frenot et al. in press). The combination of increased human activity in the region and the lowering of barriers to the transfer and establishment of biota through climate change leads to predictions of further increases in rates of exotic introduction and consequential impacts on native biota and biodiversity (Frenot et al. in press).

Weedy plant species from temperate and Mediterranean ecosystems have a long history of establishment in northern boreal and Arctic regions (Forbes 1995). Their migration north of the Arctic tree line is most common along road and railway corridors with connections to the south, but numerous incidental introductions have also occurred in places such as Baffin Island, Greenland, Svalbard, and remote portions of the Russian Arctic. Many of the introductions establish first on disturbed ground. Many persist for decades or even centuries without additional anthropogenic or zoogenic influence, although an ongoing disturbance regime favors the maintenance and spread of new populations.

Introductions of exotic mammals have had substantial impacts on many polar ecosystems. Until the advent of human influence, sub-Antarctic islands and many islands in the Bering Sea had no indigenous terrestrial mammals, so seabirds nested safely on the ground or in burrows (CAFF 2001). Arctic foxes (*A. lagopus*) were deliberately introduced to many Bering Sea islands as a fur resource, and cats, sheep, rabbits, reindeer, and cattle were introduced to some sub-Antarctic islands. At the same time, rodents (rats and mice) were inadvertently introduced to many islands.

As seen elsewhere when predators or competitors were introduced to previously isolated communities, these animals generally reduced, and in some cases drove to extinction, populations of marine birds, waterfowl, and other ground-nesting birds, through either habitat alteration or direct predation (Frenot et al. in press). Exotic plants have frequently been introduced as a by-product of animal introductions, typically accidentally in forage material or as resistant stages transported within the animal's digestive system. Introduced mammals have been successfully eliminated from some islands, resulting in recovery of bird nesting success. On Svalbard in Scandinavia, the introduction of the rodent *Microtus rossiaemeridionalis* led to the introduction of a tapeworm and associated disease problems (Henttonen et al. 2001). Muskrat (*Ondatra zibethica*) was introduced in 1905 into central Europe from North America and later to Finland and several places over the Soviet Union because of its valuable pelt (Hoffmann 1958). It has spread widely beyond the areas of introduction. Sable (*Martes zibellina*) has also been introduced to the Siberian Arctic.

One of the largest crab species in the world, the king crab (*Paralithodes camtschaticus*), was transferred by the Russians from the Bering Sea to the Barents Sea beginning in about 1960. Since it was first observed in Norwegian waters in about 1980, the species has spread eastward and southward along the coast (Sundet 1998). Although this species is a valuable catch, it causes problems to fishing gear and has reduced sea urchin populations in the Barents Sea. Marine introductions have to date been of very limited impact in Antarctic seas, although this perception may derive in part from a lack of monitoring.

25.4 Trade-offs, Synergies, and Management Interventions

Given the complex web of changes in ecosystem services in polar regions and their sensitivity to changes in global and regional drivers, changes in some ecosystem services inevitably affect others, either positively or negatively. (See Figure 25.9.) Identification of these interactions, whether they are trade-offs or synergies, facilitates the design of policies that enhance a broad array of services and reduce the likelihood that policies focused on a specific service will inadvertently damage others.

25.4.1 Synergies between Climate Regulation, Subsistence, and Cultural Resources

The most pervasive synergy among ecosystem services in polar regions links climate regulation, subsistence use, and cultural re-

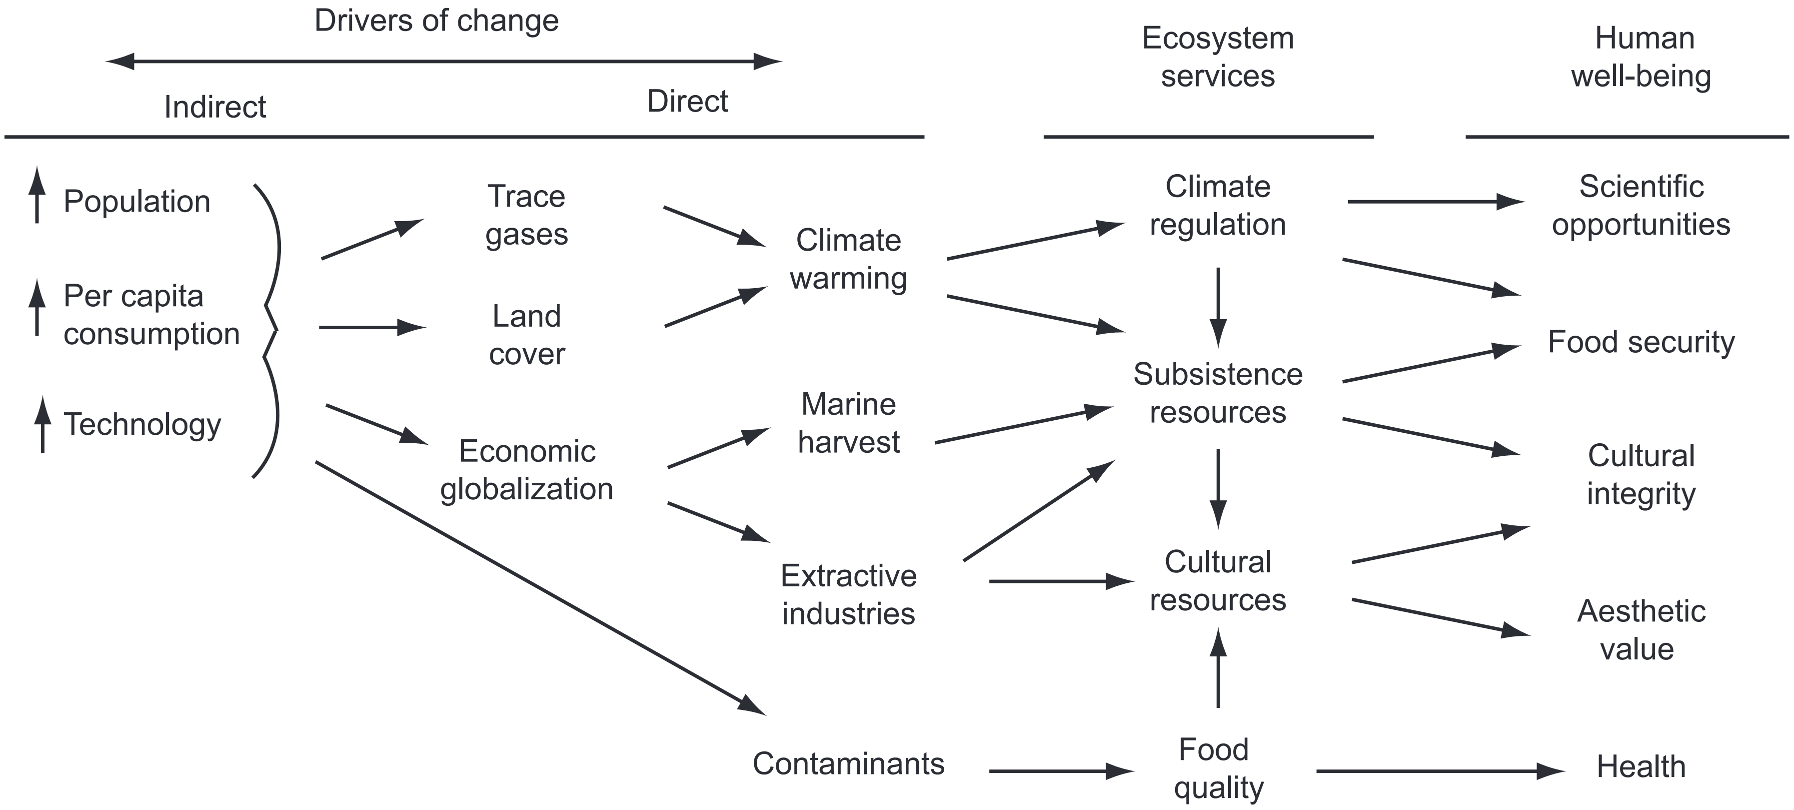

Figure 25.9. Links between Drivers of Change, Ecosystem Services, and Human Well-being in Polar Regions

sources. (See also Chapter 5.) Until recently, the magnitude of land use change in polar regions has been modest, allowing Arctic residents to maintain a substantial dependence on subsistence resources for food and clothing and for their cultural ties to the land. These same attributes make polar regions important to non-Arctic residents for existence and aesthetic values.

Fortunately, management strategies that foster the sustainability of these cultural resources have a *high certainty* of maximizing the retention of biodiversity, particularly in wetlands, and of maintaining the capacity of polar regions to serve as the planet's cooling system by maintaining current large stocks of soil carbon and preventing thaw of permafrost that would enhance methane emissions (as described earlier). Conversely, industrial development or pollution that seriously alters these ecosystems detracts from the aesthetic values that are important to both polar and non-polar residents, reduces ecosystem capacity to sustain biodiversity and subsistence resources, and increases methane and carbon emissions, a positive feedback to climate warming.

Policies that recognize these synergies sustain all these services simultaneously. For example, policies that allow local people to pursue traditional subsistence activities within protected areas contribute to biodiversity and cultural integrity while meeting the aesthetic needs of both Arctic and non-Arctic residents (Watson et al. 2003). Alternatively, policies that exclude subsistence use from protected areas create trade-offs between the subsistence needs of local residents and the aesthetic and recreational interests of non-Arctic residents. Current national regulations permit subsistence use in protected areas of the North American Arctic. In Russia, indigenous peoples are often excluded from protected areas, even though laws may permit subsistence uses (Fondahl and Poelzer 2003). Subsistence use in protected areas is generally prohibited in Fennoscandia.

25.4.2 Synergies and Trade-offs between Subsistence and Cash Economies

Residents of all Arctic nations participate in a mixed economy in which individuals and communities depend on both subsistence harvest from the land and sea and imports of food, fuel, and other products from outside the Arctic. Among many Arctic indigenous peoples, participation in a mixed cash-subsistence economy has been a way of life for more than a hundred years, with fur trading being the original base of the cash economy. This economy has both positive and negative impacts on subsistence activities; in recent years, participation in the cash economy has increased dramatically (AHDR 2004).

On the one hand, this reduces the necessity and time available to acquire food from the land, thereby reducing the transmission of cultural traditions to younger generations. Substance abuse, television, fast foods, and other attributes of a cash economy have also detracted from the central role of subsistence in the lives of rural Arctic people. On the other hand, cash income provides access to new harvesting technologies (Chance 1987) and other material benefits. Motorboats and vehicles (such as snow machines, off-road vehicles, and in some places aircraft) give people continued access to lands for hunting, herding, fishing, and gathering.

In all Arctic nations, government policies consolidated semi-nomadic indigenous peoples into permanent settlements by the mid-twentieth century in order to provide schools and other services. If residents of these communities had not had a cash income to help them purchase motorized transport, they would have been less able to reach the large areas typically required for subsistence. However, reliance on these technologies make industrial commodities a necessity, not just a supplement to the traditional economy (Kirkvliet and Nebesky 1997). These technologies also alter the balance between hunters and the hunted, raising new challenges for conservation and game management.

The intertwining of subsistence and market economies creates winners and losers in what was, until recently, a fairly egalitarian society and introduces new challenges of balancing time and money in household production. Gender roles change in areas where women obtain wage-earning jobs more frequently than men. Continued viability of a community may require increased specialization. Some individuals who work full-time for pay, for example, have insufficient time to participate in traditional activities, whereas others who are unable to obtain jobs serve as full-time hunters to meet the overall subsistence needs of their communities (Stabler 1990; Kruse 1991; Chabot 2003). These groups are linked through a traditional system of reciprocity that redistributes market and subsistence products.

All Arctic nations recognize the potential lack of viability of market economies in northern regions when semi-nomadic indigenous peoples are consolidated in permanent settlements and have subsidized northern communities heavily (Duerden 1992). The consequence, however, is that Arctic mixed economies are now vulnerable to withdrawal of government support, as witnessed in Russia after the collapse of the Soviet Union or in cases of reduced support in Alaska (Knapp and Morehouse 1991). Products derived from locally available fish and wildlife resources often offer important sources of cash that supplement wages and transfer payments from governments.

However, subsistence economies are vulnerable to declines in global markets for these commodities, which include seal or muskrat pelts (as changes in cultural values reduce global demand for furs), salmon (as fish farming increases alternative supplies), and reindeer antler (as cultural change in Asia reduces demand) (Myers 2000). When world market prices are high, regional resource management institutions may be unable to respond to the increased incentives for unregulated or illegal harvest (such as for Kamchatka salmon or Greenland cod) (Hamilton et al. 2000) or overgrazing by reindeer (Forbes 1999). On the other hand, government policies to conserve stocks may prevent Arctic people from taking advantage of the only viable commercial activities available (as with the International Whaling Commission ban on commercial whaling).

Specialization on one or two products also increases the vulnerability to ecological change. In Greenland, for example, northward movement of warm currents in the 1930s reduced seal harvests by 60%, but local residents switched to fishing for cod, with financial assistance from the Danish government (Hamilton et al. 2000). When the cod fishery collapsed in the 1980s in response to a combination of overfishing and colder currents, those communities that had boats large enough to fish for offshore shrimp continued to prosper, whereas those communities that had only small boats and therefore no access to the offshore shrimp fishery declined in income and population (Hamilton et al. 2000)

25.4.3 Synergies and Trade-offs between Industrial Development and Cultural Resources

There is a fundamental trade-off between the bundle of services associated with environmental protection (aesthetic resources for Arctic and non-Arctic residents and the capacity of ecosystems to provide subsistence resources and to store soil carbon that contributes to climate regulation) and the services provided by industrial development that provides cash income. Most Arctic regions are ruled by nations with a non-Arctic population majority and have governments housed outside the Arctic. Therefore non-Arctic strategic and economic considerations often weigh heavily in decisions about Arctic development. Political decisions by the United States and Russia, for example, have strong effects on polar regions because of the nations' large demands for resources and strong influence on polar development (AHDR 2004).

An ongoing challenge for the governments of Arctic nations is to create options that maximize the economic benefits of industrial development, including wages and services for local residents, without seriously compromising the integrity of ecosystem services. This challenge may become more complex if warming leads to increased development and further immigration of nonindigenous people (Whiteman et al. 2004).

New technologies provide opportunities to minimize the impact of industrial development on ecosystem services of Arctic wetlands, including ice roads that minimize the areal extent of transportation infrastructure, improved pipeline designs that reduce the probability of oil spills, and lateral drilling that maximizes access to oil reservoirs from a limited number of surface installations. However, these advances are relatively ineffective in preserving the aesthetic qualities of wilderness, and some of these options are threatened by climatic warming. As winter temperatures rise, permanent roads and bridges will increasingly replace ice roads for overland access, augmenting the disturbed area for a given development. In Alaska, the number of days on which the oil industry is permitted by the state to use off-road vehicles has decreased by 50% since 1970 because of both warmer autumn conditions and increased environmental awareness by managers. (See Figure 25.10.) In Yamal in northern Russia, melting of ice-rich permafrost exacerbates deterioration of forage from trampling and overgrazing by reindeer (Forbes 1999).

Where Arctic residents have opportunities to capture some of the economic benefits from industrial development through both employment and corporate investments, benefits in the form of improved public infrastructure, educational services, and health care can be significant (as in North Slope Borough, Alaska, for instance). Trade-offs can be decreased where communities of resource users are afforded adequate authority in development planning and operation policies to ensure that community concerns are adequately addressed.

Other opportunities for synergies between conservation and development involve compromises that concentrate development in certain areas, leaving other areas protected for the subsistence, cultural, and climate-regulating services that they provide.

25.4.4 Institutional Trade-offs in Managing Ecosystems and Their Services

In the Antarctic, international conventions form the framework for decisions about resource management. The Antarctic Treaty was ratified in 1961, with additional instruments added in subsequent years. Comprehensive protection of the environment was

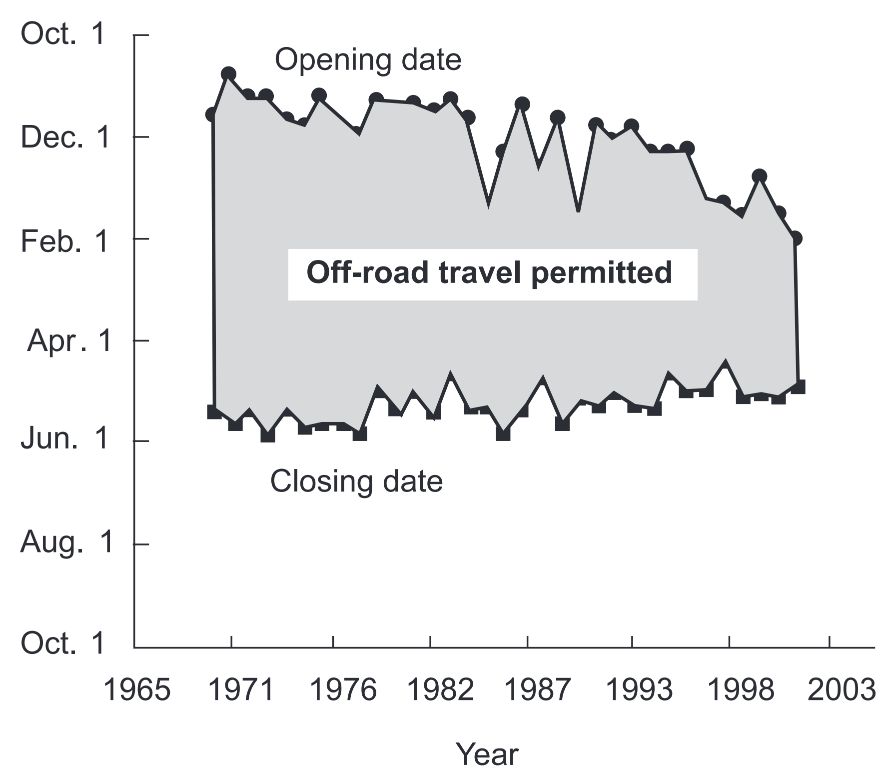

Figure 25.10. Trend in Dates Allowed for Travel by Seismic Vehicles on Alaskan Arctic Tundra, 1970–2000 (Alaska Department of Natural Resources)

achieved with the ratification of the Protocol on Environmental Protection, known as the Madrid Protocol, in 1998, which prohibited any activity relating to mineral resources, with exception for scientific research. Environmental assessment of all activities was required by the Madrid Protocol, ensuring that cumulative as well as immediate impacts are prevented. The Convention on the Conservation of Antarctic Marine Living Resources of 1980 permits fishing in the waters surrounding Antarctica, but only under the guidance of ecosystem management. This convention takes account not just of the dynamics of the exploited stocks but also their interactions in the ecosystem and the links to the physical environment.

Under these and other conventions, Antarctica now has the most stringent restrictions on use rights and the most advanced system of protected areas of any major region of the world. Nonetheless, Antarctica remains vulnerable to indirect human impacts such as pollution, stratospheric ozone destruction, and greenhouse-gas-induced climate change.

In contrast to Antarctica, institutions of the Arctic have evolved most actively at local and regional levels (AHDR 2004). Local stakeholders have asserted rights to develop their own rules and regulations governing use of natural resources and the right of their traditional institutions to be recognized by external parties. Both the outcomes of these efforts and the forms of local control differ regionally. In Alaska, Native corporations own about 12% of the land, and the federal government recognizes a rural subsistence preference regarding the use of living resources located on the 60% of the land remaining under federal jurisdiction. The U.S. federal government defends indigenous rights to use marine mammals and has established community development quotas to ensure that local groups have a stake in the region's marine fisheries.

The 1982 Canadian constitution acknowledges the validity of existing aboriginal rights, and the settlement of a number of comprehensive claims there has transferred to indigenous peoples both cash payments and title to large landholdings, along with recognized use and management rights in even larger traditional-use areas. In Greenland, there is no system of private property or well-defined use rights to land and natural resources, but the indigenous-controlled Greenland Home Rule has authority to make most decisions about the use of terrestrial and marine living resources. Devolution of authority to regional or local governments with good systems of accountability increases responsiveness of governments to the concerns of local stakeholders.

In Fennoscandia and Russia, national institutions have traditionally regulated natural resources, and local stakeholders have had greater difficulty establishing their rights. In Scandinavian countries, an ongoing struggle to secure Saami rights to land and natural resources has met with limited success. The state provides various forms of assistance to reindeer and coastal Saami. However, secure use rights have proved elusive, especially in Sweden, where the courts have generally denied claims to indigenous rights despite state recognition of these rights a century ago (Hahn 2000).

Recent federal laws in Russia theoretically allow indigenous peoples to establish long-term rights to land through the creation of both extensive Territories of Traditional Nature Use and smaller "commune lands" for pursuit of traditional activities (Kryazhkov 2000), although laws are difficult to implement in some areas and are not always enforced (Fondahl and Poelzer 2003). Recent outmigration of Russian and other nonindigenous residents may reduce pressures arising from competition over land and resource use. Efforts to devise a comprehensive system of rights and rules governing the use of land and natural resources in the region have repeatedly failed in the Duma.

A particularly significant innovation in governance in the circumpolar north—especially in the North American Arctic—has been the creation of co-management arrangements designed to forge partnerships between state governments holding formal authority to manage living resources and local user communities (such as the Porcupine caribou herd in Canada) (Osherenko 1988; Berkes et al. 1991). Co-management implies a sharing of power between resource users and state governments in various functions of resource management (monitoring, planning, enforcement, policy-making, and so on). These arrangements continue to evolve and are proving beneficial in regions where government agencies and resource users are together tracking the trends of climate change and monitoring the impacts of industrial development while exploring options for human adaptation.

In Fennoscandia, where traditional migration pathways conflict with complex patterns of private and Crown ownership, easement rights provide secure access (Hahn 2000). However, the amount of accessible, high-quality pasture available has decreased in many areas as a result of extensive forestry, tourism, hydropower, mining, and border fences and the concomitant increases in heavy trampling and grazing on the remaining lands (Forbes 2004b).

Oil, gas, and mineral developments have generally provided few long-term jobs for local residents. In North America, however, where local governments and land claims organizations provide an institutional framework for mitigation and compensation, extractive industries have provided substantial cash infusions to communities. Nevertheless, anxiety persists among Arctic residents about the cumulative effects of historical and proposed activities on resources and cultures (NRC 2003; AHDR 2004). In Russia's Yamal, where local residents have little influence over resource extraction, change has hit a crisis point, challenging the ability of local residents to adapt to the pace of oil and gas development (Krupnik 2000).

In the Arctic, the early development of international arrangements (the 1920 Svalbard Treaty guaranteeing signatories access to coal reserves, for example, or the 1973 Polar Bear Agreement committing signatories to the implementation of conservation measures) involved little input from local stakeholders. More recently, the Arctic Council and its forerunner, the Arctic Environmental Protection Strategy, have provided an important forum for the indigenous peoples of the Arctic to advance their agendas, including matters relating to the use of living resources. These international conventions then provide a basis for groups to go back to their home countries and demand the rights specified by these conventions. The Arctic Council has also devised and promoted an initiative designed to create and enlarge a Circumpolar Protected Areas Network.

25.5 Polar Systems and Human Well-being

25.5.1 Human Population Changes in the Arctic

Population in the circumpolar Arctic increased rapidly after 1960 as a result of immigration associated with expanded resource development and government activities in the north (AHDR 2004). However, change has been uneven, with much slower growth in Fennoscandia than in Russia or North America. (See Table 25.4.) Most of the population growth occurred in urban centers tied to industrial activities or public administration, so population density remains very low in rural areas across the Arctic. This pattern of growth has changed markedly since 1990. Growth has slowed in

North America and Greenland, and population has declined in Arctic Fennoscandia and particularly in Russia. Although the indigenous population has grown at a rate of about 1.5% annually, its share of total population has declined. Indigenous peoples have become ethnic minorities in all Arctic regional government jurisdictions except Greenland and portions of Canada (Nunavut and the Northwest Territories). (See Table 25.5.) Nonindigenous population growth in the latter could make indigenous peoples a minority there, too, within a decade.

Drivers of population change differ significantly for indigenous and nonindigenous residents. For the nonindigenous, most of whom are of European ancestry, past cycles of population change coincided with changes in world demand for Arctic resources (Sugden 1982). In the twentieth century, the Arctic became important to international security; this led to increased military presence and to government policies that boosted industrial development (Armstrong et al. 1978; Osherenko and Young 1989). The easing of tensions after the collapse of the Soviet Union led to the scaling back and closure of military and industrial installations in most Arctic nations and to a reevaluation of regional industrial policies. This change had the greatest impact on the nonindigenous population in the Russian Arctic. Arctic areas of Russia have lost nearly 25% of their inhabitants since 1990, while the population of the Russian North as a whole has declined by 13%. The withdrawal of government support led to rapid outmigration of ethnic Russians and other nonindigenous people (Heleniak 2003). The indigenous population remained relatively stable but suffered a decline in living standards.

Net outmigration has tempered the effects on indigenous population growth of the relatively high birth rates and increasing life expectancy (AMAP 2003). Migrants seek education and jobs in northern urban centers or outside the Arctic; some, but not all, return later in life. In Alaska, for example, there may be as much as 1% per year net population outflow (Huskey et al. in press). More women than men leave small rural communities, leading to a gender imbalance among unmarried adults in many parts of the

Table 25.5. Arctic Indigenous Population, 1960–2000. Share of total population is shown in parenthesis. (Knapp 2000 for 1960–90; 2000 data from national census as noted)

Arctic (Hamilton and Seyfritt 1994). Consolidation of the population into larger settlements improves job prospects and reduces the cost of providing infrastructure and services. This trend also increases pressure on local renewable resources near population centers, as people attempt to continue hunting and herding traditions, and it weakens cultural ties to ancestral homelands. Traditions of reciprocity often continue between urban indigenous residents and their rural kin, so outmigration provides some economic benefits to rural communities, although the magnitude of these benefits is uncertain.

25.5.2 Patterns and Trends in Human Well-being

Most polar regions are governed by industrial nations with substantial economic resources. Human well-being in these regions is therefore largely the product of choices made by the people and leaders of these nations rather than a lack of national resources to fulfill human goals. The eight Arctic nations account for 40% of global carbon emissions, so there are direct within-country links between the anthropogenic sources of climate change and the components of the global society that are currently most directly affected by this warming.

Polar regions are important to the well-being not only of the residents but also of the global population, which depends on polar regions for climate regulation and for providing extensive areas that remain wild and relatively unaffected by human activities and serve as critical areas for many culturally and otherwise important migratory species. This potential to provide for human well-being has not been fully met and is currently threatened by global human impacts on the climate system and by inadequate attention to human impacts within polar regions on ecosystems and the services they provide. The increased pressure that polar systems are experiencing implies that we are approaching critical thresholds (such as the thawing of permafrost and vegetation change), although the nature and timing of these thresholds are regionally variable and uncertain. Crossing these thresholds would likely cause a cascade of ecological changes with large effects (some negative, some positive) on human well-being. These changes could appear quickly and be irreversible (Dasgupta 2001; Chapin et al. 2004).

There is substantial variation in the well-being provided by ecosystems in different polar regions (AHDR 2004). There are few permanent residents in Antarctica, and there have been no clear trends in the mass balance of the Antarctic ice sheet on which the global population depends for climate regulation and control of sea level, as described earlier. There are indications of greater deterioration in the capacity of Arctic regions to provide a cooling system for the planet and to provide the aesthetic values of wilderness.

25.5.3 Cultural and Economic Ties to Ecosystem Services

The deterioration of cultural ties to subsistence activities among indigenous peoples is the most serious cause of decline in well-being within the Arctic. (See Figure 25.11.) There has been a gradual loss of connection to the land through change in lifestyles, loss of indigenous languages, and dominance of nonindigenous

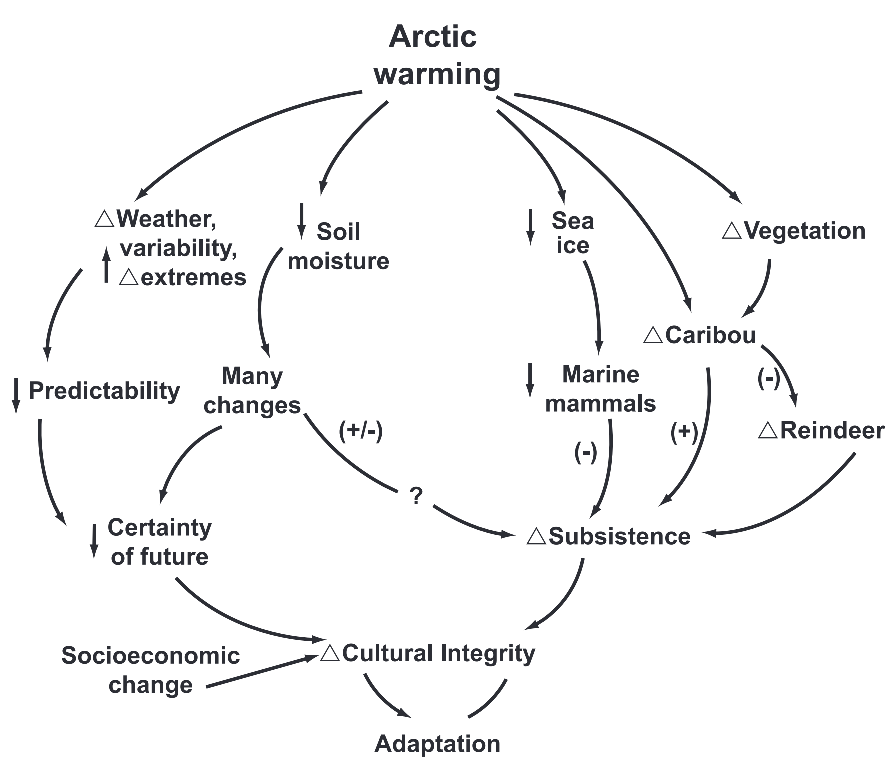

Figure 25.11. Specific Links between Arctic Warming and Well-being of Arctic Indigenous Peoples (see also Figure 25.9)

educational systems over indigenous peoples. In cultures with an important oral tradition, the death of elders and the reduced experience of a younger generation in living on the land have eroded traditional knowledge. Changes from nomadic to sedentary lifestyles (among Saami and Nenets herders, for instance), the moving of children to distant schools for education, economic infusions into communities from oil development, and migration to cities have all further weakened cultural traditions and the sense of self-sufficiency that makes these traditions meaningful.

The effects of regional climate warming on ecosystem services have contributed to the decline in cultural connections to the land. As the climate warms, traditional cues for predicting environmental variability no longer work. This strips Arctic residents of their considerable knowledge, predictive ability, and self-confidence in making a living from their resources and may ultimately leave them as ''strangers in their own land'' (Berkes 2002). This increases their vulnerability to both climatic and social changes (Norton 2002). Nonetheless, indigenous cultures continue to exhibit substantial resilience as a result of short-term coping mechanisms (such as prey switching in response to changing animal abundances) and long-term adaptation through application of new tools and technologies, such as global positioning system navigational aids (Sahlins 1999; Berkes and Jolly 2001).

Industrial development interacts with cultural and climatic change to create both positive and negative effects on human well-being. The greatest positive effect is increased income associated with oil development in North America and tourism in Fennoscandia and with government subsidies that are funded in part by industrial development. These wages enable people to buy snow machines, guns, boats, GPS units, and other equipment that enhances their capacity to harvest food from the land. Depending on the level of harvest, this can sustain subsistence activities or (for example, in the Russian Arctic) can lead to overharvesting. The environmental deterioration and changes in animal behavior associated with industrial development are major concerns of indigenous peoples throughout the Arctic because this threatens their subsistence lifestyles and cultural ties to the land. The jobs provided by industry and government sectors are important motivations for emigration of younger people from rural communities to urban centers.

Because of the interdependence between Arctic economies and global markets, indigenous peoples are doubly exposed: to both climate change and changes caused by the global processes affecting markets, technologies, and public policies. Having access to traditional food resources and ensuring food security will be a major challenge in an Arctic affected increasingly by climate change and global processes (Nuttall et al. in press). The low diversity of economic options in the Arctic renders it vulnerable to changes in both the local resource base and global economic trends and markets and explains the widespread northern phenomenon of boom-and-bust cycles (Chapin et al. 2004). Enhancing local economic diversification is a critical step toward increasing Arctic resilience.

The development and collapse of the Soviet economy in Russia had numerous impacts on the well-being of northern residents. Many non-indigenous residents of the Russian Arctic have left since 1990, whereas indigenous residents have largely remained, because they had no family ties outside the Arctic. Despite this reduction in demand for food and services, the economic subsidies and marketing system that were the primary economic base for Russians in the Arctic have virtually disappeared. This situation has reduced the economic incentive to maintain domestic reindeer, leading to a liquidation of some herds to support food needs. Hunting of wild mammals and birds has increased to meet food needs, straining the capacity of northern ecosystems to provide the services that northern people will require over the long term.

Resolution of the property rights of indigenous peoples in North America has been a key institutional change that strengthens their ties to the land. These changes in property rights promise enhanced resilience in the North American Arctic but remain a challenge in Eurasia (Osherenko 2001; Fondahl and Poelzer 2003).

25.5.4 Environmental Effects on Human Health

Increased UV-B radiation due to ozone depletion directly increases the risk of skin cancer and sight damage, particularly to people with fairer skin (Altmeyer et al. 1997). It also suppresses immune responses and thus increases susceptibility to disease (De Gruijl et al. 2002). Ozone depletion occurs at both poles but is most pronounced and extensive in the south. In the austral spring, when ozone depletion is strongest over Antarctica, ozone-depleted parcels of air move northward, leading to increased UV-B exposure to southern regions of Australia, New Zealand, Africa, and South America.

Bioaccumulation of contaminants in northern biota represents a potential health risk to northern peoples, as described in detail in Arctic Monitoring and Assessment Programme reports (MacDonald et al. 2002) The impacts of environmental deterioration on human health are regionally variable in the Arctic and are generally most pronounced in eastern Canada and the North Atlantic (AHDR 2004). However, studies conducted outside the Arctic have shown that even ''low'' concentrations of POPs and other endocrine disruptors interfere with hormone function and genetic regulation, indicating that developing organisms are easily put at risk of impaired reproductive, immune, and neurological function (Guillette and Crain 2000).

The ubiquity of POPs in the Arctic environment raises concern for the safety of future generations of Arctic peoples (AMAP 2003; Downie and Fenge 2003; Godduhn and Duffy 2003). As with POPs, the young and unborn are generally most vulnerable to subtle sublethal effects of heavy metals. In coastal Canadian and Greenland communities where marine mammals are a significant food source, concentrations of POPs in mothers' milk are high enough to be considered a health risk (Deutch and Hansen 2000; Muckle et al. 2001; AMAP 2003), and consumption of wild foods has been restricted in several cases in the eastern Canadian Arctic.

Of the small number of studies on the impact of environmental contaminants on human health in the Arctic, few have detected significant health effects. Health assessments suggest that the benefits of traditional foods, including lower risk of heart disease, generally outweigh the risks from contamination, because these foods are more nutritious than are store-bought substitutes (AMAP 2003). Regardless of the medical impacts of contaminants, the widespread perception of health risks by local residents reduces their sense of well-being.

Human populations that depend on caribou and reindeer are vulnerable to radionuclide accumulations whenever nuclear fallout occurs. Such populations suffer the physiological effects of radiation, the economic effects of lost resources, or both. For example, after the explosion at the nuclear power station at Chernobyl, cesium-137 and strontium-90 concentrations increased dramatically in lichens and reindeer in Scandinavia, where tens of thousands of reindeer had to be destroyed (MacDonald et al. 2002).

25.5.5 Aesthetic and Recreational Values

The Arctic and Antarctic include some of the largest wilderness areas on Earth. Establishment of protected areas of various types is the conventional way to protect landscapes, ecosystems, and habitats in the terrestrial environment. Treaties have provided Antarctica with a high level of protection that restricts development (as through Annex V of the Protocol on Environmental Protection to the Antarctic Treaty). Increasing tourism in Antarctica reflects the growing recognition of its aesthetic and recreational values.

Protected areas cover approximately 15% of the terrestrial Arctic. However, they are unevenly distributed across ecosystems and habitats. Over 27% of Arctic glaciers but less of the vegetated Arctic is protected (CAFF 2001). A strategic plan to establish a Circumpolar Protected Areas Network was completed in 1996 and endorsed by the eight Arctic nations (CAFF 1997). The initial burst of creating new protected areas has since come to a standstill, particularly in the Russian Arctic (WWF 2002). Owing to the rapidly changing climate, reserves cannot successfully protect species unless they have flexible boundaries or adequate interconnections that allow redistribution or migration in response to climate change (Elmqvist et al. 2003; Callaghan et al. in press). In addition to current practices of protecting rare and threatened species, conservation may become necessary for more widespread Arctic species that decline in response to climate warming.

25.5.6 Opportunities for Scientific Study

Polar regions have been key sources of new information that improve human understanding of the Earth system. Ice cores from Antarctica and Greenland have revealed detailed records of climatic and environmental changes that have occurred over the past million years (EPICA 2004). Antarctica, in particular, has been an important scientific platform for many disciplines, including space and atmospheric sciences, geomagnetism, astronomy, paleoclimatology, biogeochemistry, and human physiology. For example, subglacial lakes that have not been exposed to the atmosphere for 500,000 years may contain a unique archive of the past environment and biota (Karl et al. 1999).

Because of polar amplification of climate change, the ecological impacts of warming are evident earliest and most clearly at high latitudes, providing society with a preview of changes that may become more widespread. In a region of near-pristine wilderness, relationships between ecosystems, species, and environment are more clearly defined than in populated regions where human influences can mask these relationships. In addition, the lure of polar regions for young people wishing to experience wilderness provides a unique opportunity to involve the next generation in working toward a more sustainable future.

Main Messages

Approximately 24% of Earth's terrestrial surface is occupied by cultivated systems. Cultivated areas continue to expand in some areas but are shrinking in others. As the demand for food, feed, and fiber has increased, farmers have responded by expanding the cultivated area, intensifying production (for example, higher yields per unit land-time), or both. Globally, over the past 40 years intensification of cultivated systems has been the primary source (almost 80%) of increased output. In countries with high levels of productivity and low population growth rates, the extent and distribution of land under cultivation is stabilizing or even contracting (for example, Australia, Japan, the United States, and Italy). The area in agricultural production has also stabilized and begun to contract in China. But some countries, predominantly found in sub-Saharan Africa, have had persistently low levels of productivity and continue to rely mainly on the expansion of cultivated area.

Globally, opportunities for further expansion of cultivation are reducing. Since nearly all well-suited land is currently cultivated, continued expansion draws more economically marginal land (steeper slopes, poorer soils, harsher climates, or reduced market access) into production—often with unwelcome social and environmental consequences.

Cultivated systems specialize in the provision of food, feed, and fiber, often at the expense of other ecosystem services. Cultivation has affected the provision of other services in three ways: by conversion of biologically diverse natural grasslands, wetlands, and native forests into less diverse agroecosystems; by the choice of crop species grown and the pattern of cropping in time and space; and by the manner in which crops, soil, and water resources are managed at both plot and landscape levels. For many ecosystem services, significant losses arise as a direct consequence of conversion to agriculture. Subsequent impacts are conditioned primarily by the intensity of cultivation in time and space, by the type and amount of applied inputs, including water, nitrogen, and pesticides, and by the effectiveness with which production inputs and residues are managed.

Two key "win-win" strategies have emerged to increase economic benefits to farmers while reducing negative ecosystem aspects of cultivation: first, increasing the productivity of existing cropland through intensive management of specialized cropping systems and use of improved crop, soil, and water management practices and, second, designing more diverse crop and agroforestry systems that provide improved livelihood options as well as supporting greater levels of biological diversity and other environmental services at a local level.

Because food security requires that increasing demand for food be met, difficult choices about ecosystem service trade-offs are faced when evaluating alternative cultivation strategies. For example, intensification of production to gain more output per unit land area and time runs the risk of unintended negative impacts associated with greater use of external inputs such as fuel, irrigation, fertilizer, and pesticides. Likewise, area expansion of production reduces natural habitat and biodiversity through land use conversion and decreases the other environmental services that natural ecosystems provide. Which strategy has the least overall impact on ecosystem services depends on the specific context.

This assessment strongly suggests that pursuing the necessary increases in global food output by emphasizing the development of more environmentally and ecologically sound intensification is likely to be the preferred, and in many cases the only, long-term strategy.

Improved cultivation practices can conserve biodiversity in several ways: sustaining adequate yield increases on existing cropland in order to limit expansion of cultivation, enlightened management of cultivation mosaics at the landscape scale, and increasing diversity within cropping systems. At the global level, conversion of natural habitat to agricultural uses is perhaps the single greatest threat to biodiversity. Hence, sustaining yield increases on existing farmland to meet growing human food needs will be essential for the conservation of existing biodiversity. At the local level, advances in ecological science coupled with field-based experimentation have yielded improved insights as to how farmers might configure and manage cultivated systems so as to enhance opportunities for wild biodiversity through, for example, habitat creation, wildlife corridors, refugia, and buffers around sensitive areas. More has also been learned about maintaining viable collections of wild relatives of commercially cultivated products, particularly in farming communities (in-situ conservation). But such approaches are most likely to be used where there are demonstrable benefits to farmers.

The economic benefits of pollinators, biological control of pests, soil bacteria, insects, birds, and other animals are better understood and are increasingly being articulated to farmers and the agricultural community. Successes include the rapid and extensive spread of integrated pest management in Southeast Asia and the growing acceptance of the role of sustainability-focused platforms such as eco-agriculture, agroecology, and integrated natural resource management by both subsistence and commercial farmers.

Cultivated systems have become the major global consumer of water. While rain-fed croplands might consume more or less water than the natural plant communities they replaced, irrigated areas consume significantly more. About 18% of the area of cultivated systems is irrigated, but the crop output generated by such irrigation represents about 40% of global food production. While irrigation systems divert 20–30% of the world's available water resources, chronic inefficiencies in distribution and application result in only 40–50% of that water being used in crop growth.

Growing water demand for uses other than agriculture is increasingly competing with water demand for food production in many areas, and more transparent and equitable approaches to water allocation are needed. There is significant scope to achieve substantial increases in irrigation efficiency from improvements in water delivery systems (irrigation system maintenance and design; drip irrigation) and from improvements in water application methods (improved irrigation scheduling). Water harvesting practices, including small tanks, runoff farming, and zai (dug pits that concentrate water at the plant), have also proved effective, as have structural landscape features such as shelterbelts that reduce evapotranspiration.

In addition to water quantity trade-offs, intensification of food production involving increased use of applied nutrients and agricultural chemicals can lead to water pollution that degrades downstream freshwater, estuarine, and marine ecosystems and that limits downstream water use or raises its costs. Technologies or practices that increase nutrient use efficiency and minimize the need for pesticide application can greatly reduce water pollution from intensive agriculture. Inappropriate farming practices on sloping land prone to erosion and expansion of rain-fed cropping onto sloping lands with marginal soils can result in severe erosion that also contributes to pollution of rivers, water bodies, and estuary or marine ecosystems.

Cultivation has accelerated and modified the spatial patterns of nutrient cycling. Most pressing is the disruption of the nitrogen cycle, caused primarily by the application of inorganic fertilizers, which included around 85 million tons of nitrogen in 2000. Nitrogen is the most commonly limiting plant nutrient and a major constituent of dietary protein. While some form of augmentation of naturally "fixed" N is an essential component of more productive cultivation, application of inorganic N increases emission of nitrous oxide, a potent greenhouse gas, and contributes to acid rain, soil acidification, and eutrophication and, through these changes, to biodiversity loss.

The best opportunity for limiting these negative effects is to increase the efficiency in the handling and application of fertilizers, as well as increased or rationalized use of organic sources of nitrogen (such as mulching, animal manure, and legume crops) to substitute for inorganic fertilizers and increase nitrogen use efficiency. Some landscape elements (ponds and buffer strips, for example) can also provide cost-effective means for mitigating water contamination. In some countries, notably the United States, Japan, and the Netherlands, there has been significant progress in improving N use efficiency and even in decreasing N application rates on several major cereal crops.

A clear distinction must be made, however, between the overuse or inefficient use of nitrogen in some parts of the world and the desperate need for substantial increases in the amount of nitrogen (and other nutrients) applied to crops in regions like sub-Saharan Africa where yields are low and often declining—precisely because of the cumulative depletion of soil nutrients. Phosphorus is another nutrient that must be applied to maintain crop yields on most agricultural soils, and lack of adequate phosphorus significantly limits agricultural productivity in regions where phosphorus fertilizers are not available or affordable.

The impact of cultivation on climate regulation can, as with biodiversity, best be viewed in two distinct stages. When natural ecosystems have been converted for cultivation, carbon-based greenhouse gases are generally released and carbon sequestration potential is reduced to an extent dependent upon the original land cover and the means of conversion. Thereafter, the impact of cultivation on climate regulation is intimately linked to production system choices and management practices. Frequent cultivation, irrigated rice production, livestock production, and the burning of cleared areas and crop residues now contribute about 166 million tons of carbon a year in methane and $1,600 \pm 800$ million tons in CO_2. About 70% of anthropogenic nitrous oxide gas emissions are attributable to agriculture, mostly from land conversion and nitrogen fertilizer use.

But while agriculture contributes to greenhouse gas emissions, it also represents an opportunity for mitigation. Minimum tillage and tree-based production systems are two of a growing number of practices being adopted by farmers for their direct productivity and income benefits, which also represent successful strategies for mitigating GHG emissions from cultivated systems. The cultivation of biofuels (such as corn, sorghum, and sugarcane used for ethanol production) is seen as having great potential, although these are of relatively minor significance at present. However, a growth in demand for biofuels would result in expansion of cultivated areas or displacement of traditional crops or both unless there is a concomitant acceleration in the rate of gain in crop yields to offset the grain and biomass used for biofuels and bio-based industrial products.

While better practices and new technologies have been and must continue to be developed to reduce the negative environmental impact of cultivation, such measures will only be adopted if they generate benefits for the farmer in a time frame of relevance to the socioeconomic context in which cultivation takes place. For example, adoption of improved soil and water conservation practices has been low in many developing countries where farmers are often poor and have few assets, limited access to credit, and uncertain access or rights to land and water resources. From an economic perspective, many negative ecosystem service impacts are production "externalities"—impacts whose costs, while real from a broader social perspective, are not factored into production decisions.

In richer countries, public funds are increasingly being used to provide incentives for producers to take greater account of the external negative impacts of production. These have included investments in payments to producers to help offset the additional costs of environmentally friendly practices, research and development of new technologies and practices that reduce the trade-offs between food provision and other ecosystem services, and environment-related regulation and enforcement systems for the agriculture sector. But the principle of engaging the potential beneficiaries of improved cultivation practices in some form of dialogue with producers continues to define new institutional arrangements to better manage production externalities. Examples are watershed user groups, commodity boards, organic certification systems, and trading of carbon credits.

National policies, international agreements, and market forces play a significant role in determining farmers' choices about the scale of cultivation, the selection of the cultivation system, and the level and mix of production inputs—all of which influence trade-offs among ecosystem services and external impacts on other ecosystems from cultivated systems. For example, where governments have invested in agricultural research and extension, productivity growth rates have been higher and area expansion rates often lower. Likewise, although investments in irrigation schemes and subsidized seeds, fertilizers, and pesticides have almost certainly resulted in depletion of river flows and increased salinization, eutrophication, and biodiversity loss, they have also led to greater productivity per unit of arable land, which reduces pressure for the expansion of cultivated systems into marginal areas and natural ecosystems. Agricultural subsidies in many industrial countries have encouraged overproduction while at the same time reducing the economic viability of cropping systems in poorer countries by driving down the prices of traded commodities such that unsubsidized (and sometimes domestically taxed) producers in those countries find it hard to compete.

Some, mainly richer, countries have introduced "conservation" or "set-aside" programs to encourage farmers to take environmentally sensitive land out of production. Others, such as Costa Rica, have gone further through programs that explicitly compensate farmers for delivering ecosystem services. Governments are playing an increasing role in ensuring that farmers will profit from cultivation choices that deliver the broad array of ecosystem services valued by society, including but not limited to food production.

Significant challenges will be faced at both global and regional levels to meet increasing food, feed, and fiber demand and to do so in ways that support key environmental services. At the global level, the rate of increase in cereal yields is falling below the rate of projected demand, which will likely lead to a large of expansion of cultivated area unless yields can be increased. Many more low-input systems in marginal lands may soon reach irreversibly low levels of soil quality and face increasingly erratic climatic patterns and new crop and livestock pests and diseases, such as coffee and banana wilt and avian flu. Such trends could lead to the collapse of important cash and food producing systems on a regional basis. There is also growing concern that market liberalization, coupled with the inability of farmers and governments in poorer countries to make the investments necessary to raise the productivity of their predominantly subsistence and smallholder agricultural sectors, may lead to further impoverishment of rural populations. A warmer global temperature associated with climate change is an emerging challenge to sustaining yield increases in currently favorable crop production areas and may decrease yield stability in dryland cropping systems dependent on rainfall.

26.1 Introduction

Human transformation of natural ecosystems for production of food, fiber, and fuel has occurred on a massive scale—cultivated systems now occupy 24% of Earth's terrestrial surface and are the single greatest land use by humans.[1] Although there are a wide variety of cultivated systems, this chapter focuses on those that constitute major providers of food, feed, or fiber or that have significant impacts on the provision of other ecosystem services, at regional or global scales. In this chapter, ecosystem services are divided into those that provide food, feed, fiber, and other cultivated outputs and ''other services'' that include, for example, biodiversity, fresh water, nutrient cycling, and cultural services.

Despite a tripling of the human population in the twentieth century, global food production capacity more than kept pace with demand. In fact, per capita food supply increased while food prices decreased in real terms. (See Chapter 8.) At the turn of the millennium, cultivated systems provided around 94% of the protein and 99% of the calories in human diets (FAOSTAT 2003). At the same time, they represented a major source of income for the estimated 2.6 billion people who depend on agriculture for their livelihoods (FAOSTAT 2004).

Despite these successes there are still many parts of the world, often the poorest, where the productive capacity of cultivated systems has stagnated or even declined in the face of increased food demand from growing populations. Local disruption of cultivation by drought, flood, pests, disease epidemics (crop, animal, or human), armed conflict, and social unrest can be catastrophic in human, economic, and environmental terms. The prospect of providing sufficient food to sustain another 2 billion people by 2020 has rightly focused attention on the very real threats to food security and income generation if the productivity of cultivated systems cannot keep pace with this demand.

But food security and concern for the more than 852 million who currently go hungry each day (FAO 2004) are only part of the challenge faced by cultivated systems. Human well-being depends not only on a sufficient and safe supply of food, feed, and fiber but also on access to clean water and air, timber, recreational opportunities, cultural and aesthetic pleasure, and so on. Cultivation often has a negative impact on provision of these services.

For example, cultivated systems tend to use more water, increase water pollution and soil erosion, store less carbon, emit more greenhouse gases, and support significantly less habitat and biodiversity than the ecosystems they replace. Hence, as the share of the world's natural ecosystems converted for cultivation has increased, the overall supply of ecosystem services other than food, feed, and fiber has fallen (Wood et al. 2000), despite growing demand for these additional services. Cultivated systems are under increasing pressure, therefore, to meet the growing need for cultivated products as well as to supply an amount and quality of other ecosystem services. Appropriately responding to this ''double burden'' represents a critical, long-term challenge to modern agriculture (Conway 1999; Runge et al. 2003).

This chapter assesses the global extent, distribution, and condition of cultivated systems with regard to their continued capacity to both deliver food, feed, and fiber and contribute to the broader range of ecosystems services on which human well-being depends.

26.1.1 The Emergence of Cultivation

Agriculture first emerged almost 10,000 years ago in several different regions, including Mesopotamia, eastern China, meso-America, the Andes, and New Guinea (Smith 1998). The extent of agriculture and its impact on ecosystem services tracks population pressures at local, regional, and global scales. While human population and agricultural extent maintained a relatively steady rate of increase for much of human history, both increased dramatically with the rapid rates of scientific discovery, economic development, and global trade that accompanied the Industrial Revolution and as a consequence of European economic and political control (Richards 1990). The direct impact of European settlement and accompanying agricultural technologies was seen in North and South America, Southern and Eastern Africa, and Australia/New Zealand. Other parts of the world also experienced significant cropland expansion as they connected to European markets.

In 1700, most of the world's cropland was confined to the Old World. (See Figure 26.1 in Appendix A.) While indigenous peoples elsewhere modified the landscape, their impact was not as large as that of the Europeans, who used more advanced cultivation technologies that supported higher population densities. Since 1700 cropland has increased by 1,200 million hectares (466%), including major expansion in North America and the former Soviet Union, with the greatest expansion occurring in the past 150 years. Indeed, more land was converted to cropland in the 30 years after 1950 than in the 150 years between 1700 and 1850.

The rate of cropland expansion in China has been steady throughout the last three centuries. Cropland in Latin America, Africa, Australia, and South and Southeast Asia expanded very gradually between 1700 and 1850, but subsequently expanded rapidly. Since 1950, cropland area in North America has stabilized, while it has decreased in Europe and China. Cropland area increased significantly in the former Soviet Union between 1950 and 1960 but has decreased since then. In the two decades before 2000, the major areas of cropland expansion were located in Southeast Asia, parts of Asia (Bangladesh, Indus Valley, Middle East, Central Asia), in the Great Lakes region of eastern Africa, and in the Amazon Basin. The major decreases of cropland occurred in the southeastern United States, eastern China, and parts of Brazil.

Since the middle of the twentieth century there has been a major shift in emphasis away from area expansion toward intensification of agriculture, which produces greater yields per unit time and area (Ramankutty et al. 2002). This shift was made possible by widespread investment in irrigation systems, mechanization, cost-effective means of producing inorganic fertilizers (especially nitrogen), and new crop varieties that could better exploit water and nutrients. Declining availability of suitable agricultural land and growing competition for land from human settlements, industry, recreation, and conservation have also increased pressure on existing farmland.

Hence, most of the increase in food demand of the past 50 years has been met by intensification of crop, livestock, and aquaculture systems rather than expansion of production area. For example, Bruinsma (2003) states that for all developing countries over the period 1961–99, expansion of harvested land contributed only 29% to growth in crop production versus the contribution of increases in yields, which amounted to 71%. Expansion of harvested land accounts for both expansion in arable land (23%) and increases in cropping intensity (6%). Furthermore, the share of growth in crop production attributed to yield increases varies by region; sub-Saharan Africa has the smallest portion (34%) and South Asia has the largest (80%). Inclusion of industrial countries lowers the global contribution of harvested area expansion to crop production growth, as a consequence of their greater reliance on increased yields.

Today, nearly all of the world's suitable land is already under cultivation. Although Africa and Latin America contain the majority of the world's remaining stock of potentially cultivatable lands, most of this currently supports rain forest and grassland savannas that provide many other ecosystem services and are crucial habitat for fauna and flora in natural ecosystems (Bruinsma 2003). In many parts of North America, Europe, Japan, and China, where productivity has grown faster than demand, land is increasingly being withdrawn from cultivation. The decline would likely be even more rapid in the United States, the European Union, and Japan in the absence of production-related subsidies (Watkins 2003). On a global basis, there has been a steady decrease in area devoted to the major cereal crops—maize, rice, and wheat, which account for the majority of calories in human diets—amounting to 2.4 million hectares per year since 1980 (FAOSTAT 2004).

26.1.2 Typology of Cultivated Systems

While there are several global frameworks for classifying the biophysical potential of agriculture (e.g., Koeppen 1931; Papadakis 1966; FAO 1982), none fully capture the enormous diversity of cultivated systems and practices on a global basis. The most comprehensive approach to date covers the farming systems of the developing world (Dixon et al. 2001), which identifies and characterizes a total of 44 crop, livestock, mixed, forest-based, and fishery-based systems, using agroecological, management, and commodity-related criteria. However, the omission of cultivated systems of North America, Western Europe, and Oceania limits its application to a global assessment.

In the absence of a widely accepted and truly global cultivated system framework, the MA assessment makes use of a schema built on easily accessible, more highly aggregated system characteristics, based on two key dimensions of cultivated systems—the agroecological context and the enterprise/management context. (See Table 26.1.) The agroecological context is defined by (sub-)tropical and temperate conditions, reflecting broad day length, radiation, and thermal differences, and by (sub-)humid and (semi-)arid conditions, reflecting differences in rainfall and evapotranspiration regimes. The importance and distinctiveness of highland and mountain cultivated systems in the (sub-)tropics is further recognized. Cultivation enterprises and practices themselves are divided into six broad categories: four crop-based categories (irrigated, high external-input rain-fed, low external-input rain-fed, and shifting cultivation) as well as confined ("landless") livestock production and freshwater aquaculture. Combining the agroecological and enterprise/management dimensions generates a matrix into which most of the world's important cultivated systems can readily be categorized. (Extensive grazing systems are not treated here as cultivated systems but are dealt with in Chapter 22.)

26.1.2.1 Irrigated Systems

The roughly 18% (250 million hectares) of total cultivated area that is irrigated accounts for about 40% of crop production (Gleick 2002). Irrigated systems are served by water from impoundment or diversion structures, boreholes, and wells or other means of delivering water. From an investment perspective, irrigation systems range from large civil engineering works delivering water to hundreds of thousands of hectares in Pakistan and India (Barker and Molle 2004) through farm-based wells that use small pumps to tap groundwater aquifers all the way to small-scale community-based systems powered by draught animals and manual labor, such as those found in West Asia, North Africa, and the Sahel (Oweis et al. 1999). In addition to increasing and stabilizing the yields of individual crops, irrigation can extend the growing period and allow two or even three crops to be grown each year on the same piece of land, where water availability and temperature permit such intensification.

26.1.2.2 Rain-fed Systems

Rain-fed agricultural systems account for the largest share (about 82%) of the total agricultural land area and exist in all regions of the world. In Asia and the Pacific, for example, rain-fed agriculture represents about 223 million hectares, or 67% of the total arable land (Asian Development Bank 1989), and rain-fed production accounts for 16–61% of agricultural GDP in this region (excluding Pakistan as part of West Asia).

Rain-fed systems are prevalent in both high and low yield potential areas, as largely determined by the amount and distribution of precipitation in relation to crop water requirements. Lower potential lands, also referred to as marginal or less-favored lands, are discussed in Chapter 22 (and also occur in higher-altitude mountain systems, see Chapter 24). The discussion here focuses on more-favorable rain-fed areas where both high and low levels of external inputs are used to produce crops. Pressure on these systems is increasing as arable land becomes scarcer; as the productivity of existing irrigated lands declines due to a reduction in water availability or to land degradation, especially salinization; and as food demand increases.

Rain-fed systems may involve both annual and perennial crops as well as livestock. In Asia, the rain-fed humid/sub-tropical systems and arid/semiarid areas include a range of mixed crop-livestock systems, which can be categorized into lowland and upland systems. The former is more associated with crop cultivation due to higher levels of soil moisture. Rain-fed lowland rice, for example, is defined as nonirrigated, but the topography is generally flat and the soil surface is inundated for at least part of the crop cycle with sustained flooding. Rain-fed upland rice, on the other hand, is grown on well-drained fields that are never flooded. Major rice cropping systems in the rain-fed lowlands are rice-wheat, rice-pulses (including chickpea, lentil, peanut, and pigeon pea), and rice-mustard. Maize, sugarcane, and cotton are also important crops in humid lowland areas of tropical/subtropical Asia. Cropping systems that use more drought-tolerant cereal crops such as sorghum and millet are found in semiarid rain-fed lowland areas.

The uplands, by comparison, have sloping to hilly topography, and typically have less fertile soil that is easily degraded by erosion and nutrient depletion without the use of appropriate husbandry practices. (See also Chapter 24.) Although both annual crops (such as cereals, legumes, roots, and vegetables) and perennial ones (such as coconuts, oil palm, rubber, and fruit trees) are grown, agroforestry systems involving the latter are especially important. Rain-fed areas have relatively large populations of livestock, and their contribution via animal manure to crop cultivation, food security, and the livelihoods of poor people is significant (Devendra 2000). Overstocking and uncontrolled grazing of ruminants are major problems in semiarid rain-fed regions where land tenure rights are not well defined, such as in the Sahel region of sub-Saharan Africa.

26.1.2.3 Shifting Cultivation

Shifting cultivation, also called "swidden" agriculture or "slash-and-burn" agriculture, is one of the oldest forms of farming and consists of cropping on cleared plots of land, alternated with lengthy fallow periods. These systems are the dominant form of agriculture in tropical humid and subhumid upland regions and are typically associated with tropical rain forests.

Table 26.1. Global Typology of Cultivated Systems with Examples

		Tropical and Sub-tropical (62%)			Temperate (38%)	
Farming System[a]		Warm Humid/Subhumid	Warm Semiarid/Arid	Cool/Cold (Highland/Montane)	Humid/Subhumid	Semiarid/Arid
		(26%)	*(12%)*	*(24%)*	*(22%)*	*(16%)*
Irrigated	(18%)	rice (e.g., East, Southeast Asia) rice-wheat (e.g., Pakistan, India, Nepal)	rice (e.g., Egypt, Peru)			cotton
Rain-fed—high external input (crops, livestock, tree crops	(82%)	rice-wheat (e.g., Pakistan, India, Nepal)		tea, coffee plantations (e.g., East Africa, Sri Lanka)	maize and soybean–Argentinean pampas, U.S. corn belt small grains (wheat, barley, rapeseed, sunflower, oats) and mixed crop-livestock systems (e.g., West and North Central Europe)	
Rain-fed—low external input (crops, livestock, tree crops)		staple tropical crops in humid tropics (e.g., yam, cassava, banana in SSA)	mixed crop, livestock (e.g., Sahel, Australia)	cereals/tubers (e.g., High Andes)	mixed crop–livestock systems (e.g., Europe)	wheat–fallow systems (e.g., Central Asia, Canada, United States, Australia)
Shifting cultivation	NA	e.g., Amazon Basin, Southeast Asia				
Industrial confined livestock	NA	"landless" livestock systems, e.g., cut and carry systems, mixed low-intensity livestock/crop systems, beef feeding lots, broiler and pig houses				
Freshwater aquaculture	NA	e.g., artisanal ponds, industrial cages				

[a]High-level aggregations of the global farming systems typology developed by Dixon et al. 2001.

Notes: Agroecological characterization according to FAO Global Agroecological Zones (FAO/IIASA 2001). Total area shares shown in parentheses are for settled agriculture (e.g., excluding shifting cultivation areas). Derived from FAOSTAT 2004. Breakdown of cropland by agroecological zones from Wood et al. 2000. The MA cultivated systems do not encompass marine and coastal aquaculture (Chapter 19) and extensive grazing systems (Chapter 22).

Shifting cultivation is practiced on about 22% of all agricultural land in the tropics and is the primary source of food and income for some 40 million people (Giller and Palm 2004). While the contribution to global food security is negligible, given the low yields and general lack of infrastructure in areas where shifting cultivation predominates, this method of cultivation has a potentially large impact on regional and global ecosystem services through its effects on biodiversity, greenhouse gas emissions, and soil nutrients. (For a more comprehensive analysis of such effects in the humid tropics, see the MA Sub-Global Assessment of the Alternatives to Slash and Burn program.)

Although these systems are generally associated with soils of low fertility, they are highly sustainable and resource-conserving in areas with low population density. High population density increases the pressure on available land and resources, reducing the time available for a regenerative fallow between cropping cycles. One method used to raise productivity and reduce land degradation in areas of shifting cultivation is ''alley cropping,'' growing tree crops in conjunction with annual crops. In the Philippines, for example, alley cropping in sloping upland rice areas with *Flemingia macrophylla* showed that over two years, average soil loss was cut down to 42 cubic meters per hectare, compared with 140 cubic meters under traditional practices, together with concurrent increases in rice yields (Labios et al. 1995).

26.1.2.4 Mixed Crop and Livestock Systems

Mixed crop-livestock farming systems, where crops and animals are integrated on the same farm, represent the backbone of smallholder agriculture throughout the developing world, supporting an estimated 678 million rural poor. In Asia, more than 95% of the total population of large and small ruminants and a sizable number of pigs and poultry are reared on small farms with mixed crop-livestock systems, which are dominant in both irrigated and rain-fed areas in humid and subhumid environments.

Mixed farming systems enable farmers to diversify agriculture, to use labor more efficiently, to have a source of cash for purchasing farm inputs, and to add value to crops or their by-products. Mixed farming systems provide the best opportunities to exploit the multipurpose role of livestock in many rural societies (Devendra 1995). A number of crop-animal interactions are important and dictate the development of mixed systems. These include animal traction for field operations, animal manure, and animal feeds from crops, as evident in sub-Saharan Africa (McIntire et al. 1992) and Asia (Devendra and Thomas 2002). These interactions have demonstrated the important contribution that animals make to increased production, income generation, and the improved sustainability of annual and perennial cropping systems.

Crop-livestock systems can be separated into those that mix animals with annual and perennial crops; of the two, the use of the latter has been more limited. Examples of integrated annual crop-animal systems include rice, maize, cattle, and sheep in West Africa; rice, wheat, cattle, sheep, and goats in India; rice, goats, duck, and fish in Indonesia; rice, buffalo, pigs, chicken, duck, and fish in the Philippines; rice, vegetables, pigs, ducks, and fish in Thailand; and vegetables, goats, pigs, ducks, and fish in Viet Nam. Examples of integrated perennial tree crop-animal systems include rubber and sheep in Indonesia; oil palm and cattle in Malaysia and Colombia; coconut, sheep, and goats in the Philippines; and coconut, fruit, cattle, and goats in Sri Lanka. In West Asia and North Africa, integration of sheep with wheat, barley, peas, and lentils is common, together with olives and tree crops.

With annual cropping systems, ruminants graze native grasses and weeds on roadside verges, on common property resources, or in stubble after the grain crop harvest. Crop residues and by-products are also fed to livestock throughout the year or seasonally, depending on availability. In the perennial tree crop systems, ruminants graze the understory of native vegetation or leguminous cover crops. Non-ruminants in these systems mainly scavenge in the villages, on crop by-products, and on kitchen waste. However, village livestock systems can evolve into more-intensive production systems depending on the availability of feeds, markets, and the development of co-operative movements. This is evident in many parts of Central America, West Africa (Nigeria), Southeast Asia (Indonesia), and South Asia (Bangladesh).

Because of the synergies between crop and livestock components, mixed crop-livestock systems have shown themselves to be both economically and environmentally robust from a smallholder perspective. It is likely that smallholder mixed farms will remain the predominant form of agricultural land use in rain-fed cropping regions in developing countries where labor is abundant.

26.1.2.5 Confined Livestock Systems

Confined livestock production systems in industrial countries are the source of most of the world's poultry and pig meat production and hence of global meat supplies. Such large-scale livestock systems are also being established in Asia to meet increasing demand for meat and dairy products. In addition, beef and mutton are produced from intensive confined feeding operations, the former mostly in North America and the transition states of Eastern Europe. The majority of sheep and goat fattening under "landless" (non-grazing) conditions occurs in the Near East and in much of Africa. Cut-and-carry, zero-grazing dairy production systems are similar to confined systems in industrial countries in that hand feeding and disposal of manure are involved. These systems involve cutting feed, crop residues, or litter and transporting them to livestock that are confined in pens on the farm.

The use of purchased cereals and oilseeds for feed in confined livestock systems allows separation of crop production and utilization of feed in livestock rations. These concentrated feeds are less perishable and easier to transport than the livestock products. Even if several kilograms of concentrates are needed to produce one kilogram of meat, it is still cheaper to establish the production system near the consumer market and to transport the feeds to the animals. A significant share of the increase in cereal imports to developing countries over recent decades has occurred to provide feed for the expanding poultry or pig industries (Delgado et al. 1999).

Animal confinement facilitates the management of nutrition, breeding, and health but increases the labor and infrastructure requirements for feeding, watering, and husbandry of the livestock. Apart from the capital embodied in the animals, additional investment is needed in providing fencing, housing, and specialized equipment for feeding and other activities. Special equipment is also needed for animal slaughter and meat processing or for milk cooling and processing. There are economies of scale in the provision of such processing services and the associated product marketing, and possibly in the supply of inputs (feed and feed supplements) and genetic material (such as day-old chicks or semen). This has often led to either co-operative group activity or vertical integration of smallholder producers with large-scale processing and marketing organizations.

While there are good economic arguments for the concentration of large numbers of animals associated with many confined systems, there can be significant impacts on surrounding ecosystems. Problems often arise in the disposal of large amounts of manure and slaughtering by-products. While some types of manure can be recycled onto local farmland, soils can quickly become saturated with both nitrogen and phosphorus because it is too costly to transport manure, which has relatively low nutrient concentration, for long distances. Manure treatment or digestion to produce methane can help minimize pollution, but even in countries with strong regulation and enforcement systems, nutrient and bacterial leakage to water courses can occur, with consequential impacts on freshwater and aquatic systems (de Haan et al. 1997; Burton et al. 1997).

Confined systems tend to be located near markets in peri-urban areas. Distance from these centers, or from their main transport routes, has an important influence on the net prices received for farm products. Similarly, location in relation to urban centers affects access to markets for purchased inputs and the costs of such inputs (Upton 1997). Transport costs vary from one commodity to another, depending on the perishability and bulk-to-value ratio. Milk and eggs are relatively perishable and therefore are most often produced intensively in peri-urban zones. Furthermore, agricultural enterprises dependent on purchased inputs, such as concentrate feeds, are likely to be established in peri-urban zones with easy access to input markets. In contrast, ruminant meat can be produced in more-distant rural areas and transported as live animals to urban markets for slaughter.

26.1.2.6 Freshwater Aquaculture Systems

Aquaculture involves the propagation, cultivation, and marketing of aquatic plants and animals from a controlled environment and usually involves tenure and ownership, as opposed to the open-access or common property systems that occur in land agriculture. Aquaculture can be applied in coastal (mariculture), brackish, or fresh water (inland), but this chapter focuses on freshwater aquaculture. (Coastal and brackish aquaculture systems are discussed in Chapter 19.) There are four types of production systems: ponds, cages, raceways, and recirculating systems:

- Earthen ponds are most common for both small-farm and commercial production systems, and they may be specifically designed and built for aquaculture. Ponds for aquaculture (called dike or levee ponds) require an adequate amount of water of sufficient quality and clay soils that retain water. The size of a levee pond depend on its planned usage, whether as a holding, spawning, rearing, or grow-out pond.
- Cage culture uses existing water resources (lakes, ponds) but encloses the fish in a cage or basket that allows water to pass freely. Its main advantage is ease of harvesting. Small lakes, mining pits, and farm ponds may be used for cage culture. The potential for expanding cage farming is more limited in areas where freshwater bodies are already actively used.

- Rectangular raceways are mostly used in industrial countries (whereas ponds and cages are common in developing countries). Rectangular raceways are almost exclusively used for trout production and require large quantities of cheap, high-quality water. Using gravity, water passes from a spring or stream through raceways arranged in a series on slightly sloping terrain.
- Water recirculating systems are also common in industrial countries. Water is recirculated rather than passing through once; hence, less water is needed than for a pond or open raceway. Most recirculating systems are indoors, allowing growers to maintain more control on water characteristics like temperature. Clearly, this type of production requires high initial capital investment.

In addition, production systems can be distinguished by the level of production intensity or amount of inputs (labor, feed, materials, or equipment) used. Such production intensity can be extensive, where low levels of external inputs result in lower production levels, or intensive, where higher levels of inputs of technology and greater degree of management generally increase yield (FAO 2003).

Aquaculture can also be land-based or water-based. Land-based aquaculture consists mainly of ponds, rice fields, and other facilities built on dry lands. Carp and tilapia are the most commonly grown species in freshwater ponds, while shrimp and finfish are cultivated in brackish-water ponds. Water-based systems include enclosures, pens, cages, and rafts and are usually situated in sheltered coastal or inland waters. Pens and cages are made up of poles, mesh, and netting. Cages are suspended from poles or rafts that float, while pens rest on the bottom of the water body (FAO 2003).

Unlike livestock, where only a limited number of species are farmed, aquaculture production involves many species of aquatic organisms, although some predominate. In freshwater aquaculture alone, some 115 freshwater species of finfish, crustaceans, and mollusks were cultured in 2000, with finfish contributing the bulk of production. Over the period 1991–2000, carp (and other cyprinids) and tilapia (with other cichlids) ranked first and second respectively in global freshwater fish production, accounting for 76–82% and 5–6% respectively of the total (FAO 2002).

Though a number of freshwater species were cultivated, only a few freshwater species, like carp, milkfish, and tilapia, have been domesticated—that is, breeding agencies (government and private) produce fry as a source of fingerlings for aquaculture. This contrasts with the livestock and crop sectors, where selective breeding has been able to develop superior animal breeds and crop varieties suitable for intensive production. As a result, many forms of freshwater aquaculture are still very dependent on wild sources of fish spawn, seed, or young fish.

Aquaculture operations can have both positive and negative impacts on the environment. On the positive side, if aquaculture is integrated with agriculture, environmental benefits include recycling, lower net pollution, and reduced use of pesticides and fertilizers. On the other hand, some aquaculture operations can have damaging effects on water quality and quantity and aquatic biodiversity—similar to the externalities associated with confined livestock feeding operations or intensive, high-input cropping systems.

26.1.2.7 Major Cropping Systems

Among the tremendous diversity of crops and cropping systems, both in terms of agroecologies and management practices, five major cropping systems stand out in importance. These systems supply a substantial portion of the world's food, occupy a large portion of the world's cultivated lands, or both. The major systems are shifting cultivation in the forest margins of tropical Africa, Asia, and Latin America; irrigated lowland rice systems in Asia; irrigated rice-wheat systems in the Indo-Gangetic Plains of India, Pakistan, Nepal, Bangladesh, and south-central China; rain-fed wheat in north, west, and central Europe; and rain-fed maize-soybean systems in the United States, southeast Canada, Argentina, and south-central Brazil. Estimates of the scale of these systems are provided in Table 26.2.

The highly productive irrigated rice-based cropping systems are practiced in regions with fertile soils and access to supplementary ground or surface water. The wheat and maize-soybean rotations are located on deep, fertile soils in regions that typically have adequate and consistent rainfall during the growing season. Because of these natural endowments, these systems provide food to about half the human population and do so on a relatively small area. In addition to meeting local food needs, these systems account for more than 80% of all grains that enter international markets.

To sustain high yields in these systems, modern farming practices are employed, including high-yielding varieties and hybrids, substantial fertilizer inputs, and integrated pest control methods that include use of herbicides, insecticides, and fungicides when other management practices are inadequate. For example, three cereals—rice, wheat, and maize—receive 56% of all nitrogen fertilizer applied in agriculture (Cassman et al. 2003). Yield increases in these systems during the past 50 years are estimated to have avoided the need to expand cultivation by hundreds of millions of hectares globally, thus helping to maintain the ecosystem services derived from tropical and temperate forests, grasslands, and wetlands (Waggoner 1994; Evans 1998; Cassman 1999). Given the 670 million hectares of global cereal production in 2000, each 1% increase in productivity is equivalent to saving 6.7 million hectares of additional land that would be required for cereal production, keeping cropping intensity constant. (For a discussion of cropping intensity, see Bruinsma 2003:127–37.)

However, the relatively high levels of nutrients, pesticides, and water applied to these systems can deplete water resources, reduce water quality, increase greenhouse gas emissions, and accelerate the loss of terrestrial and aquatic biodiversity (Hooper et al. 2003; Mineau 2003). While nutrient losses from applied nitrogen fertilizer via denitrification release N_2O, a powerful greenhouse gas, to the atmosphere, recent studies have also demonstrated that these intensive cropping systems can sequester carbon in soil organic matter, thus reducing global emissions of CO_2 (Bronson et al. 1998; Lal et al. 2003; Paustian et al. 1997). Achieving global food security for an increasing and rapidly urbanizing population will depend on sustaining continued yield increases in these major high-potential cereal production systems.

The key challenge to sustaining cereal yield increases to meet anticipated demand while also protecting ecosystem services is to use crop and soil management practices to greatly increase the efficiency with which fertilizers, water, and other external inputs are used. For example, greater efficiency of nitrogen fertilizer use allows more grain to be produced per unit of applied nitrogen, reducing nitrogen losses and diminishing associated negative impacts on ecosystem services (Dobermann and Cassman 2002). Likewise, substantial increases in water use efficiency can be achieved by investment in improved irrigation infrastructure, better irrigation scheduling, and application equipment, such as a shift from furrow irrigation to subsurface drip irrigation (Howell 2001). Ensuring continued progress toward ecological intensification of these major cereal cropping systems requires long-term and sufficient investments in research and extension.

Table 26.2. Extent of the World's Major Cropping Systems and Population Dependent on Them as the Major Source of Cereal Supply. The population given is of the countries or regions where these cropping systems represent the predominant form of agriculture. Food production from the high potential systems, which include the two irrigated rice-based systems, rain-fed wheat, and rain-fed maize-soybean, not only accounts for a major food source for the countries and regions in which they occur but also accounts for a large majority of all traded grain that crosses international borders. (Compiled from Giller and Palm 2004; Dixon et al. 2001; Huke and Huke 1997)

Cropping System	Area	Population	Region/Countries
	(mill. hectares)	*(million)*	
Shifting cultivation	1,035	40	Forest margins in tropical Africa, Asia, Latin America
Irrigated continuous lowland rice	24[a]	1,800	Tropical/sub-tropical lowlands of Asia
Irrigated rice-wheat annual double crop	17[a]	248	Indo-Gangetic Plains of India, Pakistan, Nepal, Bangladesh, and south-central China
Rain-fed wheat	40	500	North, west, central Europe
Rain-fed maize-soybean	85	420	United States, southeast Canada, Argentina, southcentral Brazil
Total	1,227	2,968	

[a] Continuous irrigated lowland rice systems in the tropics and sub-tropical lowlands of Asia produce two and sometimes three rice crops per year. A total of 49 million hectares of harvested rice is obtained from these systems (McLean et al. 2002; Huke and Huke 1997). Similarly, the rice-wheat systems produce 17 million hectares of each crop on an annual basis, for a total harvested grain area of 34 million hectares (Huke and Huke 1997), which supports an agricultural population of 248 million (Dixon et al. 2001).

26.1.2.8 Assessing the Global Distribution and Intensity of Cultivated Systems

While the global typology is helpful in broad stratification of the major cultivated systems, the spatial extent, distribution, and condition of cultivated systems requires further analysis. For mapping purposes in this assessment, the global extent of cultivation has been defined on the basis of rain-fed and irrigated croplands only. There is no comprehensive information, even at a national scale, on the number and location of industrial livestock and freshwater aquaculture enterprises.

The global cropland map is a composite of an updated version of the 5-kilometer resolution PAGE Agroecosystems Map (Wood et al. 2000) that incorporates revisions of the underlying 1992–93 1-kilometer resolution AVHRR datasets, combined with the 10-kilometer resolution global irrigation map produced by University of Kassel and FAO (Döll and Siebert 1999).[2] (See Figure 26.2 in Appendix A.) The revisions aim to identify all occurrences of agriculture, even those that are minor cover components under the classification scheme. (This was limited by the seasonal land cover naming convention, which did not identify an agricultural component if it occupied less than 30% of the land cover class area.)

Intrinsic weaknesses in the dataset include regional variations in the reliability of the satellite data interpretation, reflecting differences in the structure of land cover and in the availability of reliable ground truthing data (Brown and Loveland 1998) (See Box 26.1.) Specific agricultural land cover types for which interpretation is considered problematic include irrigated areas, permanently cropped areas (especially tree crops in forest margins), mixed smallholder agriculture, and extensive pasture land.

For mapping purposes, the extent of cropland is defined as areas where at least 30% of a 1x1-kilometer grid cell is classified as cropland through the interpretation and ground truthing of satellite imagery. By this definition, it is likely that a significant share of the 1,035 million hectares of shifting cultivation as practiced in the humid tropics is not detected and classified as cropland because fallow periods are typically greater than five years, implying that no more than 20% of the land area is actually planted to crops at any given point in time.

Within the physical extent of cultivated systems (rain-fed and irrigated cropland), an existing agroecologically based characterization schema has been used to delimit cultivation system subtypes (Wood et al. 2000). This is a 16-class schema that provides a spatial visualization of the location and extent of most elements of the cropland typology presented in Table 26.1. (See Figure 26.3 in Appendix A.) The classification of climatic variables into tropical, sub-tropical and temperate, humid, subhumid, semiarid, and arid are made in accordance with FAO's agroecological zones approach implemented in a global spatial database (FAO/IIASA 2001). The agroecological classification also relies on slope and the presence or absence of irrigation technologies. Slope is an important attribute in terms of potential for mechanization as well as for increased surface runoff and soil erosion due to cultivation. The slope data used in this characterization are also derived from the FAO/IIASA digital agroecological database, and the irrigation data are from Döll and Siebert (1999).

Cultivated systems are extensive. Globally, they cover 36.6 million square kilometers, or approximately 27% of land area (24% if inland waters, Greenland, and Antarctica are included in the definition of land area). (See Table 26.3.) By intersecting the extent of agriculture with maps of global population, it is estimated that 74% of the world's population lives within the boundaries of cultivated systems and that cultivated systems overlap in significant ways with other systems, such as forests, mountains, and drylands. Close to half of all cultivated systems are located in dryland regions, where cultivation is strongly linked to livelihoods and resource issues—particularly poverty, land degradation, and water scarcity.

The characterization presented in Figure 26.3 identifies domains within which biophysical and environmental constraints and opportunities are broadly similar from a cultivation perspective and where common ecosystem service impacts might be faced. However, as this chapter illustrates, it is the specific type of cultivation practiced in any location and the precise ways in which cultivation is managed that ultimately determine the type and scale of impacts on ecosystem services and human well-being. Integrating additional information about the ways in which cultivated systems are managed can only be accomplished at smaller geographic scales (see, e.g., Dixon et al. (2001) for a regional ap-

BOX 26.1

Reliability of Satellite-based Global Assessments of Cultivated Systems

Obtaining global-scale information about the location and extent of cultivated systems is fraught with difficulties. Satellite-based remote sensing offers a visualization of land cover for the entire globe in a more or less uniform way, and several publicly available, coarse-resolution (1km pixel size) datasets offer opportunities for locating cropland. These include Global Land Cover 2000 (GLC2000), MODerate resolution Imaging Spectrometer (MODIS) land cover, GLCCDv2, and the cultivated systems extent used by the MA, which is a cropland-focused reinterpretation of GLCCDv2. (More information on these datasets is available at edcdaac.usgs.gov/glcc/background.asp (GLCCDv2), www-gvm.jrc.it/glc2000 (GLC2000), and edcdaac.usgs.gov/modis/mod12q1.asp (MODIS). The MA reinterpretation of GLCCDv2 is based on methods described in Wood et al. 2000.)

However, a comparison of these data sources reveals large differences in the extent and distribution of areas classified as cropland. The GLCCDv2 imagery and the MA extent represent land cover in 1992–93, while the GLC2000 and MODIS imagery are for the year 2000. Clearly, land cover change took place between these years, but the significant differences between the 1992–93 and 2000 cropland areas, as well as those between the two 2000-based assessments of cropland, cannot be explained by changes over time alone. Many of the differences result from the use of different data sources, methodologies, and classification systems. These findings raise concerns about our present ability to detect cropland reliably using globally applicable analysis of coarse-resolution data sources, and they cast extreme doubt on the possibility of assessing cropland change by comparing global data sets from different sources.

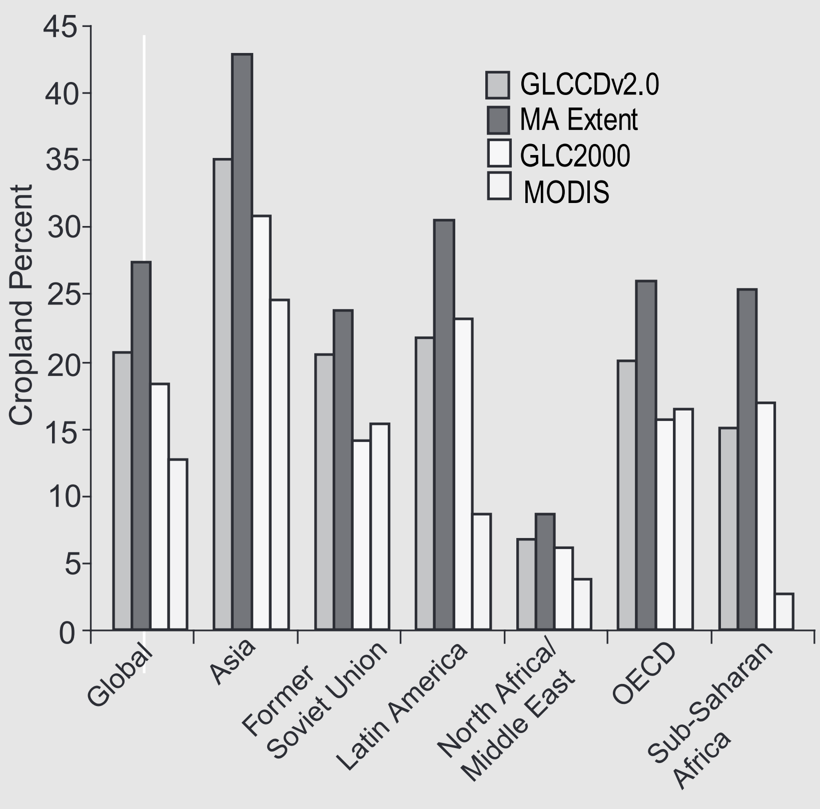

Figure A. Comparison of Cropland Estimates by Region and Data Source

Figure A compares the share of land area that falls within the extent of cultivated area, by region, for these four different land cover data sets. The extent of cultivation is defined as any cell classified as cropland or a cropland mosaic. Cropland mosaics are areas that appear in the imagery as composites of multiple landscape types (cropland and forest, for example, or cropland and grassland). The variations across the globe are large: in sub-Saharan Africa, MODIS land cover classifies less than 3% of the total land area as cropland, while according to the classification adopted by the MA, just over 25% of land in sub-Saharan Africa falls within the extent of cultivated area.

Part of this discrepancy is definitional. For mapping purposes, the MA classifies areas as "cultivated systems" if at least 30% of the land cover grid cell appears to be cropland. MODIS land cover and GLC2000, on the other hand, use higher cutoffs of about 50% cropland. The MA considers that ecosystem services are already likely to be significantly affected by cultivation at the lower cutoff.

Most of the differences among datasets involve the "mosaic" land-cover classes. Mosaic landscapes are some of the most important ones from an ecosystem service perspective, as they are likely to be transitional areas where change is taking place or where agricultural systems exist in close proximity to natural biodiversity. They are also some of the hardest to classify. In contrast to large, intensively farmed agricultural systems found in much of the industrial world, smaller plots of agricultural land, mixed in with forest or grassland, are more difficult to distinguish. Isolated or even clusters of small cultivated plots and fields, even if they can be identified as agriculture, are easily lost due to the coarse resolution of the data.

Figure B (see Appendix A) compares the geographic location of cropland and cropland mosaic classes used by the MA to the MODIS and GLC2000 land cover classifications for Africa. Africa is among the most challenging continents for mapping cropland because of generally small field sizes and mixed cropping systems. Areas of agreement are shown in orange, and areas of near-agreement (classified as cropland in one dataset and cropland mosaic in the other) are shown in yellow. Blue areas are those classified as either cropland or cropland mosaic by the MA, but not classified as cultivated in the other data sets. Much of the additional area within the MA cultivated systems compared with other datasets can be attributed to its lower threshold for defining cultivated landscapes—that is, a grid cell is considered to be a cultivated system if at least 30% of it is cropland.

Given the difficulties in classifying cultivated areas using coarse resolution satellite data, cultivated area maps and statistics derived from such data should be interpreted with caution. Mapping changes over time presents an additional set of challenges, as it requires comparing data sets that may be mismatched in multiple ways. Much more needs to be done to improve the reliability of publicly available regional- and global-scale spatial cropland data, including improved use of higher-resolution data such as LANDSAT and SPOT imagery, the use of consistent methodologies and classification systems over time, and field validation.

proach and Wortmann and Eledu (1999) for a national application in Uganda).

26.2 Cultivated Systems and Ecosystem Services

To achieve increased production of food, feed, and fiber, cultivated systems use biodiversity and numerous supporting, regulating, and provisioning services such as pollination, nutrient cycling, soil formation, and fresh water for irrigation. While cultivated systems depend on such services, they in turn also influence the supply of a host of other services, including food, feed, and fiber; clean water; climate regulation; pollution control; flood control; viable populations of wildlife; clean air; and scenic qualities (Allen and Vandever 2003). Some types of production systems, such as

Note: By definition, these MA systems may overlap spatially, so area totals cannot be added across columns without risk of counting areas and populations twice. Note also that the global cultivated total includes areas and populations contained in ecosystems other than those shown in the breakouts.

multitiered, tree and crop-based farming systems, can be very effective in building up soil nutrients, reducing soil erosion, enhancing water-related, climate, and flood regulation services, and even promoting biodiversity. But they often possess other features less attractive to farmers, such as high labor needs, longer establishment and payoff times, or lower food productivity.

Because cultivated systems are so extensive, pressure is growing for them to make a greater contribution to meeting human needs for services other than food, feed, and fiber. They may do this by being managed to have less impact on supporting and regulating services, by consuming fewer provisioning services, or by supplying more of all three types of services. Moreover, effects on specific services at a local level may differ from the aggregated effects of a given cultivated system at a regional or ecosystem level.

26.2.1 Biodiversity

There are several dimensions to biodiversity in cultivated systems. These systems contain cultivated or ''planned'' biodiversity—that is, the diversity of plants sown as crops and animals used for livestock or aquaculture. This is largely domesticated biodiversity and is supplemented by wild food sources. Together with crop wild relatives, this diversity comprises the genetic resources directly needed for food production. (See Table 26.4.)

Agricultural biodiversity is a broader term, also encompassing the ''associated'' biodiversity that supports agricultural production through nutrient cycling, pest control, and pollination (Wood and Lenne 1999). Sometimes biodiversity that provides broader ecosystem services such as watershed protection, as well as biodiversity in the wider agricultural landscape, is also included in this term (FAO/SCBD 1999; Cromwell et al. 2001; Convention on

Key:
italics Definition of genetic resources for food and agriculture
Different definitions of "agricultural biodiversity"

Biological Diversity 2000). In addition, cultivated systems contain biodiversity beyond that used in or directly supporting production systems. Since agriculture is now so widespread, strategies for biodiversity conservation should address the maintenance of biodiversity within these largely anthropogenic systems as well as the aggregate impact of various cropping systems and management practices on biodiversity at regional levels.

The multiple dimensions of biodiversity in cultivated systems make it difficult to categorize production systems into ''high'' or ''low'' biodiversity systems, especially when spatial and temporal scales are also included. Figure 26.4 attempts to illustrate how different types of production systems relate to three biodiversity-related variables (building upon the approach of Swift and Anderson (1999)). The Figure also focuses on a single production system—tropical lowland rice—to illustrate how the levels of various dimensions of biodiversity can vary with management practice.

Thus the relationship between cultivated systems and biodiversity is manifold: biodiversity is cultivated in such systems (genetic resources for food and agriculture); biodiversity supports the functioning of cultivated systems (associated agricultural biodiversity); and cultivated systems harbor biodiversity beyond agricultural biodiversity of functional significance. In addition, cultivated systems have an impact on biodiversity outside the cultivated field in surrounding areas and through both expansion and intensification of agriculture. The following sections focus on these four issues.

26.2.1.1 Maintenance of Cultivated Species and Genetic Diversity

Diversity at species and genetic levels comprises the total variation present in a population or species in any given location. The cultivated species diversity of some production systems such as shifting cultivation and home gardens is high. Most major staple crops, however, are grown in monoculture. Even such systems may contain other dimensions of agricultural biodiversity: intensive rice ''monocultures,'' for example, can support small areas of vegetable cultivation (on the dikes between paddies) as well as fish cultivation. In fact, in some rice-growing areas in South and Southeast Asia, fish may provide most of the local dietary protein. Genetic diversity can be manifest in different phenotypes and their different uses. It can be characterized by three different facets: numbers of different entities (such as the number of varieties used per crop or the number of alleles at a given locus); evenness of the distribution of these entities; and the extent of the difference between the entities (as in the case of pedigree date, for example) (UNEP/CBD 2004). Crop genetic diversity can be measured at varying scales (from countries or large agroecosystems to local communities, farms, and plots), and indicators of genetic diversity are scale-dependent.

The conservation and use of plant genetic resources for food and agriculture has been comprehensively reviewed by FAO (FAO 1998). Since 1960, there has been a fundamental shift in the pattern of intra-species diversity in farmers' fields in some regions and farming systems as a result of the Green Revolution. For major cereal crops, the germplasm planted by farmers has shifted from locally adapted and developed populations (landraces) to more widely adapted varieties produced through formal breeding systems (modern varieties) (Smale 2001, 2005; Heisey et al. 2002; Morris and López-Pereira 1999; Morris and Heisey 1998; Cabanilla et al. 1999). While there is no absolute dichotomy, traditional, landrace-based farming systems tend to contain higher levels of crop genetic diversity in situ than modernized systems. Depending upon the species (and its breeding system), traditional landrace-based farming systems also tend to include a higher number of varieties and more genetic variation within varieties.

Adoption of modern varieties among the three major cereal crops—wheat, rice, and maize—has been most rapid where land is scarce and where there is a high degree of market integration. In general, modern varieties of these crops have been adopted in ''high potential'' production areas, which have favorable climatic conditions, good soils, and either adequate rainfall or irrigation. They have been less successful in marginal areas, where landraces are still widely cultivated and are often the main source of crop germplasm.

Roughly 80% of the wheat area in the developing world is sown to modern semi-dwarf varieties. However, landrace varieties are grown extensively in Turkey, Iran, Afghanistan, and Ethiopia, with smaller pockets in countries of the Near Eastern and Mediterranean region (Morocco, Tunisia, Syria, Egypt, Cyprus, Spain, and Italy) (Heisey et al. 2002). Over three quarters of all rice planted in Asia is planted to improved semi-dwarf varieties, although farmers continue to grow landrace varieties in upland rain-fed areas, as well as in deep-water environments. Landrace varieties are grown in upland areas of Southeast Asia (Thailand, Laos, Viet Nam, and Cambodia), as well as in parts of West Africa (such as Mali and Sierra Leone) (Smale 2001; Cabanilla et al. 1999).

Relative to wheat and rice, maize has a much higher proportion of area planted to landraces. In Latin America, most of the maize area is planted to landraces, as is a higher proportion of the maize grown in sub-Saharan Africa (Morris and López-Pereira 1999). However, it can be expected that there has been genetic exchange between modern maize varieties or hybrids and maize landraces in some of these areas (Morris and Heisey 1998).

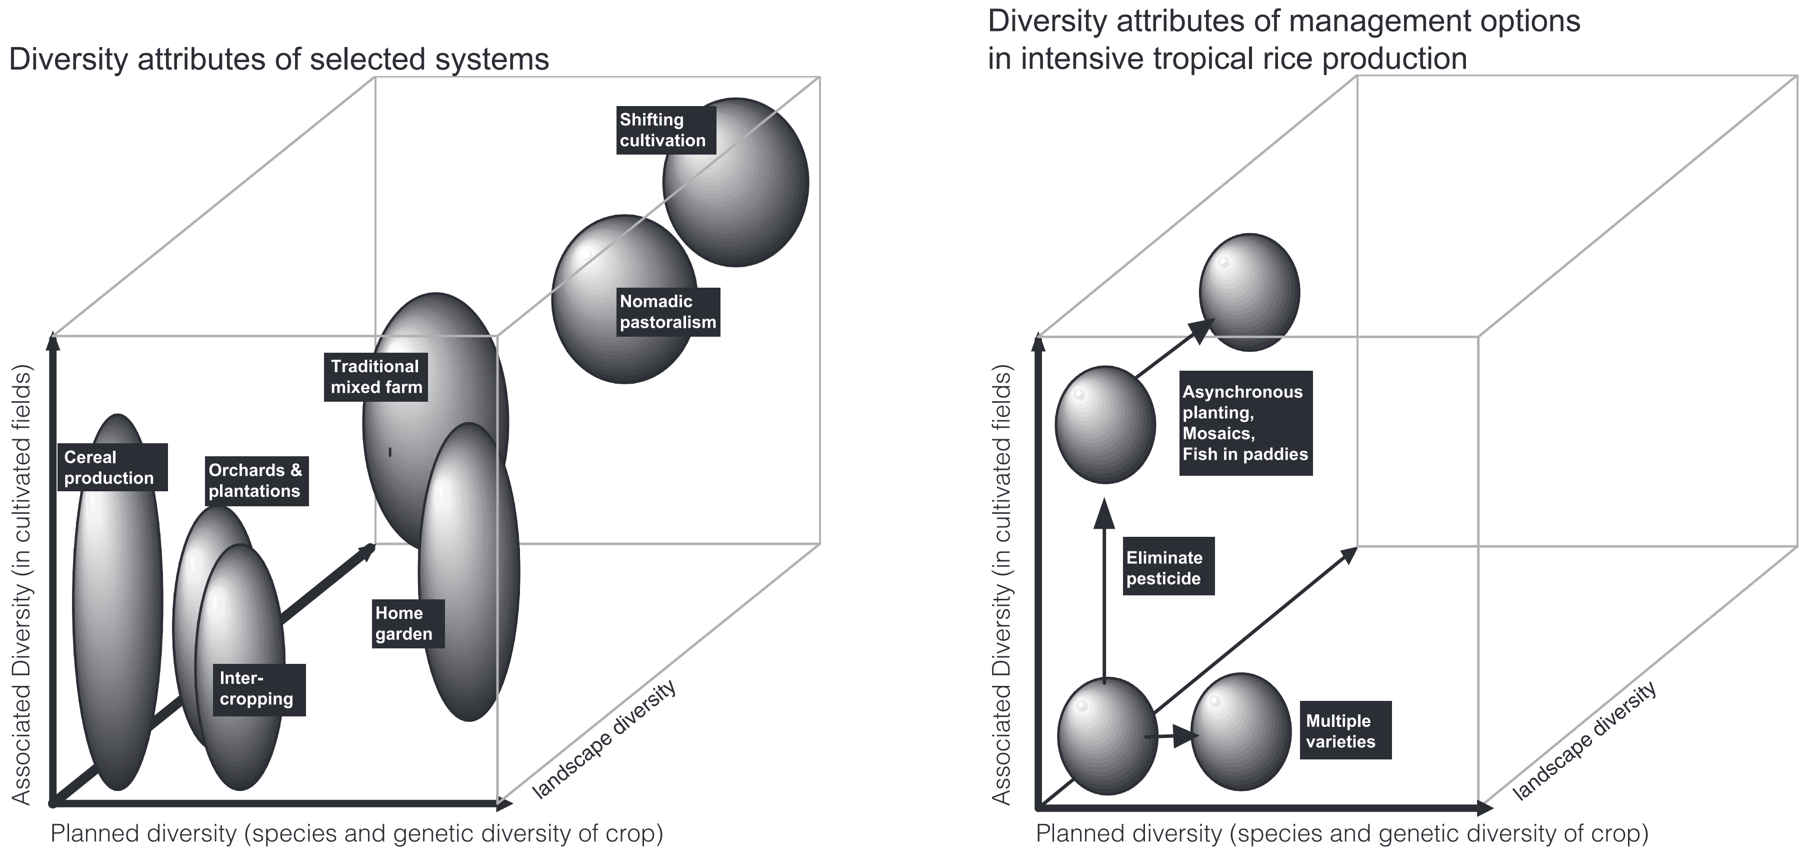

Figure 26.4. Dimensions of Diversity in Selected Production Systems

For some other major crops, such as sorghum and millet, the picture is quite different. While sorghum- and millet-growing regions of North America and parts of India have modernized systems, in the African Sahel, where these crops provide the main food source, there has been very little adoption of modern varieties and traditional practices prevail.

Farmers continue to use landraces rather than modern varieties for a range of different reasons which can be categorized into different groups (FAO 1998; Brush et al. 1992; Gauchan 2004; Meng 1997; Smale et al. 2001; Van Dusen 2000). First, landraces provide a wider range of end uses and have distinct culinary purposes, which may also contribute to maintaining a balanced diet. For example, in the Sahel and other dryland areas of Africa, certain varieties of sorghum produce better porridge, while others are better for boiling, and entirely different varieties are used for brewing beer. Some crop varieties have long stalks for animal feed or fencing, while others have sweet stalks that provide a refreshing snack in the field. Markets may have specific requirements, distinct from preferences at home, and some varieties have distinct cultural uses.

Second, production factors and risk management provide additional motives for continued use of landraces. Farmers frequently explain that they select different landraces to match differences in soil water regimes, even within the same field. Varieties with different maturities may be used to spread labor requirements through the season. Where weather patterns are uncertain or diseases are prevalent, planting several varieties can spread risk. Poor farmers are more likely to be faced with failures in insurance markets and thus use natural resource allocation as a means of insuring. Maintaining a diverse set of crop varieties to insure against production or market risks may be the most accessible means of insurance available to low-income households, whereas higher-income households with greater access to formal financial markets or other means of risk management may be more likely to risk a narrower portfolio of crop varieties. In addition, some traditional varieties (of millet, for instance, in West Africa) are photoperiodic: the time of maturity is set by day-length changes, allowing planting time to be varied according the start of the rains while still ensuring that the crop is ready for harvest on time (Niangado 2001).

Finally, in some unfavorable and heterogeneous environments, appropriate modern varieties have simply not been developed or are not available. Breeding for such environments requires a decentralized approach to exploit "genotype x environment interaction" (Simmonds 1991; Ceccarelli 1994; de Vries and Toenniessen 2001). Participatory approaches to plant breeding are, however, having some success in developing suitable varieties for such areas (Ceccarelli et al. 2001; Weltzein et al. 1999; Cleveland and Soleri 2002).

Though empirical evidence is limited, both theory and observation suggest that genetic heterogeneity provides greater disease suppression when used over large areas. Some studies, including those of wheat mosaic virus (Hariri et al. 2001), fungal pathogens of sorghum (Ngugi et al. 2001), and rice blast (Zhu et al. 2000), have shown that mixed planting of resistant varieties with other varieties can reduce the disease incidence across the whole crop, while possibly extending the functional "lifespan" of the resistant genotypes. However, evolutionary interactions among crops and their pathogens mean that improvement in crop resistance to a pathogen is, in most cases, likely to be transitory. Thus, maintaining stocks of genetic diversity for plant breeding is critically important.

Cultivated systems also support a high diversity of livestock. Globally, there are 6,500 breeds of domesticated animals, including cattle, goats, sheep, buffalo, yaks, pigs, horses, chicken, turkeys, ducks, geese, pigeons, and ostriches. A third of these are under near-future threat of extinction due to their very small population size. Over the past century, it is believed that 5,000 domesticated animal and bird breeds have been lost. The situation is most serious in industrialized farming systems, with half of current breeds at risk in Europe and a third at risk in North America. While only 10–20% of current livestock breeds are at risk in Asia, Africa, and Latin America, it is likely that the risk of breed loss will increase as these countries pursue the path of economic development followed in industrial countries (FAO/UNEP 2000; Blench 2001).

26.2.1.2 Management of Associated Agricultural Biodiversity That Supports Production

The biodiversity of fauna and flora found in agroecosystems often plays an essential role in supporting crop production (Swift et al. 1996; Pimbert 1999; Cromwell et al. 2001). Earthworms and other soil fauna and microorganisms, together with plant root systems, maintain soil structure and facilitate nutrient cycling. Pests and diseases are kept in check by parasites, predators, and disease control organisms, as well as by genetic resistances in crop plants themselves. Insect pollinators also contribute to cross-fertilization of crop species that outcross.

As the examples in this section illustrate, it is not only the organisms that directly provide such services that are important, but also the associated food webs, such as alternative forage plants for pollinators (including those in small patches of wild lands within agricultural landscapes) and alternative prey for natural enemies of agricultural pests. Agroecosystems vary in the extent to which this biological support to production is replaced by external inputs. In industrial-type agricultural systems, they have been replaced to quite a significant extent by inorganic fertilizers and chemical pesticides; but in the many areas, particularly in the tropics, agricultural biodiversity provides the primary forces governing nutrient availability and pest pressure.

26.2.1.2.1 *Soil biodiversity*

Soil organisms contribute a wide range of essential services to the function of terrestrial ecosystems by acting as the primary driving agents of nutrient cycling and regulating the dynamics of soil organic matter formation and decomposition, soil carbon sequestration, and greenhouse gas emission. They modify soil physical structure and hydraulic properties that influence root growth and function and nutrient acquisition. In addition, many pollinators as well as natural enemies of agricultural pests spend part of their life cycle in the soil.

Soil biodiversity is responsive to the management of cultivated systems (Giller et al. 1997). Cultivation drastically affects the soil environment and hence the number and kinds of organisms present (Karg and Ryszkowski 1996; Ryszkowski et al. 2002). In general, tillage, monoculture, pesticide use, erosion, and soil contamination or pollution have negative affects on soil biodiversity. In contrast, no-till or minimal tillage, the application of organic materials such as livestock manures and compost, balanced fertilizer applications, and crop rotations generally have positive impacts on soil organism densities, diversity, and activity. Soil condition can thus be improved by farm practices and, indeed, some soils are in effect created by farmers (Brookfield 2001).

26.2.1.2.2 *Pollination*

Over three quarters of the major world crops rely on animal pollinators. While bees are the principal agents of pollination, flies, moths, butterflies, wasps, beetles, hummingbirds, bats, and others serve also as pollinators. Approximately 73% of the world's cultivated crops, including cashews, squash, mangos, cocoa, cranberries, and blueberries, are pollinated by bee species, 19% by flies, 6.5% by bats, 5% by wasps, 5% by beetles, 4% by birds, and 4% by butterflies and moths (Roubik 1995). Of the hundred or so crops that make up most of the world's food supply, only 15% are pollinated by domestic bees, while at least 80% are pollinated by wild bees and other wildlife. The services of wild pollinators are estimated to be worth $4.1 billion a year to U.S. agriculture alone. Wild plants and weeds provide alternative forage and nesting sites for pollinators, whose diversity is directly dependant on plant diversity, and vice versa (Kevan 1999). Forest-based pollinators in Costa Rica have been shown to increase the value of coffee production from a single farm by approximately $60,000 per year by increasing yields and improving crop quality (Ricketts et al. 2004).

Many pollinating species are at risk of extinction, and pollination is now regarded as an ecosystem service in jeopardy, which requires attention in all terrestrial environments—from intensive agriculture to wilderness (Buchmann and Nabhan 1996). Pollinators are declining because of habitat fragmentation, agricultural and industrial chemicals and associated pollution, parasites and diseases, the introduction of exotic species, and declines in non-crop nectar and larval food supplies. Due to declining pollinator populations, an increasing number of farmers around the world are now paying for pollination services, importing and raising pollinators to ensure that crop seed yields are not limited by lack of pollination. Despite their tremendous importance, little is known about wild pollinator populations or the consequences of their decline (Kevan 1999; Kevan and Phillips 2001). (See Chapter 11 for further information on pollinators.)

26.2.1.2.3 *Pest management*

Insects, spiders, and other arthropods often act as natural enemies of crop pests. Research in the rice fields of Java has documented that other components of arthropod diversity are important in this respect (Settle et al. 1996). Without alternative food sources, populations of natural enemies would be directly dependent on the plant pest, which in turn is directly dependent on the rice plant for food. Such a linear system would be expected to give rise to seasonal oscillations in populations at the various trophic levels. In the Javanese rice fields, however, "neutral" arthropods, mostly detritivores and plankton feeders, such as midges and mosquitoes, provide an alternative source of food for the natural enemies of rice plant pests, thus stabilizing the populations of the natural enemies and providing better pest control. Furthermore, the detritivores depend on high levels of organic matter in the paddy soils, which provide the food source for an array of microorganisms (bacteria and phtytoplankton) and zooplantkton.

Further stability is provided by spatial and temporal heterogeneity at the landscape level. In Central Java, for example, the landscape is made up of a patchwork of small to intermediate sized plots of paddy rice (patches of between 10 and 100 hectares), planted continuously to rice at differing times throughout the year, with only a short fallow period and interspersed with patches or lines of trees and shrubs. There is some evidence of greater abundance of natural predators in such landscapes (as compared with more-uniform rice environments found in West Java, for instance) and that asynchronous planting of rice and the patches of uncultivated land mean that there are always alternative food supplies for natural enemies (Settle et al. 1996).

26.2.1.3 Conservation of Wild Biodiversity in Agricultural Landscapes

Besides the services required to sustain agriculture, biodiversity in agricultural ecosystems has a wider significance. Agricultural ecosystems represent substantial portions of watersheds, which are often landscapes that support recreation and tourism. They also harbor important biodiversity in their own right. Moreover, biodiversity in agricultural landscapes has powerful cultural significance, partly because of the interplay with historic landscapes associated with agriculture and partly because many people come into contact with wild biodiversity in and around farmland. In fact, in some regions elements of biodiversity now only exist in areas dominated by agriculture. Management of biodiversity in such areas is therefore an essential component of an overall approach to its conservation.

Indeed, in some parts of the world, notably Europe, biodiversity conservation has in recent years been acknowledged as one of the aims of agricultural policy. In spite of this, the negative trend of biodiversity in agricultural ecosystems, which was initiated with the intensification of agriculture in the latter part of the twentieth century, still prevails in Europe. Indicators such as the populations of farmland birds tend to show a negative trend (Birdlife International 2004). (See Figure 26.5.) Other indicators also show a loss in wildlife distribution and habitat as a consequence of intensification in agricultural production (Mankin and Warner 1999; Gall and Orians 1992). In developing countries, however, the expansion of agriculture is considered to be the greatest threat to extinction of threatened bird species, and a recent study suggests that intensification of agriculture in these areas to avoid further expansion of cropland would reduce this threat to biodiversity of bird species (Green et al. 2004).

One positive landscape-wide impact noted in sub-Saharan Africa, South Asia, and Southeast Asia is the trend of growing more trees for a wide variety of purposes. Trees can stabilize and enhance soils, can contribute to plant biodiversity in the landscape, and may provide habitat for a variety of birds, reptiles, small mammals, and insects. Some birds and small mammals can be important sources of revenue in farmlands, such as when farmers make agreements with outfitters and hunters and plan their management in an integrated way. Wildlife in cultivated systems can contribute to food security by providing an important source of animal proteins for the most marginal rural settlers. It should be noted, however, that the introduction of trees and other woody vegetation into some ecosystems, particularly remnant tracts of grassland or where area-sensitive grassland species are present, can have negative consequences to those species and become invasive woody perennials in these ecosystems (Allen 1994; Samson et al. 2004). (See Chapters 4 and 11 for more on alien invasive species.)

26.2.1.4 Impacts of Agricultural Practices on Biodiversity

Cultivated systems have large impacts on other ecosystems and on the services they supply. The most obvious impact is through expansion of cultivated systems. Globally, agricultural land has expanded by around 130,000 square kilometers a year over the past 25 years, predominantly at the expense of natural forests and grasslands. In addition, a rapid increase in coastal aquaculture has led to the loss of many mangrove ecosystems. Though future rates of conversion are expected to be much lower in absolute terms, assuming no shortage of staple food crops, the locations of major agricultural expansion frequently coincide with remnants of those natural habitats with high biodiversity value (Myers et al. 2000).

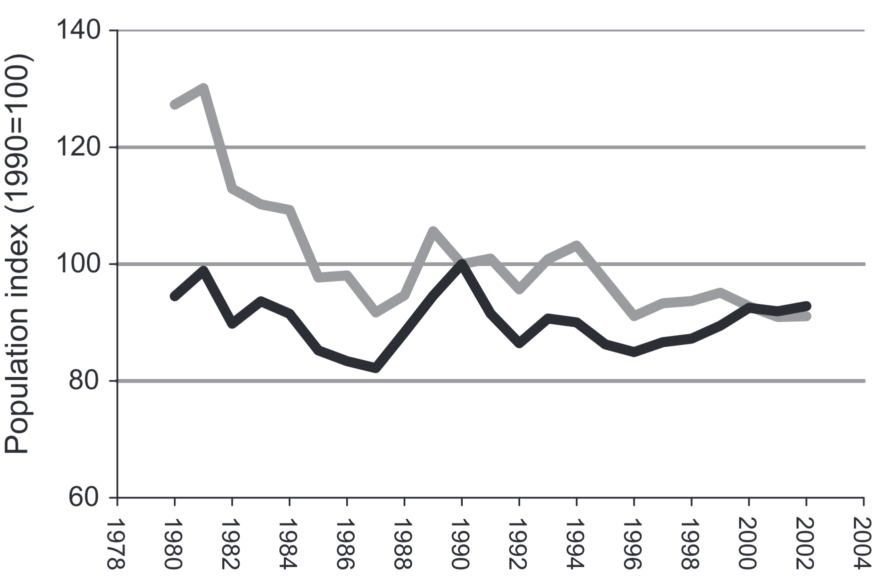

Figure 26.5. Supranational Multi-species Indicator of European Bird Populations, 1980–2002. Farmland birds (grey line: 18 countries, 23 species, ± 1.96 SE) and woodland, park, and garden birds (black line: 19 countries, 24 species, ± 1.96 SE). The index for the base year, 1990, is set to 100. Data come from the Pan-European Common Bird Monitoring Scheme, an initiative of the Royal Society for the Protection of Birds, the European Bird Census Council, and BirdLife International.

Other externalities associated with cultivated systems include the use of water and nutrients and the pollution of ecosystems resulting from excess use of pesticides and nutrients. Irrigated agriculture is a major user of fresh water. Both the direct loss of wetland habitats from conversion and the pollution of inland waters by excess nutrients have major negative impacts on inland water biodiversity. (See Chapter 20.) Despite increases in water use efficiency, total water demand for agriculture is increasing and in many regions is projected to outstrip supply over the coming decades. (See Chapter 7.)

Agriculture is the major user of industrially fixed nitrogen, and only a fraction of this fertilizer is used and retained in food products. The excess nitrogen leads to biodiversity loss in inland water, coastal, and marine systems through eutrophication and to loss of terrestrial plant diversity through aerial deposition. (See Chapters 18, 19, and 20.) Conversely, the soils of several cultivated systems, especially in Africa South of the Sahara, are nutrient-depleted. This is especially problematic where fruits, vegetables, and other crops are exported or transferred on a large scale from rural areas to large urban centers. Significantly greater use of fertilizers will be necessary in some regions to maintain soil nutrient stocks and support increased production by these systems.

Pesticides and herbicides have direct impacts on biodiversity through the degradation of ecosystems. Birds are particularly vulnerable to losses in invertebrate populations due to the use of pesticides and herbicides (Hooper et al. 2003). Especially important are those pesticides and herbicides that are persistent organic pollutants, since they have effects on large spatial and temporal scales. Many of the more persistent chemicals are being phased out and replaced by others with much lower toxicity that are less persistent. However, the overall use of pesticides is still increasing (FAOSTAT 2004).

26.2.1.5 Concluding Comments on the Relationship between Biodiversity and Cultivated Systems

Although cultivated systems often have a negative impact on it, biodiversity remains essential for the productivity and sustainability of cultivated systems. In modern industrial agricultural systems, many components of biodiversity relevant to agriculture can be separated from the production system (such as ex situ germplasm collections and plant breeding programs). Biodiversity is still required for production, however, even if partially maintained ex situ.

In addition, some of the services provided by biodiversity can, to a certain degree, be provided by externally provided services. For example, market integration and insurance services can substitute for risk management provided by crop genetic diversity, and other forms of pest management, including the use of pesticides, can substitute for pest and disease control. But it is important to note two points. First, poor farmers often do not have the option of introducing modern methods for services provided by biodiversity because of the lack of market integration or heterogeneity of the environment or because they cannot afford the alternatives. Second, substitution of some services may not be sustainable and may have negative environmental and human health effects (for example, the reliance on toxic and persistent pesticides to control certain pests can have negative effects on the provision of services by the cultivated system and other ecosystems connected to the cultivated system).

The relative cost-effectiveness of biodiversity-based over substitute services is sensitive to many factors and may be amenable to the application of incentive measures. The levels of biodiversity in cultivated systems and the ecosystems services they provide can be manipulated directly or indirectly by management practices. For instance, practices such as integrated pest management and minimal tillage agriculture, as well as multicropping, the use of genetic diversity, and mosaic landscaping can increase biodiversity in cultivated systems. However, if such measures reduce crop yields per unit land area-time, the aggregate effects of such practices could result in the expansion of crop area at the expense of natural ecosystems, thus trading increased biodiversity within cultivated systems for a decrease in the extent of natural ecosystems and the biodiversity they contain.

26.2.2 Fresh Water

Agriculture is by far the most consumptive human use of fresh water. Water requirements for cultivation are large; it takes 500 liters, 900 liters, 1,400 liters, and 2,000 liters of transpired water to produce 1 kilogram of potatoes, wheat, maize, and rice respectively (Klohn and Appelgren 1998). Other crops, such as sugarcane and bananas, are even more water-demanding.

Cultivation both relies on and influences the provision of fresh water. Both the quantity and quality of water resources can be affected, as well as the timing and distribution of water flows in local catchments and large river basins. The impact of cultivation on freshwater quantity is much larger in irrigated than in rain-fed systems. Deforestation associated with rain-fed cultivation tends to increase the amount of water available for agriculture because of reduced transpiration losses. Impoundments for irrigation can regulate downstream flows, while seasonally bare soil and field drainage systems can accelerate runoff and reduce infiltration, resulting in more severe local flooding and decreased dry weather flows (Bruijnzeel 2001). Water quality effects have been reported for all forms of cultivation, including confined livestock systems and aquaculture, but the nature and magnitude of impact can vary substantially. Poorly managed cultivation, particularly on sloping lands, is often associated with soil erosion, high silt loading, and downstream sedimentation. Intensive, high-input production systems can result in water pollution from leaching or runoff that carries nutrients, pesticides, or animal wastes to waterways (National Research Council 2000; de Haan et al. 1997).

The negative impact of cultivation on water resources can limit options for, and increase the cost of downstream water use (for example, through reduced domestic water supply or recreational opportunities). It can also have additional negative effects on the supply of other ecosystem services (such as reducing aquatic biodiversity and increasing nutrient flows) and on the condition of other ecosystems (the integrity and productivity of inland waters and coastal systems, for instance). (See Chapters 19 and 20.)

This section briefly reviews the sources and means by which fresh water is provided to and utilized by cultivated systems, identifies some of the issues surrounding water use efficiency, and considers some of the most important environmental consequences of cultivation on water resources.

26.2.2.1 Irrigation

Irrigation involves the withdrawal of groundwater and the diversion of surface water resources to help meet the transpiration requirements of crops and to lengthen the growing period when rainfall alone is insufficient to support crop growth. By mitigating moisture deficits, irrigation can significantly increase yields and total crop biomass, stabilize production and prices (by dampening the effects of rainfall variability within and across seasons), and encourage production diversity. But irrigation requires increased freshwater use and promotes more-intensive land use with regard to labor and other inputs, such as improved seeds, fertilizers, and pesticides (because such inputs are usually needed to achieve the yield increases that are possible when water limitations to crop growth are removed).

Of the 9,000–12,500 cubic kilometers of surface water estimated to be available globally for use each year (UN 1997), between 3,500 and 3,700 cubic kilometers were withdrawn in 1995 (Shiklomanov 1996). Of that total, about 70% was withdrawn for irrigation (Postel 1993). According to the World Bank (2000), the share of extracted water used for agriculture ranges from 87% in low-income countries to 74% in middle-income countries and 30% in high-income countries. By 2002, there were 276 million hectares of irrigated cropland globally—five times more than at the beginning of the twentieth century. While this irrigated area represents only 18% of all croplands, irrigated agriculture provides about 40% of the global food supply (FAOSTAT 2004; Bruinsma 2003; Wood et al. 2000).

The wide variability in freshwater endowments between regions and countries has a large influence on the potential for the development and long-term viability of irrigated agriculture. While the 206 cubic meters per capita withdrawn annually for agriculture in Africa represents 85% of total water withdrawals on that continent, the 1,029 cubic meters per capita withdrawn for agriculture in North America represents just 47% of that continent's withdrawals (World Resources Institute 2000). Compared with high-income countries, mostly located in subhumid/humid temperate and sub-tropical climates, many poor countries tend to have scarcer water supplies and relatively large agricultural demands due to the higher share of agriculture in their economies.

The simplest measure of irrigation intensity is the amount of irrigation water withdrawn (or applied) per year. This is most commonly expressed as an equivalent water depth per unit area (cubic meters of water per year divided by hectares irrigated). Using data from WRI (1998) and FAOSTAT (1999) across 118 countries, Seckler et al. (1998) calculated the mean depth of irrigation globally to be about 1 meter per year on the 276 million hectares of irrigated cropland.

Although irrigation is by far the largest global water user, the net rate of increase in irrigated area has decreased steadily in each of the past four decades and now stands at just under 1% annually (FAOSTAT 2004). Expansion in irrigated area has slowed as unexploited freshwater resources have become more limited and more expensive to develop. In addition, cereal prices have trended downwards in real terms, and environmental and social objections to the construction of large-scale impoundments have grown. There is also increasing competition for water from domestic and industrial users. Such pressures have resulted in increasing regulation of the allocation of water resources in many countries and of effluent and water quality standards (including the establishment of "minimum environmental flows" in some cases). These trends have increased public awareness of water use by agriculture and have fostered greater concern by farmers and researchers about improvements in water use efficiency in cultivated systems (Tharme 2003; Benetti et al. 2004).

Irrigation can have positive in addition to negative externalities. In some rural areas, it is the only reliable source of water for cooking and cleaning. Infiltration from rice paddy systems also contributes to groundwater reservoirs that are important sources of water in urban areas, as well as contributing to flood control and prevention of saltwater intrusion (Renault and Montginoul 2003).

Water loss also occurs with aquaculture through evaporation and pond seepage. Pond seepage may be as much as 2.5 centimeters per day, while as much as 1–3% of the fish pond volume may be lost daily (Beveridge and Phillips 1993).

26.2.2.2 Water Use Efficiency

Irrigation systems, particularly those involving surface water impoundment and conveyance, are often inefficient in terms of water loss through evaporation and leakage. Water efficiency is defined as the ratio of water used by crops to the gross quantity of water extracted for irrigation use. Global estimates of irrigation efficiency vary, but the average is around 43% (Postel 1993; Seckler et al. 1998). Seckler et al. (1998) estimate that arid agroecosystems have more efficient irrigation—for example, 54% and 58% efficiency for the two driest groups of countries, compared with 30% for the least water-constrained countries. China and India show irrigation efficiencies of around 40%, and they strongly influence the global average because of their large irrigated area. Irrigation efficiencies typically range from 25% to 45% in Asia, but up to 50–60% in Taiwan, Israel, and Japan (Seckler et al. 1998:25).

Recognizing the large potential for water efficiency improvements in agriculture, and spurred by increasing competition for water, many technologies have been developed to enhance the effectiveness of water use in both irrigated and rain-fed cultivation. Postel (1999) describes how microirrigation systems, such as drip and micro-sprinklers, often achieve efficiencies in excess of 95% compared with standard flood irrigation efficiencies of 60% or less. She cites significant water productivity gains for a wide range of crops, resulting from the shift from conventional to drip irrigation in India. For example, water use declined as much as 65% in the case of sugarcane cultivation, and water productivity increased by 255% in cotton. The reason for these increases in irrigation efficiency is that a precise water application can both reduce total water use and increase yields. Sugarcane and cotton yields increased 20% and 27% respectively, along with substantial reductions in water use. Postel (1997) indicated that as of 1991, only 0.7% of irrigated farmland worldwide was being microirrigated. While this fraction is expected to have increased since 1991, no recent, comprehensive global data are available (Gleick 2002).

Other techniques for improving water use efficiency in both irrigated and rain-fed systems have included furrow diking, land leveling, direct seeding, moisture monitoring, low-energy precision application sprinklers, low pressure sprinklers, water accounting, and stomatal control by chemical signaling (Gleick 2002; Davies et al. 2003). Complementary strategies have included the development of more drought-tolerant crop germplasm (Edmeades et al. 1999; Pantuwan et al. 2002), experimentation with policies that foster water markets or other economic or regulatory arrangements, and institutional reforms that engage farming communities more directly in improving water resource management (Postel 1997; Subramanian et al. 1997).

Water conservation methods, such as mulching, deep tillage, contour farming, and ridging, also help increase water use efficiency by ensuring that the rainwater is retained long enough to ensure infiltration into the soil root zone (Habitu and Mahoo 1999; Reij et al. 1988). These approaches can be complemented by "water harvesting" techniques involving the small-scale concentration, collection, storage, and use of rainwater runoff for both domestic and agricultural use.

Increasing effective rainfall use through improved water harvesting technologies and water conservation methods has largely been pioneered in arid and semiarid regions, and water harvesting techniques have been classified in various ways (Reij et al. 1988). Pacey and Cullis (1986) described three broad categories: external catchment systems, microcatchments, and rooftop runoff collection, the latter used almost exclusively for nonagricultural purposes. External catchment rainwater harvesting involves the collection of water from areas distant from where crops are grown (Oweis et al. 1999). Microcatchment techniques are those in which the catchment area and the cropped area are distinct but adjacent (Habitu and Mahoo 1999). Microcatchments generate higher yields per unit area than larger catchments (Bruins et al. 1986) and they are simple, inexpensive, and easily reproduced where land is available (Boers and Ben-Asher 1982). Microcatchments have been used in Asia, Africa, America, and Australia, where they are often used for medium water-demanding crops such as maize, sorghum, millet, and groundnuts (Habitu and Mahoo 1999), but evidence of large-scale adoption and impact is so far limited.

Water use efficiency can also be improved by carefully designed landscapes. Studies of processes induced by shelterbelts and woods in agricultural landscapes indicate that the structure of plant cover has an important bearing on agricultural water resources (as well as on habitat and natural biodiversity). The protective effects of trees decrease wind speeds close to Earth's surface and lower saturation vapor deficits, thus decreasing evapotranspiration from sheltered fields. Fields between shelterbelts conserve moisture (Brandle et al. 2004; Cleugh et al. 2002; Kedziora and Olejnik 2002). Shelter effects are greater under dry and warm meteorological conditions compared with wet and cool weather (Ryszkowski and Kedziora 1995).

In addition, shelterbelts have been shown to decrease surface runoff rates, protect soil against water erosion, and increase soil infiltration rates, thus improving dry-season flows (Kedziora and Olejnik 2002; Werner et al. 1997). Some studies suggest that heterogeneity of plant cover structure, including trees in agricultural landscapes, also generates meso-scale atmospheric circulation, which can increase regional or local precipitation (Pielke et al. 1991, 1998) and recycling of water in the landscape (Lawton et al. 2001; Stohlgren et al. 1998). Counterbalancing these positive effects, tree shelterbelts also compete for land, nutrients, and water with crops and also shade them, which can reduce crop yields or total crop output.

With rapid urbanization and growing competition for water resources (particularly in arid and semiarid regions), as well as budget constraints for effective treatment of growing wastewater volumes, the reuse of urban wastewater for agriculture is receiving increasing attention. Wastewater is being used as a low-cost alternative to conventional irrigation water to support vegetable production in urban and peri-urban agriculture, despite the health and environmental risks that might be associated with this practice. It is suggested that raw wastewater use in agriculture is increasing at close to the rate of urban growth in developing countries, where urban and peri-urban land is available (Scott et al. 2004).

Just how prevalent wastewater irrigation is today is a matter of conjecture, as no reliable global data exist. However, as an important step toward a global figure, Rachid-Sally et al. (2004), Cornish and Kielen (2004), and Ensik et al. (2004) present assessments of the area irrigated with wastewater at the country level, with estimates of 9,000 hectares for Viet Nam, 11,900 hectares for

Ghana, and 32,500 hectares in Pakistan. As the recycling of wastewater for irrigation grows, there are increasing concerns about the long-term human health consequences (Scott et al. 2004).

26.2.2.3 Impacts on Water Quality

Besides their effect on water quantity, cultivated systems can have negative impacts on freshwater quality through pollutants contained in the drainage water, runoff, and effluents. Where irrigation depletes rivers and aquifers that receive increased agricultural pollution, quality impacts are exacerbated because of reduced dilution capacity. Physical loading of water resources with inorganic (soil particles) and organic sediments or particulate matter, as well as chemical loading of plant nutrients, especially nitrogen, phosphorus, and pesticides, can often occur as a result of cultivation or intensive livestock and aquaculture operations (Sharpley and Halverson 1994; Owens 1994;).

Agricultural impact on water quality is also mediated through erosion brought about by poor crop cover, field drainage, and cultivation operations, particularly on sloping lands. Gleick (1993) estimates that about 22% of the annual storage capacity lost through siltation of U.S. reservoirs is due to soil erosion from cropland. Water-borne transportation of nitrates and phosphates is quite common where external nutrients are applied in excess or inefficiently and can cause eutrophication of surface waters. In some countries, such as Belgium and the Netherlands, the nitrogen input to some crops has in the past exceeded 500 kilograms per hectare (Wood et al. 2000).

Phosphorus transportation into aquatic ecosystems is the principal cause of blue-green algae blooms in reservoirs, and the anoxia in the Gulf of Mexico is one example of eutrophication attributable to nutrient enrichment (Snyder 2001). The off-site economic impact of water quality changes attributable to cultivation include damage to water-based recreational facilities, fisheries, navigation, water storage facilities, municipal and industrial water users, and water conveyance systems as well as increased flooding or inundation of low-lying urban areas and civil structures.

Salinization and waterlogging are two significant consequences of poor irrigation management and inadequate drainage (Ghassemi et al. 1995). Salinization occurs through the accumulation of salts deposited when water is evaporated from the upper layers of soils and is especially important in irrigated arid areas where evaporation rates are high. Since most crops are not tolerant of high salt levels, salinization decreases yields. This problem is particularly severe in arid and semiarid areas, such as Pakistan and Australia. Waterlogging is more common in humid environments and in irrigated areas where excessive amounts of water are applied to the land.

Ghassemi et al. (1995) estimated that around 45 million hectares, representing 20% of the world's total irrigated land, suffers from salinization or waterlogging. Losses amount to approximately 1.5 million hectares of irrigated land per year (Ghassemi 1995 quoting Dregne et al. 1991) and about $11 billion annually from reduced productivity (Postel 1999), representing about 1% of the global totals of both irrigated area and annual value of production respectively (Wood et al. 2000). Once salinization has occurred, rehabilitation for further cultivation is difficult and costly, but successes via specific vegetation strategies, using tree species, have been documented (Cacho et al. 2001; Barrett-Lenard 2002).

Freshwater aquaculture operations are strongly linked to water quality in terms of both the necessary quality of incoming water as well as the impacts of aquaculture effluents. Wells and springs are the best sources of water, but other sources are used if a number of water quality characteristics, including temperature, dissolved oxygen, ammonia, nitrites, nitrates, pH, alkalinity, and hardness, are within viable ranges. Water pollution risks arise in aquaculture when large amounts of harmful materials are added to the water body, adversely affecting its local and effluent water quality.

Fish culture operations, especially in intensive aquaculture, require fishmeal or fish feed. Feed contains nutrients such as nitrates and phosphates, and excess of these nutrients can lead to eutrophication and triggering of intense growth of aquatic plants (micro and macro). While in some aquaculture systems phytoplankton are themselves used as a food, overproduction of aquatic plants, particularly algae, causes algal blooms and can consequently lead to clogging of waterways, depletion of dissolved oxygen, and hindrance of light penetration to deeper water depths affecting photosynthetic and other metabolic functions of aquatic organisms. Thus unused feed, algal blooms, and detritus from the fish themselves impose additional pollutant loads when they discharge into external freshwater sources.

Pond and recirculation systems, as well as integrated agriculture-aquaculture systems, pose fewer risks of external pollution than the more open cage and raceway forms of aquaculture (Boyd 1985; Beveridge and Phillips 1993). In some cases, freshwater aquaculture ponds can improve water quality by acting as sinks for sediments (Stickney 1994).

To reduce the direct discharge of effluents and increase water use efficiency, wastewater from integrated agriculture-aquaculture systems has been used for irrigation. Where fresh water is available, aquaculture is a good way of using marginal land that is less suited to crop and livestock agriculture. Freshwater aquaculture ponds can be designed to contribute positively to soil and water conservation by dissipating the energy of overland flow and reducing erosion and downstream flooding.

26.2.3 Food

Trends in food provision, predominantly derived from cultivated systems, are assessed in detail in Chapter 8. This short section simply summarizes relevant key findings of that chapter.

The production of food and other products is, by design, the primary goal of cultivated systems. The global demand for food continues to be driven by population growth (albeit at a slowing rate), by the increasing real incomes of many households worldwide, and by evolving consumer preferences for more convenient, safer, and nutritious foods. Furthermore, wealthier consumers in industrial countries are increasingly willing to pay more for foods produced and marketed in ways that are perceived to be more environmentally sustainable and socially equitable.

From a food supply perspective, the scale of conversion of natural ecosystems for cultivation purposes, and the nature and extent of the trade-off between provision of food and of other ecosystem services within cultivated systems, has been shaped by the cultivation practices and technologies accessible to farmers. The decisions of most farmers about which crops to produce and how to produce them has also been influenced by a wide range of economic signals and, particularly in richer countries, by regulatory standards.

Farmers and, increasingly, scientists have accelerated the processes of domestication and adaptation of plant species and available germplasm through breeding and biotechnology to enhance food output from crops and animals across a very broad range of environmental and agronomic conditions. Use of transgenic crop varieties developed with recombinant DNA technology is increasing rapidly worldwide in both industrial and developing countries. Although this technology holds tremendous promise to increase productivity significantly and to improve end-use properties of crops for both rich and poor producers, the widespread use of transgenic crops, often referred to as genetically modified organisms, continues to generate controversy with regard to ethical, environmental, equity, and intellectual property issues.

Over the past half-century, and at a global scale, food provision has more than kept pace with growth in demand, leading to a significant, long-term decline in the real price of food and allowing an ever-growing share of a rapidly increasing world population to be fed adequately at reasonable cost. Nevertheless, there remain significant causes for concern about food provision on several fronts. First, there remains a persistent and, recently, growing population of undernourished people, estimated at 852 million for 2000/02 (FAO 2004). Second, in many of the same countries where hunger and poverty persist, population growth rates tend to be high, and expansion of food production is failing to keep pace with demand. In the face of population pressure, often compounded by limited access to resources and technologies, poor intensification practices have all too frequently degraded the productive capacity of existing cultivated areas. Depletion of soil nutrient stocks in subsistence systems has, for example, reduced the productive capacity of large areas in sub-Saharan Africa.

Third, the linear rate of increase in the yields of the three major cereals (maize, rice, and wheat) is falling below the rate of increase in demand in many of the world's major production areas (Cassman et al. 2003). Moreover, global warming from human-induced climate change may reduce crop yield potential and thus decrease the rate of yield gain (Peng et al. 2004; Lobell and Asner 2003; Rosenzeig and Parry 1996; Brown and Rosenberg 1997). Fourth, there are concerns of growing divergence, rather than convergence, between the economic, science, and technology capacities of richer and poorer nations with regard to food production. This divergence is hindering efforts to promote the emergence of profitable and sustainable smallholder agriculture in poorer countries. Finally, there is growing recognition that virtually all forms of cultivation have involved trade-offs between provision of food and provision of other ecosystem services. See Chapter 8 for further details on food provision.

26.2.4 Non-food Products

Besides producing food, cultivated systems provide other products such as fiber (cotton, flax, and jute, for instance), biofuels, medicines, pharmaceutical products, dyes, chemicals, timber, and other non-food industrial raw materials. Non-food crops account for nearly 7% of harvested crop area (Wood et al. 2000). Based on FAOSTAT 2004, the annual value of non-food crops from cultivated systems, excluding timber, is about 3.4% of total agricultural production ($50 billion, compared with $1.4 trillion for food crops).

In 2003, the reported primary production of fiber crops worldwide was about 25 million tons. Cotton is the major fiber crop and is extensively grown in China, the United States, and India, accounting for 15.6 million, 10.4 million, and 6.3 million tons, respectively, and providing 5.2 million, 3.9 million, and 2.1 million tons of cotton lint. Flax, another fiber crop, is widely grown in China and France, which produce around 500,000 and 86,000 tons respectively (FAOSTAT 2004).

In industrial countries, biofuel crops currently represent a relatively small proportion of output from cultivated systems. However, diversion of grain and crop biomass for biofuel and bio-based industrial feedstocks could grow substantially with increasing oil prices and continued improvements in the energy efficiency of crop production and bio-fuel conversion. Another approach is through crop genetic engineering to enhance traits facilitating production of plastics and other bio-based industrial feedstocks. Current U.S. maize production systems produce a net energy surplus based on a complete life-cycle analysis, including the embodied energy content of all inputs and operations (Shapouri et al. 2003). It is likely that future gains in energy yield and in efficiency of biofuel production or conversion to feedstocks will increase competitiveness of these renewable resources, especially if fossil fuel prices rise significantly.

Improvements in crop yields and nitrogen fertilizer efficiency are the most promising avenues through which to achieve increased energy output and overall efficiency. Both these factors would also contribute to reducing the negative impact of cultivation on ecosystem services through reductions in greenhouse gas emissions, replacement of fossil fuel usage with a renewable energy source, reduction of NO_2 emissions, and a decrease in nitrogen losses via leaching, denitrification, and volatilization.

If use of grain and crop biomass for biofuel and bio-based industrial feedstocks were to expand, however, it would place additional burdens on other cultivated systems to continue to meet growing food demand and could promote additional area expansion of cultivation and, perhaps, upward pressure on food prices.

26.2.5 Nutrient Cycling and Soil Fertility

Essential nutrients are required to sustain all life and include the macronutrients such as nitrogen, phosphorus, potassium, calcium, magnesium, and sulfur, which are present in plant tissues at relatively high concentrations (0.1–2.0% on a dry weight basis), and micronutrients such as iron, zinc, and copper, which are required in very small quantities (1–50 parts per million). (See Chapter 12.) Of the essential nutrients, nitrogen and phosphorus have the greatest impact on environmental quality and ecosystem services because they can easily move from cultivated systems to other ecosystems and accumulate to potentially polluting levels.

Moreover, a large proportion of the total global load of reactive nitrogen and phosphorus cycles through agricultural systems, because these nutrients are required in large quantities to maintain crop yields. For example, nitrogen fertilizer applied to cropland represents more than 50% of the annual load of reactive nitrogen attributable to human activities (Smil 1999). Likewise, phosphorus contained in cultivated plants, livestock manure, and recycled organic matter represents 24–40% of the annual global phosphorus flux in terrestrial ecosystems (Smil 2000). While other nutrients are also important, their use in agriculture and their effects on global ecosystem services are much smaller and more localized. Hence, the discussion of nutrient cycling in this chapter will focus on nitrogen and phosphorus. (See Chapter 12 for a wider discussion on nutrient cycling and Box 26.2 for a discussion of "virtual trade" in crop nutrients.)

26.2.5.1 Nutrient Resources in Cultivated Systems

Nutrients available for uptake by crops are derived from resources and processes that are either internal or external to the cultivated system. Internal sources include the weathering of nutrients from soil minerals, which is a very slow process producing only small amounts of plant-available nutrients, and nutrients released in the decomposition of soil organic matter. All SOM is derived from the decomposition of organic materials that include crop and weed residues returned to soil, and livestock manure, mulch, and

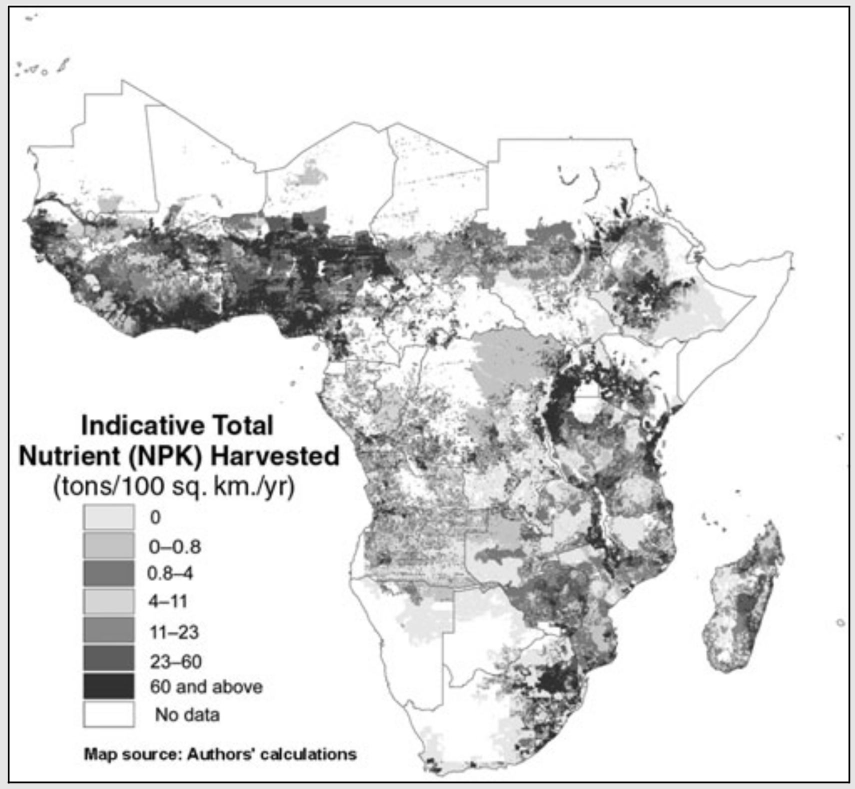
BOX 26.2

Virtual Trade in Crop Nutrients

Nutrients are often a scarce and limiting factor in African cropping systems. Traditionally, farmers have relied on fallow or applied animal and green manure to maintain soil fertility, but pressure to expand output to meet growing food demand has led to shorter fallow periods and increased cropping intensity without corresponding increases in organic nutrient inputs. Since chemical fertilizers are too costly or not available for most farmers, cultivation has progressively led to depletion of soil nutrient stocks over much of sub-Saharan Africa. Here two dimensions of this process are assessed: the total amount of nutrients removed in the harvested component of crops and the net flux (the "virtual trade") of nutrients across national borders by examining the share of domestically produced commodities exported as well as the nutrient composition of imports.

Figure A provides a spatially disaggregated estimate of the total amount of nitrogen, phosphorus, and potassium extracted from agricultural soils each year in the harvested part of crops. Assuming crop residues are recycled, this extraction represents the lower threshold for the amount of nutrients that must be replaced to maintain soil fertility. If crop residues are also removed for fuel, fodder, or building materials, then the nutrients removed in these residues must also be replaced. For each country, the amount of each nutrient removed at harvest was assessed by applying nutrient content/concentration coefficients (amount of nutrient contained in each unit weight of harvested product) to the average annual production (1999–2001) of each of 20 regionally important crops as well as an "other" composite to represent the remaining crops.

The spatial distribution of individual crops was assessed by fusing data from sub-national production statistics; maps of cropland, irrigation, population density, and biophysical crop suitability; and other secondary information, according to the method described by You and Wood (2004). The individual estimates of harvested nutrients for each crop in each (10x10 kilometer) pixel were summed to produce a single NPK total per 100 square kilometers. Areas with larger amounts of nutrient removal are shown in darker shades. Because the amount of nutrients applied in these areas as fertilizer or organic inputs falls far short of these removal rates, failure to adequately replenish soils through the use of applied nutrients is lowering soil fertility and reducing land productivity in many, if not most, of the areas shown.



To assess the overall flux of nutrients attributable to trade, the nutrient content coefficients were applied to the quantities of crops traded. The results for Africa (including north of the Sahara) show that a total of about 7.4 million tons of NPK are contained in the harvested crops of Africa each year (see Table), of which just over 1 million tons (14%) is contained in crop exports from the region. However, crop imports to the region contain around 2.5 million tons of NPK, about 34% of total domestic harvested removal.

This pattern of crop trade provides a net nutrient inflow into Africa of around 1.5 million tons per year. There are major geographical imbalances, however, between locations where nutrient are removed (plots and

compost applied to cropland. SOM contains substantial amounts of nitrogen, phosphorus, and sulfur, although these nutrients are unavailable for plant uptake when they are chemically bound in macro-modules within the organic matter. They only become available when these macro-modules are decomposed by soil microbes and microflora.

Maintaining a high SOM content and the soil microbe and microflora communities supported by SOM is therefore important for preserving soil fertility. Cropping practices that lead to a reduction in SOM result in a proportional decrease in the internal supply of nutrients and greater amounts of external inputs are needed to sustain crop yields. Conversely, cropping systems that increase SOM can reduce the need for applied nutrients. Crop residues and roots that are returned to the soil also decompose through microbial action and release nutrients that are available for crop uptake. A portion of these residues is converted to SOM, and thus the balance of organic matter input relative to SOM decomposition determines whether SOM increases, decreases, or stays the same. Burning of crop residues during fallow periods releases nutrients to the soil through the ash, although most of the nitrogen and some of the phosphorus are lost to the atmosphere in the combustion process.

Another internal source of nutrients, especially nitrogen, is biological nitrogen fixation, which is performed by symbiotic bacteria in association with forage and food legumes and by free-living nitrogen-fixing microorganisms that live in the rhizosphere of plant roots. Prior to the advent of modern farming practices and commercial fertilizers, BNF was the primary source of nitrogen in cultivated systems. In low-input cropping systems and in many natural ecosystems, however, BNF is often limited by a deficiency of phosphorus and other essential nutrients (Vitousek et al. 2002). In addition to BNF, nutrients from livestock manure are another internal source of nutrients in integrated crop-livestock farming systems.

Nutrient sources of external origin include inorganic fertilizers and livestock manure produced in confined feeding operations that are not associated with an integrated crop-livestock farming system. Secondary sources of external nutrient input include wet and dry deposition through nutrients contained, respectively, in rainfall and wind-blown dust, although the amount of nutrient addition from these sources is typically very small. Irrigation can provide substantial external inputs of nitrogen, potassium, calcium, magnesium, and sulfur in areas where groundwater or surface water used for irrigation contains relatively high concen-

BOX 26.2
continued

fields in cultivated systems) and locations where imported nutrients are used, primarily in urban areas and populated rural areas connected to the coast by a few transport corridors. Even within countries there are large movements of nutrients that exacerbate soil fertility problems. In Uganda, for example, *matooke,* the basic food staple produced by cooking the fruit of the East African highland banana, used to be prepared such that skins, stems, and other residues were recycled locally. Now, 30–50% of the country's 9 million tons per year of *matooke* enters the market system, and entire banana bunches with stems are shipped away to urban markets, primarily in Kampala. Here, though, wastes are often used as feed in confined livestock systems, especially for pigs.

Nutrient Content of Harvested Crop Products

	N	P	K	Total NPK
	(thousand tons per year)			
Production				
Eastern Africa	714	105	483	1,301
Northern Africa	738	114	383	1,235
Southern Africa	683	127	422	1,232
Western Africa	2,106	420	1,125	3,651
Harvested Product: Africa	4,241	766	2,412	7,419
Exports[a]	550	147	352	1,049
Imports[a]	1,448	439	634	2,522
Net trade flow of embodied crop nutrients[a]	+898	+292	+282	+1,427
Fertilizer consumption	2,462	953	485	3,900

[a] Derived from FAOSTAT (average 1999–2001) and nutrient content database

Comparing harvested nutrients to applied fertilizer estimates, a rough indication of the regional nutrient shortfall is apparent. Both nitrogen and potassium replenishment from fertilizers at the regional scale are significantly less than the nutrients removed in harvested crop product. This shortfall will be even greater to the extent that crop residues are not recycled and applied nutrients are not taken up by the crop (typically, nutrient uptake rates from applied nutrients are quite low). The shortfall is reduced where organic nutrients are applied but, typically, overall nutrient NPK balances in East and West Africa have been estimated at greater than −60 kilograms per hectare per year (Henao and Baanante 1999; Stoorvogel and Smaling 1990). Moreover, in African soils a large share of applied phosphorus fertilizer is fixed in the soil complex and is unavailable for plant use.

Clearly this aggregate assessment hides many important details. One is the lack of complete nutrient balances for specific crops and cropping systems. Some crops such as legumes can improve the nitrogen balance of soils through symbiotic nitrogen fixation in association with nitrogen-fixing bacteria, and high-value crops, often for export, are much more likely to receive fertilizers. Of the primary regional export crops, cotton, groundnuts, and cocoa contain the largest absolute quantities of nutrients, while of the major imports, nutrient totals are largest in wheat, soybean, and maize. Trade in oil palm and sugar accounts for a large share of nutrient flows as both import and export crops in different parts of sub-Saharan Africa. Unless the steady depletion of nutrients is reversed in the region and soil nutrient stocks are restored, it will be very difficult to sustain the rate of growth in food supply that will be required to meet food demand. In fact, Africa currently depends on the net import of more than 30 million tons of the three major cereals—rice, wheat, and maize—and the past two decades indicate an increasing trend of reliance on imported grain.

trations of these nutrients. Irrigation water also delivers sodium and chloride, important salts in the process of soil salinization.

26.2.5.2 Nutrient Balance and Maintenance of Soil Fertility

Maintenance of soil fertility is crucial for sustaining the food production capacity of cultivated systems. Harvesting of plant parts removes nutrients from the system and eventually depletes soil nutrient stocks unless nutrients are replenished through application of fertilizers or manures or, for nitrogen, by leguminous crops. Nutrient losses also occur through soil erosion and leaching of water-soluble nutrients when water percolates below the active root zone. For nitrogen, losses occur as a result of ammonia volatilization and denitrification, the latter releasing nitrous oxide, a potent greenhouse gas. The overall nutrient balance of a cultivated system is therefore determined by the difference between the inputs and outputs of each essential nutrient.

Internally generated nutrients are the primary source of nutrients in subsistence cropping systems where farmers do not have access to or cannot afford fertilizers or manure. The shifting cultivation systems practiced in remote areas in the humid and subhumid tropics are examples of subsistence systems that rely almost entirely on internal nutrient sources (Nye and Greenland 1960). Depletion of soil fertility occurs in many continuously cropped cereal production systems practiced on soils of low inherent fertility in India, Southeast Asia, and sub-Saharan Africa that primarily produce rice, millet, and sometimes sorghum under rain-fed conditions. In these systems, yields are relatively low and highly variable because of low soil fertility and lack of adequate rainfall.

Greater nitrogen input from BNF and increased use of livestock manure are generally not feasible in these continuous cropping systems because high human population density does not allow diversion of arable land away from food crops to non-food legume cover crops or forage crops. Dual-purpose grain legumes such as cowpea and pigeonpea, which can provide an income source to farmers in addition to improving soil fertility, have provided a partial solution to this problem (Giller 2001).

On good soils with adequate rainfall or irrigation, commercial fertilizers are used to support high yields and to maintain soil fertility. From a global perspective, such systems represent the foundation of the human food supply and include the irrigated lowland rice systems of Asia, the rain-fed wheat systems of northern and central Europe, and the maize-soybean rotations in the North American prairies and comparable environments of Argentina and Brazil. Relatively high doses of nitrogen and phosphorus are applied in these systems, which can lead to substantial nutrient losses without skillful management techniques that foster high nutrient use efficiency and nutrient retention in soil. Nitrogen is the most difficult nutrient to control because it is extremely mobile and can be lost rapidly via a number of pathways (Smil 1999). Average uptake efficiency from applied fertilizer is typically only about 30–50% (Cassman et al. 2002), which means there is significant scope for increasing uptake efficiency and reducing the potential for nitrogen losses.

The past half-century has seen large increases in the application of nitrogen and phosphorus fertilizers in high-production cropping systems (Galloway and Cowling 2002; Smil 2000) (see Figure 26.6), although application rates vary markedly by region and crop. This injection of external sources of N and P to cultivated systems has expanded and accelerated global nutrient cycles and, as a result of the inefficiencies in fertilizer application and uptake and the loss of fertilizer nutrients, has played a role in reducing environmental services through decreased water quality (Di and Cameron 2002; Howarth et al. 2002; Sharpley and Halvorson 1994; Spalding and Exner 1993), in the loss of diversity in aquatic plant and animal species (Rabalais 2002), and in emissions of N_2O (Bouwman et al. 2002) and NO_x, which can cause respiratory problems in humans (Wolfe and Patz 2002).

A number of technologies have been developed to increase the efficiency with which applied nutrients are used to produce food. One challenge is to match precisely the amount of nutrients available at any given time to the immediate crop requirements, without deficiency or excess, throughout the crop growth period (Matson et al. 1997; Tilman et al. 2002; Dobermann and Cassman 2002). In small-scale agriculture that is typical of high production systems in developing countries, this precision is best achieved through field-specific management because blanket recommendations cannot account for field-to-field variation in soil conditions and crop nutrient status. In large-scale agriculture that is typical of high-potential systems in industrial countries, site-specific management will be required to accommodate the substantial variation in crop and soil properties within individual large production fields.

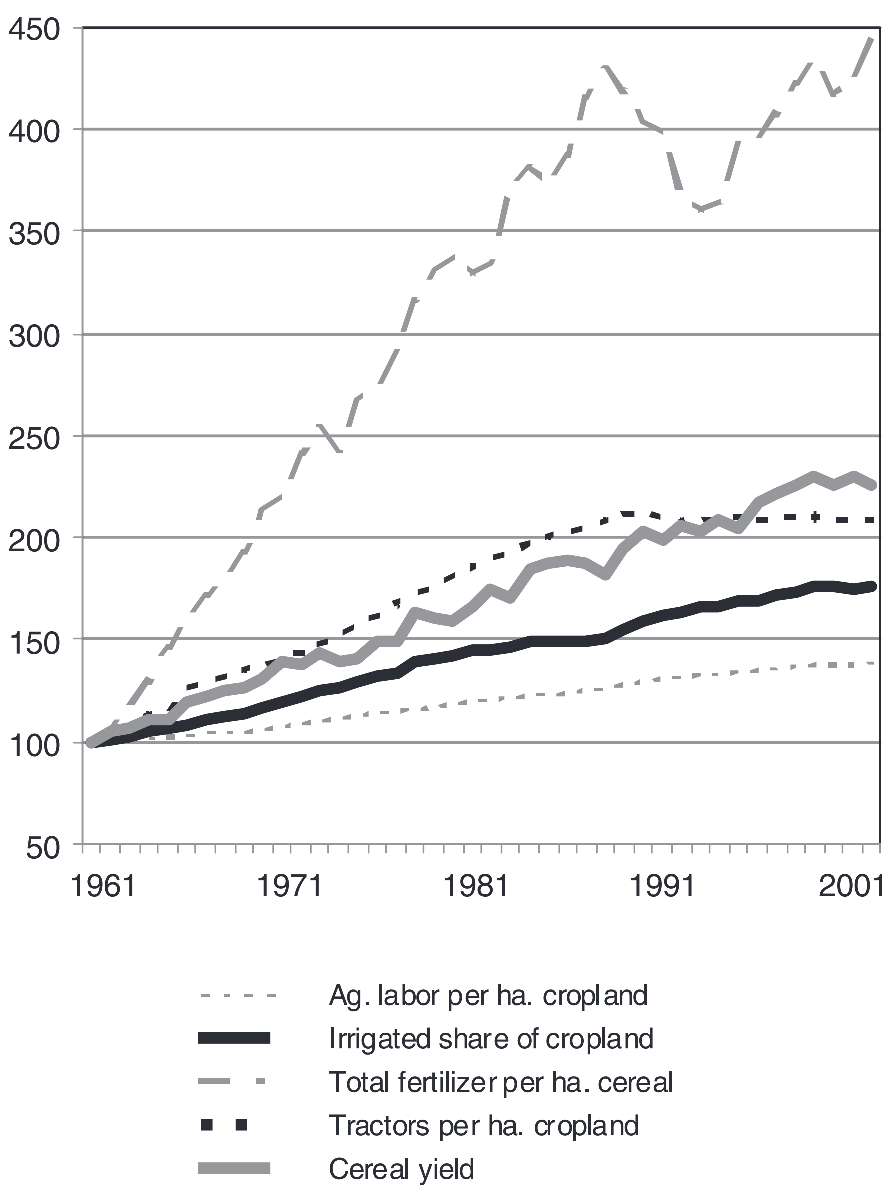


Figure 26.6. Trends in Intensification of Crop Production, 1961–2003. All variables are indexed at 100 in the base year 1961. (FAOSTAT 2004)

Recent research has demonstrated in on-farm studies the potential for significant increases in nitrogen uptake efficiency using these approaches (Dobermann and Cassman 2002). Success in developing these approaches and achieving adoption by farmers, however, requires substantial long-term investments in research and extension to ensure that the improved management practices are well adapted and cost-effective to specific cropping systems and agroecological zones.

While organic nitrogen sources, such as livestock manure and legume cover crops used in ''organic'' agricultural production systems, can be substituted for commercial nitrogen fertilizers, these practices are not feasible in the high-potential cereal production systems of developing countries, where population density is high and arable land resources are limited. Moreover, net profit was found to decrease when organic nitrogen sources were used in place of N fertilizer; which has limited adoption of such practices in tropical lowland rice systems (Ali 1999).

In contrast, ''organic'' production systems that rely entirely on organic nitrogen sources are becoming more popular in Europe and North America, although they still account for less than 2% of crop production. Between 1992 and 2001, the extent of organic cropland in the United States grew by over 200%, from about 163,000 hectares to 526,000 hectares. Organic systems are feasible, and even profitable, in these countries because people can afford to pay higher prices for their food, and there is adequate land to support the crop rotations, legume cover crops, and forages that are needed to supply adequate nitrogen.

It is not clear, however, that environmental benefits would accrue from widespread adoption of organic agriculture if these systems were forced to produce as much grain as conventional systems do today, because it is just as difficult to control the fate of nitrogen from organic sources as it is from nitrogen fertilizer (Cassman et al. 2003). But use of both organic or fertilizer nitrogen need not be an ''either-or'' decision. In most conventional systems, farmers use organic nitrogen sources and rotate with legume crops to minimize the need for nitrogen fertilizer when it is cost-effective to do so.

Although nutrients obtained from livestock manure remain a significant source of nutrient input to cultivated land, their relative contribution has declined substantially in association with the increase in availability and use of commercial fertilizers. On a global basis, Sheldrick et al. (2003) estimate that the contribution of nutrients from livestock manure has decreased from 60% in 1961 to 25% in 1996 for nitrogen, from 50% to 38% for phosphorus, and from 75% to 57% for potassium. However, because livestock manure also contains substantial quantities of organic matter, it can help improve soil physical and chemical properties that determine soil quality. The total amount of nutrients recovered in livestock manure in 2000 was estimated to be 34 million tons of N, 9 million tons of phosphorus, and 23 million tons of potassium.

While livestock in developing countries of Africa and Latin America produce substantial quantities of nutrients in livestock manure, most of this manure originates from grazing cattle and is therefore difficult to collect and use on cultivated land. In contrast, some industrial countries, such as the Netherlands, with large livestock industries that produce cattle, pigs, and poultry in confined feeding operations produce as much nitrogen in manure as their farmers use in nitrogen fertilizer, and the phosphorus and potassium content of this manure exceeds the amount used in fertilizer. (Environmental concerns associated with nutrient losses from large-scale, confined livestock production systems are discussed in earlier in this chapter.)

In contrast to high-potential systems, environmental damage from nutrient losses is not a concern in subsistence cropping systems that are practiced on soils of low inherent fertility in large areas in the tropics. Instead, severe nutrient deficiencies and depletion of soil fertility are the major threats to ecosystem services. Deficient nutrient supply limits food production capacity and profit, which contributes to malnutrition, susceptibility to disease, and economic insecurity. Severe depletion of soil fertility results in a spiral of soil degradation that can eventually render the land unsuitable for crop production. When abandoned, such degraded land can no longer support the native plant and animal communities it previously hosted, and invasive plant species often take over (Cairns and Garrity 1999; Lumbanraja et al. 1998). Subsistence farmers who abandon such land must then cultivate additional areas, thus expanding the area at risk of degradation.

While it is possible to sustain cropping with judicious use of fertilizers (Nye and Greenland 1960; Reardon et al. 1999), access to external supplies is often limited by lack of roads, infrastructure, and markets. Likewise, it is generally not possible to maintain fertility with only organic sources of nutrients because the inherent soil fertility is too low (Sanchez 2002). Integrated use of both organic nutrient sources and fertilizers appears to be the most promising option. Success in gaining adoption of such approaches has been limited by poverty, land tenure policies, and inadequate investment in the development of basic infrastructure, markets, credit, and extension services.

26.2.6 Atmospheric and Climate Regulation

Although carbon dioxide, nitrous oxide, and methane occur naturally in the atmosphere, their recent increase is largely a result of human activity. This increase has altered the composition of Earth's atmosphere and may affect future global climate (IPCC 1996). (See also Chapter 13.) Agriculture contributes to changes in atmospheric concentrations of each of these three greenhouse gases, significantly so in the case of CH_4 and N_2O, of which it contributes 50% and 70% respectively of the total anthropogenic emissions (Bhatia et al. 2004). Frequent cultivation, irrigated rice production, livestock production, and burning of cleared areas and crop residues now release about 166 million tons of carbon per year in methane and 1,600 $\pm$ 800 million tons of carbon per year in CO_2. Agricultural systems emit carbon dioxide through the direct use of fossil fuels in field operations (such as tillage, harvesting, irrigation pumping, transport, and grain drying), the indirect use of embodied energy in inputs that require the combustion of fossil fuels in their production, and the decomposition of soil organic matter and crop residues. The direct effects of land use and land cover change (including conversion of forest and grasslands) also resulted in net emission of 1.7 gigatons of carbon per year in the 1980s and 1.6 gigatons annually in the 1990s (IPCC 2000). Burning of standing biomass is a pivotal component of shifting cultivation that emits nitrous oxide in addition to carbon dioxide.

Cultivated fields can be a source or a sink for carbon, depending on the specific circumstances of carbon dynamics during cultivation. Factors having the greatest impact on the carbon balance include crop yield levels, removal of crop residues for fuel or livestock forage, crop rotations that include a pasture phase or perennial forage legume, and tillage. During much of the past century, most cropping systems have undergone a steady net loss of soil organic matter (Lal et al. 2003; Paustian et al. 1997; Lal 2004; Lugo and Brown 1993). Global average soil organic carbon density is estimated at 102 tons of carbon per hectare of land within the extent of agriculture (Wood et al. 2000), and the total global store of soil organic carbon within the extent of agriculture is estimated at 368 gigatons, with 43% of this in temperate zones.

However, with the steady increase in crop yields, which increases crop biomass and the amount of residue returned to the soil, and with the adoption of conservation tillage and no-till cropping systems, net carbon sequestration is estimated to occur in the maize-soybean systems of North America (Paustian et al. 1997), as well as in continuous irrigated lowland rice systems where soils remain flooded for most of the year, reducing the rate of soil organic matter decomposition because of anoxic soil conditions (Bronson et al. 1998; Witt et al. 2000). Estimates of the potential to sequester carbon in cultivated systems on a global basis range from 400 million to 800 million tons per year, assuming that best management practices that foster net carbon storage are widely adopted (Paustian et al. 1997; Lal 2003), although adoption has been limited to U.S. maize-soybean and wheat systems and similar cropping systems in Argentina and Brazil.

Large quantities of agricultural crop wastes are produced from cultivated systems. Disposal systems for these wastes include burning them in the field; plowing them back into soil; composting, landfilling, and using as a biomass fuel; or selling them in supplemental feed markets. Burning crop residues releases a number of greenhouse gases, including carbon dioxide, methane, carbon monoxide, nitrous oxide, and oxides of nitrogen.

An additional impact of cultivation on greenhouse gases occurs from erosion. One ecological off-site impact of accelerated erosion is the emission of erosion-induced greenhouse gases into the atmosphere. While some of the organic carbon transported to depositional sites and aquatic ecosystems is buried and sequestered (Stallard 1998; Smith et al. 2001), a large fraction may be emitted into the atmosphere. Erosion-induced emission of CO_2 into the atmosphere may be about 1 billion tons of carbon a year (Lal 2003). Wind-borne sediments, which transport particulate matter over long distances, also adversely affect air quality.

Agriculture can also contribute to mitigation of greenhouse gases emissions by adopting practices that promote the retention of carbon in stable forms of SOM (called humus) or in standing biomass such as occurs in forest trees. These carbon sinks are promoted by the use of less aggressive tillage and by a reduction in the rate of deforestation to support an expansion of cultivated area. Further reductions could also be achieved in the more efficient use of fossil fuels in all aspects of crop and soil management, which would include greater fertilizer and irrigation efficiency as well as reduced tillage.

26.2.6.1 Methane Emissions

Atmospheric methane is second only to CO_2 as an anthropogenic source of greenhouse gases in the atmosphere, and agriculture accounts for between 44% (IPCC 1996) and 50% (Bhatia et al. 2004) of those anthropogenic emissions. The concentration of methane in the atmosphere has more than doubled over the last two centuries, with enteric fermentation in domestic livestock, manure management, rice cultivation, and field burning of agricultural crop wastes as the main causes. Several other agricultural activities, such as irrigation and tillage practices, may also contribute to methane emissions. About 80% of methane from agricultural sources is produced biologically (IPCC 1992; Yang and Chang 1999, 2001).

During digestion of feed intake, methane is produced through enteric fermentation in the rumen of cattle, buffalo, sheep, and goats, a process in which microbes that reside in the digestive system break down the feed consumed by the animal. These animals have the highest methane emissions among all animal types because they have a rumen, or large "fore-stomach," in which a significant amount of methane-producing fermentation occurs. The amount of methane produced and excreted by an individual animal also depends on the amount and type of feed it consumes and other environmental factors.

The need to increase food production in order to keep pace with population growth and changing consumer tastes has led to a large increase in animal production (FAOSTAT 1999), as noted earlier, and to problems related to disposing of increasing quantities of dung and urine. The problem is exacerbated by disassociation of crop and livestock production (Bouwman and Booij 1998; Ke 1998) such that the animal wastes cannot be directly returned to fields where the feed was grown, which recycles the nutrients for succeeding crops. Instead, livestock manures from large confined feeding operations must be transported greater distances to surrounding farmland. But the nutrient content of the manure is low relative to commercial fertilizers, which increases the cost of handling and transporting it. Moreover, care must be taken to ensure that the amount of applied manure does not lead to excessive accumulation of phosphorus in the soil, which can lead to phosphorus losses via erosion and runoff, resulting in degradation of water quality and health concerns (Burton et al. 1997).

The decomposition of organic material in animal manure in an anaerobic environment produces methane. The most important factor affecting the amount of methane produced is how the manure is managed, since certain types of storage and treatment systems promote an oxygen-free environment. In particular, liquid systems (ponds, tanks, or pits) tend to produce a significant quantity of methane. However, when manure is handled as a solid or is deposited on pastures and rangelands, it tends to decompose aerobically and produce little or no methane. Higher temperatures and moist climatic conditions also promote methane production.

Applying manure to agricultural land can lead to groundwater contamination by nitrates after nitrification of the ammonium nitrogen (NH_4–N) present and to emissions of ammonia (European Centre for Ecotoxicology and Toxicology of Chemicals 1994), methane (Chadwick and Pain 1997), and N_2O (Jarvis et al. 1994)—all of which contribute to climate change. Ammonia, after deposition on land surfaces and water bodies, and nitrification act as a secondary source of N_2O and may also decrease the capacity of soils to absorb CH_4 and act as a sink for this gas (Mosier et al. 1996).

Rice fields are large producers of methane, accounting for as much as one third of total anthropogenic methane emissions. When fields are flooded, anaerobic conditions develop in the soils, and methane is produced through anaerobic decomposition of soil organic matter mediated by soil microbes. In fact, both methane and nitrous oxide are simultaneously emitted, as irrigated rice fields offer favorable conditions for their production and emission (Cai et al. 1997; Bronson et al. 1997; Ghosh and Bhat 1998; Majumdar et al. 2000). Global methane emissions from rice fields are estimated to be 37 teragrams per year, while N_2O emissions are much lower, at 1.8–5.3 teragrams per year, although N_2O is a much more potent greenhouse gas (IPCC 1996).

26.2.6.2 Nitrous Oxide Emissions

Agriculture is the main source of nitrous oxide, a chemically active greenhouse gas, accounting for about 70% of anthropogenic emissions. Atmospheric concentration of N_2O is increasing at a rate of $0.22 \pm 0.02\%$ per year. Concern over N_2O emissions is particularly great because of its long atmospheric lifetime and high climate change potential (Bhatia et al. 2004). Although global atmospheric loading of N_2O is less than CH_4, the former is 310 times more potent as a greenhouse gas than CO_2 on a 100-year time-scale, while CH_4 is only 21 times more potent (Majumdar 2003). N_2O is produced naturally from a wide variety of biological sources in soil, water, and animal wastes and contributes to the depletion of stratospheric ozone. The release of nitrous oxide has increased in recent years due to more intensive agricultural practices, in particular land conversion and application of nitrogen fertilizer. A wide range of other agricultural and soil management practices can also affect N_2O fluxes, including irrigation, tillage practices, the burning of agricultural crop residues, and changes in land use, such as loss and reclamation of freshwater wetland areas, conversion of grasslands to pasture and cropland, and conversion of managed lands to grasslands or the fallowing of land (Mosier et al. 2004).

From the agricultural perspective, N_2O emissions from soil represent a loss of N from the soil system and a decrease in N use efficiency. Soil is considered to be one of the major sources of nitrous oxide, contributing 65% of the global emissions. Annual emissions of N due to N_2O emissions from agricultural systems amounts to 6.3 teragrams. Soil receiving chemical fertilizers and biologically fixed nitrogen contributes to nitrous oxide emissions during the processes of nitrification and denitrification, and the increasing use of fertilizers will lead to increased N_2O emissions unless N fertilizer efficiency can be increased as well.

Use of organic nitrogen sources instead of nitrogen fertilizer causes a substantial increase in methane emissions in irrigated rice systems, and it may not decrease nitrous oxide emissions (when both are applied at levels that achieve similar yields). Thus, from a purely climate change perspective, organic fertilizers should be used with caution in such systems.

In summary, agriculture may be contributing about 20% of current annual greenhouse gas–forcing potential. It is the largest source of anthropogenic CH_4 and a significant contributor to increases in atmospheric N_2O concentration. In contrast, cultivated systems play a relatively small role in total CO_2 emissions, and some systems have the potential to sequester carbon by use of improved crop and soil management practices, thus becoming a sink for carbon dioxide.

26.3 Drivers of Change in Cultivated Systems

Many factors have influenced the evolution of cultivated systems and their capacity to meet the increasing demands placed on them. (See Figure 26.7.) These factors have driven the changes that have occurred in cultivated systems and will continue to do so in the future. This section reviews the nature these drivers, their interactions and extent, and their impact on system performance.

Although the Figure is a simplification of the context and dynamics of cultivation, it illustrates three key points: that the number of drivers and interactions among them are potentially large; that important feedback mechanisms exist that influence the ability of cultivated systems to generate desired cultivated products and ecosystem services; and that individual drivers can simultaneously have positive and negative impacts (for example, a new

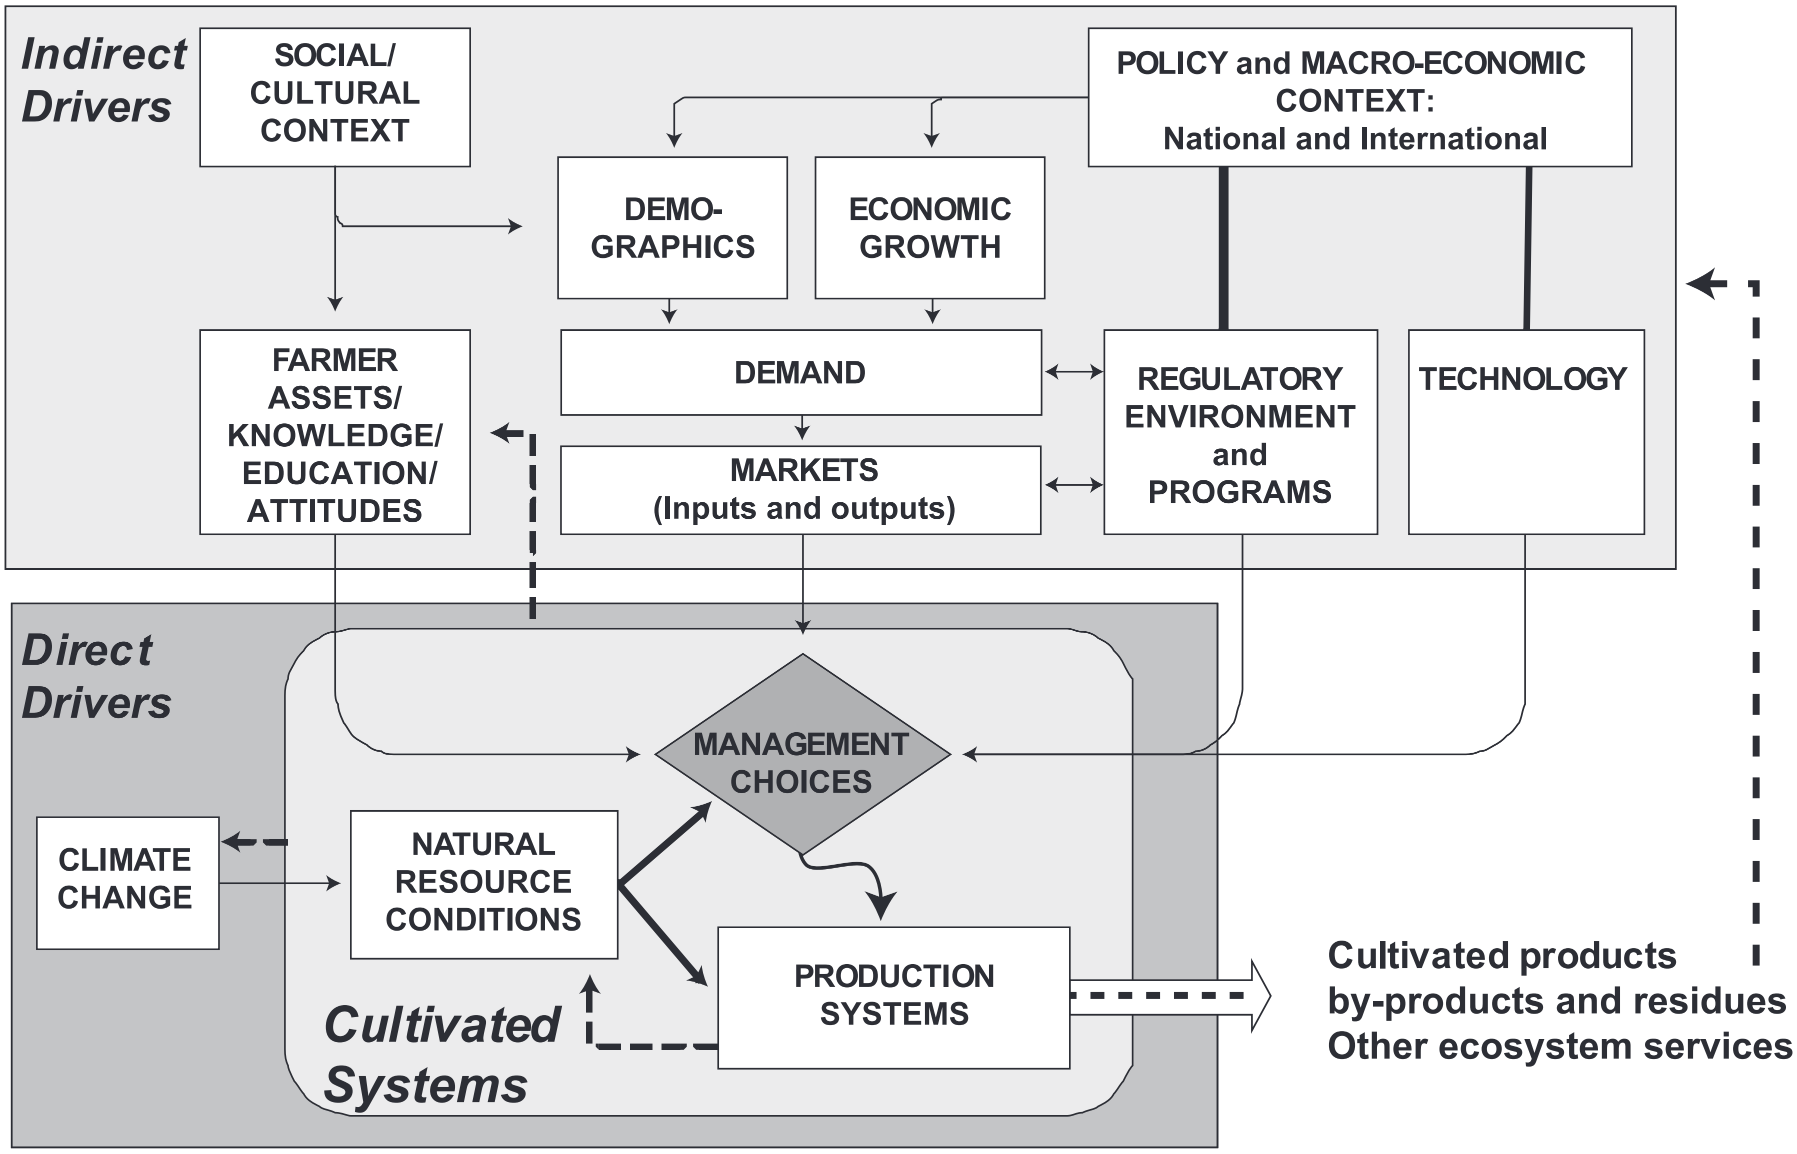

Figure 26.7. Interactions between Drivers of Cultivated Systems

technology that increases the yield of outputs might also generate a negative impact on ecosystem services).

The central role of the "manager" of the cultivated system is also highlighted in this conceptual model, whether the manager is an impoverished subsistence farmer with two or three hectares of remote hillside in East Africa or a professional agronomist in a multinational corporation that cultivates a 5,000-hectare cash crop plantation in Southeast Asia. Within any given socioeconomic and environmental context, it is the sequence of choices made by these managers about what to produce and how to produce it that drives the long-term capacity of cultivated systems to deliver products and ecosystem services. These choices are driven by farmers' incentives to take particular courses of action and by their capacity to act on those incentives. Through a better understanding of the key drivers of change, decision-makers are better placed to target policy and investment interventions for improving the economic and environmental outcomes of cultivation.

In keeping with the MA conceptual framework, drivers are grouped into two broad categories: indirect—those that influence the demand for both cultivated products and other ecosystem services, as well as the overall feasibility and attractiveness of different cultivation options—and direct—those that come into play at the actual site of cultivation.

26.3.1 Indirect Drivers

Many of the indirect drivers of change relevant to cultivated systems have already been described in Chapters 3 and 8, so this section focuses on a selective synthesis together with complementary material of more specific relevance to a cultivated systems perspective.

26.3.1.1 Demand for Cultivated Products and Other Ecosystem Services

The scale and structure of demand for cultivated products as well for other ecosystem services from agricultural landscapes has been broadly shaped by three drivers: demographic change, economic growth, and changing consumer preferences.

Over the past 50 years population growth has been the single most important global driver determining the aggregate demand for food and other cultivated products and shaping the extent and intensity of cultivation. Between 1960 and 1999, world population doubled to 6 billion, with an average growth rate of around 1.7% per year, while aggregate per capita food energy consumption grew at just over 0.5% per year. In industrial as well as developing countries, 60–70% of the total increase in calories consumed between 1961 and 2002 was accounted for by population growth (FAOSTAT 2004).

Population growth rates are declining, however, and currently stand at around 1.4% per year globally, although with major regional differences. Developing countries now account for over 95% of global population growth and hence a correspondingly greater share of the pressure to expand food output from cultivated systems. High population growth rates are negatively correlated with income levels. Hence, the population in poorer countries are typically less well nourished or even undernourished compared with populations in rich countries. Food insecurity in poor countries or regions often results from the low productivity of local cultivated systems (UN Hunger Task Force 2005). In Europe and some richer developing countries, population growth rates are stagnant or negative, so population growth is no longer a driver of food demand, and this trend will continue globally as economic development proceeds and population growth rates continue to fall (United Nations Population Fund 2004).

Economic growth is another strong stimulus of demand. As incomes rise in many developing countries, a large share of the increased income is used to purchase a greater and more diverse food supply. Compounding both population growth and increased purchasing power, social and cultural change—often linked to urbanization, increased female participation in the workplace, and increased exposure to food industry advertising and to public health and nutrition information—have changed consumer preferences with regard to the type, amount, and quality of food they demand. This includes growing preference for animal protein, (particularly chicken and pork), for fruits, vegetables, and oils, and for more processed and convenience foods and declining preference—as a share of per capita consumption—for starchy staples and cereals (FAOSTAT 2004). The rapid growth in industrial-scale, confined livestock systems and aquaculture have been direct consequences of these trends. Urbanization not only alters food preferences, it also changes the age and sex structure of rural populations and increases remittances—both factors that influence cultivation practices. (See Chapters 3 and 8.)

Many of the same demographic and socioeconomic changes have also increased the demand for a broader range of ecosystem services beyond food, such as fresh water, clean air, wildlife conservation, and recreation. Since cultivated systems now dominate many of the populated landscapes of the world, they have come under increasing pressure to play a greater role in delivering more (or consuming less) of these other services, while at the same time continuing to meet growing food needs (Wood et al. 2000).

Cutting across demographic and economic factors is the issue of poverty, which severely curtails livelihood opportunities. From a cultivation perspective, poverty limits access to production inputs such as credit and to new technologies that improve crop and soil management. Poverty is also often associated with a lack of security in terms of access to or title to land and other natural resources, in turn diminishing farmers' incentives and ability to choose production practices with long-term payoffs. Without such incentives, cultivated systems are focused on meeting short-term needs, and increasingly intensive cultivation under such conditions has often resulted in the degradation of soil and water resources that are required to maintain even low levels of productivity. This process has been called a "downward spiral" of productivity and degradation (Scherr 2000; Ehui and Pender 2005; Wiebe 2003). Ultimately such a degradation spiral can lead to abandonment of the cultivated system and migration to other locations that are likely to be of more even more marginal production potential (Barbier 1997; Chopra and Gulati 1997).

26.3.1.2 Policy, Legal, and Sociocultural Context of Cultivation

The policy, regulatory, and cultural environment have profound impacts on the incentives to produce more and higher-quality food, to engage in local, regional, and international trade, to invest in long-term productivity and enhanced cultivated system capacity, and to reduce the off-farm impacts (the externalities) of cultivation. The distinct and evolving nature of policies and institutions across and within countries influences the effectiveness of markets and hence choices about where, what, how, and how much to cultivate as well as the incentives, if any, for farmers to reduce or eliminate negative externalities caused by their cultivation practices (Uri 2001; Eicher 2000).

Agricultural, trade, and food security policies can distort incentives to produce and trade cultivated products in one way or other. These include price policies that favor either domestic rural producers (such as the U.S. Farm Bill and the EU Common Agricultural Policy) or urban consumers (such as the food price control schemes prevalent in many developing countries). The level and effectiveness of investments in education, infrastructure (roads, irrigation, rural electrification, and telecommunications), and credit have been shown to be strongly related to improvements in agricultural productivity and rural incomes (Fan et al. 2000; Fan and Hazell 2001; Zeller and Sharma 1998; Wiebe 2003). Investments in agricultural research and technology transfer have been especially strong drivers of change in cultivated systems, as described later in this section.

Resettlement policies, though now less common and certainly of lesser scale, have had significant impact on the conversion of natural ecosystems over very large areas for cultivation, with consequent, large-scale environmental consequences. The massive transmigration program from Java to the outer islands of Indonesia and the colonization policies of the Brazilian government, implemented largely during the 1960s and 1980s, are two notable examples (Fearnside 1997).

The nature and strength of land tenure and resource use laws and customs have been shown to strongly influence the willingness of farmers to engage in cultivation beyond meeting subsistence needs, as well as to invest in sustainable land management practices (Soulé et al. 2000; Meinzen-Dick et al. 2002). Similarly, the effectiveness of collective action can significantly affect the productivity and sustainability of cultivated systems. This is true not only for proper management and utilization of open access and common property resources such as pastures or woodlots, but also where the productivity of individually managed plots and fields would benefit from collective action, such as coordination of agronomic activities so as to pool labor, minimize pest and disease problems, or make the best use of available water resources (Meinzen-Dick et al. 2002).

Inheritance laws and customs are also relevant. The practice of dividing land among heirs, particularly common in Asia, has so fragmented holdings in some areas that the scale of cultivation operations limits their economic viability over the long term (Maxwell and Wiebe 1999).

In recognition of the potential environmental costs of cultivation, the growing demand for improved environmental services, and the lack of incentives for farmers to consider externalities, governments have played an increasing role in influencing crop selection and cultivation practices through both regulatory and voluntary incentive schemes. Regulatory policies have included systems of wildlife and watershed protection and conservation that have sought to exclude or restrict cultivation in areas considered to have high biodiversity, hydrological, watershed protection, or amenity value. Where cultivation pre-existed in such areas, or where land and population pressure external to such areas has been high, these policies have often created conflict with farming communities (Gillingham and Lee 2003; Maikhuri et al. 2000). This has led to the emergence of more enlightened and participatory approaches to the design and management of conservation areas in partnership with local communities (Farrington and Boyd 1997).

Other approaches have included the zoning and regulation of certain types of cultivation or cultivation practices, such as large-scale confined livestock feeding operations, that present local waste and odor problems or use of certain categories of pesticides. While such restrictions are often associated with punitive sanctions, their effectiveness has varied depending on the technical and economic validity of the regulation standards applied, the deterrent value of the sanctions, and the rigor of enforcement (Kleijn et al. 2004).

Voluntary strategies, particularly in richer countries, involve incentive payments to farmers linked to production or conservation practices that are considered to be more environmentally sound (Dobbs and Pretty 2004; Wu et al. 2004). Increasingly these policies are being aligned with the ''boxes'' established under the auspices of the World Trade Organization that govern permitted levels and types of domestic support to agriculture. One goal of the WTO is to ''decouple'' support to farmers from production and price level, as a means of reducing trade distortion (WTO 2004). The U.S. 2002 Farm Bill provides for support to farmers related to programs for resource conservation, wildlife habitats, and wetlands within cultivated systems (National Resources Conservation Service 2002), and similar programs operate in most, if not all, OECD countries. But the WTO provisions that accommodate such programs are still controversial among many developing countries: they see them as an indirect means of providing otherwise restricted or disallowed income support, which places their own farmers at a competitive disadvantage (*The Economist* 2003).

It is difficult to generalize about the net effect that national policies have had on cultivated systems. However, in those countries where policies tend to expand production to levels that would otherwise be uneconomic—such as cotton in the United States, sugar in the European Union, and rice in Japan—it is likely that more land is being kept in production and more agricultural pollution is taking place than would otherwise be the case. Another implication is that, to the extent that such subsidies distort trade, less area is allocated to the cultivation of these crops in competitor countries, such as cotton in West Africa and India, sugar in the Brazil and Australia, and rice in Viet Nam.

As subsidies and other barriers to trade are removed in these and other commodity sectors, adjustments in global patterns of production will take place. The net local and global consequences of such changes on cultivated systems and ecosystems services depends primarily on the relative yield levels (as those determine the harvested area required for a given level of production) and the specific production inputs and practices used in each location, such as the nature, management, and mix of inputs and practices for plant, soil fertility, water, and pest and weed management. These in turn depend on local markets, farmer characteristics, resource conditions, and management choices.

26.3.1.3 Markets

The existence and efficiency of markets, and the extent to which farmers are able to participate in them, provide perhaps the strongest signals shaping cultivation decisions for an ever increasing number of farmers. Even where subsistence goals dominate household production strategies, survey data indicate that households frequently engage in markets to varying degrees. Markets include those for cultivated outputs (main products and by-products), inputs (such as labor, land, seeds, fertilizers, and pesticides) and those, often at a nascent stage, for ecosystem-related services such as carbon sequestration and habitat conservation.

Essential ingredients for the development of markets include a stable monetary system, accepted procedures for establishing and enforcing contracts, viable entry costs for market participation, financially acceptable search and transaction costs, and adequate access to physical infrastructure and transportation. As described earlier, incentives for market development and participation have also been shaped by policy factors that directly affect markets through transfers (taxes or subsidies) or other barriers related to production, consumption, or trade.

High transaction and transport costs limit market opportunities since they increase the farmgate cost of inputs and reduce the farmgate value of outputs. The geographic scope of market potential is also influenced by the bulk density and perishability of cultivated products and by the unit value of the product itself. Where markets function effectively, where products can be cultivated competitively, and where demand exists, the geographic distances between production and consumption can be very large, as seen in the global cereal markets. Other examples include the cultivation of high-value horticultural crops, of flowers and ornamentals in the cool tropical highlands of Central and northern South America for the U.S. market and in Kenya and Uganda for UK supermarkets, of out-grower schemes in Indonesia for the Dutch flower industry—all of which use air transportation—as well as the production, packaging, and shipping of fresh fruit and vegetables in California to all parts of the United States by rail and road transportation.

Thus, where it has been possible to lower marketing and transportation costs, the geographic distances between production and consumption becomes less relevant, and producers, and the cultivation systems they manage, are exposed to an increasingly broad range of market opportunities. This is often a double-edged sword—on the one hand, providing increased incentives to expand or intensify production with possible negative ecosystems consequences, while on the other hand providing greater incentives to preserve the long-term sustainability of the production base that might foster more positive outcomes for ecosystem management (Lopez 1998; Kaimowitz and Angelsen 2000).

But there remain significant obstacles for smallholders in developing countries to engage more in local, regional, and international markets. Many relate to constraints to market entry through insufficient access to credit or information about market needs and to the insufficiency and variability of the quantity and quality of farm outputs to engage in stable marketing arrangements. At the same time, there appear to be growing barriers to trade arising from stricter sanitary and phytosanitary standards being imposed by importing countries. While fears of pest, virus, and disease consequences for plant, animal, and human health are undoubtedly genuine and call for effective safeguards, these regulations have become another contentious issue under the WTO. As with subsidies and environmental payments, many developing countries regard the sanitary and phytosanitary requirements and regulations imposed by richer countries as another mechanism for imposing indirect trade barriers (Henson and Loader 1999; Athukorala and Jayasuriya 2003).

There are several market niches that link cultivated products with what are considered to be improved standards of cultivation with regard to ecosystem outcomes or ethical issues. These are products designated as, for example, organic, bird-friendly, shade-grown, fair-trade, and humane from an animal welfare perspective (Harper and Makatouni 2002; Lockie et al. 2002). The organic food movement is perhaps most developed in Europe, but it can probably be considered a global scale phenomenon, especially with richer consumers.

The term ''organic'' is open to many different interpretations but can include avoiding or minimizing the use of pesticides, inorganic fertilizers, antibiotics, GMOs, fossil fuels, and so on as well as promoting biodiversity at various levels. Broadly accepted standards are beginning to emerge in some markets (Guthman 1998; European Union 2000; USDA 2004), as well as widely-accepted market certification procedures, such as those of the UK's Soil Association (2004). Currently, almost 23 million hectares globally are reportedly explicitly managed according to organic principles (IFOAM 2004). Of this total, some 46% are reported in Australia/Oceania, 23% in Europe, and 21% in Latin America. While the United Kingdom and Germany have about 4% of cultivated land under organic production, the United States has less than half a percent, although these systems contribute some 3–5% of fruit and vegetable production (Greene and Kremen 2003).

26.3.1.4 Prices

The ability of farmers to respond to changes in prices of inputs and products is an important indicator of the resilience of food production systems. Producer decisions about what and how much to produce (or to harvest, in the case of wild fisheries) are strongly influenced by the relative prices of outputs (maize versus beans, for instance, or cod versus plaice), as well as of essential inputs (such as the maize/nitrogen fertilizer price ratios). Consideration of time frames and the need to maximize return on fixed assets are important determinants of the willingness and ability of producers to respond to price signals.

Output responses are quicker and stronger for short-term production cycles than for longer ones. Thus adjustments in annual cropping can be made in a short time frame, whereas decisions about changing animal herds or perennial crops that take longer to develop their economic potential are more complex. The average price of food has been on a downward trend for some 40 years, and many poor smallholders who have limited access to productivity-raising technologies and practices often face situations in which their on-farm costs per unit of product, plus the unit costs of transportation and marketing, are higher than the market price of their products. In the case of marine fisheries, prices have increased, reflecting the scarcity as more and more fisheries are fully exploited, as well as increased costs because of increased fishing effort.

Increased farmgate prices—for example, for higher-quality or better-timed products or brought about by temporary shortfall in supply—can raise producer incomes and increase incentives for more investment in the underlying production system. This could have positive or negative outcomes for ecosystem services other than food, depending on the type of investment. Furthermore, increased profits from increased productivity might be a spur to bring more land into production, including more conversion of natural ecosystems (Kaimowitz and Angelsen 2000). Ironically, falling prices can also have equally ambiguous outcomes, ranging from providing incentives to raise productivity to removing incentives to make any further investments—likely with negative ecosystem impacts.

26.3.1.5 Technology and Information

One of the most widely researched areas in the field of agriculture is the impact of technical change on the productivity of cultivated systems. Assessments at programmatic and national scales typically suggest that the contribution of technical change to overall productivity growth is in the range of 30% to 50% (Evenson and Gollin 2003; Ruttan 2002; Roe and Gopinath 2001). Technologies include better-quality inputs such as improved crop varieties with higher genetic potential and increased pest and disease resistance, improved livestock breeds and fish species, better cultivation techniques such as zero tillage, improved agronomic practices such as the timing and placement of applied nutrients and water, and better storage and other post-harvest technologies. In countries where a sufficiently large base of commercial farmers exist, the private sector plays an important role in technology development and delivery, but in virtually all countries public investment in agricultural research and extension are important and well established if not always adequately funded areas of public policy (Pardey and Beintema 2001). These investments reflect both the importance of the agricultural sector to the rural economy and the generally high levels of economic payoff to agricultural R&D investments.

During the past 50 years, crop genetic improvement and improved technologies for managing soil nutrients and pests have come predominantly from investment in research and extension conducted by public-sector institutions such as universities and national and international agricultural research centers (Pardey and Beintema 2001). In recent decades, however, investment in private-sector research has increased markedly, especially for improvement of commercial crops such as maize, soybean, and cotton that require purchase of new seeds each cropping season for achieving optimal yields.

Today, agricultural research investment in the private sector exceeds that in the public sector, with consequences on research priorities (Pardey and Beintema 2001). The private sector focuses on improving crop traits that result in greater seed sales, emphasizing relatively short-term research successes. Private-sector research has also given greater emphasis to use of modern tools of molecular genetics to develop crop varieties with traits controlled by single genes. (See Box 26.3.) Many of the major crop development constraints, such as yield potential, drought tolerance, and nitrogen use efficiency, however, are controlled by numerous genes, and progress will require greater scientific effort and longer-term investment. The private sector has few incentives at present to invest in technologies aimed at improving environmental services.

The focus of public investment is on research producing "public goods" (knowledge and technologies that can be used by all, without exclusion, such as a new soil conservation practice), as well as research that is too long-term, risky, or otherwise financially unattractive to the private sector but that would yield social benefits, such as more environmentally sustainable production practices. In the past, publicly-funded research has focused on understanding and increasing crop yield potential, achieving greater fertilizer use efficiency, protection of water and soil quality using conservation tillage systems, and reducing pesticide use through integrated pest management.

BOX 26.3

Crop Breeding and Genetics

Plant types and agricultural techniques that are better suited to farmers' needs could go a long way toward improving the productivity of cultivated systems and thus the livelihoods of farmers. Genetically modified crops provide economic gains to farmers that have shown to be large in the case of cotton and soybeans. Extending these gains to other "orphan" crops that are planted by smallholders could, in the presence of appropriate regulatory policies, have significant poverty-reducing effects. Stress-tolerant varieties have the potential to benefit producers; nutritionally enriched varieties have the potential to benefit consumers as well.

Many people are concerned about the prospects of biotechnology. Concerns center on the science itself, control over the science, access to the science, environmental effects, and human and animal health effects (FAO 2004a). Addressing these concerns separately and in a case-specific manner is essential for analyzing the costs and benefits of genetic technologies as they are applied to crops.

Studies of economic returns into public-sector agricultural research have documented substantial and consistent returns on investment as a result of higher yields and farm profits, increased labor productivity and prices, and lower prices of staple grains for consumers (Alston et al. 2000). Despite this evidence, recent trends in public funding of research and technology transfer in both industrial and developing countries show general decline at a time when constraints to sustaining yield growth while protecting environmental services are becoming more complex and scientifically challenging. If maintained, this decline will affect agricultural research outputs globally, with serious consequences for the ability of crop productivity growth to keep pace with food demand and for opportunities to improve the environmental characteristics of new technologies.

The overall efficiency of converting research investment into yield gains at the farm level is an important driver of food supply. For example, the total research investment in both public and private sector for maize genetic improvement increased 3.4-fold in inflation-adjusted dollars from the mid-1970s to the mid-1990s in the United States while the rate of gain in U.S. maize yields remained constant at about 100 kilograms per hectare per year during this period (Duvick and Cassman 1999). Therefore, the efficiency of converting investment in maize genetic improvement to greater yields at the farm level has decreased by about 70%.[3] (See Chapters 4 and 8 for further extensive treatment of the role of science and technology.)

A particular area of concern has been the relatively low adoption of many technologies designed to improve soil and water conservation or provide other improvements in ecosystem service delivery from cultivated systems. Many of these technologies—such as use of the nitrogen-fixing azolla plant to replace nitrogen fertilizer in lowland rice production, alley-cropping with leguminous trees on plot borders, use of the tree leaf mulch on subsistence cereal crops in sub-Saharan Africa, and contour bunds and vegetative field border strips to reduce erosion for hillside cropping systems—are often labor-intensive, provide benefits after several years, or provide benefits off-site. These characteristics often make them unattractive to farmers in countries where conservation efforts are not subsidized and in situations of limited assets (including labor) and insecure land tenure (Lutz et al. 1994; Antle and Diagana 2003).

Changes in cultivation systems are driven by access to various types of information: market data on prices, grades, and standards; advances in cultivation practices and technologies (both for farmers and for researchers); current weather conditions and forecasts; and information on current pest and disease threats and recommended responses. Where they are available and accessible to farmers, and farmers have the capacity to use them, all these types of information have economic value (Solow et al. 1998).

26.3.1.6 Farmer Characteristics

Ultimately, it is farmers who make decisions about the nature and management of cultivated systems, decisions that affect the delivery of both cultivated products and ecosystem services. Thus the cultural, socioeconomic, and educational background as well as the expectations, preferences, and risk attitudes of farmers and farm households all play a role in shaping cultivation decisions.

In the case of subsistence, resource-poor farmers, it is the reduction of production risks while best using family labor that is the driving force behind decision-making (Willock et al. 1999). There may also be different attitudes to risk, crop management, and even crop selection and cropping patterns on the landscape among men and women farmers. In general, women-headed households focus more on meeting food self-sufficiency needs using a diverse portfolio of products to meet a range of nutritional and domestic needs. Male-headed households have generally been shown to be less risk-averse and often focus on the production of cash crops. Farmer age and education level are also considered to be important factors in conditioning willingness to accept new ideas and technologies (Soulé et al. 2000).

Often farmers and farming communities have a very large amount of accumulated indigenous and science-based knowledge, but experience and new knowledge continue to evolve. Indeed, it is the interplay between indigenous knowledge, access to new technologies, and risk aversion that are major determinants of decisions about cultivation practices and evolution of farming systems. Considerable effort is being made to improve understanding of this process (e.g., Röling and Wagemakers 1998) and to advance it through better designed interactions between farmers, researchers, and technology support specialists (Loevinsohn et al. 2002).

26.3.2 Direct Drivers

Direct drivers are those that manifest themselves at the point of cultivation. As shown earlier in Figure 26.7, we can broadly identify three types of direct drivers:

- management choices made at plot, field, pen, or pond level about the scale of cultivation and what to cultivate and how;
- the production system itself—its specific mix of inputs including labor, production practices, and outputs in terms of cultivated products as well as other residues; and
- the natural resource base (including the local impacts of climate change) that underpins and is affected by the cultivation process.

26.3.2.1 Management Choices

To a large extent the potential productivity and ecosystem service impacts of a cultivated system are pre-determined by the crop and resource management choices farmers make, which are often extremely constrained in the case of poor farmers. Key drivers involve strategic decisions about which crops to produce and the cropping pattern in time and space, how much area to devote to cropping, and tactical decisions about specific production practices involving crop and soil management involving nutrients, water, and pest control.

In the face of growing demand for cultivated outputs, several key factors are involved in these choices from an ecosystem service perspective. First, the choice about what to produce often has direct implications on services. For example, perennial crops reduce cultivation needs and are often associated with more ground cover and less soil disturbance, which may result in less soil erosion and lower carbon emissions. The more uniform landscapes of annual crops grown in monoculture reduce biodiversity and can increase the risk of erosion on sloping land unless conservation tillage practices are used that leave adequate crop residues to protect the soil surface. Cultivation of high-value cotton and horticultural crops often uses substantial amounts of pesticides to ensure adequate product quality to meet consumer demand, and growing tobacco in some developing countries is frequently associated with high consumption of fuelwood for drying purposes.

A second strategic factor with a large impact on ecosystem services relates to choices about how much area to cultivate, and especially whether to expand production into as yet uncultivated areas—that is whether to transform natural ecosystems or semi-natural rangeland plant communities into cultivated systems. Pressures to expand are larger if land suitable for cultivation is available at low cost and if land currently under cultivation has low or declining productivity.

The third set of choices is related to production technologies and practices, which in turn are strongly linked to strategies adopted for the intensification of production. Intensification can be achieved through increased inputs and outputs (increased yields) per hectare per harvest, or by increasing the number of harvests in a given time (such as reducing fallow periods or sequential cropping within a single growing season). This is generally termed increasing the cropping intensity. Increasing cropping intensity is often the first stage in the transformation from swidden to permanently cultivated systems, and it can be one of the major consequences of irrigation in regions where rainfall is uni-modal and sufficient for only one cropping season per year.

It is the accumulation of such management decisions by many rural households over time that ultimately drives the aggregate extent and condition of cultivated systems and their impact on ecosystem services—both within the agroecosystem in question and in adjacent or even distant ecosystems that are affected by the externalities of cultivation.

Globally, 78% of the increase in crop output between 1961 and 1999 was attributable to yield increases and 22% to expansion of harvested area. Of the expansion in area harvested, roughly two thirds was accounted for by physical expansion of arable land and the remainder was due to increases in cropping intensity (Bruinsma 2003). While the pattern of yield increases outpacing harvested area increases was true for most regions, the proportions varied. For example, only 55% of total output growth was derived from yield increases in Latin American and the Caribbean compared with 80% in South Asia. In contrast, only 34% of increased output was derived from yield increases in sub-Saharan Africa and 66% from harvested area expansion. In industrial countries where the amount of cultivated land has been stable or declining, increased output was derived predominantly through increased yield and cropping intensities.

In both physical land area and proportional terms, the largest expansion of arable land took place in Latin America and the Caribbean, where expansion of the agricultural frontier accounted for about half of the increase in crop output, with cropping intensities static (Bruinsma 2003). For, example soybean production expanded by some 25 million hectares in Brazil and Argentina between 1981 and 2004, largely through expansion of arable land (Fearnside 2001; James 2004). And conversion of forest and savanna to agropastoral systems was widespread throughout South and Central America. By contrast, of the 66% of increased crop output that was due to increased harvested area in sub-Saharan Africa, about half was attributed to increase in cropping intensity and the rest to increased cultivated area.

Some of the factors that drove these trends have been described earlier: the Green Revolution in Asia; resettlement policies in Brazil; environmental conservation programs in Europe, North America, and Oceania; and so on. But a key underpinning factor in all these cases is the difference in relative endowment or scarcity of land, labor, and capital in the various regions. These endowments have, for example, shaped national technology generation strategies, such as investment in land-saving R&D in Asia and labor-saving R&D in North America (Hayami and Ruttan 1985). At the farm level, area expansion has been pursued in regions of relative land abundance, and intensification has been the preferred strategy where land or labor are scarce and capital more abundant.

Figure 26.8 illustrates the distinct levels and trends in land productivity (total value of crop and livestock outputs per unit of arable land) and labor productivity (total value of crop and livestock output per agricultural worker) from 1961 to 2001 for different regions. Western Europe, with extreme land constraints, shows high land and improving labor productivity. The United States, with high capital and limited labor, has shown high and increasing land and labor productivity. Asia, with little additional land and abundant labor, has shown high and increasing land productivity but low labor productivity. Sub-Saharan Africa remains low in both dimensions, and while some limited progress has been made in land productivity (but by 2001, only reaching levels that are still below or equal to the starting point of all other regions in 1961), virtually no gains have been made in labor productivity.

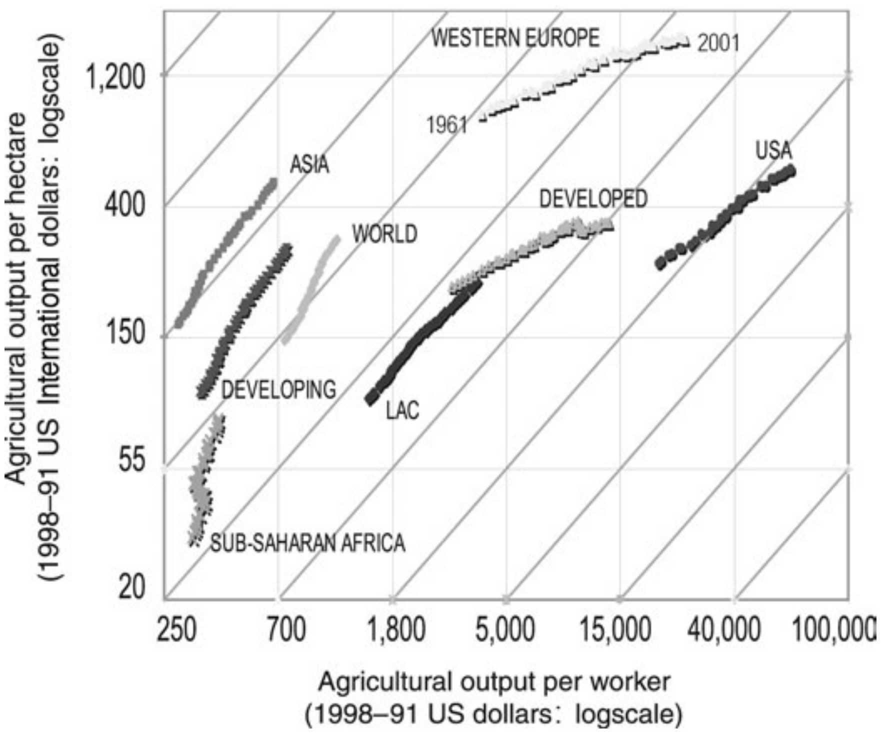

Figure 26.8. Growth in Land and Labor Productivity by Region, 1961–2001. The graph is derived from an assessment of crops and livestock only. Output values were computed for individual commodities using the FAOSTAT production time series and average world prices estimated by FAO for the period 1989–91 (FAO 1997). "Land" is the sum of arable and permanent cropland and pasture in each year. "Labor" is the population economically active in agriculture: as defined by FAO. The diagonal lines represent pathways of equal growth in land and labor productivity.

26.3.2.2 Natural Resource Conditions and Production Systems

Natural resource conditions are described briefly here because the impact of production processes, ecosystem services, and cultivated system management that influence natural resources have been covered in greater detail elsewhere in the chapter. Furthermore, many production system practices represent direct responses to changes in natural resource conditions described in previous sections (declining soil productivity, for example).

The range of feasible cultivation options open to farmers is fashioned by a number of indirect drivers: input and output markets, the regulatory environment, accessibility of usable and profitable technologies and information, the cultural context and socioeconomic condition of the farm household, and the farmer's knowledge base, goals, and attitudes to risk. But specific cultivation decisions for each site are made taking into account the set of prevailing local natural resource conditions, particularly the availability of land and water; the type and variability weather conditions; the quality of soil and water; the prevalence of pests, diseases, and weeds; and other potential natural hazards such as erosion and flooding. Key among these factors for crop-based systems are the availability of land suitable for cultivation and the depth, water-holding capacity, fertility, and workability of soils. The quality and reliability of water are important for all forms of cultivation but are most critical for irrigated systems. Rain-fed systems are subject to the usual uncertainties of weather, exacerbated by the impacts of climate change—increasing temperatures, shifting rainfall patterns, and greater variability in seasonal rainfall.

As a result of the high degree of heterogeneity of natural resource endowments and climatic variability over relatively short distances, it is difficult to make uniform management recommendations for production technologies or practices at scales above the field level. For example, recent results from on-farm tests in intensive irrigated rice systems of South and Southeast Asia confirm the benefits of taking a "field-specific" approach for nutrient management to optimize yield, fertilizer efficiency, and profit (Cassman et al. 1996; Dobermann et al. 2002). Such specificity highlights the challenge of developing and scaling up the adoption of new technologies from field to district/county and to regional scales, and the magnitude of this challenge increases in proportion to the complexity and sophistication of crop and soil management practices. In less favorable production environments where natural resource endowments are relatively poor and there is little infrastructure or market development, it is particularly difficult to support farmer adoption of new technologies. Such is the case in sub-Saharan Africa, where not only are production conditions extremely heterogenous but public and private institutions that support technology generation and transfer are often quite weak.

Some drivers related to natural resource condition are unpredictable and largely uncontrollable, such as weather variability, climate change, and the emergence of new pests and diseases, and can at best only be managed once they occur. Others include on-site conditions that both affect and are affected by production, such as soil nutrient dynamics, soil water status, erosion, and weeds. These are mostly controllable conditions if farmers have sufficient resources, access to information, and technologies that provide profitable solutions to address these constraints.

26.3.3 Summary of Drivers as Potential Points of Intervention

The drivers affecting the evolution of cultivated systems and their capacity to produce cultivated outputs and services are many and are interrelated. It is tempting to simplify the complexity of these direct and indirect drivers and focus only on the field-level issues that affect provision of food and environmental services. That would be, and indeed has been, a mistaken approach. The literature of technology adoption examined in this assessment is, despite the many significant successes, replete with examples of failed "fixes" at the farm level in broader contexts where income levels, security, property rights, equity, financial and agricultural markets, health, education systems, and so on were inadequate to provide the proper enabling environment and incentives for farmers to make the type of productive, long-term investments that are required to deliver economic and environmental benefits in a sustainable fashion.

Regardless of the productivity and profitability of cultivated systems from a farmer perspective, the central MA concerns of how best to deal with the externalities of cultivation remain a major challenge in all cultivated systems. As described earlier, many of the impacts of cultivation on ecosystem services occur away from the farm, outside the agroecosystem boundaries, which provides little or no incentive to farmers to invest in reducing them. Likewise, consumers are increasingly demanding affordable and safe food, which means continued increase in cultivated yields and product quality at the same time as addressing concerns about negative impact on environmental quality.

Our assessment documents that a number of approaches have been used to address these concerns: the development of productive, environment-friendly, profitable ("win-win-win") technologies or practices, the regulation of farming practices on a statutory or voluntary basis (such as effluent standards and penalties versus watershed stakeholder institutions), and, more recently, payments designed to promote improved environmental outcomes. Continued experimentation with, improvements in, and integration of such strategies, involving several indirect drivers listed in Figure 26.7, will be central to progress from both a food security and environmental sustainability perspective.

26.4 Trade-offs, Synergies, and Interventions in Cultivated Systems

The preceding sections examined the condition and trends of ecosystem services and the major driving forces that shape them, highlighting how it is the response of farmers to these trends and pressures, using means that best match their opportunities and constraints, that largely determines the various outcomes of cultivation. This section summarizes some of the trade-offs that have been faced in balancing between food provision and other ecosystem services and briefly reviews a number of approaches and interventions that appear to reduce such trade-offs: integrated pest management; integrated agriculture-aquaculture; farm-scale options for mitigating carbon emissions, increasing carbon sequestration, and minimizing soil erosion; and agroforestry. Such approaches have shown results both in farmers' fields and in reducing off-site effects, but they are often very knowledge-intensive, require additional land or labor, and take time to yield benefits—all factors that can limit broader adoption unless more cost-effective interventions can be developed or non-distorting incentives can be provided.

26.4.1 Trade-offs

The world's cultivated systems embody a diverse array of biophysical constraints and production strategies. The specific quantity and mix of outputs generated by each system, including the supply of ecosystem services in both the short and the long term, is a consequence of the interaction among natural and managed processes, including the use of external inputs (chemical, physical, mechanical, or biological). The extent to which specific management interventions result in trade-offs or in synergies among system outputs (such as the impact of increased food output efficiency on water and nutrient cycling and biological diversity) is often both system- and location-specific.

Some clear trade-offs have been observed in the evolution of the world's dominant cultivation systems. For example, most flat, well-watered, fertile areas have increasingly been managed to simplify ecosystem function and to specialize in the efficiency of food production. Sustaining the high levels of food output such systems provide has generally and significantly reduced the supply of other ecosystem services from cultivated areas. High food-yielding cultivated systems have often required substantial externally derived inputs to sustain yield levels, such as additional reserves of water and nutrients, as well as the use of herbicides, insecticides, fungicides, and external energy sources.

The integration of cultivated systems into commercial food, feed, and fiber markets has usually provided the knowledge, incentives, and financial resources to maintain and often increase their already high food production capacity. However, the impact of intensive cultivation on the provision of ecosystem services both within and beyond the extent of cultivation has been equally substantial, resulting in the depletion of natural and human-made water reservoirs, water pollution, the disruption of global nutrient (particularly nitrogen) cycles, increased carbon- and nitrogen-based gas emissions, and an accelerated loss of terrestrial and aquatic biodiversity (Merrington et al. 2002). The global extent of farming and the specific trade-offs it entails imply that agriculture is the single largest threat to biodiversity and ecosystem function of any single human activity (Clay 2004).

While the evolution of the world's other dominant crop-based cultivation systems, low-input, smallholder rain-fed systems, has been markedly different, they too have increasingly been faced with significant trade-offs in the provision of ecosystem services. In general, low-input systems consume less energy and emit fewer pollutants. They also tend to accommodate higher levels of agricultural biodiversity with regard to more diverse crop mixtures and crop varieties.

Within many of these systems, increasing the provision of food would have a significant positive effect on human well-being, especially in cases where they support poor rural populations in areas with underdeveloped markets and where a lack of purchasing power prevents farmers from importing food from more-productive systems. Increases in food provision in low-input systems are likely to come from land-clearing and expansion, however, which reduces the services provided by pre-existing forest or grassland systems. (See Box 26.4.) Intensification in such low-input systems sometimes has within-system sustainability trade-offs—reduced soil fertility due to nutrient depletion when fertilizer inputs are underutilized or not available.

26.4.2 Integrated Pest Management

The goal of integrated pest management is to achieve economical protection from pest damage while minimizing hazards to crops, human health, and the environment (Kogan 1998; Bajwa and Kogan 2002). IPM takes advantage of existing ecosystem dynamics or sometimes involves the introduction of new, competing organisms to control pests.

Successful IPM practices achieve multiple goals at once, but careful monitoring and high levels of technical expertise are necessary. IPM farmers must choose from a wide array of options: cultural, biological, chemical, physical, mechanical, and genetic techniques. They must also have detailed understanding of numerous key factors:

- cropping histories (variety, seeding date, fertilization, seed treatment, tillage system); the timing and date of any pest control methods; environmental conditions before, during, and after treatment; past, present, and future plans for cropping; pesticide use history; and yield results;
- pest information, such as pest identity, growth conditions, development, reproduction and spreading modes, damage symptoms, and natural enemies; and
- field scouting, which involves systematic sampling of pest populations.

Only by understanding the ecology and economics of their cultivated systems can farmers make informed choices about appropriate levels of pesticide use (Kenmore 1996).

Following the Green Revolution, IPM scored several striking successes, notably in Indonesia, where the introduction of simple methods allowed farmers to halve the money they spent on pesticides (Orr and Ritchie 2004). Attempts to generate such successes in Africa have been mixed. In the 1970s, mealybug infestations caused crop losses of up to 80% in African cassava plants; today, cassava mealybug damage is minimal thanks to the introduction of a parasitic wasp predator that maintains mealybug populations at a low level. This biological control method was free to farmers and environmentally benign (Herren and Neuenschwander 1991). Results were more limited elsewhere. In Malawi, for example, the major field pests of maize, beans, pigeon pea, and sweet potato were targeted using 18 different IPM strategies, but site variability, risk of reduced profitability, and overly complicated trials were all obstacles to adoption.

IPM has also had some success in industrial countries. In 1993, the U.S. government set a goal of having 75% of U.S. agriculture managed under IPM programs by 2000 (Fernandez-Cornejo and Jans 1999). While IPM has significant potential, however, that potential has yet to be fully realized. Despite extensive research into IPM programs, implementation is lagging (Sorensen 1993; Steffey 1995; Hutchins 1995). Many examples of cost-effective IPM trials exist, but in practice economic and institutional incentives are often not sufficient to encourage farmers to take on the risk of switching to integrated pest management (Sorby et al. 2003).

26.4.3 Integrated Agriculture-Aquaculture

Many freshwater species can adapt to an integrated farming system, where the wastes produced by one species are used by another species cultured in the system. IAA allows farmers to optimize resource flows and increase productivity by recycling nutrients between the various components of the system. In general, livestock manure is used as fertilizer for a crop species, the residues of which are fed to herbivorous fish. Fish excreta and other components of the pond humus are then recycled as manure for crop cultivation.

Such low-waste approaches reduce the discharge of nutrient-charged wastewaters into the environment, thus mitigating eutrophication and lowering net pollution compared with each cultivation component functioning independently. IAA systems also offer greater scope for more-efficient use of perhaps scarce water resources not only within the IAA system and but also by using IAA wastewater for irrigation. This both reuses water and delivers the residual levels of nutrients it contains directly to soil and crops. IAA systems have been developed for fish-duck farming, fish-chicken farming, fish-pig farming, rice-fish farming system in integrated areas, rice-shrimp farming, fish-vegetable farming, or fish-aquaponics farming (Lightfoot 1990).

Pig-grass-fish systems in China are used in both large-scale state-operated farms and in smaller-scale family-operated ones. Excreta from pig production is reused and treated as fertilizer for high-yielding fodder grasses, which serve as the main feed for herbivorous fish. Pig excreta are also applied directly to fish ponds, where it supports the growth of phytophankton—another source of fish feed. Wastes and residues that accumulate at the bottom of the fish ponds are harvested and recycled as manure for grass cultivation, completing the nutrient cycle. Pig-grass-fish systems are more labor-intensive than systems that use purchased feed inputs, and they also require substantial land area to grow the grass; however, their ability to simultaneously capitalize on in situ vitamins and proteins and to minimize waste makes them models of nutrient efficiency (Yang et al. 2001).

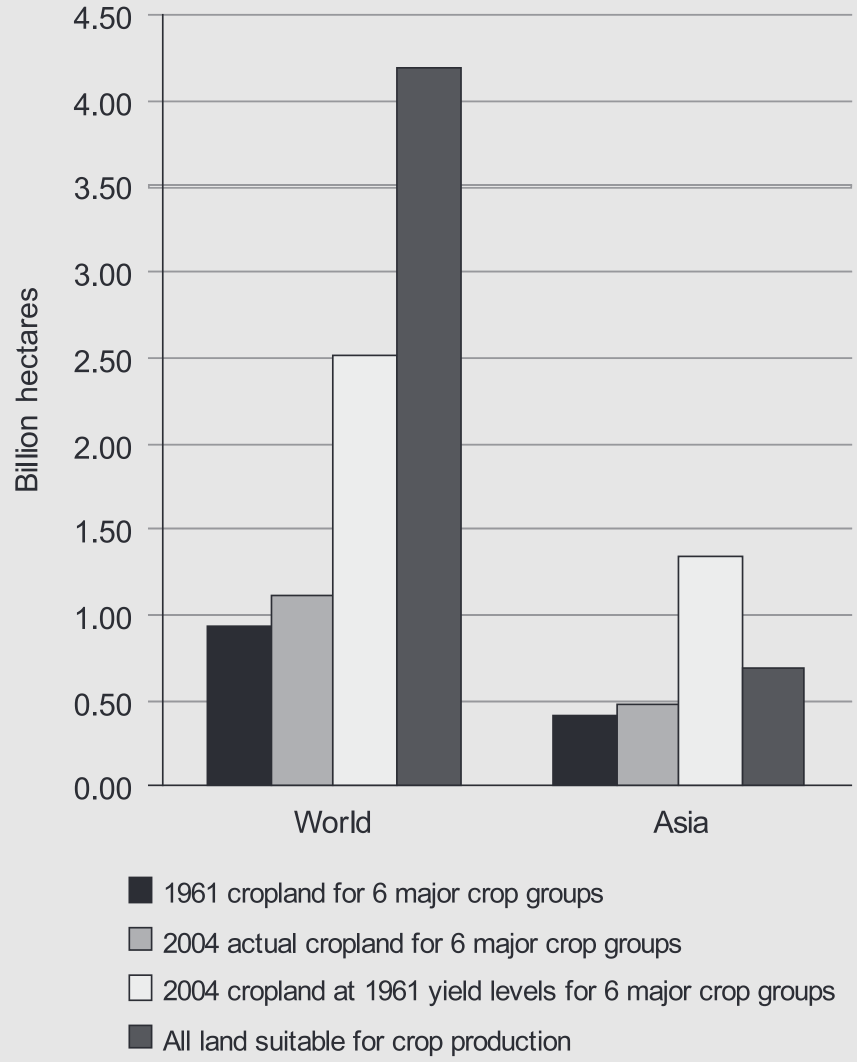
Another example of IAA systems is fish/fruit/vegetable cultivation in India, in which pond embankments are planted with fruit and vegetable crops. This provides several benefits: pond mud can be used as crop fertilizer, thus decreasing the cost of organic manures; pond water can be used to irrigate crops; fruit and vegetable residues can be used as low-cost fish feed; and plants

BOX 26.4

Aggregate Impacts of Trade-offs in Cultivated Systems: Land Use Perspective

At a regional or global scale, one measure of trade-off is the amount of land that needs to be brought into production according to different levels of food productivity. The "land-sparing" impact of modern farming practices has largely been achieved through yield increases brought about by the use of crop monocultures with improved crop varieties, fertilizer inputs, and irrigation where farmers have access to supplemental water. For example, if yields of the six major crop groups that are cultivated on 80% of the total cultivated land area had remained at yield levels farmers achieved in 1961, it would require an additional 1.4 billion hectares of land to meet global food demand in 2004. (See Figure.) This represents 34% of total land area suitable for crop cultivation and would have required conversion of large areas of uncultivated land that currently support rain forests, grassland savannas, and wetlands. In Asia alone, it would require an additional 600 million hectares, which represents 25% more land area than is suitable for cultivation on this continent. Asia would have had to be heavily dependent on food imports if crop yields had remained at 1961 yield levels.

The key ecological question is therefore whether environmental services other than food production at regional and global scales would be enhanced by focusing food production on less land under intensive management with high yields versus expanding cultivated area in lower-yielding systems that use farming practices that seek to preserve environmental services at the field and local levels. Few studies have addressed this issue using sound, ecological analytical methods. One recent study found that farming is already the greatest extinction threat to birds and evaluated the impact of land-sparing high-yield systems with "wildlife-friendly" farming practices on bird species persistence using ecological models (Green et al. 2005). The results suggest that high-yield farming may allow more bird species from a range of taxa to persist in developing countries. More such studies with other threatened fauna and flora species are needed to answer this critical question.



Land Used to Produce Major Crops in 1961 and 2004 and Land That Would be Needed to Produce Them in 2004 at 1961 Yield Levels. The six major crop groups included in this analysis are cereals, oil crops, pulses, root and tuber crops, sugar crops, and fiber crops. They accounted for 87% of all cropland in 1961 and 80% in 2004.

growing on the embankment strengthen the dikes (Tripathi and Sharma 2001).

26.4.4 Options for Mitigating Carbon Emissions and Increasing Carbon Sequestration

Several actions taken by farmers reduce overall greenhouse gas emissions. Those with the greatest potential for reducing emissions include increasing crop yields and return of crop residues; increasing the efficiency with which energy-requiring inputs (such as fertilizers and irrigation) are used; reducing or eliminating tillage operations; modifying crop rotations that include grass pastures and legumes; and increasing renewable energy production from biomass that either substitutes for consumption of fossil fuels (such as ethanol) or replaces the inefficient burning of fuelwood or crop residues and so avoids carbon emissions (Wassmann and Vlek 2004; Lal 2002; Antle et al. 2001). When considering biofuels as substitutes for fossil fuels, the greenhouse gas emissions associated with production and transport must also be taken into account to determine the net effect on greenhouse warming potential of the system.

It is notable that higher yields and input use efficiency result from farmer adoption of the best available crop and soil management technologies, and they contribute to increased profits. Reducing tillage improves yields and profits in rain-fed systems that are often limited by drought. The viability of modified rotations and bio-energy production systems depends on a number of economic factors that are often beyond the control of farmers and typically do not favor adoption.

In addition to the actions just described, there are a wide range of mechanisms and measures for increasing carbon sinks in agriculture. (See Box 26.5.) However, there is considerable scientific uncertainty over the magnitudes and permanence of carbon sinks and emissions in cultivated systems. In addition, the economic potential for sequestration is considerably less than the technical potential, since sequestration practices are often costly (Lewandrowski et al. 2004).

26.4.5 Strategies for Minimizing Soil Erosion

Accelerated erosion has numerous adverse ecological and economic impacts to both ecosystems that are sources of erosion and those that receive sediments and sediment-borne contaminant (Lowdermilk 1953; Olson 1981; Oldeman 1998; Scherr 1999; Lal 2001). The on-site ecological impacts lead to disruption in cycles of water, carbon, nitrogen, phosphorus, sulfur, and other elements; a reduction in effective rooting depth; and a decline in soil quality. The on-site economic impacts are associated with reduction in agronomic productivity, which may be caused by reversible productivity effects due to loss of soil fertility, and re-

BOX 26.5

Approaches to Increasing Carbon Storage and Reducing Greenhouse Gas Emissions (Pretty et al. 2002)

Increase carbon sinks in soil organic matter and aboveground biomass.

- Replace inversion ploughing with conservation- and zero-tillage systems.
- Adopt mixed rotations with cover crops and green manures to increase biomass additions to soil.
- Adopt agroforestry in cropping systems to increase aboveground standing biomass.
- Minimize summer fallows and periods with no ground cover to maintain soil organic matter stocks.
- Use soil conservation measures to avoid soil erosion and loss of soil organic matter.
- Apply composts and manures to increase soil organic matter stocks, including crop residue recycling.
- Improve pasture/rangelands through grazing, vegetation, and fire management both to reduce degradation and increase soil organic matter.
- Cultivate perennial grasses (60–80% of biomass belowground) rather than annuals (20% belowground).
- Restore and protect agricultural wetlands.
- Convert marginal agricultural land to woodlands to increase standing biomass of carbon.

Reduce direct and indirect energy use to avoid greenhouse gas emissions (carbon dioxide, methane, and nitrous oxide).

- Conserve fuel and reduce machinery use to avoid fossil fuel consumption.
- Use conservation or zero-tillage to reduce carbon emissions from soils.
- Adopt grass-based grazing systems to reduce methane emissions from ruminant livestock.
- Use composting to reduce manure methane emissions.
- Substitute biofuels for fossil fuels.
- Increase N fertilizer use efficiency (as manufacture of N fertilizer is highly energy-intensive).
- Use integrated pest management to reduce pesticide use (avoid indirect energy consumption).

Increase biomass-based renewable energy production to avoid carbon emissions.

- Cultivate annual crops for biofuel production, such as ethanol from maize and sugarcane.
- Cultivate annual and perennial crops, such as grasses and coppiced trees, for combustion and electricity generation, with crops replanted each cycle for continued energy production.
- Use biogas digesters to produce methane, substituting for fossil fuel sources.
- Use improved cookstoves to increase efficiency of biomass fuels.

duction in soil organic matter and attendant water-holding capacity, versus more permanent, sometimes irreversible adverse impact on soil quality such as reduction in effective rooting depth with an accompanying decline in available water and nutrient retention capacities. While the reversible effects may be mitigated by use of additional inputs (such as fertilizers, organic amendments, and supplemental irrigation), the more permanent changes to soil quality that reduce productivity cannot be easily or economically alleviated.

Estimates of the global impact of erosion on agricultural productivity vary widely because of differences in methodology. Estimates of potential yield losses in the absence of farmers' decisions are greater than estimates that account for farmers' incentives to mitigate the impacts of erosion. In the absence of farmer interventions, erosion would cost the world $523 million per annum in lost agricultural productivity (Den Biggelaar et al. 2004), or 0.3% of agricultural production per year, averaged across crops, soils, and regions. Other estimates are larger: Crosson (1995) calculated the on-farm economic costs of soil erosion on a global level at about 5% of agricultural production. Oldeman (1998) calculated the global productivity loss during the post World War II period at about 13% for cropland and 4% for pastures. Off-site damages to navigation, reservoirs, fishing, and water treatment, industrial, and municipal water facilities was estimated at $2–8 billion per year in the United States (Ribaudo 1997).

Economic analysis by Hopkins et al. (2003) finds that actual losses (when farmers respond to land degradation to maximize net returns over the long term) average 0.1% per year in the north-central United States. Global impacts of erosion are expected to similarly be less as farmers anticipate and respond to land degradation.

A number of effective soil and crop/vegetation management systems have been developed to minimize soil erosion. They include conservation tillage along with use of crop residue mulch and incorporation of cover crops in the rotation cycle on cropland; controlled grazing with appropriate stocking rates and use of improved pasture species on grazing lands; and adoption of methods of timber harvesting and logging operations that cause the least amount of soil disturbance (shear blade, tree extractors) on forestland (Lal 1998, 2001).

Planting choices have a significant impact. Frequent use of cover crops in the rotation cycle, integrated nutrient management, reduced pesticide use (through use of IPM, for instance), and use of agroforestry are important to soil and water conservation. Cover crops can limit erosion and prevent the accumulation of hazardous biogeochemical compounds, such as phenolic acids, that inhibit plant growth (Ryszowski et al. 1998). These ecological measures of minimizing risks of soil erosion may be supplemented by the installation of physical conservation structures, such as terraces and grass waterways, that reduce and direct runoff along with slope stabilization structures (Lal 1991).

Erosion control is enhanced by the adoption of management regimes that reinforce natural ecological cycles and processes in crop and rangeland systems. Soil erosion can be greatly reduced if there are minimal disruptions to water and nutrient cycles and when soil fertility and physical properties are not degraded. In cultivated systems where soils are prone to erosion, development of soil-specific farming systems and use of appropriate management practices are essential components of erosion control, as is the improvement of soil structure and enhancing biotic activity of soil fauna and flora (earthworms, termites, and so on).

26.4.6 Agroforestry

Agroforestry involves the integration of trees into farming systems in ways that create an agroecosystem succession, akin to that in natural systems (Leakey 1996). Biodiversity increases with each stage in the development of this succession (Leakey 1999). Agroforestry systems take many forms—short-term improved fallows with leguminous shrubs, medicinal, or other products in low-input tropical systems of the Amazon basin; enriched forest fallows in Southeast Asia; intensive cash crop agroforestry systems with indigenous fruits and nuts in cocoa and coffee in West Africa; and contour strips in high-input maize/soybean systems in North America that mitigate erosion and runoff. The specific benefits of agroforestry vary by system but have included more profitable and nutritious food production, biodiversity conservation, improved soil resources, improved water quality, and carbon sequestration. Agroforestry systems have shown the ability to achieve multiple goals simultaneously, thus reducing the ecosystem service trade-offs inherent in crop production (Leakey 2001; Sanchez 1995, 2002).

Agroforestry systems have been shown to increase farmer incomes in sloped areas of Nepal (Neupane and Thapa 2001), in nutrient-poor farmlands of Africa (Sanchez 2002), and in Thailand (Wannawong et al. 1991), Cameroon (Palm et al. 2004), and Indonesia (Palm et al. 2004). Indigenous tree species are increasingly being domesticated to produce improved agroforestry tree products for local and regional food and medicinal markets. These improved species have been shown to generate household income, diversify production and the local economy, provide environmental services such as the mitigation of soil erosion, enhance carbon sequestration and biodiversity, and improve agroecosystem processes, like nutrient and water cycling. These multiple attributes of agroforestry are particularly valuable to subsistence-based livelihoods and simultaneously enhance the sustainability of crop production.

In the Philippines, the primary agroforestry practice is contour hedgerows, in which food crops are planted between hedges of woody perennials established along the contours of upland sloping farm plots. Prunings from the hedgerow trees or shrubs are placed at the up-slope base of the hedges to trap eroding soil so that, over time, natural terraces are formed (Pattanayak and Mercer 2002). Such hedgerows can improve soil conservation by 15–20% for a typical small farmer (Pattanayak and Mercer 2002). In addition to erosion control, biophysical effects of contour hedgerows on soil include maintenance or increase of organic matter and diversity, nitrogen fixation, enhancement of physical properties such as soil structure, porosity, and moisture retention, and enhanced efficiency of nutrient use (Nair 1993).

Besides agroforestry systems that combine trees with annual crops, there are those that combine trees with animals. Silvopastoral systems (defined as the integration of trees and pasture) are the most common form of agroforestry in the southern United States (Zinkhan and Mercer 1997). Silvopastoral systems are increasingly important in the developing world, especially in areas where perennial crops such as coconuts, oil palm, rubber, and fruit trees are found. In Southeast Asia, the integration of oil palm plantations with cattle and goats resulted in increased production of 3.52 tons of fresh fruit bunches per hectare, equivalent to 0.7 tons of palm oil per hectare. In Central America, most livestock farms include some silvopastoral systems that improve economic returns through diversification and the timing of cash flows (Henderson 1991).

Despite the potential benefits of agroforestry techniques, adoption has been relatively limited. Impediments fall into five categories: economic incentives, biophysical conditions, risk and uncertainty, household preferences, and resource endowments (Pattanayak et al. 2003). Additional research is required to domesticate novel tree species (and other crops) that can further enhance agroforestry systems. Identifying and domesticating such species could, for example, increase the availability and quality of traditional fruits and nuts rich in vitamins and minerals, which would improve the nutrition of smallholder farmers and their families (Leakey in press).

26.4.7 Constraints and Opportunities for Improved Interventions and Outcomes

The interventions just described span notions of high and low input or of tropical versus temperate agriculture. IPM, reduced tillage, agroforestry, and soil conservation, for example, have all been used in a range of agroecological and socioeconomic contexts globally. To these farm-scale interventions could be added the emergence of landscape-scale approaches that recognize and respond to the scale at which water and nutrient cycling and energy fluxes take place. Landscape approaches involve complementary and coordinated farm- and landscape-scale interventions as a means of improving long-term productivity and environmental sustainability (Baudry et al. 2000; Ryszkowski et al. 1999; Thenail 1996). Achieving the full potential of such approaches, however, requires continued development and integration of knowledge, strengthening of institutions, and improved feasibility and profitability for farmers. (See Box 26.6.)

Most approaches that seek to reduce food versus environment trade-offs require intensive use and integration of knowledge from the biological, agronomic, and ecological sciences together with farmer knowledge. Thus, the greater role and impact of such interventions is conditional on bridging perspectives of often productivity-focused scientific research with more ecosystem-focused perspectives—encompassing, for example the role of agroecological and eco-agriculture approaches (Conway 1999; Altieri 2002; McNeely and Scherr 2002). There is both much to learn and likely much to gain from, for example, improved understanding of the role of soil microbiology in improving water and nutrient efficiency in high-input systems (Matson et al. 1997; Woomer and Swift 1994), as well as rich possibilities of using biotechnology tools to enhance the productivity of low-input systems or orphan crops (Naylor et al. 2004).

Ultimately, decisions about the use of specific technologies and practices will depend on the opportunities and constraints of farmers, and there is evidence that here, too, more needs to be done to foster the adoption of practices that minimize trade-offs. Even where technologies have the potential to be profitable, many adoption decisions are affected by local institutions, particularly the effectiveness of local property rights systems and capacity for organizing and sustaining collective action.

Figure 26.9 plots increasingly secure property rights on the horizontal axis and increasing levels of collective action on the vertical axis. Some of the most successful agricultural technologies lie close to the origin in this figure. For example, the benefits of high yielding cereal varieties—the cornerstone of the Green Revolution—could be captured within a single agricultural season by individual farmers and hence did not require secure property rights or collective action. In tackling more complex objectives that include both yield and conservation goals, however, local institutional issues are more prominent.

Integrated pest management requires that farmers in an area work together to control pesticide use and to synchronize planting dates. The returns are relatively quick, however, so secure property rights are still not a major issue, and IPM appears in the upper left corner of the Figure. In contrast, planting of trees on farms (agroforestry) is a long-term investment that requires secure property rights. But since trees can be planted by individual farmers, agroforestry appears in the lower right-hand corner. Still other approaches, however, such as watershed conservation, require both secure property rights and effective collective action, and therefore appear in the upper right-hand quadrant. If these institutional conditions are not met, then the technology is not likely

BOX 26.6

Service Trade-offs in Cultivated Systems: A Case Study from the Argentine Pampas

The pampas agroecological zone is a vast, flat region of Argentina extending more than 50 million hectares and used predominantly for crop and cattle production (Satorre 2001). Agriculture in the pampas has a relatively short history (a little more than 100 years) comparable with that of the American Great Plains (Hall et al. 1992). Both agroecological zones were mostly native rangelands until the end of the nineteenth and the beginning of the century centuries, when lands were initially transformed for crop (cereals and oil seeds) and cattle production under rain-fed conditions. Where European tillage methods with a conventional plow were used, heavy erosion (dust bowls) occurred the first half of the last century, especially on the more fragile lands (Covas 1989).

Mixed-grain, crop-cattle production systems have now expanded to occupy most of the pampas and involve rotations of maize, wheat, and soybeans, with cattle pastures being integrated in various ways depending on local soil and climate conditions. Cattle operations vary from cow-calf to cattle finishing. The pampas suffers occasional droughts and floods that temporarily affect both crop and cattle production (Viglizzo et al. 1997).

A major challenge in sustaining the economic viability of the pampas low-input agroecosystems is to maintain soil quality that supports crop production and environmental services. Soil organic matter content is a key component of soil quality since it serves as a reservoir of nitrogen, phosphorus, and sulfur and has a large impact on soil physical properties that promote water infiltration, storage, and root function, all essential to support crop growth (Viglizzo and Roberto 1998).

Intensification of agricultural systems in the pampas during the past 50 years has involved a steady increase in farm area devoted to annual crop production and a consequent reduction in area allocated to perennial and annual pastures. Similar trends have occurred in the U.S. Corn Belt. From 1960 to 2001, grain production in the pampean provinces increased from 11.1 million to 43.5 million tons. Changes in soil organic matter and nitrogen dynamics associated with intensification provide an illustration of environmental service trade-offs. For example, leguminous pastures in a pasture-crop rotation can promote biological nitrogen fixation such that the soil nitrogen supply fluctuates around a value determined by the length of the leguminous pasture phase. Changes in land use that reduce or eliminate leguminous pasture decrease soil organic matter and nitrogen and phosphorus supply unless there are compensating applications of fertilizer or livestock manure (Viglizzo et al. 2001). Because current levels of N fertilizer use efficiency achieved by farmers are relatively low, there is substantial risk that nitrogen losses can damage environmental services in off-farm ecosystems.

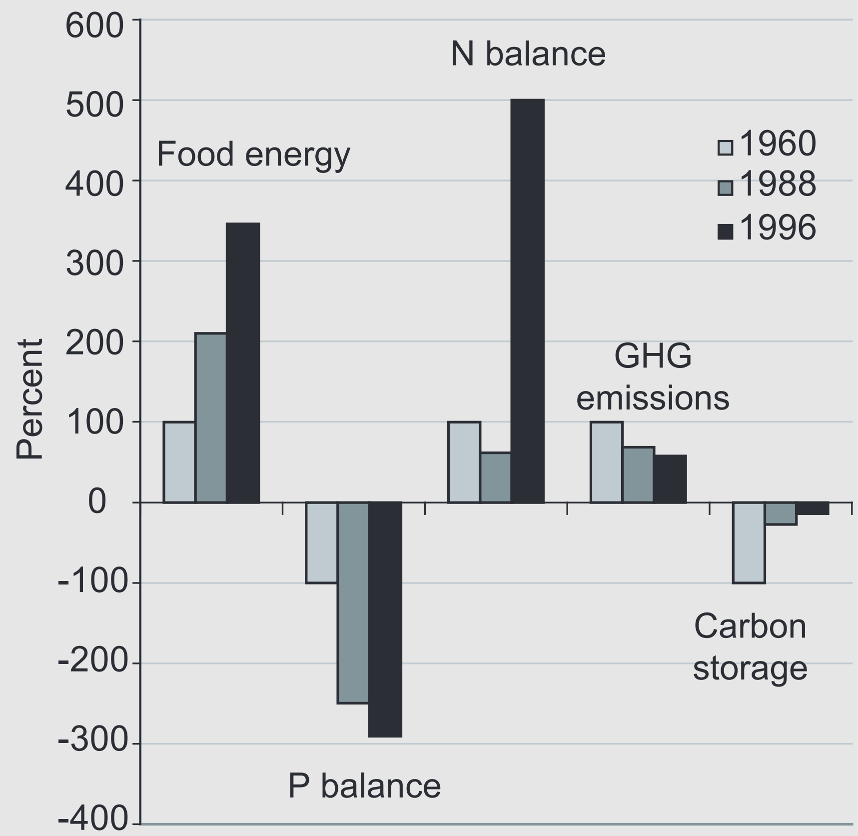


Figure A

to be adopted and maintained, regardless of its profitability and scientific soundness.

26.5 Cultivated Systems and Human Well-being

The ability of humans to convert natural systems to cultivated systems and to derive more food from each hectare of land has, for millennia, supported the growth of civilizations. Indeed, the first civilizations developed in the Fertile Crescent of the Middle East because local conditions were well suited to cultivation and the domestication of animals for livestock (Smith 1998; Diamond 1999). Similarly, in many parts of Asia, efficient and sustainable irrigated paddy fields have supported a number of prosperous cultures with high population densities over thousands of years. A stable food supply has always been the foundation on which human civilizations are built. Moreover, adequate nutrition is fundamental for human development and health.

For all the benefits they provide, cultivated systems can also pose risks to human well-being, most notably via direct health effects from, for example, the handling and use of pesticides and zoonotic diseases associated with certain cultivation practices, as well as through pollution of air and water. Cultural and amenity services of natural ecosystems are diminished when they are converted for cultivation, and that loss may or may not be compensated for by cultural and amenity services associated with cultivated systems.

This section deals with the linkages between human well-being and cultivated systems, noting that the largest single source of human well-being derived from cultivation is through the production and consumption of affordable food, fiber, and other products. The human well-being impacts mediated through food consumption are dealt with separately and in detail in Chapter 8.

26.5.1 Economic Component of Human Well-being

Cultivated systems play a vital role in global economic well-being, especially in poorer countries. In 2000, agriculture (including forestry and fishing) represented 24% of total GDP in countries with per capita incomes less the $765 (the low-income developing countries, as defined by the World Bank) (World Bank 2003). About 2.6 billion people depend on agriculture for their livelihoods, either as actively engaged workers or as dependants (FAOSTAT 2004). In 2000, just over half (52%) of the world's population were living in rural areas and, of these, about 2.5 billion people were estimated to be living in agriculturally based households (World Bank 2003). The global agricultural labor force includes approximately 1.3 billion people, about a fourth (22%) of the world's population and half (46%) of the total labor force (Deen 2000).

BOX 26.6

continued

Analysis of 85 pampas farm systems differing in their land use patterns and level of intensification (measured in terms of energy use) reveals trade-offs between the share of land used for crop production and the provision of ecosystem services. Results show that carbon storage, greenhouse gases emissions, and annual nitrogen and phosphorus balances decrease as the cropping area, use of energy derived from fossil fuels, and the net primary productivity of systems increase. Risk of pesticide contamination and soil erosion and the human disturbance of the habitat also increase, although both risk of erosion and disturbance stabilized or decreased somewhat at the highest levels of cropping intensity.

In contrast, GHG forcing potential decreases because removal of pastures and livestock grazing is associated with a reduction in methane emissions and fire used to improve vegetation quality in pastures and grazing land. The nature of trade-offs observed in the pampas varies not only by local agroecological conditions and production systems but also over time. Figure A shows how the average level and mix of ecosystem services have changed across the pampas over time. Compared with 1960, food output has increased significantly, while phosphorus balances have worsened. Nitrogen balances were positive but declining as pasture was converted to low-input cropland, but they have surged as urea application to cropland has become increasingly necessary. GHG emissions have fallen in line with pasture and livestock decreases, while carbon stocks continue to be depleted, but at a declining rate. Given the broad adoption of no-tillage cultivation practices in recent times, carbon stocks might now be increasing (Viglizzo 2002a, 2002b).

Both agricultural production and ecosystem services have economic value that can contribute to human welfare. Hence, the costs associated with the loss of ecosystem services caused by crop intensification should be weighed against the benefits obtained from farming. The ecosystem service valuation techniques developed by Costanza et al. (1997) were used to estimate both the market and nonmarket components of ecosystem services in pampas agricultural systems. The gross margins of crop and livestock production operations during the 1990s were assessed using standard economic valuation approaches. A comparison of the dynamics of crop and livestock gross margins and ecosystem service values related to the intensity of cropping is shown in Figure B. While the gross margin of farming production increases proportionately to the intensification of cropland, there is a relatively sharp decline in the value of ecosystem services at the earlier stages of intensification, such that about half the value of ecosystem services is lost when around 40% of the area is used for crop cultivation.

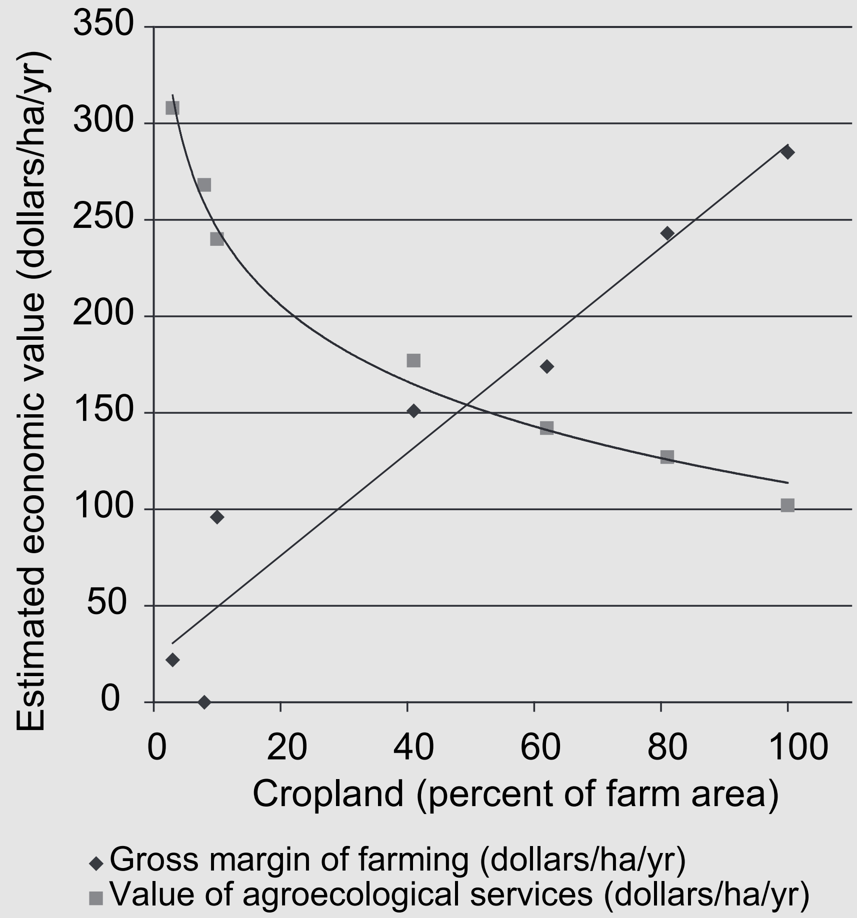

Figure B

This analysis considers only the implications of intensification within the pampas and does not examine broader geographic effects. Globally, the pampas has become a major source of grain for countries and regions where local food supply is insufficient to meet demand. Thus while reducing cropping intensity and increasing the percentage of land devoted to pastures in the pampas might improve ecosystem services locally, the loss of grain output would need to be offset by yield increases elsewhere in the pampas or by expansion of cultivated area and yields elsewhere in the world. In both cases, there would likely be negative effects on environmental services in these other locations that any comprehensive assessment of ecosystem service trade-offs would need to take into account.

In Africa, agriculture provides two thirds of all employment and half of all exports and accounts for 37% of GNP. Despite rapid urbanization and economic diversification in South Asia, agriculture continues to provide employment for over 60% of the population and generates 27% of GNP (DFID 2002). In 2000, globally, cultivated systems produced approximately $815 billion worth of food crops and $50 billion worth of non-food crops. In the same year, fisheries output was valued at $156 billion and livestock products at $576 billion. (See Chapter 8.)

Measuring the economic benefits of employment is difficult because globally comparable agricultural wage rates do not exist. One very rough proxy of gross agricultural income is the total value of agricultural production divided by the number of agricultural workers. This provides a rough estimate of the gross economic returns to labor. Globally, the average annual value of agricultural production per agricultural laborer for 1995–97 was approximately $1,027 per person (using 1989–91 average international prices). The range of estimates is quite broad—from about $50,500 per person per year for the United States down to $411 for sub-Saharan Africa (Wood et al. 2000).

Livestock provides the main source of livelihood for 650 million farmers worldwide. Despite low productivity, livestock husbandry is one of the few means for the poor to generate income, acquire assets, and escape from poverty. Sales of livestock, animal-source food, hides, and fibers through both formal and informal markets make major contributions to household income. Evidence from in-depth field studies in Asia and Africa indicates that livestock contribute as much as 76% of household incomes in some regions, and generally a higher percentage to the incomes of poorer households (Delgado et al. 1999; Kaufmann and Fitzhugh 2004).

There is a growing consensus that poverty, hunger reduction, and increased economic growth cannot be achieved in most poor countries without more fully exploiting the productive capacity of the agricultural sector (Timmer 1989; Sarris 2001; Hazell and Haddad 2001). Agricultural growth can reduce poverty through

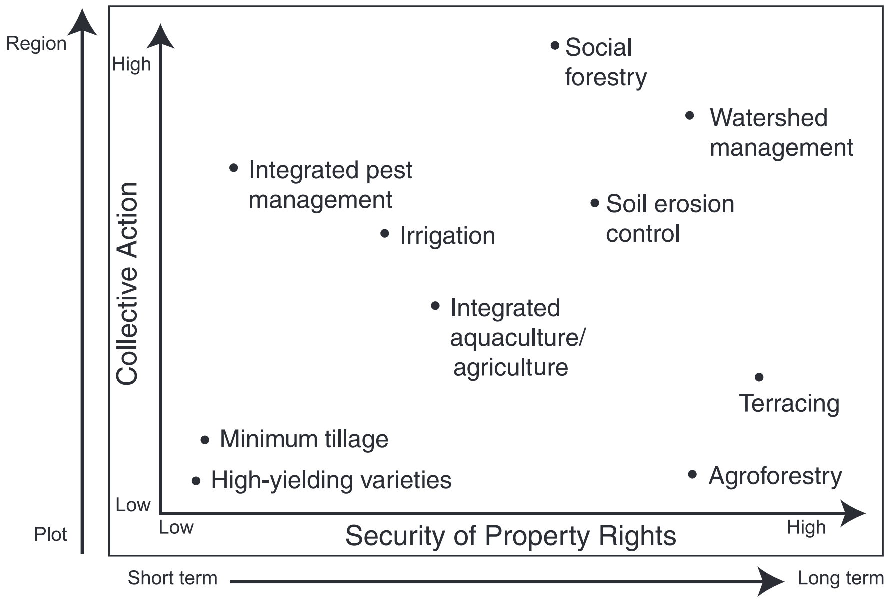

Figure 26.9. Links between Property Rights, Collective Action, and Technology Adoption in Cultivated Systems (adapted from Knox et al. 2002)

increased employment and wages and through income generated by the sale of goods produced by the poor (Datt and Ravaillon 1998). It also results in increased demand for food, services, and unskilled labor (Mellor 2000). The relationship between agricultural wages, higher yields, and poverty in the case of India is shown in Figure 26.10. Timmer (1997) has shown for 27 countries from the period 1960 to 1992 that agricultural growth reduced poverty more than growth in manufacturing did, while López and Valdéz (2000) have shown that rural growth is more effective than urban growth in reducing poverty in Peru. Growth in Peruvian agriculture was also shown to have reduced urban poverty through slower rural-to-urban migration and more affordable food prices.

Beyond the direct economic impact on employment and incomes, there are several indirect economic benefits of cultivated systems that can be even greater. These are mediated through rural growth linkages, inter-sectoral linkages including the post-harvest agribusiness sector, consumer income effects, and trade. Rural growth linkages are an important mechanism by which agricultural growth spurs growth in non-farm incomes and employment (Hazell and Roell 1983; Mellor 1966). Growth in the use of farm inputs, processing, marketing, and transport services serve to increase rural non-farm incomes. The increasing household expenditure that results enhances consumer spending and triggers a further rise in non-farm incomes and employment. For example, a $1 increase in agricultural income resulted in increases in rural income of an additional $1.88 in Burkina Faso, $1.48 in Zambia, $0.96 in Niger, and $1.24–$1.48 in two locations in Senegal (Delgado et al. 1998).

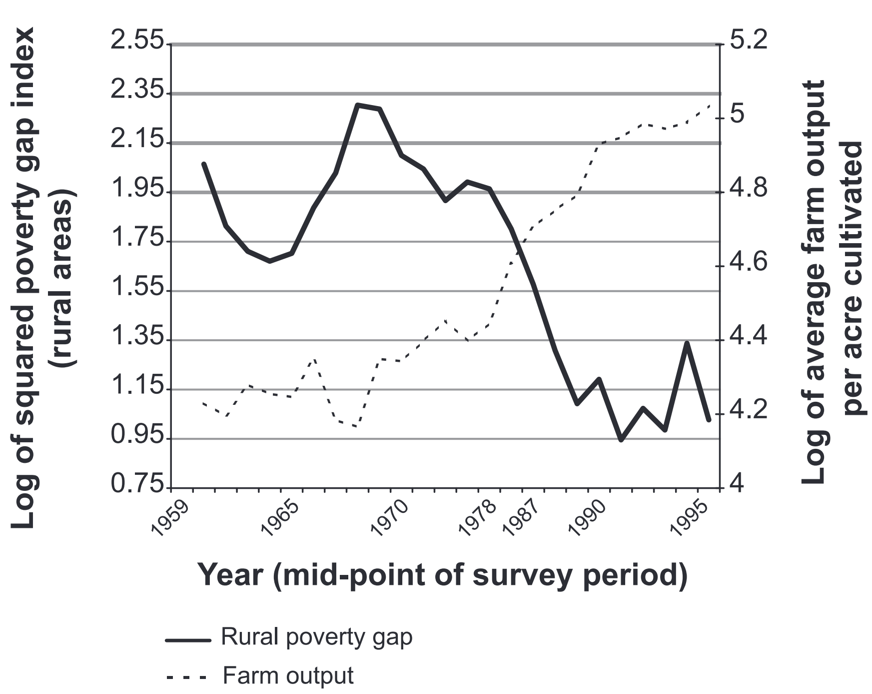

Figure 26.10. Yield Growth and Poverty Reduction in India, 1959–94 (Datt and Ravillon 1998)

In an analysis of Asia and the Near East, Timmer (1989) concluded that linked growth between industrial and service sectors and the rural economy could lead to increases in rural wages and more equitable income distribution. Mellor (2000) contends that the substantial lags between accelerated agricultural growth and reduction in poverty are strong evidence that agricultural growth reduces poverty more through indirect processes than direct ones. Furthermore, these linkages enhance overall economic growth. Rural growth linkages are particularly important because they benefit small labor-intensive enterprises and thus contribute to the alleviation of rural poverty.

It is increasingly recognized that estimates of agriculture's contribution to economic growth and human well-being at national levels are underestimated by economic indexes that focus only on farm-level added value. Upstream and downstream linkages with agro-industries, services, and trade are not properly accounted for. In Argentina, for example, primary agriculture is estimated to represent about 5% of total GDP, but this increases to 32% when the linkages with the food and agro-industry sectors are considered (IDB 2004). Similarly, agriculture in Brazil and the United States is estimated to contribute about 4% and 1%, respectively, to national GDP, while full accounting of food chain linkages gives estimates of 26% and 8% (IICA 2004).

The economic well-being generated from cultivated systems is not limited to those employed in the food supply sector. Food consumers have benefited enormously from the long-term decline in food prices. Cereal prices have fallen by about 40% in real terms during the past 40 years, resulting in increased disposable incomes for consumers. (See Chapter 8.) This allows increased expenditures on education, health, and better nutrition (Hazell and Roell 1983).

Economic well-being can be further improved through international agricultural and food markets. Trade in food not only broadens choices but also provides access to foods year-round that often can be grown locally only on a seasonal basis. It provides local farmers with new market opportunities, resulting in higher living standards for those able to participate. Food trade also helps provide more stable and secure access to food at competitive prices, but it cannot play such an effective role where prices are distorted or significant market barriers exist. A major limit to agriculture's role in the global economy is that agricultural trade barriers are on average 10 times higher than industrial trade barriers (Abbott 2005; Charlton and Stiglitz 2005).

Agriculture's effects on economic well-being are not all positive, and other sections of this chapter have described the negative impacts, including loss of biodiversity; soil, water, and airborne pollution; and health risks. Although it is difficult to quantify the costs of these externalities from agriculture, there can be significant financial and economic consequences that are explicitly and implicitly borne by society. Pretty et al. (2000) have estimated the external environmental and health costs of agriculture in the United Kingdom at £2.3 billion in 1996 using ecosystem service values derived from Costanza et al. (1997). These costs represent 13% of average gross farm returns and 89% of average net farm income in the country.

Improving formal measures of productivity by accounting properly for the full social costs and benefits of all inputs and outputs from cultivated systems, including environmental services and health as well as the economic multipliers from agricultural productivity, is critical for making more informed decisions about policies and investment in the agricultural sector, especially in developing countries, where sustainable agricultural development is the foundation for broader economic development.

26.5.2 Linkages between Cultivated Systems and Nutrition and Health

Cultivated systems contribute to human health and nutrition primarily by providing food either through subsistence agriculture or through commercial agriculture and food markets. The magnitude of the human well-being benefits derived from an adequate and nutritious food supply are so large that they are often taken for granted, especially in wealthy countries in which food costs represent a small proportion of disposable income. Likewise, it is very difficult to protect against environmental degradation and loss of ecological services in regions where people experience chronic food shortages. Unless chronic hunger and food insecurity are reduced, the poor will continue to exploit natural resources in the short run, thereby undermining the sustainability of natural ecosystems and consequent food security in the long run (Webb 2002).

The important linkages between food consumption, health, and nutrition are assessed in detail in Chapter 8. This section focuses on linkages between human health and factors other than food supply per se, such as the impact of production systems, production practices, and associated environmental externalities. The linkages are grouped into the health of farm workers and farm families and that of the broader population potentially affected by cultivation practices.

Agriculture is a hazardous occupation. Globally it is estimated that farm workers run at least twice the risk of dying on the job than workers in other sectors and that around 170,000 people die per year because of these work hazards (Forastieri 1999). In the United States, for example, the death rate among agricultural workers was an estimated 20.9 per 100,000 workers in 1996—more than five times the average for all industries (Reeves and Schafer 2003). Not only are mortality rates higher, but so are rates of accident and illness. In the United States, farmers and farm workers account for only 3% of the workforce but for nearly 8% of all work-related accidents; in Italy, some 10% of workers in agricultural production account for some 29% of workplace accidents, often related to the use of tractors, harvesting machinery, and power tools (Forastieri 1999). In developing countries, where farmers use smaller and less powerful equipment, there are likely to be fewer serious work-related accidents, although few data on these are available.

Apart from accidents, two other linkages between production and health are respiratory problems caused by working in barns and confined livestock systems and a variety of health problems linked to pesticide handling and use. A compilation of studies from Australia, Finland, Denmark, Sweden, Scotland, the United States, and Canada indicated very high levels of occupational respiratory problems in farm workers. In intensive dairy systems, about 20% of farm workers were reported to suffer bronchitis problems directly related to in-barn air quality, 5% from asthma problems, and just under 5% each with symptoms of organic dust toxic syndrome and "farmer's lung" disease. Health effects are comparable or larger for pig and poultry operations and arise largely through the presence of dust from the use and handling of hay, straw, and dry animal feeds (Omland 2002). Kansas farmers were found to be at an increased risk of death from prostate cancer, brain cancer, non-Hodgkin's lymphoma, and leukemia in a 1983–89 study; they were also at elevated risk of death from motor vehicle accidents, accidents resulting from falling objects, and machinery accidents (Frey 1991).

In addition to high risk of physical injury, the estimated 2 million farm workers in the United States face a greater risk of pesticide exposure than any other segment of the population (Reeves and Schafer 2003). On a global scale, it is estimated that 20,000 people die of adverse effects of pesticide exposure each year, 3 million are poisoned, and there are nearly 750,000 new cases of chronic pesticide exposure, such as cancer, each year (WHO and UNEP 1990). There are limited reliable data on the extent of pesticide-related illness anywhere due to poor identification of such illnesses, which leads to underestimations. The magnitude of health damage caused by agrochemical exposure will vary according to the type of agrochemical used, the mode of application/exposure, the individual susceptibility, and the climatic conditions—and each of these factors is related to the type of crop grown and specific pesticide use practices.

Pingali and Roger (1995) documented that pesticide use had an adverse impact on human health and subsequently on farmer productivity for rice farmers in the Philippines in 1991. Eye, pulmonary, and neurological problems are significantly associated with long-term pesticide exposure. In Northern Ecuador, heavy use of pesticides by potato farmers was the principal cause of death after traffic accidents for both men and women (Yanggen et al. 2004). In China, in 2001, decreased use of pesticide as a result of growing *Bacillus thuringiensis* cotton resulted in a lower incidence of poisonings (Hossain et al. 2004).

Farm workers and farm families are particularly susceptible to zoonoses—animal diseases that can be transmitted to humans through contact with infected animals. There are approximately 150 kinds of zoonoses, and many are transmitted by livestock. For example, avian influenza, or "bird flu," is a disease that humans may contract through direct contact with live poultry infected with the flu virus or direct contact with the feces, nasal, or eye discharges from infected birds (WHO 2004). In contrast, the risk of infection from consumption of poultry product is extremely low. Because there is no viable treatment, recent outbreaks caused by the H5N1 strain are considered to be one of the greatest potential threats to human health if human-to-human transmission of the disease becomes widespread (WHO 2004). The first documented infection of humans with an avian influenza virus occurred in Hong Kong in 1997, when the H5N1 strain caused severe respiratory disease in 18 humans, 6 of whom died. Cases have also recently been reported in Viet Nam, Thailand, and Cambodia (WHO 2004).

The incidence of zoonoses is high in developing countries because social and economic factors contribute to their spread (Langoni 2004). Poor sanitation can exacerbate these diseases in children by allowing the zoonotic agent to be disseminated through rainwater, streams, and brooks where children often play. Bovine brucellosis can be transmitted to humans and is a major zoonosis associated with livestock. Human brucellosis is characterized by fever and back/joint pain (Unger 2003). Further complications due to human brucellosis may include hepatitis (Masouridou et al. 2003). According to WHO data, the number of cases of human brucellosis worldwide was estimated to be about 500,000 (WHO 2005). The advent of HIV/AIDS has increased the prevalence of many zoonoses in humans because HIV can increase susceptibility to zoonotic agents by depressing the human immune system (Langoni 2004).

Contamination of surface and groundwater by pesticides and fertilizers is also reported to affect public health (Ongley 1996). Excessive waterborne nitrogen has been linked to respiratory ailments, cardiac disease, and several cancers (Townsend et al. 2003). Nitrate levels have grown in some countries to the point where more than 10% of the population is exposed to nitrate levels in drinking water that are above the 10 milligrams per liter guideline (WHO 1993). Although WHO finds no significant links between nitrates and nitrites and human cancers, the drinking water guideline is established to prevent methemoglobinemia in infants (blue baby syndrome) (WHO 1993). Water polluted by waste and runoff from grazing areas and stockyards can also cause disease. The most common diseases associated with contaminated waters are cholera, typhoid, ascariasis, amebiasis, giardiasis, and enteroinvasive *Escherichia coli*. Four million children die every year as a result of diarrhea caused by waterborne infection, although the share attributable to agriculture is unknown (Ongley 1996).

Irrigation systems provide sources of water that can improve sanitation, and thus human health, but they can also serve as a breeding ground for disease vectors. Increases in malaria have been linked to reservoir construction (De Plaen 1997; Reiff 1987). Schistosomiasis (bilharziasis), a parasitic disease that spends part of its lifecycle in a snail species and that affects more than 200 million people in 70 tropical and sub-tropical countries, has also been demonstrated to increase significantly following reservoir construction for irrigation and hydroelectric power production (DFID 1997). The two groups at greatest risk of schistosomiasis infection are farm workers involved in the production of rice, sugarcane, and vegetables and children who bathe in infested water.

Water contamination is not restricted to the developing world. The total cost of drinking water contamination from agriculture has been estimated at £120 million in the United Kingdom due to pesticides and £16 million due to nitrate from fertilizers (Pretty et al. 2000).

Recently, HIV/AIDS has added another dimension to the relationship between agriculture and human health. Gillespie and Haddad (2002) suggest that improved nutrition for agricultural workers with HIV/AIDS is important for improving their quality of life. However, ill health as a result of HIV/AIDS also affects agricultural production through reduced stamina and strength of sick farm workers and the diversion of household resources and time to care for the sick and for funerals. Subsequent decreased labor productivity can in turn affect human well-being since households may resort to growing less nutritious or less lucrative crops because they are less labor-intensive.

26.5.3 Equity and Distributional Aspects of Cultivation

At the scale of the farm and community, linkages with equity and distribution are conditioned by the existing distribution of assets and the limited access of poor people and vulnerable groups to cultivation-related resources and opportunities such as land, credit, extension, and markets. At the scale of the country and region, there are often biases in political and economic power against rural areas and against specific marginalized groups. At the international scale, there are imbalances among richer and poorer countries with regard to their ability to promote competitive agriculture through publicly-funded domestic farm support, influence on trading patterns, and the strength of public and private systems delivering improved production technologies and practices.

In theory, agricultural growth should eventually lead to more equitable distribution of both income and resources (Kuznets 1955). However, empirical evidence of agriculture's effects on promoting equity is ambiguous (von Braun 2003) or marginal at best (Deininger et al. 2004; Tsur and Dinar 1995; Bautista et al. 1998). For example, a number of studies have shown that administrative land reform was not effective in transferring land to the poor in Colombia and Ethiopia (Castagnini et al. 2004; Adenew et al. 2003). In Viet Nam, despite the rapid growth of agricultural wages in the 1990s, wage inequality fell modestly (Gallup 2002). In China, however, long-term government investments across multiple sectors, including agricultural research and development, irrigation, rural education, and infrastructure (including roads, electricity, and telecommunications) contributed not only to agricultural growth but also to the reduction of rural poverty and regional inequality (Fan et al. 2002).

The marginalization of vulnerable groups such as women and children is also a constraint to more equitable sharing of benefits from farming. Women are especially vulnerable to existing inequities in terms of wages, access to and control of production technologies, gender segregation in labor markets, and access to property and entitlement in their own right (Quisumbing and Meinzen-Dick 2001).The central role of improving gender equity in African agriculture, where women are productive farmers and key food producers, is now widely recognized (Kabutha 1999). And in Cambodia, 90% of children worked in agriculture or agriculturally related activities during 1996 (ILO 1997). Lack of education propagates vulnerability and promotes widening inequality. While widespread use of child labor in agriculture is an economic necessity in many countries as families are too poor to pay for schooling, adult males often migrate to urban areas seeking employment. In addition, sickness and care-giving—especially related to HIV/AIDS—reduces the pool of family labor in sub-Saharan Africa.

Persistent barriers to agricultural trade across international boundaries, such as export subsidies and import restrictions, limit more equitable agricultural income distribution among countries by, for instance, limiting developing-country access to EU and U.S. markets, as described earlier. But the impact of trade liberalization on the distribution of income within developing countries varies according to country-specific policy conditions and socioeconomic structure. In Latin America, for example, analysis suggests that trade liberalization has had positive effects on income equality in nine countries and negative effects in five countries (von Braun 2003).

There are growing concerns about inequalities with regard to the capacity to generate and gain access to new scientific information and technology (von Braun 2003). An increasing share of agricultural R&D globally is being funded by the private sector at the same time that the science needed to make key advances becomes more complex, costly, and, particularly for biotechnology, increasingly proprietary in nature. The fear is that large bioscience companies have few incentives to focus on the crops, constraints, and technologies most appropriate for poor farmers in tropical areas but have proprietary rights over processes and components of technologies that need to be used (Pardey and Beintema 2001).

These trends, compounded by the long-term underinvestment in agricultural R&D by most developing countries despite the economic importance of agriculture, are widening already significant gaps in scientific capacity compared with industrial countries. Increasingly it is only the larger developing countries, such as Brazil, China, India and South Africa, who can muster the investments in R&D and human capacity needed to keep their farmers competitive.

As trade liberalization proceeds, increased reliance is placed on knowledge, science and technology, and technology transfer to keep farmers in business. In addition, emerging trends in global food retail and agro-processing markets, increasing demand for food safety, and shifts in diets and preferences toward processed foods are raising concerns about the long-term future of smallholder farmers in developing countries (Lipton 2005). In part, these concerns arise from the disproportionately negative impact of structural adjustment programs on smallholders during the 1980s and 1990s brought about by the wholesale withdrawal of public-sector services (disappearing market, input services, and credit).

With regard to the specific case of genetically modified crops, recent studies have documented substantial economic benefits from the most widely adopted transgenic crops—*Bt* cotton and herbicide-resistant soybean. Non-GMO cotton varieties are highly susceptible to yield loss from bollworm and boll weevil insect pests that require as many as five or six applications of highly toxic pesticides to avoid severe yield loss. In contrast, the *Bt* cotton varieties have been transformed to contain a bacterial gene that produces a protein that is toxic to these insect pests when they feed on the plant's tissues.

Reduced cost of insecticide applications and higher yields contribute to substantial increases in profit for the farmer and lower prices for cotton, which benefit the consumer. As a result, the economic benefits from use of insect-resistant *Bt* cotton varieties were found to be evenly distributed among farmers, private-sector seed companies, and consumers in both industrial and developing countries (Huang et al. 2002; Falck-Zepeda et al. 2000). Similar studies of the distribution of economic benefits from herbicide-resistant GMO soybean have also documented balanced distribution among farmers, seed companies, and consumers (Qaim and Traxler 2005).

There are also linkages between the impact of cultivation on ecosystems services and equity. The poor and the vulnerable are likely to suffer most from environmental externalities of production, such as downstream water depletion and pollution and loss of habitat and biodiversity—particularly since the landless rely more on wild sources of food (Grimble et al. 2002).

26.5.4 Cultural Aspects of Cultivation

Cultivated systems and human culture are inextricably linked. Religious and ethical values, cultural backgrounds, and philosophical convictions are important factors linked to the sustainability of cultivated systems, rural development, and food security. Cultural practices and traditions are often integrated into cultivation norms and practices, into land inheritance, ownership, and access, and into access to other productive resources. Cultural factors and preferences can have a large influence on the demand and value of various food products in the marketplace. Likewise, traditional food taboos and food distribution along age and gender lines can have a substantial impact on nutrition by affecting the types of food that are available or culturally acceptable. (Chapter 8 contains more discussion on food and culture.)

Farmers' close ties to the land and their intimate relationship with it is an intangible aspect of farming that can outweigh maximizing short-term economic gain. In northern New Mexico, for example, small livestock operations are a critical aspect of families' and communities' way of life, maintaining cultural heritage and traditional values as well as passing those values on to future generations. Keeping land in the family and upholding traditional values are regarded more highly than material possessions or monetary gain (Raish and McSweeny 2003). Despite the commercialization of agriculture, agricultural societies still exist that value the cultural aspects of farming and, as a result, have created homesteads, communities, collective action mechanisms, and alternative technologies that allow continuation of traditional peasant agriculture (Schwarz and Schwarz 1999). It is not just farm households who value the existence of agriculture—in richer countries, the policy of publicly funded payments to farmers for ''environmental stewardship'' is broadly supported, reflecting findings of formal studies of the public's willingness to pay for maintained agricultural landscapes (Drake 1992; Olsson and Ronningen 1999).

Changing cultural attitudes toward agriculture can be traced back to the Industrial Revolution, when technological innovations that control the environment began replacing the spiritual relationship of farmers to the land. Ultimately, the evolution of agriculture in industrial countries has profoundly changed culture, eliminating the need for millions of farmers and farm workers and displacing entire communities (Bailey 1999).

The farming of animals involves a culture of its own, and ancient myths surrounding animals have deeply influenced animal production (Fraser 2001). Nurturing animals is an integral part of the ecology and economy of many farming systems; it was and is regarded as a moral responsibility in many religious and cultural traditions, with different species serving important and complementary functions. Animals are also important for moral education, because children often learn responsibility by caring for animals. These values are now embodied in broader social concerns for animal welfare, particularly with regard to industrial livestock systems.

Just one example of the strong sense of rural community spirit can be seen in *gotong royong,* Indonesia's traditional spirit of mutual help. The underlying philosophy is that people cannot live a solitary existence; they need each other, particularly family members and relatives. The practice of *gotong royong* originates from the traditional peasant subculture, which is characterized by subsistence farming, family-oriented grouping, and strong social interdependence. Even in commercial smallholder areas of Indonesia, *gotong royong* is still practiced widely in farming operations—including during land preparation, pest management, water management, weeding, and harvesting.

An example of the strong spiritual connection to cultivation is the growing of rice in Asia. For the Balinese, rice is much more than just a staple food; it is an integral part of the Balinese culture. The rituals associated with the cycle of planting, maintaining, irrigating, and harvesting continue to enrich the cultural life of Bali after thousands of years and despite the strong external cultural influences associated with tourism. Before planting, throughout the growing season, and at harvest, ceremonies are held and offerings are presented to Dewi Sri, the goddess of rice. In the middle of most rice fields, even far from villages, shrines are well maintained with flowers, fruit, and other offerings for Dewi Sri.

Gender-related cultural norms and practices also play an important role in the functioning of cultivated systems. For example, in the rural Philippines land is preferentially given to sons because rice farming requires intensive male labor (Estudillo et al. 2001). In many patrilineal African communities, the cultural custom of *lévirat* dictates that if a woman becomes a widow, she has to remarry one of her husband's brothers, which allows the woman continued access to land and food security; otherwise she would have to leave the family on the death of her husband (Estudillo et al. 2001).

Cultivated systems have a long history. Since as early as 10,000 years ago, crops have been carefully and deliberately managed by people, who in turn have reaped the benefits of increased food production. It has been argued that domesticated seed varieties and agricultural technologies were some of the most important factors in shaping the evolutionary course of civilizations (Diamond 1999). Domesticated, nutritious crops are capable of supporting larger populations, which in turn promotes innovation and technological advances. The social, cultural, economic, and political patterns and institutions that underlie both traditional rural societies and modern nation-states are in many ways products of humans' evolving ability to manage plants and animals for the production of food and other services (Diamond 1999).

Notes

1. If inland waters, Greenland, and Antarctica are excluded from this analysis, the coverage rises to approximately 27%. According to the MA definition, an area is considered cultivated if at least 30% of the underlying 1x1-kilometer land cover grid cell has been classified as cropland. This definition seeks to identify landscapes where a significant degree of ecosystem transformation has already taken place. The MA definitions of ecosystems allow for overlapping geographical extents of terrestrial systems.

2. The AVHRR-derived Global Land Cover Characterization Database V1.2 was produced by the EROS Data Center of the U.S. Geological Survey (Loveland et al. 2000) with revisions for Latin America (USGS EDC 1999). This dataset identifies approximately 200 seasonal land cover regions per continent (for example, 167 for South America and 205 for North America) based on the interpretation of a series of satellite images captured every 10 days from April 1992 to March 1993.

3. This conversion efficiency is embedded in the IFPRI IMPACT model, which was used to provide the food supply projections for the MA scenarios. (See MA *Scenarios,* Chapter 6). The conversion efficiency used in the IMPACT model was estimated by evaluating the impact of research investment on genetic improvement of major crops over the past 30 years. The recent evidence cited, however, suggests that conversion efficiencies have decreased markedly as average crop yields have increased.

Main Messages

Urbanization and urban growth continue to be major demographic trends. The world's urban population increased from about 200 million ($\sim$15% of world population) in 1900 to 2.9 billion ($\sim$50% of world population) in 2000, and the number of cities with populations in excess of 1 million increased from 17 in 1900 to 388 in 2000. As people are increasingly living in cities, and as cities act as both human ecosystem habitats and drivers of ecosystem change, it will become increasingly important to foster urban systems that contribute to human well-being and reduce ecosystem service burdens at all scales.

Urbanization is not in itself inherently bad for ecosystems. Many ecosystems in and around urban areas are more biodiverse than rural monocultures are, and they can also provide food, water services, comfort, amenities, cultural values, and so on, particularly if they are well managed. Moreover, urban areas currently only account for about 2.8% of the total land area of Earth, despite containing about half the world's population.

Urban demographic and economic growth has been increasing pressures on ecosystems globally, but affluent rural and suburban living often places even more pressure on ecosystems. Dense urban settlement is considered to be less environmentally burdensome than urban and suburban sprawl are. At the same time, urban centers facilitate human access to and management of ecosystem services through, for example, the scale and proximity economies of piped water systems.

Urban development trends do pose serious problems with respect to ecosystem services and human well-being. Ecosystem processes that provide services to urban residents tend to be neglected as a result of the continued lack of understanding and appreciation of the complex processes involved, many of which take place at some distance from the urban consumers; the difficulties that private enterprises encounter in owning, trading, and negotiating over ecosystem services (and burdens), which rarely conform to property boundaries; the difficulties that public agencies encounter in managing and regulating ecosystem services, which also tend to cross administrative and sectoral boundaries; and the fact that the people most adversely affected by the loss of ecosystem services tend to be the least influential economically and politically (such as the urban poor, future generations, and residents living far from where the decisions are being made).

The problems documented in this chapter include severe environmental health problems within urban settlements resulting from inadequate access to ecosystem services (such as clean water), the degradation of ecosystems adjoining urban areas resulting from urban expansion and demands, and pressures on distant ecosystems resulting from urban production, consumption, and trade. In affluent countries, the historical trend has been for the negative impacts of urban settlements on ecosystem services and human well-being to become more delayed and dispersed. Urban developments in other parts of the world have been taking place in a different technological and economic context, with different environmental consequences, but this trend is still globally significant.

Interrelated problems involving local water, sanitation, waste, and pests still contribute a large share of the urban burden of disease, especially in low-income countries. This typically reflects a combination of degraded or increasingly scarce ecological services generated within the urban area, minimal infrastructure (such as water pipes) tapping more-distant ecosystem services, and differential access to the ecological and derived services available within the urban area.

Problems relating to the degradation of ecosystems adjoining urban settlements are undermining their capacity to supply ecosystems services, especially in and around large, industrializing, and motorizing cities (often of middle income). This typically reflects a combination of the geographic displacement of intraurban environmental scarcities and "wastes" and increasing levels of activities using or degrading ecosystems.

The consumption and production activities that are driving long-term, global ecosystem change are concentrated in urban centers, and especially those located in upper- and middle-income countries. This typically reflects a combination of environmental displacement and increasing rates of direct and indirect consumption of energy, materials, and ecosystem services.

Although there are many examples of successful responses to urban environmental challenges, concerted responses (such as sanitary reform in many cities in the nineteenth century) have been motivated by serious crises rather than by precautionary planning and have often succeeded by displacing rather than eliminating the environmental burdens. As an increasing number of urban environmental burdens, particularly from affluent urban centers, are likely to fall on future generations and are already of global scale (such as urban emissions of greenhouse gases), past successes based on displacing the burdens spatially are of declining relevance.

When urban systems are managed more equitably and the loss of ecosystem services is purposefully addressed, the benefits to human well-being can be substantial. It is *well established* that motivated governmental and nongovernmental agencies can implement radical changes in local environmental management that reduce local burdens and benefit vulnerable groups. The experience of urban sanitary reform provides strong evidence for this. At the same time, the historical record also illustrates a tendency to displace the burdens spatially and temporally.

The regulation of urban air and water pollution, in part motivated by popular pressures, has also resulted in better air and water quality in and around cities in some parts of the world, although again there is a tendency to displace the burdens spatially and temporally.

There is comparatively little evidence of significant steps to reduce the global ecosystem burdens of cities, although there are many examples of measures that, if replicated on a large scale, would result in appreciable reductions in those burdens.

27.1 Introduction

Urban systems are centered in urban areas; in terms of ecosystem services, urban areas are primarily sites of consumption. This contrasts with the other systems assessed in this report (such as cultivated systems, drylands, and coastal systems), which primarily generate and supply ecosystem services. Urban systems exist at several scales and can be identified with individual urban settlements or networks of such settlements.

Urban settlements are agglomerations of people and their activities; although urban areas may contain a wide variety of species, it is the humans that make them urban. About half the people in the world live in areas defined as urban (see Box 27.1 for definitions), up from less than 15% at the start of the twentieth century. Combined with population growth, this has meant an almost fifteenfold increase in the world's urban population, from 200 million in 1900 to 2.9 billion a hundred years later. Over the same period, the rural population more than doubled, increasing from 1.4 billion to 3.2 billion (United Nations 2002).

The share of Earth's land area that is urban is also growing, but it remains only about 2.8% (this figure is based on the urban-rural mapping described later). Urbanization has, however, in-

BOX 27.1
Defining Urban Areas and Populations

In line with other MA systems (such as cultivated, dryland, and mountain systems), urban systems are associated with particular spatial locations, in this case urban areas. Urban areas are in turn associated with urban settlements and populations. This Box focuses on how urban areas and populations are distinguished from rural areas and populations. There are no hard and fast rules on this; although conceptual clarity is important, it must also be recognized that the dividing line between urban and rural is inevitably somewhat arbitrary. For example, many people move regularly between locations classified as urban and rural.

It is generally agreed that urban agglomerations (cities and other urban centers) tend to have larger populations than rural agglomerations (villages) do, are more likely to be the site of large facilities (such as hospitals) and higher-level administrative functions (national or local government offices, for example), and create comparatively densely settled areas, with a higher share of built-up area. Furthermore, urban residents are less likely to work in agriculture and more likely to work in industry or services. It is also agreed that there are more and less urban lifestyles and cultures. There is no international agreement, however, on the defining characteristics of urban, nor are there any scientifically accepted criteria by which to identify urban areas and populations. Moreover, many urban researchers believe that the distinction between rural and urban is becoming less relevant (Cohen 2003) and that the boundary definitions are inevitably somewhat arbitrary.

Cut-off points for identifying urban areas or populations vary within the different criteria. Minimum population density criteria commonly range between 400 and 1,000 persons per square kilometer; minimum size criteria typically range between 1,000 and 5,000 residents; and maximum agricultural employment is usually in the vicinity of 50–75%. In each case, however, cut-off points outside these ranges can easily be found.

According to a recent report on world urbanization prospects (United Nations 2002), 109 of the 228 countries covered use an administrative criterion to distinguish urban from rural localities, and 89 of these use it as the sole criterion. Population size or density was used as a criterion in 96 countries, and as the sole criterion in 46. The administrative and population-based criteria are themselves different in different countries: for example, the lower limit above which a settlement was considered urban ranged between 200 and 50,000 persons.

There are also differences in the manner in which localities are identified and settlement populations calculated. Some countries report city populations on the basis of the boundaries of the city proper; others in terms of a metropolitan area; and still others in terms of a (usually larger) urban agglomeration. These differences have persisted for many years. In the 2001 revision of the U.N. report, about half the countries in the world used estimates based on "city proper," with most of the remaining claiming to be applying the concept of urban agglomeration.

Although country-specific definitions will remain central to defining and assessing urban centers for many years to come, the basis for a more uniform definition is emerging from work using remote sensing and geographical information systems. This chapter relies on two different delineations of urban to examine urban conditions and trends: one based on the country-specific definitions used by the United Nations, and the other based on a preliminary urban-rural split developed as part of a broader mapping and indicator exercise being undertaken by the Center for International Earth Science Information Network (Balk et al. 2004).

The country-specific definitions provide the basis for the statistics on historic urban populations and short-term projections, as well as a number of the descriptive statistics on urban population, such as the share with access to improved water sources. The geospatial estimates are used for the map in Figure 27.1 and for the Tables situating urban populations in relation to coastal zones, dryland, mountains, and other MA system categories. Although the geospatial estimates remain provisional and are unlikely to be adopted by national governments in the foreseeable future, they have a number of potential advantages, including better international comparability and local verifiability, as well as the ability to portray, for example, how sets of urban centers themselves are concentrated spatially.

Many economic and social characteristics once considered quintessentially urban are increasingly found among residents of what must demographically be classified as rural areas. Alternatively, many people living in large cities do not have access to what is sometimes considered defining "urban" infrastructure, such as piped water and sewerage. Such phenomena are important to recognize, but for the purposes of this chapter people are identified as urban or rural depending on their primary residence rather than their economic or sociocultural characteristics. Thus, for example, a Kansas farmer living in a rural area but with "a university degree, hooked up to the Internet and a fax machine, with a barn full of expensive machinery, who keeps strict accounts and sells his grain on the Chicago Mart" (Friedmann 2002) would be identified as a rural person with the accoutrements of an urban lifestyle rather than an urban person living in a rural location.

volved profound changes in human ecology, and urban land area is a very poor indicator of the ecological significance of urban systems.

As illustrated in Figure 27.1 (in Appendix A) (see also Table 27.6, later in this chapter), urban settlements are themselves concentrated regionally. Africa and Oceania have the lowest shares of area in urban systems, whereas Asia has the largest. Within regions, there is also a high degree of variation. The global map also indicates that urban areas tend to be on or near the coasts.

Human systems within urban boundaries are not functionally complete ecosystems. Urban areas have been described as the human equivalent of the livestock feedlot: a spatially limited area characterized by a large population of humans living at a high density and supported by biophysical processes mostly occurring somewhere else (Rees 2003). Large urban agglomerations, or cities, are intense nodes of energy and material transformation and consumption. However, the biologically productive part of the human ecosystem, which sustains both the human and the industrial metabolism of the city, is located primarily in rural areas, as well as in oceans and other uninhabited locations. Urban dwellers still rely on rural residents to transform and tap these rural ecosystems, and much human activity in rural areas responds to urban demands. Historically, the development of urban centers has been tightly bound up with changes in the surrounding ecosystems (Cronon 1992). Increasingly, urban systems are also linked to more distant ecosystems scattered across the globe.

Although it is the concentration of humans that makes an area urban, urban areas are also home to many nonhuman species. Many studies of urban ecosystems have focused on these species and their relations with each other and with nonliving components of the urban environment. (See Box 27.2.) These may include, for example, forest, wetland, or grassland ecosystems that exist in and around cities and towns. These ecosystems provide services to humans, such as recreation in urban parks and fresh

BOX 27.2

Chapter Topic: Ecosystems in Urban Systems, Urban Systems as Ecosystems, or Ecosystems and Urban Systems?

There is a significant literature on ecosystems within urban areas and an emerging literature on the ecology of urban areas, treating urban systems as ecosystems (Hejný et al. 1990; Platt et al. 1994; Pickett et al. 1997; Brennan 1999; Grimm et al. 2000; Pickett et al. 2001). Whereas the former is consistent with traditional ecosystems analysis, which has treated human activity as disturbing rather than constituting ecosystem dynamics, the latter is more consistent with the MA, which clearly situates humans within ecosystems (MA 2003).

This chapter does not restrict itself to examining the conditions and trends of ecosystem remnants in and around urban centers, nor does it rely on treating urban systems as ecosystems or treat all urban services as ecosystems services. Related to this, although it is accepted that urban systems have social as well as biophysical dimensions, ecosystems are understood to be biophysical systems, and the value of ecosystem services is assumed to be distinct from the value intentionally added through the application of human labor. Thus the urban conditions and trends of primary concern in this chapter are biophysical; social conditions and trends that do not have clear relation to these biophysical conditions and trends are not examined in any detail, even when they have important implications for human well-being.

As the result, this chapter only covers some of the ways in which urban development affects human well-being. There is no mention of urban violence, for example, and urban inequality is only considered to the extent that it affects access to or pressures on ecosystem services. Similarly, there is no systematic treatment of the benefits that derive from urban manufacturing or commercial services, except to the extent that they rely upon ecosystem services, as defined in the glossary of this report.

water from nearby watersheds, some of which are difficult to appropriate from ecosystems that are farther away.

Understanding these ecosystems in urban areas can not only help with ecosystem management within urban areas, it can also help us understand how urban systems function more broadly (Berkowitz et al. 2003). From this perspective, not only are urban systems characterized by a varied landscape, consisting of a range of ecosystems and habitats, but the shift from rural to urban can be conceived of in terms of a series of gradients rather than a single threshold or boundary. Typical rural-urban gradients include not only increasing human population density and increasing shares of impermeable land cover, but also decreasing population density for many nonhuman species (McDonnell and Pickett 1991, 1997; Blair 1996; Natuhara and Imai 1996; Rolando et al. 1997; Denys and Schmidt 1998; Luck and Wu 2002) as well as changes in species diversity. The dynamics of ecosystem change in and around urban centers are also influenced by a number of features characteristic of how urban landscapes change, such as a high rate of introduction of alien species, high habitat diversity and fragmentation, and a high rate of (human-induced) habitat disturbance (Rebelee 1994; Niemela 1999).

Humans themselves are host to many microorganisms; changing urban settlement patterns influence the relations between humans and these microorganisms, some of which cause human diseases. Just as early shifts from hunting and gathering changed the infectious disease profile of early agriculturalists, changing patterns of human movement and settlement are still influencing infectious as well as noninfectious diseases (Anderson and May 1991; McNeill 1993). (See also Chapters 13 and 14.)

Shifts in the drivers of change in urban systems at very different scales often combine to create new challenges for humans. Urban development and trade, for example, enabled the epidemics that devastated Europe in the Middle Ages and introduced people in large parts of the world to infectious diseases they had never encountered and to which they were particularly susceptible (McNeill 1989). The affluent cities of the nineteenth century spearheaded industrialization and economic ''modernization,'' but on average the people living in these cities lived shorter lives than did their rural contemporaries (Bairoch 1988; Woods 2003). The emergence and spread of HIV/AIDS toward the end of the twentieth century has itself been an urban-centered phenomenon, with large urban populations one of the conditions resulting in its emergence as a significant human disease and with a higher urban than rural prevalence in sub-Saharan Africa, where there are indications that it is beginning to affect urbanization levels (Dyson 2003). Despite all these challenges and setbacks and the significant number of countries where life expectancies have declined in recent years (McMichael et al. 2004), on average people living in urban centers today live longer and healthier lives than ever before.

Urban areas are more spatially scattered than most other systems assessed in the MA. On the other hand, urban centers are closely interlinked. Indeed, geographers have long viewed urban systems not as individual settlements but as networks of urban centers connected by flows of capital, people, information, and commodities regionally (Armstrong and McGee 1985).

27.1.1 Classifying Urban Settlements: Size, Economic Status, and Location

Of the many ways of classifying urban settlements, three of the most common are population size, economic condition, and location. All three are used in this chapter, with the particular emphases as described in this section.

27.1.1.1 Urban Population Size

Table 27.1 summarizes the distribution of the world's population by the population class of urban settlement in the year 2000, according to both the 2001 revision of *World Urbanization Prospects* from the Population Division of the United Nations (United Nations 2002) and the urban-rural mapping undertaken by the Center for International Earth Science Information Network in support of the MA (Balk et al. 2004). As indicated, and contrary to some of the more inflated rhetoric about ''exploding cities,'' more than half of the world's urban population lives in settlements of less than half a million inhabitants, and well under 10% live in cities of more than 10 million. Because of the higher densities of the latter, the share of urban land area accounted for by these large cities is considerably less than this. As described in later sections, however, even these figures reflect a continuing demographic shift toward urban living, and toward large cities in particular, that is having a profound effect on both the socioeconomic organization of the human world and the biophysical organization of the world as a whole.

Although settlement size is clearly related to the ability of an urban center to play certain roles, the size distributions of urban settlements show little evidence of clustering around certain sizes.

Table 27.1. Distribution of World Population by Size Class of Settlement, 2000 (CIESIN et al. 2004a, 2004b; United Nations 2002)

Size Class of Urban Settlement	UN Total Population	GRUMP[a] Total Population	GRUMP[a] Settlements	GRUMP[a] Population Density	UN Share of Total Population	GRUMP[a] Share of Total Population
	(million)	*(million)*	*(number)*	*(persons per sq. km.)*	*(percent)*	*(percent)*
Urban area	2,862	2,828	24,176	770	47.3	46.7
10 million or more	225	426	23	2,192	3.7	7.0
5 to 10 million	169	265	39	1,571	2.8	4.4
1 to 5 million	675	729	353	1,223	11.1	12.0
500,000 to 1million	290	280	395	821	4.8	4.6
under 500,000	1,503	1,128	23,366		24.8	18.6
100,000 to 500,000		568	2,792	706		9.4
50,000 to 100,000		223	3,199	517		3.7
20,000 to 50,000		229	7,297	419		3.8
5,000 to 20,000		108	10,078	183		1.8
Rural area	3,195	3,224		25	52.7	53.3
Total	**6,057**	**6,052**		**46**		

[a] Global Rural-Urban Mapping Project.

Instead, in many countries there is an approximately log-linear relationship between a ranking of the sizes of urban settlements and their actual populations. This has come to be known as the rank-size distribution. When the slope is exactly negative one, this implies that the largest city is twice the size of the second largest, three times the size of the third largest, and so on. The claim that the slope does tend to be exactly one is sometimes referred to as Zipf's Law and appears to hold for some countries, such as the United States. More generally, although the slopes may vary over time and between countries, given comparable definitions and criteria for including urban centers, rank size distributions do generally conform to a log-linear relation (Brakman et al. 2001).

27.1.1.2 Urban Economic Conditions

Economic conditions are not quite such obvious features of an urban center as its population size and are less easy to define and measure.

Table 27.2 summarizes the distribution of urban population based on the World Bank's classification of low-, lower middle-, upper middle-, and high-income countries. In principle, national income accounts can be adapted to urban centers and used to calculate the urban equivalent of GNP and GDP per capita. Because the required statistics are often not available at the appropriate level, however, it is more common to refer to the per capita income of the country where the urban centers are located. This will tend to be lower than the average income of the urban population, because in most countries average incomes are higher in urban centers than in rural areas, and in some countries the disparities are very significant (Eastwood and Lipton 2000).

As indicated, urbanization levels are higher in higher-income countries, although even in low-income countries almost one third of the population lives in urban areas, and about 60% of the world's urban population lives in low- or lower middle-income countries, implying a national income of less than $3,000 per capita in 2001.

Table 27.2. Population in Urban Areas and Percentage of Total Population That Is Urban, 2000. Economies are divided according to 2001 GNI per capita, calculated using the World Bank Atlas method. The groups are low-income, $745 or less; lower-middle-income, $746–2,975; upper-middle-income, $2,976–9,205; and high-income, $9,206 or more. (Based on figures from www.world bank.org/data/countryclass/countryclass.html in May 2003; data on percentage urban based on United Nations 2002)

Economy Group	Urban Population	Share Urban
	(million)	*(percent)*
Low-income countries	718	31.2
Lower-middle-income countries	949	44.6
Upper-middle-income countries	365	77.0
Upper-income countries	731	79.2
Undesignated	99	41.7
World	**2,862**	**47.2**

27.1.1.3 Urban Location

In international statistics, urban location is conventionally summarized in terms of countries or regions. This typically means that coastal-zone settlements are combined with inland settlements, mountain with lowland settlements, and so on. Following a brief overview of the regional distribution, this section uses a newly constructed urban-rural database (Balk et al. 2004) to examine the distribution of urban populations in relation to the principal nonurban systems used in the MA. The bases for the system boundaries are summarized in Chapter 1. These systems are not mutually exclusive.

Table 27.3 provides a summary of urban population by continent, based on the regions used by the United Nations Population Division. The two lowest-income continents (Africa and Asia)

Table 27.3. Population in Urban Areas, and Share Urban, for World and Major Areas, 2000, Comparison of U.N. and GRUMP Statistics (CIESIN et al. 2004a, 2004b; United Nations 2002)

Region	UN		GRUMP[a]	
	Urban Population	Share Urban	Urban Population	Share Urban
	(million)	*(percent)*	*(million)*	*(percent)*
Africa	295	37.2	304	38.4
Asia	1,376	37.5	1,378	37.5
Latin America and Caribbean	391	75.4	352	67.9

World	**2,862**	**47.2**	**2,828**	**46.7**

[a] Global Rural-Urban Mapping Project.

are also the least urbanized. Whereas Latin America has conventionally been combined with Asia and Africa in discussions of "developing countries," its level of urbanization is comparable to that of Europe and North America. Furthermore, the overall and urban population densities in Latin America are comparable (26 and 656 persons per square kilometer, respectively) to those found in Europe (32 and 588) and North America (17 and 289). In contrast, sparsely populated Africa (27 persons per square kilometer overall) has urban areas as dense as those found in densely populated Asia (120 overall): both over 1,250 persons per square kilometer. Rural densities tend to be fairly consistent by continent with the exception of Asia, where population densities are more than four times greater than that of any other continent.

The coastal system is disproportionately more urban than other systems assessed in the MA. (See Table 27.4.) Population densities in both urban and rural areas are especially high in coastal areas because of the services available from coastal systems and the access to transportation. The population density of urban areas in the coastal zones is about 45% greater than the average density of urban areas globally.

The coastal zone is also the system with the greatest share of urban land area (10.2% globally), as indicated in the far-right columns in Table 27.4. Cultivated agricultural systems and inland water zones also have urban land areas that are higher than average. It is noteworthy that in addition these systems are more densely populated than average. Coastal, cultivated, and inland water zones tend to support the world's largest cities, as shown in Table 27.5. Conversely, mountain, forest, and dryland systems tend to support smaller settlements than the other systems. However, as Table 27.4 also shows, coastal and inland water systems are less populated than cultivated zones and thus do not contain such large shares of urban dwellers.

Many of the differences between the MA systems globally are also evident within individual continents. (See Table 27.6.) In every continent except North America, for example, the highest shares of urban population and land are in the coastal zones; even in North America the figures for the coastal zone are well above the continent average. The differences are more accentuated in some continents than others, however. Thus, whereas populations of the coastal zones of Europe and North America are only slightly more urbanized than their continental averages (84% and 90% in the coastal zones, compared with 71% and 81% on average), in Asia and even more in Africa the differences are far more striking (56% and 72% in the coastal zones, compared with 37% and 38% on average). The net result, when combined with other factors, is that the two continents with the lowest shares of population living in urban areas have the greatest number of coastal urban dwellers per square kilometer of coastal zone.

Total urban population distribution also tends to reflect a region's underlying system characteristics. For example, more than

Table 27.4. Population Estimates, Densities, and Land Areas for MA Systems, by Urban and Rural (CIESIN et al. 2004a, 2004b)

Inland water	780,000	24,000 (3.1%)	49,000 (6.2%)	48,000 (6.1%)	151,000 (19.4%)	81,000 (10.4%)	193,000 (24.8%)	79,000 (10.2%)	154,000 (19.8%)
Mountain	349,000	21,000 (6.1%)	47,000 (13.3%)	35,000 (10.1%)	77,000 (22.1%)	34,000 (9.7%)	85,000 (24.4%)	25,000 (7.2%)	24,000 (7.0%)

Note: Urban population figures have been rounded to nearest million, therefore total population does not equal the sum of populations in all settlement sizes. Percent columns do not sum to 100. Island systems are excluded.

half of Africa's urban population lives in dryland or cultivated systems because these systems predominate in Africa, even though the total population of these systems is only about 20% urban. Similar patterns are observed globally. Further, predominating ecosystems—drylands in Africa, for example—may be home to Africa's largest cities, even though they tend to be less urban overall than other systems, simply by virtue of the size of the system (and the constraints imposed by political borders).

Although it is beyond the scope of this chapter to examine the differential impact of cities across the ecosystems they inhabit, which depends heavily on local conditions, monitoring urban locations in relation to ecosystems is a potentially important contribution to policy debate and decision-making. More attention needs to be paid to preventing or restricting urban growth where this threatens ecosystem services, such as in watersheds or ecologically fragile areas. It may also be possible to identify locations where cities can benefit more from ecosystem services. It should be kept in mind, however, that urban growth in a liberal market economy occurs where investors decide to locate job-creating enterprises rather than where planners decide that growth ought to occur. Political processes can influence urban development, but urban location is not itself a policy decision.

27.1.2 Urbanization Trends

During the twentieth century, the world's urban population increased almost fifteenfold, rising from less than 15% to close to half the total population. In most middle- and high-income nations, the majority of the population to live in and work in urban areas. Many aspects of urban change during the twentieth century were unprecedented, including the size of each region's urban population, the number of nations having predominantly urban populations and economies, and the size and number of very large cities. For Europe, North America, and parts of Latin America, the most rapid urban change was mostly in the first half of the century; for most of the rest of the world, it was in the second half. During the past 50 years, most nations in Africa, Asia, and Latin America experienced rapid urban change, including cities whose population grew more than tenfold, and a growing share of the world's urban population and its largest cities have been in Africa, Asia, and Latin America. (See Table 27.7.) By 2000, most of the world's largest cities were, once again, found in Asia, not in Europe and North America. (See Table 27.8.)

Although there have been numerous cities with over 1 million inhabitants during the past 2,000 years, until recently they were rare (at most only one or two within the world at any one time), and they still existed within predominantly rural societies, except for a few city-states. Only in the late nineteenth century did London emerge as the first city with several million inhabitants; the megacities with 10 million or more inhabitants only emerged in the second half of the twentieth century. By 2001, there were 17 of these (United Nations 2002). Only with the industrial revolution did the increasing concentration of population (and production) in urban areas become commonplace.

Changes in urbanization levels were underpinned by large economic, social, political, and demographic changes. The main driver of urbanization (understood as an increase in the proportion of a population living in urban areas) is economic growth; in general, the most urbanized nations are those with the highest per capita incomes, and the nations with the largest increases in their levels of urbanization are those with the largest economic growth. Decolonization and the development of independent nation-states had large influences on urbanization levels for all of Africa and much of Asia, in part as controls on the rights of the inhabitants to live in or move to urban centers were dismantled, and in part because the building of the institutions for independent governments increased urban employment. In some countries, such as Australia, colonizing populations concentrated in urban settlements from the start, resulting in somewhat different patterns

of urban growth. In general, rapid demographic growth influenced growth rates for urban populations but had little influence on urbanization levels.

Although the general trend worldwide is toward increasingly urbanized societies, the aggregate statistics in Tables 27.7 and 27.8 obscure the great diversity in urban trends between nations (and how these change over time) and within nations, especially the large-population nations. Nations may have been urbanizing more slowly than anticipated in the past two decades because of poor economic performance, but this may not register in the official estimates of countries that have not had recent population censuses. Many of the world's largest cities have had significant decelerations in their population growth rates and have much smaller populations in 2000 than had been anticipated. In 1978, for example, the United Nations Population Division projected Mexico City's population in 2000 to be 31 million and that of São Paulo to be 26 million, whereas the population of both these cities in 2000 was estimated at 18 million (Satterthwaite 2002).

Most of the world's largest cities either have key global roles (the command-and-control centers for global or regional economies) or are centers linking large national economies with the global economy. The exceptions tend to be national capitals or former national capitals in large-population nations (such as Cairo, Lagos, and Delhi), and there are also locations that have major roles in the global economy without very large cities, as shown by Zurich and Silicon Valley. However, the world's large cities will increasingly be those that are successful in concentrating enterprises able to compete in the global economy, and the low- and middle-income nations that urbanize most will be those with more successful economies (Satterthwaite 2002).

The low-income nations in Africa, Asia, and Latin America that do not have successful economies are unlikely to urbanize much unless civil conflict or famine drives people to urban centers. However, recent trends in Africa may appear to contradict this assessment. In the most recent U.N. Population Division figures for urban trends, it appears that most of sub-Saharan Africa continued urbanizing rapidly during the 1990s, despite very poor economic performance. However, a lack of reliable census data means that most urban population statistics for the region from 1990 onwards are based on projections from older census data. In many sub-Saharan African nations, there is only one census available between 1959 and the present; for many more, there are only two. In the most recent U.N. Population Division compendium of urban statistics (United Nations 2004), very few sub-Saharan African nations had new census data from the past 10 years. Thus it is likely that many sub-Saharan African nations urbanized much more slowly during the 1990s than the U.N. figures (based on projections) suggest.

Although most urbanization will take place in the nations with growing economies, this is likely to be less concentrated in very large cities than in the past, or at least less concentrated in what are today the world's largest cities. In successful economies with good transport and communications systems and increasingly competent local authorities outside the larger cities, new investment is often targeted outside the largest cities, and most large cities are also becoming more dispersed (McGee and Robinson

Table 27.8. Distribution of World's Largest Cities by Region over Time. The statistics for 2000 in this Table are an aggregation of national statistics, many of which draw on national censuses held in 1999, 2000, or 2001, but some are based on estimates or projections from statistics drawn from censuses held around 1990. There is also a group of countries (mostly in Africa) for which there are no census data since the 1970s or early 1980s, so all figures for their urban populations are based on estimates and projections. (Satterthwaite 2002; data for 1950 and 2000 from United Nations 2002; data for 1800 and 1900 from IIED database, drawn from various sources, including Chandler et al. 1974, Chandler 1987, and Showers 1979)

1995). Within wealthier nations, urbanization has become obscured as increasing numbers of rural dwellers do not work in typical ''rural'' occupations such as forestry and farming, including those who commute to urban areas, those who are retired and live supported by pensions, and those able to work in rural areas because of advanced telecommunications systems (such as industrial or service enterprises located in greenfield sites in what are officially classified as ''rural'' areas or those who telecommute) (Pahl 1965).

27.1.3 Urban Systems and Ecosystem Services

The net flow of ecosystem services is invariably into rather than out of urban systems. These flows have increased even more rapidly than has urban population growth in recent centuries, and the average distance of these flows has increased substantially as well.

In the fourteenth century, Ibn Khaldûn could advise the planners of his day to locate new towns in well-protected locations with wholesome air, ample freshwater resources, and easy access to pastures for livestock, arable fields for grain, and forests for fuel (Khaldûn 1981). Few modern urban populations can still rely on local ecosystem services to meet their fuel, food, or water needs. The scale of the relationship between urban centers and ecosystem services has expanded, and while the global linkages may be especially evident for the more affluent cities, this expansion has been experienced by virtually all urban areas.

In light of these changing spatial relations, it is useful to distinguish among the linkages between urban systems and ecosystem services that exist within urban areas, between urban centers adjoining nonurban ecosystems, and between urban centers and distant ecosystems. Moreover, to appreciate the importance of relations between urban systems and ecosystem services, it is important to consider the negative as well as the positive effects that urban systems can have on ecosystem services. Even if urban systems are not major producers of ecosystem services, urban activities can alter the supply of ecosystem services at every scale, from within to far beyond the bounds of the urban area itself.

Within urban areas, the primary issue from the perspective of human well-being is whether the urban settlements provide a healthy and satisfying living environment for residents. Urban development can easily threaten the quality of the air, the quality and availability of water, the waste processing and recycling systems, and many other qualities of the ambient environment that contribute to human well-being. Certain groups (such as low-income residents) are particularly vulnerable, and certain services (such as those not easily traded or brought in from outside—the recreational services provided through urban parks, for instance) are of concern to all urban dwellers. Moreover, even for easily traded products, local ecosystems can be important, especially for households that lack the monetary income to purchase imports. Agriculture practiced within urban boundaries, for example, contributes significantly to food security in urban Sub-Saharan Africa (Bakker et al. 2000).

The urban area and its surrounding region is a better scale at which to understand the relations between urban development and local ecosystems. People in urban areas have historically been heavily dependent on adjoining systems for food, clean water, waste disposal, and a range of other services. The intensity of interaction between an urban system and its surroundings tends to fall off with increasing distance. Interaction also tends to be more intense along certain corridors (such as rivers and roads) and within environmentally bounded areas, such as watersheds. Because most urban centers are growing in population and extent, the peri-urban areas where the systems adjoining urban systems are located are also undergoing a twofold transformation, with arable land coming under increasingly intense cultivation and both arable and nonarable land being increasingly built over to provide space for commercial, industrial, and residential establishments and for roads and parking facilities. The more populated an urban area is, the greater its influence is likely to be on surrounding areas, although other characteristics, such as industrial production levels and per capita incomes, can also be important (Hardoy et al. 2001). (Peri-urban is used in this chapter to refer to land around the edges of an urban area, either just within or beyond urban boundaries, where land use patterns are often in the process of changing from more rural (agriculture) to more urban (buildings).)

In order to capture all the ecosystem service flows into urban areas, it is also necessary to consider the global scale, as many of the ecosystem services contributing to urban well-being do not depend upon the condition of local environments and ecosystems. Many products and amenities used in urban areas, including food, are traded extensively, and their availability depends primarily on the purchasing power of local residents. By importing goods, urban consumers are effectively drawing on ecosystem services from other parts of the planet. The institutions and practices controlling the ecosystems of origin remain outside the political reach of urban consumers (although emerging exceptions include certification systems (Bass et al. 2001)). Affluent consumers (and producers) are also increasingly likely to be contributing to pollutants whose impacts are themselves spread out across increasingly large areas (Wackernagel and Rees 1996; McGranahan et al. 2001).

Table 27.9 presents problems relating to urban systems and ecosystem services that are potentially of critical importance to human well-being at each of these three scales. Superficially, these problems can seem to represent a temporal sequence from past problems (such as bad urban water and sanitation) toward modern and even future problems (such as climate change). However, there are many urban centers today that still have bad urban water and sanitation, and the more obvious description of the current state of affairs is that all sets of problems coexist, but with different severity in different parts of the world. Similarly, although superficially there can seem to be a shift from issues involving the provisioning of private goods (such as water for home consumption) to those involving the provision of public goods (such as global climate stability), at their own scales all these issues involve externalities and public goods.

All these problems also involve issues of human well-being and social justice, with distinct spatial dimensions. Unhealthy and unpleasant living conditions involve the most vulnerable groups living in urban areas and the risks they face when local ecosystem services are lacking and alternatives are inaccessible. At the second scale, when urban development harms ecosystems in the surrounding region, there are more extensive issues of spatial injustice, although most of those affected are likely to be of the same nationality. The third scale involves burdens that urban activities impose on distant people and future generations by reducing their access to ecosystem services, either because these services are diverted to urban uses or because the ecosystems themselves are degraded: this raises international issues of spatial justice as well as issues of temporal justice.

As described in Box 27.3, the patterns described in Table 27.9 can also be represented in terms of stylized urban environmental transitions, displaying a historical tendency for more economically successful urban settlements to create more extensive and delayed environmental burdens. There is also a great deal of variation between urban centers of similar economic status, and no reason to assume that this stylized transition represents current or future urban development patterns. Currently, however, it is rare to find a very poor urban community that does not face serious environmental health hazards or a very affluent urban community that does not impose a large ecological footprint (as described later in this chapter).

27.2 Condition and Trends of Urban Systems and Ecosystems

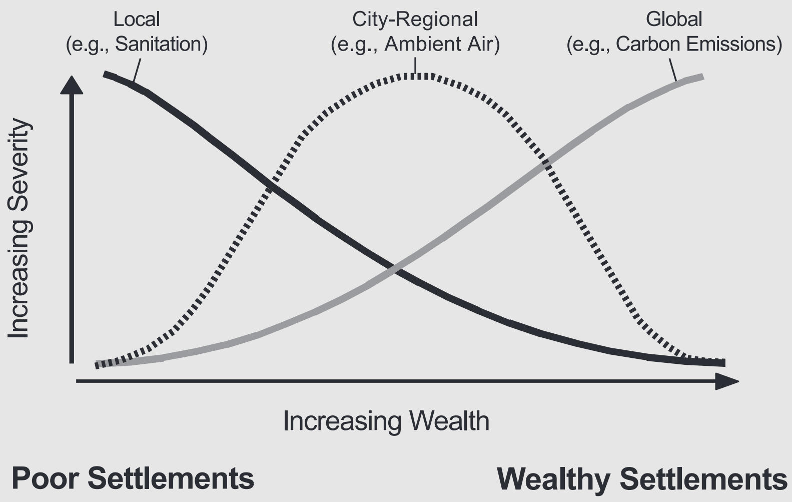
This description of condition and trends builds on the spatial classifications presented earlier. The first section examines the condi-

Table 27.9. Priority Problems in Urban Systems and Ecosystem Services at Three Different Spatial Scales

Problem and Characteristics	Intra-Urban (Urban Systems as Human Habitats)	Urban-Region (Urban Systems and Their Biospheres)	Urban-Globe (Urban Systems and Global Ecosystems)
Priority problem identified	unhealthy and unpleasant living environments	deteriorating relations with adjoining ecosystems	excessive "ecological footprints"
Urban areas most closely associated with problems	low-income cities and neighborhoods	large, middle-income, industrial cities	affluent cities and suburbs
Indirect driving forces	demographic change, inequality; trade and development that ignores ecology of infectious diseases and urban ecosystem services	industrialization, motorization; trade and development that ignores impacts on adjoining ecosystems	material affluence, waste generation; trade and development that ignores global ecosystem impacts
Direct driving forces	inadequate household access to safe water, sanitation, clean fuels, land for housing	ambient air pollution, groundwater degradation, river pollution, resource plundering, land use pressures	greenhouse gas emissions, import of resource and waste intensive goods (linear vs. circular flows)
Negative impacts associated with problem	spread of infectious diseases, loss of human welfare and dignity	loss of natural ecosystem services, "modern" diseases, declining agroecosystem productivity	global climate change, loss of biodiversity, depletion of globally scarce natural resources
Temporal characterization of key processes	rapid	varied	slow
Example of historically relevant response	sanitary reform	pollution controls	sustainable cities?

BOX 27.3

The Relationship between Economic Conditions and Urban Environmental Burdens



Shifting Environmental Burdens

Local ⟶ Global

Immediate ⟶ Delayed

Threaten Health Directly ⟶ Threaten Life Support Systems

(McGranahan et al. 2001)

This stylized diagram portrays local environmental health burdens declining with increasing urban affluence, global burdens increasing, and city-regional burdens first increasing and then declining (McGranahan et al. 2001). As with many ecological systems, the "big" processes are "slow" whereas the "small" processes are "fast" (MA 2003, pp. 114–17), with the result that the burdens associated with low-income settlements affect poor people in the present, whereas those associated with affluent settlements affect a more extensive public after a considerable delay.

A number of similar diagrams have been generated to describe urban "transitions". Smith and Lee (1993) presented an urban environmental risk transition in terms of two curves—one representing declining traditional risks (such as fecally contaminated water and food, or indoor air pollution due to smoky cooking fuels) and the other increasing modern risks (such as exposure to industrial pollution). Holdren and Smith (2000) more recently adapted the Figure reproduced here to present a risk transition that incorporates the risks arising from global threats such as climate change.

Bai and Imura (2000) and Bai (2003) presented similar curves to provide a conceptual illustration of a staged evolutionary trajectory of environmental problems in cities as they become more affluent and as their environmental burdens shift from poverty-related to production-related and finally to consumption-related challenges. Marcotullio (2004) and Marcotullio and Lee (2003) used the Figure as a basis for exploring the differences between western and rapidly developing Asian urban environmental transition histories, hypothesizing that transitions in rapidly developing countries are occurring sooner (at lower incomes), faster (increasing more rapidly over time), and more simultaneously (with greater overlaps among sets of environmental burdens) than those experienced by what are now industrial-world cities.

tion and dynamics of ecosystems in and around urban settlements. The second focuses on the condition and trends in the suitability of urban areas as habitats for humans. The third section examines how urban systems relate to adjoining ecosystems and their ecosystem services. The fourth and last section focuses on the global pressures that urban systems exert on ecosystems.

27.2.1 Condition and Dynamics of Ecosystems within Urban and Peri-urban Areas

Ecosystems in urban and peri-urban areas often display distinctive characteristics and dynamics that are neither of human design nor a hold-over from some rural past. Historically, urban planners have been inclined to focus on the purposefully designed and built components of urban systems and to ignore all but the most glaring changes in local ecosystems. Their environmental critics, on the other hand, have been inclined to focus on the loss of rural ecosystems and services. The combined effect has been the neglect of new opportunities that urban development creates for nonhuman species and ecosystems (not all of which benefit humans, of course).

27.2.1.1 Nonhuman Species and Ecosystems in Urban Areas

Although a concentration of humans is a defining feature of them, urban areas typically contain numerous opportunities for the persistence of native nonhuman species as well as the invasion or introduction of exotic species. Similarly, although a high share of built-over land is often used to identify areas as urban, urban land is far from impervious and often includes a range of different land use types, including gardens, grassland, wooded land, and agricultural land.

Urban and peri-urban ecosystems are heavily influenced by environmental change driven by people, but they also reflect the ability of plants, animals, and microorganisms to survive and exploit these changes. Urban construction and production typically conflict with wildlife and habitat conservation (Thompson 2003). They frequently result in the loss of critical wetland habitats, forest environments, and coastal sites and threaten many aspects of biodiversity. Urban development does not eliminate natural processes, however. It creates different opportunities and allows for new combinations of species through both introductions of exotic species to parks and gardens and the migration of invasive species. Many new opportunities are provided by the habitat shifts created by modification of biogeochemical cycles and the adjustment of micro- and local climates to make human life more comfortable, and some species are more able than others to exploit urban opportunities (see Rydell 1992 and Shapiro 2002 for examples relating to bats and butterflies).

Urban structures themselves provide opportunities for organisms—from the rats in the sewers to the birds nesting under the eaves of buildings. Spillages in factories, retail outlets, transport depots, and homes can create abundant food sources. Important mineral nutrients, such as calcium and magnesium, are common in building materials and find their way into urban soils (Bradshaw 2003). Parks, gardens, and zoos provide sites for a variety of plants and animals, including introduced and exotic species. Vacant and derelict sites are also colonized, and urban areas often include disused sites at various stages of succession. (See Table 27.10.)

The thermal properties of built-over land surfaces result in more solar energy being stored and converted to sensible heat (the heat energy stored in a substance as a result of an increase in its temperature), and the removal of shrubs and trees reduces the natural cooling effects of shading and evapotranspiration. The average ambient temperature in urban systems is generally 2–3 degrees higher than in nonurban systems, which can cause discomfort and even health risks in locations that are already warm

Table 27.10. Essential Steps in the Process of Natural Succession in Urban Areas (Bradshaw 2003)

Ecosystem Attribute	Processes Involved
Colonization by species	immigration of plant species establishment of those plant species adapted to the local condition
Growth and accumulation of resources	surface stabilization and accumulation of fine mineral materials accumulation of nutrients, particularly nitrogen
Development of the physical environment	accumulation of organic matter immigration of soil flora and fauna causing changes in soil structure and function
Development of recycling process	development of soil microflora and fauna possible difficulties in urban areas
Occurrence of replacement process	negative interactions between species by competition positive interaction by facilitation
Full development of the ecosystem	further growth new immigration, including aliens
Arrested succession	effect of external factors reduction of development
Final diversification	the city as a mosaic of environments high biodiversity as a result

or can lead to greater use of air-conditioning and attendant energy consumption. It can also exacerbate urban air pollution, alter rainfall patterns in and around urban centers, and change the composition of urban wildlife (see, e.g., Nowak et al. 2002). On the other hand, the heat island effect can attract warmth-seeking species to urban areas, and for people, too, more warmth is not always a disadvantage.

Within built-up areas, complex mosaics of land use emerge. The inner areas of many older North American cities, for example, have abandoned areas that may be totally neglected or derelict but that provide opportunities to create urban gardens that can be beneficial to local residents' well-being and health (Dinno 2000). In addition to abandoned spaces, there are numerous areas of vegetation that are planted or managed to some degree, ranging from roadside verges and canal and railway corridors to formal gardens, parks, urban woodlands, ponds, and lakes.

There is a trend to develop areas of more natural vegetation in cities, establishing urban nature reserves, such as the 1-hectare Camley Street Reserve adjacent to Kings Cross Station in London and the 1,215-hectare Rock Creek Park in Washington, D.C., which is 86% wooded. Preserved natural areas can become symbolic for cities, such as the 164-hectare Bukit Timah Reserve in Singapore and the 11-hectare Bukit Nanas Reserve in Kuala Lumpur. Other areas are totally ephemeral, being invaded by vegetation while awaiting development. The value of these ephemeral patches of vegetation depends on how long they are left undisturbed and on the character of their substrates. Many derelict chemical works sites can offer unusually acid or alkaline sites that provide niches for plants associated with acid peat bogs or highly saline marshes not normally found in urban areas.

Collins et al. (2000) suggest a number of reasons why new human-imposed scales for ecological processes are found within urban areas. First, compared with ecosystems in rural areas, urban ecosystems are highly patchy and the spatial patch structure is characterized by a high point-to-point variation and degree of isolation between patches. Second, disturbances such as fire and flooding are suppressed in urban areas, and human-induced disturbances are more prevalent. Third, because of the higher temperatures in urban systems, in temperate climates there are longer vegetation growth periods. Fourth, ecological successions are altered, suppressed, or truncated in urban green areas, and the diversity and structure of communities of plants and animals may show fundamental differences from those of nonurban areas (Niemela 1999; Pickett et al. 2001).

The patchwork nature of urban ecosystems is accentuated by the variety of agencies, landowners, individuals, and businesses responsible for parcels of urban land, ranging from municipal parks and gardens departments, to public hospitals and educational institutions, to private individuals and corporations. Their differing goals and practices create diversity among these managed spaces. The urban environment is thus full of ecological discontinuities. Many species overcome these, simply surmounting obstacles—for example, the way urban foxes dash across main roads to get at other food sources. For some, however, migration corridors are important, and many planning strategies incorporate green corridors along streams or public utility easements. Preliminary results of investigations in Birmingham, England, suggest that the River Cole "wildlife corridor" does not enhance the number of wetland specialist species but it may act to increase and stabilize the number of habitat generalist species (Small 2000).

Compared with relatively simple temperate forest ecosystems, temperate industrialized agroecosystems, or tropical plantations, urban areas tend to be high in species richness as a result of the high habitat diversity of urban areas (Rebele 1994). However, some of the species richness is due to introduced species and is not always conducive to high levels of biodiversity at larger scales. An imported species that initially increases the species diversity within an urban area can, in certain circumstances, become an invasive species that reduces biodiversity in the surrounding areas. For example, on March 6, 1890, 40 pairs of the European Starling (*Sturnus vulgaris*) were released in New York's Central Park. Within a few years the starlings had spread from coast to coast, and they are now one of the most common birds in the United States, competing with native species (Kieran 1995; Mittelback and Crewdson 1997).

27.2.1.2 Contrasting Urban and Peri-urban Areas

In several studies, species diversity along an urban-rural gradient has tentatively been found to be hump-shaped in distribution, with the highest diversity in areas between rural areas and the urban core (Blair 1996; Blair and Launer 1997). The generality of this pattern across taxa has not been thoroughly investigated, nor have the mechanisms leading to such a pattern. It is, however, consistent with a more general observation that peri-urban areas are more varied and changing than are central urban or more distant rural locations.

In the heart of built-up areas, there is often a large share of fixed or long-term land uses. Although one building may replace another, comparatively few green spaces are built on, few new roads are created, and few new plants are introduced. It is in the peripheries and suburbs that the most rapid land use changes typically occur, usually with a loss of gardens and other open spaces and with increases in paved and roofed impermeable areas, as apartments or compound housing units replace single family dwellings and as retail land office buildings get larger. Sometimes new green spaces are created in such redevelopment projects, although these are often landscaped and maintained.

At the edge of the built-up area, large tracts of land are affected by transient uses. These peri-urban areas (except for many protected areas, which often include river valley and transportation corridors) undergo a change from rural to increasingly urban uses. In many North American and Australian peri-urban areas, the transition typically begins with the building of isolated houses for comparatively affluent townspeople. In much of Africa, Asia, and South America, on the other hand, migrants and a mix of long-standing residents frequently occupy peri-urban areas. Extremely poor people build temporary dwellings on any land from which they are not immediately evicted, provided there are employment opportunities. They may also cultivate food for themselves, hoping to sell the surplus at the roadside or in urban markets. (See Box 27.4.) Such land cover changes introduce not only plants but also a variety of waste and other materials to the local environment, which is likely to alter both the character and the dynamics of local ecosystems.

Alternatively, land-market economics can lead to agricultural land around the city being taken out of production while the owner waits for the price for urban uses to rise. In urbanizing rice-growing areas of Asia, this process can result in a patchwork of developed former rice fields, abandoned rice fields, and rice fields that are still being cultivated. Settlements and even regions may combine characteristically urban and rural features (McGee 1991).

With tight greenbelt planning regulations around many European cities (Hall 2002), the pace of peri-urban land cover change is often not as obvious as elsewhere in the world, such as in the United States, where it has been estimated that urban area has doubled since 1960 (Heimlich and Anderson 2001). In many rapidly growing cities in low- and middle-income countries, areas that were totally rural 10 years ago may be part of suburbia today. The peri-urban transition zone migrates out from the city almost relentlessly unless tight regulations are enforced or transport costs are high, as they were when many of the more compact cities developed (Bairoch 1988; Newman and Kenworthy 1999).

Rapid urban development also creates peri-urban demands for earth resources, especially aggregates and brick-making clays, and for land for disposal of wastes. Frequently, industries with high levels of pollution or hazardous wastes are also located in peri-urban zones, so that there is a high risk of contamination from industrial chemicals and toxic substances. Thus peri-urban zones may accommodate potentially conflicting activities. The juxtaposition of emissions of chemicals, disposal of waste, and peri-urban agriculture can lead to many health hazards. Vermin from waste dumps can be a threat to crops, domestic animals, and human beings.

Where urban settlements are themselves combining into large conurbations, the distinction between urban and peri-urban areas often ceases to be meaningful. In a multicentered agglomeration, for example, an area near the middle of the agglomeration may be peripheral to several sub-centers and retain at least some features characteristic of peri-urban areas. Green areas often remain between the original major towns, particularly where there is a history of greenbelt designation. At the same time, the inner areas of the city show successive waves of building, demolition, and rebuilding as needs change and as industry and business activity grows and declines.

27.2.1.3 Ecosystem Services in Urban and Peri-urban Areas

Whereas urban development is driven by deliberate human activity, most of the ecosystem changes that occur in and around cities are unintentional. These changes affect the supply of ecosystem services, including the regulation and ecology of human diseases.

By the time a given area is urbanized, most pre-existing ecosystems are likely to be severely disrupted, if not entirely transformed. Even the ecosystems associated with lands that remain comparatively undisturbed are likely to be altered by the habitat fragmentation and pollution that typically accompany urbanization (Bradshaw 2003). New opportunities for native species may arise, but in a different context and with potentially important implications for local ecosystem dynamics. Newly introduced species find opportunities beyond their area of introduction and compete with native species.

In urban areas and their margins, ecosystems can provide an especially wide range of services. The most widely recognized services are associated with green spaces and are recreational and cultural. Parks have become a central part of the identity of many urban centers, and greenbelts are an increasingly accepted means of providing outdoor recreation facilities for urban dwellers. In the MA sub-global assessment for Stockholm, 10 potential urban ecosystem services in National City Park have so far been examined, including not only recreational and cultural values but also air filtration, regulation of microclimate, noise reduction, surface-water drainage, nutrient retention, genetic library, pollination, seed dispersal, and insect pest regulation (Bolund and Hunhammar 1999). The sustainable supply of these ecosystem services depends not only on the presence of the parkland but also on the resilience of the ecosystems that provide them. This resilience could be undermined by insufficient conservation of parkland and by increased fragmentation. Alternatively, many of these services are also provided to at least some degree by non-park land, even if a park is one of the urban sites where the scope for managing and enhancing the value of these services is greatest (Elmqvist et al. 2004).

Just as not all ecosystem services arising from urban ecosystems are from green spaces, not all green spaces are ecologically beneficial. Urban and suburban lawns, for example, provide recreational services to their homeowners, aesthetic value to the neighborhood, and a number of other ecosystem services. However, large quantities of water, fertilizer, and pesticides are applied to maintain the aesthetics of the green lawns, especially in affluent countries, with numerous adverse consequences (Robbins et al. 2001). Indeed, fertilizers and pesticides are applied more intensively to lawns in the United States than to arable lands in large parts of the world (Robbins et al. 2001).

The lack of some ecosystem services in urban systems makes them more valuable. For example, the at-field value of urban agricultural produce is greater than that produced elsewhere because it does not need to be transported so far to reach the consumer. Some ecosystem services in urban areas can become so degraded through overuse that changes that would otherwise increase service delivery are of no avail. For example, once groundwater is no longer used for drinking purposes due to low quality, a further loss in the capacity of local ecosystems to filter and clean the water is less directly relevant. The result is the importation of the service from other ecosystems (in this case, through piped or bottled water), often at higher overall cost. Moreover, high population densities and the fact that some of these services provide spatially

BOX 27.4

Urban Agriculture, Vulnerability, and Recycling

For many of today's urban dwellers, urban agriculture provides an important source of food and supplementary income, especially in times of economic crisis. Although urban agriculture is associated with environmental health risks, it also has many environmental advantages and can help to provide a range of ecosystem services within urban areas.

There are no reliable estimates of the land used, the labor applied, or the outputs produced by urban agriculture. This is not surprising. The extent of urban agriculture is particularly sensitive to where urban boundaries are drawn, because a large share is located on the margins of urban areas. More centrally located agriculture is often spatially scattered and involves a large number of small plots (or even pots and pools) and animals (domestic fowl, for instance) that are difficult to identify, let alone monitor. In many cities, agriculture is officially banned, further complicating any attempt to collect reliable statistics.

There is, however, a growing body of research detailing the importance of urban agriculture in particular locations and for particular groups (United Nations Development Programme 1996; ETC—Urban Agriculture Programme 2001). This research suggests that urban agriculture can provide a number of major benefits: income and food security for producers; employment for under- or unemployed residents; lower prices for urban consumers; environmental improvements such as reduced runoff; and avoided costs of wastewater treatment and solid waste disposal. Urban farming takes place not only in peri-urban fields but also on rooftops, in backyards, in community vegetable and fruit gardens, and on unused or public spaces. It produces high-value products like fruit, vegetables, and fish, staples such as cassava, maize, and beans, and supplementary products such as berries, nuts, herbs, and spices. Urban agricultural enterprises range from highly commercialized operations to small informal and occasional enterprises. These latter operations are typically managed by long-term urban residents, by the moderately poor, and often by women.

From the perspective of current human well-being, the most significant contribution of urban agriculture probably does not lie in the share of overall agriculture production for which it accounts, but in the food security and supplementary income it can provide to cash-strapped urban residents, and to women in particular. In response to the economic deprivations of recent decades, urban agriculture in sub-Saharan Africa provided an important safety net for those who could find the land (Maxwell 1999).

Urban agriculture reportedly grew rapidly in many African cities (Howorth et al. 2001; Page 2002; Bryld 2003), largely as an informal activity involving either on-plot cultivation in more densely settled areas or off-plot cultivation on urban peripheries and marginal lands (Rogerson 1995). The urban farmers are often not from the poorest groups (Flynn 2001), and indeed in some cities the very poor find it difficult to gain access to land. Regardless, urban agriculture has helped many urban Africans weather the continuing crisis, and where the data have been examined there is at least some evidence that urban agriculture is contributing to food security (Maxwell et al. 1998). Urban agriculture has often played a similar role in other parts of the world. For example, it emerged in Cuba in response to the decline of Soviet aid and trade and the persistence of the American trade embargo (Altieri et al. 1999; Moskow 1999).

Increasingly, proponents of urban agriculture also emphasize its ecological benefits (Smit and Nasr 1992). One of the ecological disadvantages of urban development is that it tends to replace circular flows with linear ones: ecological cycles are disrupted; materials previously returned to the soil as nutrients become urban waste; substances that are hazardous at high concentrations accumulate. Urban agriculture provides the opportunity to recycle the nutrients in urban organic waste (Eaton and Hilhorst 2003) and can be combined with "ecological sanitation" to improve public health (Esrey 2002). The cultivation of plants in urban areas can also provide other ecosystem services of particular value to urban dwellers, such as cooling and pollution reduction.

Urban agriculture does pose various problems. It can create environmental health problems including food contamination, water pollution, and the increased prevalence of disease vectors such as malarial mosquitoes (Birley and Lock 1998). When combined with ecological sanitation, there is the potential for improving public health if the systems are well managed, but there are also severe risks if management is poor. Moreover, theft can be an especially serious problem for urban agriculture. The fact that it remains illegal in a great many cities where it is practiced constrains its potential (Allen 1999). On the other hand, when agriculture is formally allowed, it often has difficulty competing against alternative urban land uses (Midmore and Jansen 2003); in some contexts, making urban agriculture legal could make it even harder for the poorest residents to gain access to the land.

In affluent cities, urban agriculture now tends to be associated with the production of high-value products supplied fresh to discerning local consumers. Because arable land is scarce and costly, farm sizes tend to be small and yields tend to be high. In the United States, for example, farming in metropolitan areas accounts for less than one fifth of the cropland but for about one third of farms and one third of the value of agricultural production (Heimlich and Anderson 2001). Even in the United States, however, urban agriculture is sometimes promoted as a means of improving food security for some of the more deprived urban communities (Allen 1999).

delimited public benefits (that is, one person's use does not detract from use by others) also help make ecosystem services more valuable in urban areas.

Some ecosystem services in urban locations are especially important to vulnerable groups. As described in Box 27.4, urban agriculture can enhance food security and supplement the livelihoods of the urban poor. In many urban areas, although the more affluent residents no longer use it, local groundwater continues to be used by those living in poverty despite being heavily contaminated. In Jakarta, for example, bottled water has become popular for those who can afford it, and piped water is available at a price in many parts of the city, but a large share of low-income households still rely on shallow groundwater and are very aware of differences in quality even among different wells in the neighborhood (McGranahan et al. 1998). Local ecosystem filtration clearly affects the quality of water, even if it often cannot make it truly potable. More generally, those who cannot afford to purchase alternatives are more dependent on local ecosystem services. This does not mean that protecting ecosystems and ecosystem services in urban areas will necessarily benefit vulnerable groups: vulnerable people are sometimes evicted from their homes in the name of environmental protection. It does mean, however, that there is the potential in many cities for policies that would both enhance ecosystem services and benefit vulnerable groups.

Among planners and decision-makers, there has historically been a strong tendency to neglect ecosystem services and other relations between ecosystems and human well-being, at least until a local or international crisis has forced such concerns onto the policy agenda. In many urban settlements, the quality of the urban groundwater and of the ambient air, for example, has been allowed to deteriorate considerably before any action has been taken (Melosi 2000; Tarr 1996). The policy debates are often very poorly informed, partly because of underlying ignorance about the processes involved, and partly because they are driven by vested interests rather than by sincere attempts to understand the nature of the problem (see, e.g., Davis 2002).

27.2.2 Urban Systems as Habitats for Humans

As long as people continue to live in urban areas, it is important for their well-being that the urban air be healthy to breathe, that there be sufficient water of adequate quality to meet domestic needs, that the urban landscape be pleasing to the eye, that the urban climate be comfortable, and generally that the urban environment be healthy and pleasant for people to live in. With urbanization, the ability of local ecosystems to provide these services tends to decline, even as the number of people per unit of area, and hence the need for these services, increases.

Many of the services once provided by local ecosystems are now provided by some combination of more-distant ecosystem services (such as water diverted to the city through constructed waterways) and manufactured services (such as water treatment plants). Even if the health benefits of the economic growth that has accompanied urbanization in most countries has outweighed the local loss of ecosystem services, these losses have been extremely important historically and remain important to this day, as described later in this section.

Urban development can bring major investments in public health infrastructure and measures to reduce exposure to environmental hazards. Without such investments and measures, urban areas would still be far less healthy than rural areas. With them, however, urban habitats are on average healthier (Montgomery et al. 2003, Chapter 7). Yet the benefits from urban investments in public health infrastructure are very unevenly distributed (Hardoy et al. 2001).

Although urban living is often associated in people's minds with industrial and motor vehicle pollution, the role of cities in facilitating the spread of infectious diseases has probably been more important to human health, and it remains important today. Humans are exceptional among animals in the high proportion of their deaths due to disease (see, e.g., McKeown 1988). Changes in human densities and travel patterns are implicated in the emergence of many of the most devastating infectious diseases.

Without sufficiently large urban settlements, a number of diseases, including measles and smallpox, could not be maintained in human populations (the measles virus, for example, can only persist in one person for a couple of weeks, and so at least 26 times a year it must move to a person who has not been previously infected) (Mascie-Taylor 1993). Trade and urban conditions helped spread the vectors and eventually the plagues that beset Europe during its early urbanization, and in the more extreme cases killed upward of 25% of the population (McNeill 1989). Urban settlements are still important to the spread of epidemics and pandemics, including, for example, HIV/AIDS (Dyson 2003; see also Chapter 14).

The water, sanitation, and hygiene problems described in the next section provide an example of urban conditions that historically created some of the most serious health problems and that remain significant to this day. In a recent World Health Organization ranking of leading risk factors in terms of attributable disease burdens, unsafe water, sanitation, and hygiene ranked sixth (WHO 2002). Water and sanitation deficiencies tend to be a particular risk in economically deprived areas, both rural and urban.

Urban exposure to chemical pollution is also important to human health and well-being. Urban development often leads to unintentional threats to health and well-being by increasing waste generation or by bringing people into closer contact with waste products, some of which contain harmful chemicals (as well as pathogens). These waste products may be in the urban air, water, or land, in public or private spaces, and in relatively more or less frequented locations. Exposure to health-threatening ambient urban air pollution is highest in large industrialized and motorized cities (McGranahan and Murray 2003), whereas health-threatening indoor air pollution is particularly severe in homes where smoky fuels are used without adequate ventilation (Saxena and Smith 2003). Neither surface nor groundwater is potable in most urban settlements, with chemical water pollution a particularly serious problem in industrial centers. Solid waste can contribute to urban air pollution (through burning, for instance) or water pollution (such as through leaching) or can result in direct exposure.

The ambient air pollution problems described in more detail later provide an example of an environmental health problem often considered quintessentially urban. The burden of disease attributable to urban air pollution is estimated to be less than one quarter of the burden from water and sanitation problems (WHO 2002). The burden of illness due to indoor air pollution, by contrast, is nearly the same as that due to water and sanitation problems (WHO 2002).

The later sections on air pollution and on water, sanitation, and health attempt to provide simplified accounts of how urban conditions affect ecosystem services (such as clean air and water) and hence human health. It is also important to recognize, however, that complex environmental interactions and enormous inter- and intraurban variation in environmental health conditions are themselves characteristic of the challenges encountered in urban habitats.

First, in the evolution of an epidemic or of an individual's health, there are discontinuities and thresholds in relations between environmental conditions and health outcomes. Thus, for example, declining sanitary conditions may initially increase the burden of endemic diarrheal diseases, and then, after crossing some threshold, allow a cholera epidemic to break out. An urban settlement's role in epidemics also depends on its size, with larger cities acting as reservoirs of disease and providing a source for outbreaks in smaller settlements below the threshold necessary to maintain the infection in the human population (Cliff et al. 1998). Alternatively, whereas the conditions in the United States and Europe were such that relatively small shifts in the ecology of malaria could lead to its disappearance, in the parts of sub-Saharan Africa where malaria is holoendemic (that is, in an equilibrium where the disease is endemic at a high level among children and adults show less evidence of the disease), the disease can persist in the face of far larger shifts (Bradley 1991).

Second, in service-deprived low-income neighborhoods the conventional boundaries between environmental health problems do not apply (McGranahan et al. 2001). As the result of home industries, occupational health hazards are often encountered in people's homes. When fecal material is not separated off and contained or flushed away, it can contaminate water supplies, become mixed with the solid waste, and attract flies and other pests. Where water is not piped into people's homes, it is more easily contaminated with fecal material and less likely to provide for good hygiene within the home, and there is a risk that water storage containers will become a breeding site for vectors of diseases such as dengue and dengue hemorrhagic fever. When solid waste is not contained and carried away, there is a significant likelihood that it will create unsightly, malodorous, and inconvenient accumulations of refuse and become a breeding ground for pests. And it will also cause air pollution when it is burned or flooding when it is washed into the drains. Combined with crowded housing, smoky fuels, the use of pesticides, and food storage problems, these multiple hazards often create extremely unhealthy living environments, especially for infants and children who have not yet built up resistance to infectious diseases (see, e.g., Cairncross and Feachem 1993; McGranahan et al. 2001; McGranahan and Murray 2003).

Third, many of the environmental conditions that facilitate the transmission of infectious diseases in deprived urban areas lie in the public domain, such as those associated with poor sanitation and solid waste removal, and create local public health risks that private actions cannot address effectively (Pickering et al. 1987; Bateman et al. 1993; McGranahan et al. 2001). Others, on the other hand, involve transmission within households. The relative importance of public and domestic routes of transmission varies, depending on the disease (Cairncross et al. 1995). Much the same applies to exposure to chemical pollutants; it is noteworthy that whereas indoor air pollution was identified as one of major risks to health in the most recent burden of disease estimates (WHO 2002), it was not even included in previous estimates (Murray and Lopez 1996).

The very nature of these interconnections makes the resulting hazards difficult to address, either through the privately negotiated trades that have historically underpinned the success of market economies or through public agency. Those who are most affected tend to have very little income or assets with which to trade and comparatively little political power with which to influence government agencies or political processes. In any case, pathogens, pests, and toxins respect neither the boundaries of private property nor those of organized communities, administrative areas, or ministerial responsibilities. These difficulties are important factors when considering both the history of urban environmental health and the contemporary situation with regard to urban water, sanitation, and air pollution.

27.2.2.1 Urban Water, Sanitation, and Hygiene and Human Health

In most parts of the world, there have been enormous improvements in urban water and sanitation since the mid-nineteenth century, when urban water and sanitation problems first gained international prominence. Nevertheless, according to the most recent global burden of disease assessment, unsafe water, sanitation, and hygiene still account for almost 6% of the burden of disease in ''high-mortality developing regions,'' exceeding all but two other risk factors (Ezzati et al. 2002). Although the ''urban penalty''—the increase in mortality rates associated with living in urban areas (see, e.g., Dobson 1997; Woods 2003)—that helped to motivate reform in the nineteenth century is no longer evident, eliminating unhealthy conditions in African, Asian, and Latin American urban areas remains a major challenge.

Urban poverty, particularly when combined with rapid urban population growth, is still closely associated with unsafe water and sanitation. Reducing the share of the population without adequate water and sanitation services is still central to the development goals and targets that have been adopted internationally, including most notably the Millennium Development Goals. (See MA *Policy Responses,* Chapter 20.)

In Table 27.11, the left-hand columns summarize the water and sanitation statistics that were used in developing exposure estimates for the burden of disease just mentioned and also used in starting to monitor progress toward the water and sanitation targets associated with the MDGs. These statistics might seem to suggest that only a small minority of urban dwellers lack provision of clean water and sanitation. Even in Africa, 85% of the urban population had ''improved'' provision for water and 84% had ''improved'' provision for sanitation by 2000. Problems are probably much more serious in rural areas, where most of the 1.1 billion people without access to improved drinking water and most of the 2.4 billion people without access to improved sanitation live (WHO and UNICEF 2000).

Unfortunately, these statistics are based on a definition of ''improved'' provision for water and sanitation that includes conditions where the risk of human contamination from fecal-oral pathogens remains high (Prüss et al. 2002). The Global Assessment from which the statistics are taken acknowledges that, because of the lack of internationally comparable data, it was not able to calculate the proportion of people with ''adequate'' provision or with ''safe'' water (WHO and UNICEF 2000).

For water supply, access to ''improved'' supplies was defined as being able to obtain at least 20 liters of water per person per day from a household connection, public standpipe, borehole, protected dug well, protected spring, or rainwater collector within 1 kilometer of the user's dwelling (WHO and UNICEF 2000). In many low-income urban settings, however, standpipes or other publicly available water sources available within a kilometer may be shared with hundreds and occasionally thousands of people, and there are often serious deficiencies in the quality of the water and the regularity of the supply (Hardoy et al. 2001; UN-Habitat 2003a).

For sanitation, ''improved'' provision was defined as access to a private or shared toilet with connection to a public sewer or a septic tank or access to a private or shared pour-flush latrine, simple pit latrine, or ventilated improved pit latrine (WHO and UNICEF 2000). In many urban settings, however, dozens of households share each latrine, making access difficult and maintenance inadequate, sometimes causing people and especially children to avoid using the latrines (UN-Habitat 2003a).

Moreover, detailed case studies often indicate levels of provision that are difficult to reconcile with the national estimates used in calculating the figures on ''improved'' provision in Table 27.11, even accepting the definitions of ''improved'' supply. For instance, the national estimates for Bangladesh show that 99% of its urban population had access to ''improved'' water supplies in 2000 (WHO and UNICEF 2000), whereas detailed studies in its two largest cities (Dhaka and Chittagong) show large sections of their populations having to rely on poor-quality water that was difficult to obtain (UN-Habitat 2003a). Similarly, the national estimates for Tanzania and Kenya show that virtually all their urban populations had ''improved sanitation,'' but detailed studies in their major cities and smaller urban centers showed otherwise, especially in the large informal areas within urban settlements where a high proportion of the population of Dar es Salaam and Nairobi live (UN-Habitat 2003a). The numbers in the right-hand columns of Table 27.11 are very crude estimates, but they suggest a far higher level of water and sanitation deprivation (UN-Habitat 2003a).

Such statistics, even if they are rigorously defined and measured, can misleadingly imply that the underlying problem is a lack of infrastructure. In effect, health risks arising from the local ecology of waterborne or water-related diseases are ascribed to the absence of the presumed solution: more extensive piped water and sanitation systems (or other ''improved'' technologies). As part of this more general tendency to oversimplify, in policy discussions it is often presumed that ''waterborne'' diseases, which

Table 27.11. Different Estimates of Number of Urban Dwellers Lacking Provision for Water and Sanitation, 2000 (WHO and UNICEF 2000; UN-Habitat 2003b)

Region	Number (and Share) of Urban Dwellers without "Improved" Provision for:		Indicative Estimates for the Number (and Share) of Urban Dwellers without "Adequate" Provision for:	
	Water	Sanitation	Water	Sanitation
Africa	44 million (15%)	46 million (16%)	100–150 million (c. 35–50%)	150–80 million (c. 50–60%)
Asia	98 million (7%)	297 million (22%)	500–700 million (c. 35–50%)	600–800 million (c. 45–60%)
Latin America and the Caribbean	29 million (7%)	51 million (13%)	80–120 million (c. 20–30%)	100–150 million (c. 25–40%)

include most diarrheal diseases, are contracted by people drinking water contaminated with fecal material.

In fact, although waterborne diseases can be spread via drinking water, they can also spread through person-to-person contact, and often by other means (Cairncross and Feachem 1993). Many waterborne diseases can be transmitted mechanically by insects, and there is some evidence that the presence of flies can make a large difference to their prevalence (Cohen et al 1991; Levine and Levine 1991; Crosskey and Lane 1993). Contaminated food is quite possibly an even greater problem than contaminated water. Insufficient water for washing is probably more important to health than poor-quality drinking water. Better sanitation facilities are unlikely to achieve their potential health improvements unless they are accompanied by changes in hygiene behavior; in some circumstances, changes in behavior are the most significant factor in reducing the prevalence of fecal-oral diseases (Curtis et al. 2000; Curtis and Cairncross 2003).

27.2.2.2 Urban Air Pollution and Human Health

Serious exposure to air pollution began with the advent of burning fuels for cooking and heat within unventilated abodes. Air pollution was a major nuisance for many and a serious concern for some in the industrializing cities of the nineteenth century (Mosley 2001), but concerted efforts to address ambient air pollution only began in the twentieth century. In particular, it was the urban air pollution episodes between the late 1940s and mid-1960s in Donora (in the state of Pennsylvania), London, Osaka, and New York City, among other locations, when many died or were hospitalized, that prompted public concern and responses including clean air legislation, regulations, and other actions.

Table 27.12 provides the sources of indoor and outdoor air pollution associated with some of the principal pollutants. The distribution, magnitude, and trends of many of these pollutants within ecosystems are addressed in Chapter 13. This section focuses on their generation and health impacts within urban systems.

Recent estimates of the global burden of disease suggest that approximately 5% of trachea, bronchus, and lung cancer, 2% of cardiorespiratory mortality, and about 1% of respiratory infections are attributed to urban outdoor air pollution (WHO 2002, and see also Ezzati et al. 2002). This amounts to about 800,000 deaths (1.4% of the total) and about 0.8% of the total global burden of disease. This burden falls predominantly on low- and middle-income countries, with 42% occurring in parts of the WHO Western Pacific Region and 19% occurring in parts of the WHO Southeast Asian Region.

Although these figures suggest that outdoor urban air pollution is an important health concern, the burden of indoor air pollution is estimated to be considerably higher (Smith and Akbar 2003; WHO 2002). Indoor air pollution concentrations tend to be highest in low-income settings, and more specifically where smoky fuels are used in homes with poor ventilation (Saxena and Smith 2003). Nearly half the world cooks with biofuels, including more than 75% of those living in India, China, and nearby countries, and 50–75% of those living in parts of South America and Africa (WHO 2002). Exposure to pollutants from burning these fuels is particularly intense for women and young children, who spend much of their time indoors, and is in aggregate substantially greater than exposure to outdoor air pollution in cities with severe air pollution problems (Smith and Akbar 2003). Although ambient air pollution is usually worse in urban centers, overall exposure to air pollution (both indoor and ambient) is higher in rural areas because most of these biofuel users are rural (Saxena and Smith 2003).

There is also considerable variation in exposure to air pollution between and within urban centers, depending on geographical factors as well as the types of activities undertaken in and around the urban centers and the fuels used to power them. Ambient air pollution has reached excessively high levels in many large cities in Asia, Africa, and Latin America (Krzyzanowski and Schwela 1999), where concentrations of ambient air pollution often rival and exceed those experienced in industrial countries in the first half of the twentieth century. Pollution from industries and power plants can account for a large share of urban emissions, and it also tends to be the target of initial pollution control measures. Vehicular pollution is also a chief contributor to overall local and regional ambient air pollution (NO_x, O_3, CO, volatile organic compounds, and suspended particles).

In general, low- and middle-income countries account for only 10% of the world's vehicles, including 20% of the buses (Elsom 1996). Growth rates for vehicle ownership, however, are two to three times higher in these countries than in high-income countries. For example, during the 1980s Pakistan experienced an annual average vehicle growth rate of 9%, Brazil's was 11%, China 14%, Kenya 26%, and both the Republic of Korea and Thailand 30%, compared with 2–3% growth in the United Kingdom and the United States (Elsom 1996). In 1990, there were 700,000 private cars in China and 5 million other motor vehicles. By 2001, this had risen to more than 5 million private cars and some 13 million other vehicles. For the next 20 years, East and Southeast Asia are expected to have the fastest-growing car markets in the world (Walsh 2003). The number of motor vehicles

Table 27.12. Sources of Outdoor and Indoor Emissions and Principal Pollutants (Murray and McGranahan 2003)

Sources	Principal Pollutants
Predominantly outdoor	
Fuel combustion, smelters	sulfur dioxide and particles
Photochemical reactions	ozone
Trees, grass, weeds, plants	pollens
Automobiles	lead, manganese
Industrial emissions	lead, cadmium
Petrochemical solvents, vaporization of unburned fuels	volatile organic compounds, polycyclic aromatic hydrocarbons
Both indoor and outdoor	
Fuel burning	nitrogen oxides and carbon monoxide
Fuel burning, metabolic activity	carbon oxides
Environmental tobacco smoke, re-suspension, condensation of vapors and combustion products	particles
Biologic activity, combustion, evaporation	water vapor
Volatilization, fuel burning, paint, metabolic action, pesticides, insecticides, fungicides	volatile organic compounds
Fungi, moulds	spores
Predominantly indoor	
Soil, building construction materials, water	radon
Insulation, furnishing, environmental tobacco smoke	formaldehyde
Fire-retardant, insulation	asbestos
Cleaning products, metabolic activity	ammonia
Environmental tobacco smoke	polycyclic aromatic hydrocarbons, arsenic, nicotine, acrolein
Adhesives, solvents, cooking, cosmetics	volatile organic compounds
Fungicides, paints, spills, or breakages of mercury-containing products	mercury
Consumer products, house dust	aerosols
House dust, animal dander	allergens
Infections	viable organisms

worldwide is expected to increase from around 660 million in 1990 to 1 billion by 2030 (Faiz et al. 1990).

Besides absolute numbers, the quality and fuel efficiency of motor vehicles also affects emissions and hence ambient air quality. High emissions per vehicle are associated with outdated technologies, older vehicles, poorly surfaced or badly maintained roads, weaker environmental legislation or weak enforcement of the regulations, poor vehicle maintenance (as vehicle emission inspections are less rigorous or nonexistent), and the dominance of low-quality fuels (such as diesel with high sulfur content) (Elsom 1996). These circumstances tend to be more common in low- and middle-income cities than in high-income cities. Leaded fuels are also more common in low-income cities and account for most atmospheric lead in countries where they are still in use.

27.2.3 Urban Systems Interrelating with Surrounding Regions

Partly because of the demands that urban systems place on ecosystems in the surrounding region, cities and towns are often presented as environmentally damaging. This is misleading, particularly if human well-being is a central concern. If urban activities and residents moved to rural areas, the demands placed on ecosystems would be more dispersed, but not reduced. Yet even if, from an ecosystems perspective, urbanization is preferable to most rural alternatives involving similar economic production levels, urban pressures are increasing rapidly as the result of population growth, economic growth, and urbanization. Moreover, for adjoining ecosystems, the concentration of people and activities in urban areas can be a particular burden. Urban centers in the vicinity of fragile ecosystems are especially problematic. Cities associated with highly polluting industries typically have a greater impact on nearby ecosystems than those dominated by service industries. Poorly managed urban development can be especially destructive to nearby ecosystems.

27.2.3.1 Urban Systems and Rural Lands

In peri-urban areas, the influence of urban development is visible and often involves the conversion of land to urban uses, as described earlier, but the less direct urban influence on somewhat more distant rural lands can be just as great and extends from demand-driven land use changes to the effects of urban remittances on rural development patterns.

In an ecological history of Chicago and the "Great West," Cronon (1992) describes how innovations in grain markets were linked to the loss of species diversity in the grasslands, how developments in meat handling and marketing affected animal stocks and living conditions on the farms, and how the urban lumber industry led to the decline of the White Pine forests on which it depended. When such changes occur, it is not just the increasing size of urban demands that influences the surrounding ecosystems, but the changing qualities of urban demands, including, for example, the tendency of many urban markets to demand standardized produce, thereby favoring monoculture and reducing biological diversity.

Although most contemporary cities do not have as great an influence on their hinterlands as Chicago once did, urban development remains a major influence on agricultural systems. A recent study of peri-urban agriculture in Hanoi documents a process that is likely to be present in the peripheries of most developing urban centers: the shift by farmers to producing higher-value goods in response to consumer demand in the urban areas (van den Berg et al. 2003). Such goods include vegetables, milk, and other perishable commodities (including from fish farming, shrimp farming, and flower production). Here, as in and around many other cities, agriculture is also disrupted by land speculation or the conversion of land to urban uses (including farmers who sub-divide and sell their land for housing, sometimes illegally). However, cities often provide surprising new opportunities for farmers: for instance, the demand for "turf" (sod) and ornamental plants for middle-class gardens in Mexico City and the demand by international tourists for authentic "pre-Columbian" food produce new opportunities for farmers around Mexico City (Losada et al. 1998; Losada et al. 2000).

While increasing urban demand for agricultural produce can be expected to lead to a larger expanse of agricultural land, urban demands for marketable wood products are often assumed to reduce tree cover. In the 1980s and 1990s, for example, urban demands for fuelwood and charcoal were often presented as leading to ''rings of deforestation'' around African and Asian cities where charcoal is a major cooking fuel (Cleaver and Schreiber 1994). However, as described in Chapter 21, such outcomes depend on the institutions guiding the resource use. Increasing urban demand can contribute to institutional conflicts over forest use. On the other hand, it can also motivate efforts to protect and plant forests. Although the slow growth of most woody products may inhibit private investment, trees can be planted, and in some circumstances an increasing demand for wood will result in an expansion of forest area.

From the perspective of human well-being, many of the more destructive relations between urban and adjoining systems involve interrelations that are neither valued within the market economy nor given priority by government agencies. Urban water demands often conflict with agricultural demands, and in many circumstances the institutions for reconciling such conflicts are neither equitable nor efficient (Baumann et al. 1998). Urban water pollution can damage downstream agriculture; conversely, the use of agricultural fertilizers and pesticides pollutes urban water sources. Cultivated systems can also lead to erosion, siltation, and more flooding in downstream urban areas, as well as damage to water storage facilities and water conveyance services. (See Chapter 26.) Urban air pollution contributes to acid precipitation, affecting forests and croplands with low buffering capacity; forest fires contribute to urban pollution concentrations as well as to urban fire risks.

Although some of these negative relationships have little to do with urban settlement patterns per se, others are directly related to the spatial concentration of urban consumption and production. Urban centers rely on adjacent ecosystem services to break down their biodegradable wastes, but when the capacities of these local ecosystems are overwhelmed, people living in downstream settlements are put at risk. These same biodegradable wastes may represent the loss of nutrients from agricultural and forestry systems. Urban consumption and production can also result in the accumulation of nondegradable and sometimes toxic substances (such as heavy metals) at waste sites, where they may leach into the groundwater or result in human exposure through some other means. Even relatively small urban centers face such problems, but they are magnified in large cities, and particularly in large industrial cities.

Again, it is important to distinguish between the often negative impacts that urban development has on ecosystems services and the often positive comparisons that can be made between well-managed urban development and alternative, less urban, development options. It has been suggested, for example, that urban development in drylands should lead to a reduced risk of desertification when compared with agricultural development (Portnov and Safriel 2004). In some circumstances, urban development can also provide the justification for expensive investments in water infrastructure, providing the basis for other developments.

27.2.3.2 Urban Development and Regional Water Systems

Historically, urban centers have often been founded near water sources and waterways, both to provide for urban water demands and to take advantage of water transport. As described earlier, the coastal zone is not only the most urbanized of all of the major systems identified for the MA, it is also the most densely populated with rural dwellers. A disproportionate number of urban centers, including especially large urban centers (over 500,000 people), are located at or near river mouths, which are also ecologically critical sites, particularly for some migratory aquatic and bird species. (See Chapter 20.)

Water is also a resource with a strong regional dimension. Freshwater resources from surrounding regions are still the major source of water for urban consumption, unlike many other resources that can more easily be imported great distances. Intraregional water flows provide critical connections between urban systems and the surrounding regions; as indicated earlier, unintentional changes to these water flows can create serious problems. Even groundwater aquifers can have a regional dimension. The flow of water represents the largest material flow in and out of urban areas, and it has been estimated that water represents about 90% of all material entering megacities (Decker et al. 2000).

In assessing the water relations between urban centers and their surrounding regions, it is important to consider:

- Urban→Upstream: how measures designed to meet urban demands for water and hydropower have changed the upstream water flows, affecting, for example, the availability of water for urban and nonurban users upstream.
- Upstream→Urban: how upstream water and land use changes not specifically designed to change urban water conditions have affected the qualities and quantities of water available to or flowing through urban centers.
- Urban→Downstream: how urban water and land use changes have affected the qualities and quantities of water available downstream (including coastal waters).

There are some changes that are not captured by these three categories. Thus, for example, dams and water diversions created to serve urban demands affect not just upstream users, but also those downstream, in all the river basins affected. While competition for good-quality water is often central to these relations, changes in urban water regimes can also influence flood risks, biodiversity, wetland and delta ecosystems, fisheries, migratory aquatic species, and a range of other less obvious water-related issues. Moreover, groundwater depletion often leads to land subsidence, which can have severe consequences in urban areas.

During the nineteenth and twentieth centuries, rapidly growing and economically successful urban centers relied on bringing in water from increasingly distant sources (Tarr 1996). Conflicts between urban and nonurban users have been common. Urban water use requires a higher-quality and more stable supply than that in most rural uses (for irrigation, for example), and the social, economic, and political importance of cities often ensures that their demands are given priority. The manner in which the water demands of Los Angeles were allowed to dominate over those of Owens Valley provides a well-documented example (Kahrl 1982; Reisner 2001).

When water is diverted from agriculture to urban areas, agricultural productivity can be severely affected. For example, in the Hai river basin in China, most of the freshwater resources captured by large reservoirs are directed to meet the increasing water demands from Beijing and Tianjin, and access to water has become the limiting factor in the region's agricultural productivity (Bai and Imura 2001). On the other hand, with decreases in water availability, farmers have traded off grain production for other more economically productive uses for their land and their time, not all of which are so dependent on water, and despite declining water resources, incomes have been increasing (Nickum 2002).

In most parts of the world, the spatial range of urban water withdrawals is expanding. In countries with capital-intensive water infrastructure, some of the regional water systems have become so closely integrated that it is no longer meaningful to link urban centers with spatially delimited supply networks: as with electricity systems, they are simply ''attached to the network'' (Baumann et al. 1998). Even where there is less water infrastructure, cities are reaching further upstream for more and fresher water resources, sometimes even from other river basins. In Africa, where inadequate infrastructure is often cited as a major problem, in the early 1970s many urban centers still used groundwater supplies as their primary water sources, but by the 1990s the primary water sources were more likely to be rivers, and increasingly these river sources were more than 25 kilometers away (Showers 2002).

Investment in tapping water supplies that are further away is often undertaken when less costly alternatives have not been explored. Moreover, when cities and surrounding rural areas compete for water resources, ecological water requirements (the water needed to maintain ecosystem function and local hydrological cycles) are often neglected. In many situations, demand-side management is an inexpensive means of freeing up water supplies and could be used to avoid tapping distant water supplies or undermining ecological functions (Baumann et al. 1998). Alternatively, economic analysis of other measures to improve water supplies in New York City found that in many cases it would be cheaper for the city's residents to pay upstream individuals and enterprises operating in the city's upper watershed to adopt less damaging practices than to invest in more water supply and treatment facilities. Investing in water filtration in New York is estimated to cost approximately $6 billion for design and construction and $300 million in annual operating expenses (NRC 2000; Pires 2004).

Urban centers themselves can cause a wide range of problems for people and ecosystems downstream, including those in other urban locations. Urban areas usually have a high percentage of paved areas, which concentrates rainwater rather than dissipating it. This tends to intensify flooding and can cause flash floods. Changes in the water flows can also affect downstream fish stocks, recreational opportunities, and biodiversity. (See Chapter 20.) Sewers convey human waste out of urban locations, often releasing it untreated in local waterways or coastal waters. Human waste not only poses a health risk for people who might come to ingest the contaminated water, it causes eutrophication and damages aquatic ecosystems downstream. (See Chapter 12.) Chemical water pollution is also a major problem, particularly around large industrial centers.

Coastal zones are among the worst affected by urban development, and they combine many of the most critical land and water issues. As indicated earlier, the share of land in coastal zones that is urban is particularly high, and land conversion and habitat losses of coastal wetlands, dune systems, and coral reefs are often irreversible. (See Chapter 19.) Urban areas at river mouths often constitute bottlenecks for aquatic migratory species. Other important situations related to urban areas in coastal systems are the development of ports out of natural harbors, the dredging of shipping channels, and the development of industrial centers in the coastal fringe. Port development also creates the risks of species invasion, with large ships in harbors acting as vectors for species introduced via ballast-water transfer and hull fouling.

Although high levels of urbanization are not in and of themselves a problem, urban development undertaken with little regard for its ecological implications can be extremely destructive. Dispersed rural settlements can bring about more vegetation fragmentation than population concentration in urban areas, with a strong negative impact on the health of inland water systems. The concentration of population in urban areas makes it easier to treat wastewater and avoid pollution, as point pollution sources are more likely to be controlled or eliminated. There are also many opportunities in urban areas for reusing wastewater and for engaging in demand-side management for conservation and for improving well-being. There are indications that water-management systems are slowly changing, with more attention being given to improving water use efficiency and productivity and less of a tendency to assume that water shortages must be met by more water infrastructure (Gleick 2003). On the other hand, concentrating settlement concentrates the burdens, and where urban development is poorly managed, concentration will make local disturbances even worse.

27.2.4 Urban Systems Creating Global Ecosystem Pressures

If the environmental shortcomings of the affluent city in the nineteenth century were unsanitary slums and environmental health problems within the city, and those of the affluent city in the twentieth century were urban pollution and environmental degradation in and around the city, then the major environmental burden of the affluent city in the twenty-first century is likely to be the global burden it imposes, often on ecosystems far removed from the city itself.

The importance of global trade and of global environmental burdens has grown considerably over the past two centuries, and especially in the last few decades. (See Chapter 3.) Urban development has been an integral part of this process; all urban centers are engaged to some degree in the production and consumption of internationally traded goods and in contributing to globally burdensome wastes such as greenhouse gases, persistent organic pollutants, and ozone-depleting substances. In general, however, global ecosystem pressures derive from the consumption and wastage undertaken to support the lifestyles of the world's more affluent residents, most of whom live in the urban centers of high-income countries. As much as two thirds of total consumption and pollution can be traced to cities in rich countries alone (Rees 1997).

Increasing long-distance trade spreads the ecological burden of consumption, but it also increases the likelihood that consumers will neglect the costs of ecological pressures and damage. If a population depends on local ecosystems and degrades these through excessive growth or overexploitation, the negative consequences (declining productivity) are more likely to inhibit further growth. Trade serves to short-circuit such negative feedback and may even lead to positive feedback. Urbanites who live mainly on imported goods lose their incentive to conserve remaining local or regional stocks of natural capital (biophysical resources). Thus, a city interested in promoting economic growth may sacrifice prime cropland on the urban fringe to ''highest and best (economic) use,'' permanently destroying the land's agricultural potential. Second, people living on imports are less likely to be aware of the negative ecological or social consequences of unsustainable production processes in the distant regions that are supplying them. The most successful traders are those who seek out and find the least-cost supplies, whether the low costs are based on a real comparative advantage or on the fact that the loss of ecosystem services is not being costed into the supply chain.

Urban systems are also vulnerable to global environmental shifts, including climate change and its consequences. In addition to the direct effects of warming on the habitability of urban centers, many cities are vulnerable to flooding from sea level rise or to damage from tropical storms. Nevertheless, most assessments of the global pressures of urban development focus first and foremost on impacts outside urban boundaries, recognizing that in the long run these impacts too will affect the well-being of urban residents.

27.2.4.1 Ecological Footprint Analysis

Ecological footprint (or eco-footprint) analysis is a quantitative tool that estimates the load imposed on the ecosphere by any specified human population in terms of the land and water (ecosystem) area dedicated to supporting that population (Rees 1992; Rees and Wackernagel 1994; Wackernagel and Rees 1996). It does not capture the dynamics of either ecosystems or markets, nor does it provide the basis for assessing whether any given ecological burden involves economic externalities or can be justified in terms of human well-being. Summing up ecological footprints is inevitably complicated by the diversity of services that any given ecological area can provide. Ecological footprint estimates are revealing, however, not only in demonstrating how much more extensive urban footprints are than the urban areas themselves, but also in allowing the ecological pressures of different urban centers or different population groups to be compared, at least roughly.

An eco-footprint analysis begins with the quantification of the material and energy resources required to support the consumption demands of the study population at its present material standard of living. The method is based on the fact that many of these resource and waste flows can then be converted into a corresponding productive land and water area. Thus, the ecological footprint of a specified population can be formally defined as "the area of land and water ecosystems required, on a continuous basis, to produce the resources that the population consumes, and to assimilate the wastes that the population produces, wherever on Earth the relevant land/water is located" (Rees 2001). A complete eco-footprint analysis would therefore include the ecosystem area that the population effectively appropriates to supply its needs through all forms of economic activity, including trade, plus the area it needs to provide its share of certain (usually free) land- and water-based services of nature, such as the carbon sink function.

The size of the eco-footprint depends on four factors: population, the average material standard of living, the productivity of the land/water base (whether local or "imported" in trade goods), and the efficiency of resource harvesting, processing, and use. Regardless of the relative importance of these factors and how they interact, every population has an ecological footprint. (For full details of the methodology, see Wackernagel et al. 1999; Rees 2001, 2003; World Wide Fund for Nature 2002; Monfreda et al. 2004.)

Eco-footprint analysis reveals that the residents of the more urban high-income countries impose a vastly larger load on Earth than do the residents of low-income countries. The citizens of high-income countries such as the United States and Canada have average ecological footprints of 8–10 hectares, or up to 20 times larger than the eco-footprints of the citizens of the world's poorest countries such as Bangladesh or Mozambique (see, e.g., World Wide Fund for Nature 2002).

Because consumption, production, and trade data are generally compiled at the national level by domestic statistical offices and international agencies, it is easiest to estimate national eco-footprints. Data specific to lower-level political entities such as states, provinces, or cities are generally much harder to come by. Nevertheless, a rough estimate of the eco-footprint of any given city can be made by multiplying the city's human population by the national per capita ecological footprint, and methods do exist for developing estimates at sub-national levels (see method applied in Wackernagel 1998).

Various researchers have estimated urban eco-footprints by using different assumptions and levels of detail. Despite methodological differences, such studies invariably show that the eco-footprints of typical modern cities are two to three orders of magnitude larger than those of the geographic or political areas they occupy (see, e.g., Rees 2003).

A city may represent as little as 0.1% of the area of the host ecosystems that sustain it. Such fractions emphasize that even in a stable world, no city or urban region as presently configured could be sustainable on its own. Moreover, the combined requirements of urban systems are increasingly unsustainable in the long run; in a politically unstable world, dependence on extensive and often distant ecosystems raises issues of shorter-term sustainability.

27.2.4.2 The Urban Sustainability Multiplier

Although cities, particularly high-income cities, have large eco-footprints, they also provide many opportunities to lighten the human load on Earth's ecosystems. To begin with, cities are concentrations of buildings and associated infrastructure, and the "built environment" is a key consumer of materials and energy, with considerable scope for savings. To a first approximation, the construction, operation, and maintenance of the built environment accounts for 40% of the materials used by the world economy and for about one third of energy consumption. Studies indicate that buildings in the United States account for between 15% and 45% of the total environmental burden in each of eight major categories of impact used for life-cycle assessment (an integrated "cradle to grave" approach to assessing the environmental performance of products and services) (Levin et al. 1995; Levin 1997). However, given equivalent levels of consumption, increased human density is associated with lower eco-footprints.

Many other attributes of urban life provide leverage in dealing with the energy and material dimensions of sustainability. Together these factors contribute to what might be called the "urban sustainability multiplier" and include the following (Rees 2003):

- high population densities, which reduce the per capita demand for occupied land;
- lower costs per capita of providing piped treated water, sewer systems, waste collection, and most other forms of infrastructure and public amenities;
- a high proportion of condominiums, apartment buildings, and other multiple-family dwelling units, which reduces per capita consumption of building materials and service infrastructure;
- increasing interest in eco-neighborhoods and forms of cooperative housing, which reduces demand for appliances and personal automobiles;
- easy access to the necessities for life and to urban amenities by walking, cycling, and public transit. This further reduces the demand for private automobiles, thereby lowering fossil energy consumption and air pollution (some residents even adopt an auto-free lifestyle);
- a high density and diversity of communication infrastructure, reducing the need for energy-intensive travel to face-to-face meetings;
- greater possibilities and a greater range of options for material recycling, reuse, remanufacturing and a concentration of the specialized skills and enterprises needed to make these things happen;
- economies of scale and agglomeration economies that make electrical co-generation possible and facilitate the use of waste

process-heat from industry or power plants for local (neighborhood) water and space heating, thus reducing demand for energy; and

- the opportunity to implement the principles of low-throughput ''industrial ecology'' (that is, the creation of closed-circuit industrial parks in which the waste energy or materials of some firms are the essential feed-stocks for others).

Walker and Rees (1997) provide a graphic illustration of the economies associated with housing type and attendant urban form. They show that the increased density and consequent energy and material savings associated with high-rise apartments, compared with single-family houses, reduce the part of the per capita urban ecological footprint associated with housing type and related transportation needs by about 40%. Such gains are independent of building materials used. Similarly, Kenworthy and Laube (1996) detail how personal energy consumption associated with transportation needs is dramatically inversely related to urban density. The sprawling cities of Australia and the United States feature vastly less energy-efficient transportation systems than can be found in wealthy, compact Asian cities. European cities generally fall somewhere in between.

27.3 Important Processes Driving Change

This section explores some of the important drivers of urban system change and their impact on urban systems and, at least indirectly, ecosystem services. Drivers can have either direct or indirect impacts on urban development. (See Chapter 1.) Among indirect drivers being considered in this assessment, those associated with globalization, technological change, political shifts (including institutional and legal framework changes), and demographic shifts are of particular importance for urban systems. Direct drivers for urban centers include, among other things, changes in land use (the expansion of cities and urban areas) and user rights and structures.

Contemporary urban development around the world also reflects the fossil fuel economy; energy use and availability are primary urban drivers. Without petroleum-based fuels and the transportation systems they underpin, existing urban systems would be inconceivable, not just because they would be unsustainable but because they would be dysfunctional (Droege 2004). More generally, energy underpins economic growth, globalization flows, and technological advances, all of which operate through urban centers. Globally, urban activities, including intra- and interurban transport, consume approximately 75 percent of the world's fossil fuel production (Droege 2004). Urban activities in high-income countries account for a disproportionate share of this consumption, but even urban centers in very low-income countries have levels of energy consumption that are higher than the historical norm.

Globalization and other drivers are experienced differently in different parts of the world. The urbanization and feminization of poverty (United Nations Centre for Human Settlements 2001; Chant 2003), the aging of populations (Lutz et al. 2004), and the adoption of telecommunication technologies are all examples of trends that are common to many different types of cities but that take different forms (see, e.g., United Nations Centre for Human Settlements 1996, 2001).

The following sections examine drivers and urban development in low-, middle- and high-income cities. This division has been selected because of its political significance as much as its empirical relevance.

27.3.1 Low-income Cities and Middle-income Cities with Economic Difficulties

Not all nations and their cities have benefited economically from globalization. Many nations have not benefited from contemporary trade and foreign direct investments flows, which underpin globalization, and therefore their urban centers are not considered ''world cities'' (see, e.g., Friedmann 1986, 1995). These include, for example, cities in the lowest-income economies of Africa, Asia, and Latin America (Lo 1994; Gilbert 1996; Rakodi 1997). Macroeconomic conditions and national debt burdens have played an important role in the recent development of some of these cities, and the predominance of agricultural and mineral trade and the lack of manufacturing have made them more dependent on rural than on urban economic activity and more susceptible to changes in commodity market prices. When global primary commodity prices fell in the early 1980s and interest rates increased, many of these countries experienced recessions combined with high inflation and increased debt. Foreign and domestic investment typically slowed, housing finance became less available, and infrastructure deteriorated. Without foreign investment, the application of new technologies slowed, particularly digital information and communication technologies, which further exacerbated the ''digital divide'' (United Nations Centre for Human Settlements 2001).

Regulatory frameworks, including policy documents, laws, traditions, regulations, standards, and procedures, influence urban development, although often not in a straightforward manner. The lack of provision of adequate shelter and the generation of slums themselves are often due in part to inappropriate regulatory frameworks (Payne and Majale 2004). The lack of appropriate institutional structures helps drive ecological and environmental trends within and around cities in this category. Ability to finance infrastructure and provide public services depends heavily on intragovernmental institutional arrangements, because capital markets rarely provide an adequate source of finance in low-income countries and because users, or potential users, in these cities are typically unable to pay the large costs associated with construction (United Nations Centre for Human Settlements 1996). Lack of access to land, because of its high cost or inadequate property rights and land tenure arrangements, has facilitated the development and expansion of slum and squatter areas within urban settlements (Hardoy et al. 2001).

These direct and indirect pressures have combined to affect cities in this category in a number of ways. One important outcome has been a reshaping of urban structure through the expansion of urban slums and squatter (sub-) settlements. The UN Habitat suggests, for example, that squatter settlements house 40–50% of the people living in Calcutta; 50–60% of those living in Bombay, Delhi, Lagos, and Lusaka; and 60% or more of those living in Dar es Salaam, Kinshasa, Addis Ababa, Cairo, Casablanca, and Luanda (see ''Global Trends'' from the Global Urban Observatory, at www.unchs.org/habrdd/global.html). Informal areas within urban settlements are not aberrations; rather, they are the dominant means through which cities in this category are growing. Moreover, many of these are expanding in ecologically sensitive areas, such as on steep hillsides, riverbanks, and wetlands (Hardoy et al. 2001).

The results of these pressures on human ecology have been just as stark as changes in urban form. The increase in size of cities without adequate infrastructure has put pressure on the basic ecosystem services necessary for healthy life. Inadequate and unsafe piped water supply, a lack of proper sewerage and stormwater drainage, lack of provision for garbage collection and disposal, and indoor air pollution that results from burning biomass have all affected human health and well-being (Bartone et al. 1994; McGranahan et al. 1996). The shift of population to urban areas, the lack of access to safe drinking water, the lack of the simplest latrines, the spread of preventable diseases and health risks, inadequate secure and healthy shelter, and hunger have combined to move considerable poverty and poverty-related problems from rural to urban settings (United Nations Centre for Human Settlements 2001).

Flooding and a general proneness to other natural disasters affect these communities more than more-wealthy settlements. Natural disasters act as both a driver and a consequence of current development patterns. Without adequate governance, regulation, and public spending, increasing numbers of the urban population are locating on floodplains, within swamps, and in other ecologically sensitive areas. This development pattern is making parts of a large number of cities vulnerable to natural disasters. Among the total reported deaths from disasters between 1993 and 2002, more than 53% were in countries at low levels on the Human Development Index, compared with just 4% of deaths in countries with high levels and 42% in countries with medium levels of human development (International Federation of Red Cross and Red Crescent Societies 2001).

Although most of the ecological challenges remain localized and associated with health and safety issues, activities within cities in this category have generated city-wide ecological impacts. Natural resources in and directly around these cities are being depleted as urban populations search for space to live, biofuels for cooking, and water for daily needs (World Commission on Environment and Development 1987; Hardoy et al. 2001). The pressures inherent in consumption patterns of citizens in cities of this category are far less than those created by more affluent urban residents, but the context can mean that these pressures have serious consequences both locally and throughout the metropolitan region.

In some cities in this category there are promising signs of economic growth. For example, since the 1980s many if not most Latin American countries have experienced positive growth, notwithstanding fluctuations (Tulchin 1994). Recently, some of the cities in Asia that were previously disconnected from the world economic system of trade and foreign direct investment have become connected to it, and cities such as Phnom Penh and Hanoi are on the brink of rapid economic growth. This growth, however, does not ensure either improved well-being for all or decreased ecosystem impact. Indeed, citizens in rapidly developing cities may be experiencing intensive local ecological deterioration while increasing their burdens on hinterlands and ecosystems at larger scales and farther away.

27.3.2 Rapidly Growing Middle-income Cities

Cities in this category are undergoing rapid development and are sometimes included as ''second-tier'' world cities (Taylor 2004). They are the locations of the world's new industrial production systems, and many of them are in Asia. The most obvious impacts of indirect drivers are increasingly rapid economic development. For example, during the mid-1990s Jakarta's economy was growing at 8.2% annually (Soegijoko and Kusbiantoro 2001) and Shanghai's at 14.2% annually (Ning 2001). This growth has been facilitated by the transnational connections between these cities and international investment capital. Many of the cities in this category are linked to the global economy and have experienced the world city formation process—the process by which the world's capital accumulates in cities through global trade and investments (Friedmann and Wolff, 1982), as they become manufacturing production centers (Lo and Yeung 1996; Lo and Marcotullio 2001).

Rapid economic growth has been driven, in some cases, by the emergence of clusters of private-sector organizations applying new technologies to production processes in and around cities (Hall 1995). For example, new industrial regions have sprung up in and around some cities within this category: Guangzhou, Kuala Lumpur, Seoul, Singapore, and Taipei, which are among the leaders of the high-technology and computer industries.

Rapid growth has been associated with rapid urbanization, rapid urban growth rates, and large urban sizes. The trend, particularly within the rapidly developing world, has been toward very large urban agglomerations, or megacities and megaurban regions (Fuchs et al. 1994; McGee and Robinson 1995; Gilbert 1996).

Although cities in this category have been able to compete successfully within the global economy, they have paid the price in terms of disruption to local ecosystems (Lo and Marcotullio 2001). The growth of the largest cities has slowed over the past few decades, but at the same time their internal ecosystem service conditions have worsened, suggesting that rapid demographic growth is not the primary source increasing urban environmental burdens (Brennan 1999). For example, the larger, slower-growing Asian megacities are among the world's most severely environmentally distressed (Asian Development Bank 1997).

In contrast to the experiences of cities in industrial countries, where the emergence of ecological challenges appeared over longer periods of technological and socioeconomic change and in a more sequential order, rapidly developing cities may experience a new mix of environmental challenges at lower levels of income that increasingly appear concurrently (Marcotullio 2004). Within a single city there are often pressing challenges associated with basic sewage and sanitation, industrial water and air pollution, greenhouse gas emissions, and green space.

In Bangkok, for example, transport accounts for 70% of urban energy consumption. The level of the city's GDP is three times the national average, and 70–80% of the city's population has been described as ''middle class'' (Plumb 1999), with the associated increased consumption levels that wealth brings. At the same time, Bangkok, like many of these cities in this category, has substantial numbers of people without water supply and sanitation services. Further, Bangkok is a major source of pollution, both industrial and residential, for the Chao Phraya River and a growing source of consumption, with related wider ecological impacts. Hence, Bangkok is experiencing several different sets of burdens simultaneously (Marcotullio 2003).

Given the forecasts for urbanization and industrialization in the Asian region, the overlapping burdens experienced within cities in this category are not likely to disappear in the medium term. The same may be said for rapidly developing cities in other parts of the world. From the policy perspective, this phenomenon has produced important questions concerning how to manage this mix of environmental problems in order to ensure the well-being of the urban population, the ecological integrity of urban region, and the long-term viability of economic growth.

27.3.3 High-income Cities

Cities that are at the top of the global networked hierarchy are also rapidly growing as producers of business services for global capital and finance (Sassen 1991; Honjo 1998). During the recent past, those in North America have been undergoing restructuring, as some have moved from industrial to service-dominated economies and others have grown as rapidly as cities in the developing world. Other than the influence of globalization flows, particularly important drivers of urban system change in this category include demographic shifts, technological advances, and institutional and policy changes.

Important demographic shifts include the reduced birth rate, the increase in the older population, and the decrease in household size. Most of the OECD nations have stopped growing in size and are experiencing increases in the proportion of aged populations (Lutz et al. 2004). This has substantially affected urban population structures. For instance, while the proportion of the elderly is greater in the nonmetropolitan regions of the United States than in the metropolitan regions, more than 74% of the older population resides in metropolitan areas, and the number and share of the elderly are increasing in both (Glasgow 2000). In 1990, the U.S. population over 65 years of age living in metropolitan areas reached 23.1 million. This has social and economic consequences: increasing numbers and proportions of the elderly translate into both proportionately fewer middle-aged care providers and proportionately fewer contributors of social security funding.

Accompanying the low or even negative overall natural increase in urban populations in the United States and Europe, average household size has shrunk to fewer than three, and the number of single-person households has increased to 25% in Europe and 20% in the United States. In Europe, the increased demand for new households is expected to account for 12.5 million new dwelling units in 2000–05 and for 11.5 million units in 2005–10. Despite the stabilization of the size of the urban population, the increasing number of households is still driving the demands for construction materials, space for building, energy, transport, and natural resources. Satisfying these demands can have an adverse impact on biodiversity (Keilman 2003; Liu et al. 2003).

Another important driver for urban system change is technological advance. Advances in transportation and communications have allowed the decentralization of industry and the loss of manufacturing jobs from urban centers. At the same time, the increasing application of information and communication technologies has facilitated both an expansion of markets and control over national and international economic space (globalization) and the rise of the service sector dominated by advanced business services (Sassen 1991). Moreover, within the OECD, new industrial regions based upon these technologies have sprung up around the older industrial areas (such as the Western Crescent around London, the southwest sector of Paris, the south of France, the Munich region, Silicon Valley, and Los Angeles) and some older cities (such as Munich and Tokyo) have transformed themselves into high-tech centers. Contrary to former predictions that these technologies would make cities unnecessary, dense human concentrations within the new global economy are increasingly important (see, e.g., Sassen 1991; Taylor 2004).

Environment-related policies within cities of this category have played an important role in providing cleaner and more habitable internal urban environments and have therefore become important ecosystem drivers. User charges, including utility charges for water and wastewater and pollution charges for solid waste, affect the use of these services. (See Chapter 7.) Air quality is protected in many urban areas by user charges such as road tolls (used as a traffic regulator) and pollution charges used to control and reduce emissions. Land use is regulated through user charges such as betterment charges and access fees to parks and beaches, which are widely used, in part to protect landscapes. Zoning and transferable development policies have been extensively used to conciliate environmental and development aims, including conservation of greenbelts, wetlands, cultural heritage sites, and coastal areas, and for the preservation of open space, green space, and farmland in urban hinterlands (World Resources Institute 1996).

On the other hand, decreasing household sizes, increasing vehicle ownership and usage, highway development, air-conditioning, mall construction, and new building technologies combine to facilitate land use change at urban fringes (Rusk 2001) and hence directly affect hinterland ecosystems. U.S. cities are consuming land at rates faster than that of population growth. For example, the Washington, D.C., area lost 85,000 hectares of farmland, forest, wetlands, and other open spaces during the 1980s, and California continues to lose wetlands at a rate of almost 2,000 hectares per year. Environmentally related impacts of sprawl are increasingly evident, as urbanization in these economies is associated with the degradation of water resources and water quality, changes in hydrology, increased inputs of water pollution and nutrients, and increased acidity and higher water temperatures of lakes, ponds, and streams (US Environmental Protection Agency 2001). There are also growing concerns about the health implications of this urban sprawl (Frumkin et al. 2004).

Moreover, increased transportation has also had significant global ecosystem impacts through greenhouse gas emissions. In 1997, the U.S. transportation sector accounted for 32% of national carbon emissions from fossil fuels, or 473.1 million tons of carbon. From 1984 to 1997, carbon emissions from transportation increased by 25% (rising from 379 million tons). In addition, vehicle use contributes to emissions of two other greenhouse gases, methane and nitrous oxide. Total emissions of these gases for the United States in 1997 were 213 tons of methane and 205 tons of nitrous oxide (US Environmental Protection Agency 2001).

27.4 Responding to the Environmental and Ecological Burdens of Urban Systems

Many of the reasons why ecosystem services and environmental problems in general have tended to be neglected in urban systems are similar to the reasons they have been neglected elsewhere.

- *Ecosystem services are provided through complex and poorly understood processes, taking place mostly beyond urban boundaries.* It is often difficult to understand how ecosystem changes affect human well-being, and hence which ecosystems are of particular value and which changes will result in the greatest losses (MA 2003). In urban areas, people are also likely to be even less aware than rural dwellers of how dependent they are on ecosystem services and how their actions affect distant ecosystems.
- *Ecosystems services (and environmental burdens that affect ecosystems) are difficult for private agencies to own and trade.* Only a small share of ecosystem services accrue to the owner of property where the ecosystem is located, and it is rarely feasible for the owner to charge beneficiaries for the services that they receive. It is equally difficult for those affected by ecosystem change to negotiate with those who are causing the changes to take place. Thus property owners rarely have the incentive to take account of how they are altering the availability of ecosystem services. Attempts have been made to develop markets for ecological or environmental services, but these remain rudimentary.
- *Ecosystem services are difficult for public agencies to manage or regulate.* Ecosystems located on private land are difficult for government agencies to regulate in the best of circumstances. Even where public land is involved, the benefits of ecosystem

services typically cross administrative and sectoral boundaries, and often no agency has the responsibility and capacity to care for the relevant ecosystems.

- *The groups most vulnerable physically and socially tend to be the least influential economically and politically.* The urban dwellers most dependent on local environmental services and conditions are the urban poor in low-income countries. Alternatively, among those most likely to be affected by global ecological degradation and resource depletion are future generations, who do not even have a political or economic presence.

There have been some notable successes despite these difficulties. This applies at all scales, from the intraurban environmental health issues so common in low-income areas to the global pressures associated with affluent urban lifestyles. The enormous variation in and among urban centers makes it difficult to generalize about the relevance of these successes. Moreover, even if they reflect the potential for addressing urban environmental and ecological challenges, the relevance of past successes to future responses is limited.

The concerted responses to sanitary threats that emerged in a number of cities in the nineteenth century are testimony to the potential for changing urban environmental management when the need arises. They included elements addressing each of the four challenges just noted and combined them in what came to be known as the sanitary movement (Melosi 2000).

Enormous progress was made in the study of urban public health issues: the nineteenth century saw eventual ascendance of the bacterial theory of disease over alternatives such as miasma theory, which held the diseases were contracted from the vapors emitted by, for example, urban filth (Rosen 1993). Municipal and national governments were put under pressure to organize sanitary improvements, and although there was successful resistance to demands to control air pollution (Mosley 2001), water and sewerage improvements received widespread support (Melosi 2000). There was public debate over the appropriate organization form for local water and sanitation networks (Jacobson 2000), and in many cities private enterprises helped undertake major public infrastructure projects. The increasing efforts to address water and sanitation were linked to changes that had given more political influence to the urban residents at risk (Szreter 1998, 2002).

Despite these successes, the problems that motivated the nineteenth-century sanitary reforms remain some of the major challenges for twenty-first-century urban areas. It has been estimated that more than 900 million people live in urban slums, characterized as having inadequate housing and basic services (UN-Habitat 2003b, 2003c). As indicated, a poorly documented but appreciable share of urban and rural dwellers do not have access to adequate water and sanitation, and this remains one of the major causes of preventable illness and death globally. The ecology of disease in low-income urban settlements remains poorly understood, debate over the appropriate roles of the public and private sectors continues, and the political influence of slum dwellers is still not sufficient to secure needed improvements. Moreover, conventional infrastructure projects, involving waterborne sewage systems and long-distance water conveyance, can have large environmental as well as economic costs.

The urban environmental problems that helped motivate the environmental movement in industrial countries in the twentieth century also remain a major challenge. There is a considerable body of work on sustainable cities (Haughton and Hunter 1994; Satterthwaite 1999; Beatley 2004), and the agenda for action agreed on at the United Nations Conference on Environment and Development in 1992 (*Agenda 21*) explicitly attempted to ground global aspirations in local initiatives (*Local Agenda 21*s).

Moreover, numerous technologies have been developed that, if adopted on a large scale, would radically reduce the ecological footprint of urban settlements. For example, industrial parks that promote the use of wastes from one production process as inputs into another are emerging in Canada, Denmark, the United States, and many countries in Asia, following the model set by Kalundborg in Denmark (Cohen-Rosenthal and Musnikow 2003). Rapid bus transit systems in Latin American cities such as Bogotá, Quito, and Curitiba provide successful alternative examples to the previous solutions of heavy and light rail (Fjellstrom 2003). Fuel-efficient cars and cleaner fuels are becoming increasingly available, creating a potentially significant influence on reducing local and global burdens of urban transport systems. Indeed, some have argued that the technological bases for reducing environmental pressures manyfold, without sacrificing human well-being, have been available for some time now (Weizsäcker et al. 1997).

There is no evidence, however, that the tendency toward increasing ecological footprints per capita has been reversed, even in upper-income countries where footprints are the largest and least sustainable. In part this is due to the large use of materials to produce the tools necessary for high-technology products. For example, manufacturing one desktop computer and a 17-inch cathode ray tube monitor requires at least 240 kilograms of fossil fuels, 22 kilograms of chemicals, and 1,500 liters of water. In terms of mass, the total amount of materials used is about equal to that of a midsize car (Williams 2003). The large energy and material inputs for these products, without recycling, does not suggest a dematerialization of the "knowledge society" in the near future.

In summary, although past trends demonstrate considerable potential for addressing urban environmental and ecological burdens, they do not indicate whether this potential will be realized. Historically, concerted responses have been a reaction to crises rather than the result of forward thinking. Sanitary reform, for example, emerged at a time when epidemics flourished as the result of unsanitary urban conditions, and it has proved far more difficult to maintain in the face of less dramatic diseases. It is possible to interpret the history of some of the world's affluent cities as a series of victories over ecological and environmental challenges: first a sanitary revolution (nineteenth century), then a pollution revolution (twentieth century), and now an anticipated sustainability revolution. It is also possible, however, to interpret this same sequence as a process of displacement that has left most contemporary cities in a very difficult situation.

28.1 Introduction

This chapter draws on previous chapters to present a portrait of the major changes in the condition of ecosystems, the services they provide, the drivers of change, and the prospects for sustainability. It is organized around major questions and issues rather than around services and systems per se. The time frame for considering these issues is generally the last several decades, although in some instances this has been expanded where data allow or if needed to illustrate some particularly important points.

The chapter examines some of the implications of the observed trends and trade-offs for the continued capacity of ecosystems to provide services for human well-being but does not consider different trajectories into the future or possible policy responses, as these are considered in the *Scenarios* and *Policy Responses* volumes of the MA. Finally, the chapter outlines some of the major needs for continued research and data, focusing primarily on the areas that most severely hampered the ability of the MA Condition and Trends Working Group to reach conclusions.

28.2 How Have Ecosystem Services Contributed to Recent Improvements in Human Well-being?

Substantial improvements in human well-being in many parts of the globe have been apparent over the last half of the twentieth century. (See Chapter 5.) World population has more than doubled over the last 50 years (see Table 28.1), and consumption of many ecosystem services has grown even more. (See Chapters 7–17.) Life expectancy has increased in most areas of the world and infant mortality rates have declined almost everywhere, with the exceptions of the former Soviet Union and sub-Saharan Africa. Famines have become less common, and hunger has declined in absolute terms, although it remains a significant problem in some specific regions. (See Chapters 6 and 8.) Arrayed against this aggregate pattern of gains is the growing disparity of wealth, both between and within countries, and the failure of Africa in particular to share in the decades of major economic gains and the growth in social and institutional capabilities. (See Chapters 5 and 6.)

Table 28.1. Global Population and Life Expectancy, 1950, 1975, and 2000 (United Nations 2003)

Population size	1950	1975	2000
		(million)	
Industrial countries	813	1,047	1,194
Developing countries	1,706	3,021	4,877
Africa	221	408	796
Asia	1,398	2,398	3,680
Europe	547	676	728
Latin America and Caribbean	167	322	520
North America	172	243	316
Oceania	13	22	31
World	**2,519**	**4,068**	**6,071**

Life expectancy, both sexes combined	1950–55	1970–75	1995–2000
		(years)	
Industrial countries	66.1	71.4	74.8
Developing countries	41.0	54.7	62.5
Africa	37.8	46.2	50.0
Asia	41.4	56.3	65.7
Europe	65.6	71.0	73.2
Latin America and Caribbean	51.4	60.9	69.4
North America	68.8	71.6	76.4
Oceania	60.3	65.8	73.2
World	**46.5**	**58.0**	**64.6**

Numerous factors have contributed to these overall global improvements in human well-being, including major gains in manufactured and social capital, increased efficiencies associated with research and technology development, and the emergence of more-effective national and international institutions. (See Chapter 3.) But the human capacity to exploit ecosystem services has played a central role, and people have been extraordinarily successful in most of the world in using those services to meet a wide range of needs, such as food, clean air and water, shelter and protection from natural hazards, and cultural fulfillment. As human populations and individual well-being have increased, so has the consumption of ecosystem services, leading to increasing demands on ecosystems to provide for people.

The use of ecosystem services has also changed in its nature, in large part due to research and technology development, allowing for more-efficient use and production of services such as clean water and food and for partial substitutes to be developed for other services, such as for some fibers and for some cultural services. However, the parallel increased efficiency of use of many ecosystem services has been offset by increases in the absolute amounts of consumption of services, giving rise to serious concerns about the sustainability of their supply. (See Chapters 7–17.) In addition, the increasing consumption of some ecosystem services is clearly resulting in trade-offs in other services and thereby in the availability of certain benefits to people around the world. Such trade-offs in services, and thereby human well-being, are occurring across temporal and spatial scales; some areas and some people have gained, but at the same time some areas and some people are losing out.

Social and institutional issues are important in the effective use of ecosystem services. The enormous expansion of human capital has been crucial in securing both greater efficiency in and simply greater use of natural resources. Social institutions play an important role in facilitating growth, avoiding overexploitation, and managing environmental impacts. A decision-making environment with transparency, extensive flows of information, accountability, and minimization of corruption is a key to efficient uses of ecosystem services. The weight of evidence, however, suggests that current international disparities in income and wealth and in gender equality seriously constrain the development of institutional capabilities to support major future gains in human well-being. Well-functioning legal and judicial systems also contribute to sustainable development and the protection of environmental assets.

28.3 Which Areas Have Seen the Biggest Changes in Ecosystems over the Last Several Decades?

Changes in land cover, driven by the way people use land, are perhaps the most important single change in terrestrial ecosystems, affecting the supply of services. (See Chapters 21–27.) Although there has been a rapid expansion in the availability of data and information on ecosystems, there has not yet been a systematic examination, using global and regional observations, of the status and trends in land cover. This section summarizes a synthesis of the available information on rapid land cover change for about 1980 to 2000. Coastal and marine systems have also undergone dramatic changes during this period—for example, through the loss of mangrove forests and degradation of coral reefs in coastal areas (see Chapter 19), the declines in the abundance of marine fishes, and degradation of the sea bed in many areas (see Chapter 18). Of all the broad ecosystem types, inland waters are thought to be the most altered by human actions, particularly through the decline in water quality (see Chapters 7, 15, and 20) and the loss and fragmentation of wetlands (see Chapter 20).

The types of land use change included in the terrestrial analysis presented here are forest cover changes (deforestation and forest expansion), land degradation in drylands, and expansion of urban settlements. (See Box 28.1.) Information is also presented on recent changes in cropland extent.

Deforestation has been the most frequently measured process of land cover change on a regional scale; more datasets are available for the tropics than the boreal zones. During the 1990s, deforestation and forest degradation appeared to be more frequent in the tropics than elsewhere. (See Figure 28.1 in Appendix A and Chapter 21.) In particular, the Amazon Basin and Southeast Asia had large concentrations of deforestation ''hotspots.''

It is possible that areas of deforestation or degradation in the boreal or temperate regions (such as Canada or Siberia) are underrepresented. For example, forest degradation in Siberia, mostly related to logging activities, has been rapidly increasing in recent years. Moreover, the frequency of major fires, which are a natural disturbance factor in boreal forests, has increased globally since 1960. (See Chapter 16.)

There also remains uncertainty even within regions for which data are available. National statistical data indicating no net loss of forest can mask more detailed trends, such as a combination of deforestation in some regions and expansion of plantation forests in others. Some European countries, the United States, and Canada all experienced an overall increase in forest cover at the national level. (See Chapter 21.)

Most of the known areas of degraded dryland are found in Asia (see Figure 28.2 in Appendix A and Chapter 22), although not all the drylands of the world have been well studied. Major gaps occur in knowledge of dryland areas around the Mediterranean basin, in eastern Africa, in parts of South America (North of Argentina, Paraguay, Bolivia, Peru, and Ecuador) and in the United States. If all drylands were equally well studied, the global distribution of the most degraded land might turn out to be different, but the patterns currently observed in Asia would likely remain the same. The available data do not support the claim that the African Sahel is currently a desertification ''hotspot.'' (See Chapter 22.)

The most populated areas of the world are located in the Gangetic plain of northern India, on the plain and north plateau of China, and on the island of Java in Indonesia. The most populated cities, with more than 750,000 inhabitants, are mainly located on the eastern coast of the United States, in Western Europe, and in India and East Asia. The most rapidly growing cities are located around the tropical belt, however, rather than in temperate regions. (See Figure 28.3 in Appendix A and Chapter 27.)

Data availability to determine cropland expansion and abandonment varies regionally. However, it is likely that the largest and most rapid areas of cropland increase are found in Southeast Asia, followed by Bangladesh, the Indus Valley, parts of the Middle East and Central Asia, the region of the Great Lakes of eastern Africa, and the southern border of the Amazon Basin in Latin America. (See Chapter 26.) North America accounts for most of the main areas of decrease in cropland (in the southeastern United States), followed by Asia (eastern part of China) and South America (parts of Brazil and Argentina). Areas of decrease in cropland extent are located in most other continents, although Africa is the only continent where no decrease in cropland was identified. Data quality issues are extremely important in evaluating these trends, and a graphic presentation of these changes, together with the associated data and an assessment of the data, is available at www.MAweb.org.

BOX 28.1

Constructing the Land Cover Change Maps

Deforestation and forest degradation. The map of the main areas of deforestation and forest degradation is based on three types of data sources: expert opinion gathered through formal procedures, remote sensing-based products, and national statistics. To avoid the coarse scale of national statistics, priority was given to the remote sensing and expert opinion data. The final map identifies, for each "forested" grid cell, how many input datasets covered the area and how many times it was considered as a main area of deforestation or forest degradation by these different datasets. A second color code represents the reliability (estimated in terms of convergence of evidence) of the information—that is, the frequency of detection as a hotspot relative to the number of data sets covering the area (see legend for color code). The information based on (sub)-national statistics provides average annual rates of deforestation and should be considered as secondary to the other sources because it is not at a fine resolution. When that rate is higher than 3% per year, the area is considered as rapid change.

Desertification. The map of the main areas of degraded land is constrained by lack of reliable data compared with the maps on deforestation and cropland extent. Most available data are quite heterogeneous in terms of monitoring methods or indicators used.

Changes in urban extent. While urban areas are defined as any region with population density greater than a threshold, the impact of urbanization on land cover is better measured by the change in built-up area. The final map shows the spatial distribution of the population density in 1995 and identifies the most populated and most rapidly changing cities of more than 750,000 inhabitants.

28.4 What are the Main Drivers of Change That Affect Ecosystems, Ecosystem Services, and Associated Human Well-being?

The human and environmental forces that drive changes in ecosystems, and thereby changes in ecosystem services and human well-being, are highly variable from place to place. As such, generic explanations or statements of causality are difficult to create. Driving forces are almost always multiple and interactive, so that a one-to-one linkage between particular driving forces and changes in ecosystems and ecosystem services is usually not possible. (See Chapters 3, 4, and 11.) Similarly, the linkage between particular changes in ecosystem services and various indicators of human well-being is often not well understood. (See Chapters 5 and 7–17.) In both cases, the causal linkage is almost always highly mediated by other factors, thereby complicating statements of causality or attempts to establish the proportionality of various contributors to changes. Analyses of driving forces generally distinguish between direct factors (the immediate causal agents of change) and the more indirect underlying factors that themselves cause change in the direct drivers. (See Chapter 3.)

Drivers of biodiversity loss are reasonably well understood, at least qualitatively. It is *well established,* for example, that habitat conversion, degradation, and fragmentation on land (usually for agricultural expansion) and in the oceans (mostly associated with fishing activities) have been the most important direct drivers of biodiversity loss globally in the recent past. Although habitat change will continue to be an important threat to biodiversity, the impacts of climate change, invasive non-native species, pollution, and nutrient overload are all increasingly important. (See Chapter 4.)

Some other linkages between drivers and impacts are also well known. In the case of impacts on human health, for example, it is known that burning wood, charcoal, and dung in poorly designed stoves has serious adverse effects on indoor air quality and is thought to be responsible for some 1.6 million deaths per year, almost all in developing countries. (See Chapters 9 and 27.) There is a complex set of driving forces affecting the increasing risk of infectious diseases in humans, including logging, dam and road building, agricultural expansions, urban sprawl, and pollution of coastal areas. (See Chapter 14.) With regard to adverse impacts on inland waters, land use change, nutrient overload, and pollution have been the key human driving forces. (See Chapter 20.)

Population growth, economic development, and increasing consumption and production are all important indirect drivers of change in ecosystems and ecosystem services. However, increasing attention is being given to the role of government policies relating to, for example, investments in rural roads, irrigation, credit systems, and agricultural research and extension, which have often served to expand food production. (See Chapter 8.) Policies that restrict trade, capital, and labor flows have conditioned access to international markets and have structured the international food system and global patterns of food production and consumption. Small-scale food producers in many poorer countries have been particularly affected by many such policies, as have general patterns of nutrient cycling. (See Chapter 12.)

28.5 Is There Evidence That Changes Made to Ecosystems in Order to Increase Provisioning Services Have Altered Regulating, Cultural, or Supporting Services?

The growth in human well-being at the global scale over the last several decades has come in large part because of increases in provisioning services from several major ecosystems. These changes have been particularly significant in cultivated systems, where the largest changes in the recent past have been as a result of intensification rather than the large-scale conversion of uncultivated land to agriculture (see Chapters 8 and 26), and in coastal and marine systems, where changes have occurred due to increased fish harvest and the increasing addition of nutrients in coastal systems (see Chapters 8, 12, 18, and 19). Over the last 50 years forests have also been changed dramatically, with the largest changes in tropical and sub-tropical forests, where there has been substantial clearing and transformation of previously forested land for agricultural and timber production. (See Chapters 9 and 21.) Changes in forests in the temperate and boreal zone, while regionally important, have generally been small in the recent past compared with changes in the sub-tropics and tropics, and they have often involved increases in forest cover. (See Chapter 21.)

This section explores the major changes in ecosystem provisioning services over the last several decades and the trade-offs that have come as a result of the increased focus of human management on provisioning services. Over the past 50 years, there have also been substantial changes in some of the regulating, cultural, and supporting services that ecosystems provide, and those that are considered to be the most important are presented here. In some cases, these have been the direct result of managing ecosystems primarily for their provisioning services. In other cases, they are the direct result of transformation of ecosystems and habitat to other uses entirely. The major trade-offs in other services for the enhancement of provisioning services have come from the influence of ecosystems on atmospheric composition and climate feedbacks, nutrient cycling, the spread of disease, and biodiversity itself.

28.5.1 Food

Globally, ecosystems have met the rising demand for food over the last 50 years. The availability of basic food items such as cereals has increased faster than population growth, and the price of staple food items for many people is lower. (See Chapter 8.) There are significant regional differences in the accessibility to food, however.

Marine capture fisheries are the exception to the general increase in food availability. Globally, fish catches have declined over the last 10–15 years, and prices for fish from capture fisheries have risen. (See Chapters 8 and 18.) Although the cultivation of some of the targeted marine species has the potential to offset this decline at cheaper prices than for capture fisheries, the current high dependence on wild capture fisheries suggests that this potential will not be realized in the next few years.

The last 50 years has witnessed major successes in global agriculture, largely the result of improved crop varieties, synthetic fertilizer, irrigation, and other agricultural technologies, although expansion of land area under cultivation has played a role in many developing countries, particularly in sub-Saharan Africa. (See Chapter 26.) Food production from croplands has outpaced population growth over the last several decades when viewed in the global aggregate, with increases in food output per capita most rapid in East Asia. Yet in the world's poorest regions, especially in sub-Saharan Africa, yields have not benefited from advances seen elsewhere, and food insecurity persists. In sub-Saharan Africa, per capita food output has declined. (See Chapter 8.)

The intensification of agriculture underlies the enormous increase in the flow of food provisioning services over the last several decades, including of crops, livestock, and aquaculture. The trade-offs associated with the increases in this service are many, most prominently:

- major impacts on nutrient cycling, as rapid growth in the application of excess synthetic fertilizer contributes nitrogen and phosphorus to inland waters and coastal systems (see Chapters 12, 19, and 20), and
- loss of biodiversity in cultivated systems with monocultures associated with intensive agriculture (see Chapters 4 and 26).

The increase in land area under cultivation associated with agricultural extensification has involved a different set of trade-offs, most notably:

- habitat fragmentation and loss of biodiversity as land (mainly forest) is cleared for cropland (see Chapters 4 and 21), and

- impacts on atmospheric composition, particularly the greenhouse gas carbon dioxide, and climate regulation as biomass is cleared for cropland (see Chapters 13, 21, and 26).

Over the long term, declines in supporting and regulating ecosystem services, such as soil fertility, water cycling, and genetic resources, potentially undermine the ability of food production to keep pace with population growth in the absence of new, major technological advancements in agriculture. Those relying on subsistence agriculture are among the poorest and the most directly vulnerable to reductions in these ecosystem services, as their lack of economic resources limits access to alternative food sources. (See Chapter 7.)

28.5.2 Water

Over the last 50 years, people's access to water has also improved globally, although—like food—there are regional differences in quantity and quality of supply. (See Chapter 7.) The regulating and provisioning of water and its associated benefits (such as for food production through irrigation, or energy production through hydropower) has been a key factor in improving human well-being. The provisioning services of cultivated and dryland systems in particular have been possible primarily through the delivery and regulation of water through irrigation and flood control. The capacity of ecosystems to provide clean and reliable sources of water, however, is in decline in many parts of the world. (See Chapters 15, 16, 20, 21, and 24.)

Human well-being has improved through managing water use, controlling floods, providing transportation, irrigation, generating hydroelectricity and pollution control. The trade-offs for these improvements have included habitat fragmentation and loss, biodiversity loss, increases in certain human health risks, and declines in sediment supplies to the coastal zone. Levels of organic pollution (such as human and animal wastes and excess fertilizers) and inorganic pollution (such as pesticides, heavy metals, and PCBs) are increasing, much of which is from cultivated and urban systems. (See Chapters 15, 26, and 27.) Many of these pollutants are ultimately deposited in freshwater, coastal, and marine systems, affecting aquatic habitats, fish stocks, and the health of local human populations. (See Chapters 15, 19, and 20.)

The deterioration of the quantity or quality of fresh water is especially acute in cultivated systems, dryland systems, urban systems, and wetlands. (See Chapters 20, 22, 26, and 27.) The per capita availability of water has declined significantly since 1960 and the trend is expected to continue, albeit more slowly, until at least 2010. (See Chapter 7.) Economic development, including food provisioning and other water uses, will be most affected in those areas experiencing or at risk of water scarcity, particularly drylands. (See Chapter 22.)

28.5.3 Fish

Total fish supply has increased over the last 50 years but the cost to the sustainability of fish stocks and to the quality of many coastal and marine environments has been high. (See Chapters 18 and 19.) Technological changes followed by economic subsidies have fueled the expansion of fisheries into every ocean. Many fishing fleets are continuing to fish further offshore and deeper to sustain catches and to meet the growing demand for fish products, and this has led to a number of targeted stocks in all oceans having collapsed due to overfishing. (See Chapter 18.) More recently, the demand for selected marine products throughout the year has fueled the growth of inland, coastal, and offshore aquaculture, with consequential impacts to ecosystems. For example, the development of shrimp aquaculture has accounted for a significant loss of coastal habitat, in particular mangroves, in many tropical countries. (See Chapters 8 and 19.)

Globally, per capita consumption of fish is increasing, especially in Asia and the Americas, while in Europe and Africa consumption growth is moderate. Aquaculture production is increasing in both freshwater and marine systems at a rate of approximately 1 million tons per year , and it now supplies almost one third of all fish consumed, thereby sustaining increasing per capita consumption. (See Chapter 19.) However, much of the increase in marine aquaculture is in high-value species such as shrimp and salmon and therefore is not necessarily meeting the needs of poor consumers. Capture fisheries also provide employment and subsistence opportunities for many of the world's poor, many of whom are without access to property or property rights.

Provisioning of fish for food directly and indirectly (via fishmeal, animal feed, and fertilizers) has in many places resulted in degradation of coastal and marine systems and of other ecosystem services. (See Chapters 18 and 19.) Overfishing of many fish stocks in shallow coastal shelf systems has changed highly diverse, complex, and robust coastal ecosystems into systems of reduced diversity and resilience. (See Chapter 19.) Due to fishing pressures, for example, the Gulf of Thailand has changed since 1970 from a system with a high diversity of fish, including top predators, to one dominated by small, short-lived species that support a low-value fishery from which catches are mainly used for feed in the high-value invertebrate aquaculture industry. Such a reduced-diversity system may be more sensitive to external impacts and has a lower capacity to deliver ecosystem services. (See Chapter 11.)

Many coral reefs have shifted to algal-dominated systems where recovery is highly unlikely due to a combination of overfishing, disease, and climate change. (See Chapter 19.) The impact of destructive fishing practices such as bottom trawling and bombing exacerbates the problem of overfishing and restoration of depleted stocks. (See Chapter 18.) Although our understanding of the impact of overfishing in deep water and pelagic systems on regulating and supporting services is limited, the exploited species in some deepwater systems such as seamounts that were fished in the 1970s have not been recorded since then (see Chapter 18), suggesting that such systems are unable to recover over the short to medium term.

Overfishing has also affected the cultural services provided by marine and coastal systems. Many communities whose culture is based on a long history of fishing are in decline, with many fishers and their families migrating to urban areas. Those who choose to remain find that their social and economic conditions often decline. (See Chapter 18.)

28.5.4 Atmospheric Composition and Climate Feedbacks

Ecosystems influence air quality and climate, both through natural processes that maintain the status quo and through management-induced changes that can be either detrimental or beneficial to human well-being. (See Chapter 13.) Ecosystems play an important role in cleansing the atmosphere of pollutants. Changes in ecosystems as a result of human activity are one of the main drivers of change in climate and air quality, along with fossil fuel burning and industrial emissions, and concentrations of key greenhouse gases and other atmospheric constituents will continue to change in the future as a result of human impacts on ecosystems.

The most important changes in ecosystems leading to changes in atmospheric composition and climate feedbacks have been land clearing for agriculture, ranching, and urbanization—mostly through deforestation and biomass burning, although draining of wetlands has also been important, as has the increase in rice cultivation and livestock production. (See Chapters 9, 13, and 21.) These activities have resulted in an increase in concentrations of many trace gases in the atmosphere that subsequently change the chemistry of the troposphere and reduce the atmosphere's own capacity to remove pollutants (atmospheric cleansing capacity). These trace gases also act as pollutants themselves, act as fertilizing agents, change ozone concentration in the troposphere, and affect global climate (through impacts on radiative forcing, greenhouse gases, and cloud formation). Finally, ecosystem changes such as decreasing forest cover alter the physical properties of Earth's surface that in turn influence climate and hydrology, although these effects have likely been relatively smaller than the direct effects on atmospheric composition. (See Chapter 13.)

28.5.5 Nutrient Cycling

Nutrient cycling has been affected significantly in the last few decades, mainly from large-scale changes in agriculture and its inputs. (See Chapters 12 and 26.) As such, most of the trade-offs with other services can be tracked by focusing on areas where agriculture has changed substantially.

Changes in the extent and management of cultivated lands are nothing new. Before the Industrial Revolution, both because human populations were smaller and because there was a need to maintain forests and woodlands for fuel, the expansion of agricultural land was relatively small. Between 1950 and 1980, however, more land was converted to cropland than in the 150 years between 1700 and 1850 (see Chapter 26), due to both the needs of growing human populations and the availability of coal as an energy source. Cropland expansion has been estimated at about 1,200 million hectares over roughly the last 300 years.

With the exception of many tropical regions, which have experienced recent expansion of croplands, much of the potentially productive agricultural land appears already to have come under cultivation, thereby limiting potential for further expansion. (See Chapter 26.) Instead, there have been major increases in the intensification of the management of cultivated lands, including the increased addition of nutrients. This is reflected in part in the available data for the application of nitrogen-based fertilizer and in the observation that cropland yields have largely continued to rise on a per-hectare basis even as the rate of cropland expansion has dropped in much of the world. (See Chapters 8 and 26.)

The changes in the nitrogen cycle have been dramatic. Fertilizers spread on agricultural land, enhancement of N-fixation by planted legumes, biomass burning, fossil fuel combustion, land clearance, and wetland drainage have contributed to a doubling of natural inputs of nitrogen to ecosystems. (See Chapter 12.) The increase of biologically available nitrogen due to these sources, coupled with the leaching of phosphorus fertilizers and wastes, has led to substantially increased eutrophication in a number of aquatic systems. (See Chapters 19 and 20.) The increase in number, extent, and severity of periodically anoxic zones in estuarine systems around the world, for example (see Chapter 19), is a direct consequence of this trade-off.

Impairment of the nutrient cycling service is due to a disruption of a number of regulatory mechanisms that operate at different spatial and temporal scales. (See Chapter 12.) In soils, for example, synchrony between nutrient supply and demand by plants is a complex system whose stability requires a minimum biodiversity of plants and soil organisms. The intermediate storage of nutrients in soil aggregates is often decreased by a severe depletion of the abundance and diversity of the plants and soil organisms that create this structure. Another effect of human activities on nutrient cycling has been the impairment or removal of the buffers, such as riparian forests and wetlands, that naturally ensure a close cycling of nutrients and thereby reduce losses to other compartments of the biosphere. (See Chapter 12.)

28.5.6 Spread of Disease

Historically, many diseases have emerged from altered ecosystems or domesticated animals (such as tuberculosis, measles, plague, and HIV), while other disease agents are in the process of adapting to human-dominated systems. Newly resurgent diseases deserve special attention if they have recently increased in incidence or emerged in a new geographical location, if they are of major public health importance and economic impact, or if they are difficult to control (such as antibiotic-resistant strains). Among these, malaria, leishmaniasis, dengue, and schistosomiasis are of major concern for the tropics; West Nile virus and Lyme disease in North America and Europe; and Japanese encephalitis in Asia. (See Chapter 14.) Also, food- and water-borne diseases stemming from intensive livestock or fish production are a growing concern. (See Chapter 8.) Approximately 75% of all emerging diseases are zoonotic (coming from animals), thus stressing the importance of further investigation of the role of biodiversity and ecological dynamics that are now recognized as central to disease prevention.

The most important drivers of ecosystem change that have affected infectious disease risk include tropical deforestation, road building, expansion of irrigation and dam building, local and regional weather anomalies, intensification of animal production systems, urban sprawl, poor sanitation, and pollution of coastal zones. (See Chapter 14.) The groups most vulnerable to disease risks from these changes include poor populations with little shelter or sanitation, which increases exposure to these risks, who have few financial resources to respond adequately. Activities such as international trade and travel have also led to an increase in infectious diseases. West Nile virus and monkeypox in North America and SARS globally are prime examples.

The magnitude and direction of altered disease incidence depends both on the type of land use change and the size of the human population exposed. Migration to a newly accessible forest or shoreline of a dam, for example, results in higher potential for disease epidemics. And the type of land use change, whether from mining, irrigation, dam construction, deforestation, or other causes, will promote specific diseases depending on geographic location. Major changes in habitat can both increase or decrease the risk of a particular infectious disease. (See Chapter 14.)

While many systems, such as forests, drylands, or cultivated systems, contain a distinct set of infectious diseases, several major diseases (including malaria and dengue) are more ubiquitous occurring across many ecosystems. For example, malaria is transmitted by 26 differing species of Anopheline mosquitoes that are each dominant in varying habitats and geographic locations. While *Anopheles gambiae* and *An. funestus* are the primary malaria vectors in Africa, *An. darlingi* is the primary carrier in South America, and *An. dirus* is in parts of Southeast Asia. Each species responds differently to a specified land use change, and it is therefore difficult to generalize ecosystem change effects across many regions.

On the other hand, some diseases such as yellow fever can be transferred across ecosystems. The natural zoonotic cycle of yellow fever occurs between mosquitoes and monkeys high in forest canopies, but the disease can move into savanna, agricultural, and even urban areas facilitated by human economic activities such as logging or forest clearing for crops and livestock.

Large preserved natural systems, due to their physical and biological characteristics, are relatively unreceptive to the introduction of many invasive human and animal pathogens that are brought in through human migration and settlement. For example, schistosomiasis, Kala-azar, and cholera have been introduced in the Amazon region but have not been able to become established in the natural forest system. (See Chapter 14.)

Higher levels of biodiversity can reduce the risk of some vector-borne diseases via a ''dilutional effect'' or by maintaining natural predators. (See Chapters 11 and 14.) The former effect has been documented in the case of Lyme disease in North America and is likely true for many diseases where the capability of an animal host to be infected and carry a disease agent varies greatly across the intermediate animal hosts on which an insect vector must feed. Schistosomiasis in Lake Malawi provides a good example of the relationship of disease emergence to natural predators, as it rose rapidly following overfishing of fish predators on the snail intermediate host for the parasite that causes the disease.

28.5.7 Biodiversity

It is *well established* that losses in biodiversity are occurring globally at all levels, from ecosystems through species, populations, and genes. (See Chapter 4.) The current documented rate of species extinction is two orders of magnitude higher than the average rate of species extinction from the fossil record, and there is a continuing trend for conversion of naturally occurring, species-rich ecosystems into more intensively managed habitats with reduced biodiversity. Losses at the population level are variable but substantial in certain systems, such as marine, freshwater, and agricultural systems, and more common in large and long-lived species. Figure 28.4 (in Appendix A) presents the aggregate global trends in populations of well-studied species. The extent of loss of genetic diversity is less well understood and is mainly inferred from declines in higher levels of biodiversity organization, although recorded losses in agricultural genetic diversity are widespread. (See Chapters 4 and 26.)

There are some instances where biodiversity is increasing, in terms of extent of habitat and species composition, such as in temperate forest areas in the northern hemisphere. (See Chapters 4 and 21.) However, available data show aggregate global declines in both the distribution and diversity of biomass. Although widespread, losses of biodiversity are currently particularly prevalent in areas of high species richness, such as tropical forests and coral reef systems. (See Chapters 4, 19, and 21.) Inland waters are also likely to be experiencing high levels of biodiversity loss in most parts of the world. (See Chapter 20.) Habitat conversion (generally for agricultural expansion), degradation, and fragmentation continue to be the most important direct drivers of biodiversity loss globally, although there is an increasing impact of invasive non-native species, of nutrient pollution, and of climate change in many systems. Island systems in particular have historically been affected by the introduction of exotic species, with widespread negative impacts on native island biodiversity.

The impacts of current trends of biodiversity loss on human well-being are multifaceted. While people benefit directly from components of biodiversity in the form of provisioning services and are therefore affected directly by declines in availability of those elements of biodiversity that are providing those goods, the more fundamental role of biodiversity is in the functioning of ecosystems and thereby in the capacity of ecosystems to provide the full range of ecosystem services. (See Chapters 4 and 11.) Both the amount of living material (biomass) and its diversity and distribution play important roles in determining the capacity of systems to provide services now and into the future. Evidence suggests that decreases in the amount of live biomass have directly affected the capacity of some ecosystems to provide services, such as the capacity of tropical forests to regulate local and regional climate (see Chapter 13) and to protect from natural hazards (see Chapter 17) or the capacity of marine, coastal, and inland water systems to provide food (see Chapters 8, 18, 19, and 20). And these services show declining trends.

Current understanding of the consequences of losses in the diversity of biomass is poor and on the whole is limited to a selection of species that play particularly obvious roles in ecosystem functions, such as pollinators for the provision of food services. (See Chapter 11.) The consequences of losses in most rare or restricted-range species are likely to be subtle. Indeed, some provisioning services, such as timber and food, appear most efficiently produced from less diverse systems, such as forest plantations and agricultural landscapes, as evidenced by the wide coverage of cultivated systems. (See Chapter 26.)

However, all ecosystem services are ultimately reliant on ecosystem functions and on the interactions between elements of biodiversity. (See Chapter 1.) It is also likely that more diverse systems are more resilient, resistant, and adaptable to changes in drivers. (See Chapter 11.) Among the most important factors identified is the degree of functional redundancy found between species within an ecosystem. For example, in many ecosystems there are several species that fix nitrogen. If the loss of any one of them is compensated for by the growth of others and there is no overall loss in nitrogen fixation, then the impacts of the loss of the species are reduced, in terms of the system's capacity to fix nitrogen.

There may, of course, be other consequences of the loss of these species. The possibility of significant losses of function increases as more species, and variability within species, are lost and as redundancy is reduced—that is, there is an asymptotic relationship between biodiversity and ecosystem functioning. Greater functional redundancy represents greater insurance that an ecosystem will continue to provide both higher and more predictable levels of services. (See Chapter 11.)

Although there have been significant benefits derived from the commercial exploration of biodiversity across a range of industrial sectors, and particularly from pharmaceutical bioprospecting, the consequences of losses of genetic and species diversity on bioprospecting potential remains largely speculative, especially in marine and coastal areas. (See Chapter 10.) Unlike some other services where there are minimum thresholds, however, overall declines in the amount of biodiversity proportionately reduce the resource base from which commercial exploration is possible.

There have been significant impacts of declining biodiversity on cultural services. Globally, many cultural values associated with the conservation of components of biodiversity, particularly relating to the amount and diversity of natural systems and of species and populations, continue to be affected directly through the current trends in declining biodiversity. (See Chapter 17.)

28.6 Is There Evidence That the Capacity of Ecosystems to Provide Services Is Reaching Critical Levels?

In addition to documenting the actual trade-offs that have been made while managing ecosystems for different services, the extent to which those trade-offs have resulted in a reduction in the capacity of ecosystems to provide services is also important to consider. If the underlying capacity of ecosystems to provide a range of services has been reduced, then there are obvious implications for the future not only of the ecosystems and services in question, but also for human well-being.

Of the services and systems examined in this report, it is clear that at a global level there are two issues where the capacity to continue to provide services has most clearly declined. One is marine and coastal capture fisheries, as described earlier in this chapter and in Chapter 18. It is now *well established* that the capacity of the oceans to provide fish for food has declined substantially and in some regions showing no sign of recovery. The other is the loss of biodiversity, in large part because the rates of loss (of species diversity) are so much more rapid than the creation of new diversity through evolutionary processes. (See earlier section and also Chapter 4.) The implications of this loss are less immediately clear than those of the decline of marine fisheries, but over the long run they are likely to be considerably more important. In addition, some systems have eroded their capacity to provide services on a regional basis, such as inland waters (Chapter 20), forests (Chapter 21), and drylands (Chapter 22). The implications of this regional reduction in capacity are explored more fully in the next section.

Understanding how the decline in the capacity of ecosystems to provide services has occurred is as important as documenting where the capacity has declined. A good deal of ecosystem change and corresponding decline in ecosystem services is gradual and occurs over long time frames. Such chronic loss of ecosystem services certainly affects human well-being but over decadal or intergenerational time frames. However, some ecosystem changes are nonlinear or abrupt and sometimes irreversible. The reasons for such nonlinearities include:

- intrinsic features of the ecology of certain ecosystems (that is, ecological thresholds),
- the magnitude and nature of the impact causing change (such as changes occurring in response to technological advances), and
- the features of the drivers of change (such as social and cultural "ratchets" that allow change in only one direction).

While each of these is described here separately, it should be noted that they are often present in tandem, particularly when large-scale ecosystem changes occur.

Significant changes in ecosystem structure and function can occur when certain triggers result in changes in the dominant species. An excellent example of this is provided by coral reef ecosystems that undergo rather sudden shifts from coral-dominated to algal-dominated reefs. The trigger for such phase shifts, which are for all intents and purposes irreversible, is usually multifaceted and includes increased nutrient input leading to eutrophic conditions and the removal of herbivorous fishes that maintain the balance between corals and algae. (See Chapter 19.) Once the thresholds for the two ecological processes of nutrient loading and herbivory (one an upper threshold and one a lower threshold) are passed, the regime shift occurs within months, and the resulting ecosystem, though stable, is less productive and less diverse than before the transformation. Human well-being is affected not only by reductions in food supply and income from reef-related industries (such as diving and snorkeling, aquarium fish collecting), but also by increased costs accruing from the decreased ability of reefs to protect shorelines, as algal reefs are more prone to being broken up in storm events, leading to shoreline erosion and seawater breaches of land.

Nonlinear changes in ecosystem structure and function can also occur at the regional level, affecting, for example, regional climate. (See Chapter 13.) The vegetation in a region influences climate through albedo, transpiration, and the aerodynamic properties of the surface. In the Sahel region of North Africa, vegetation cover is almost completely controlled by rainfall. When vegetation is present, rainfall is quickly recycled, generally increasing precipitation and in turn leading to a denser vegetation canopy. Model results suggest that land degradation leads to a substantial reduction in water recycling and may have contributed to the observed trend in rainfall reduction in the region over the last 30 years. In tropical regions, deforestation generally leads to decreased rainfall. Since forest existence crucially depends on rainfall, the relationship between tropical forests and precipitation forms a positive feedback, which, under certain conditions, theoretically leads to the existence of two steady states: rainforest and savanna. Some models suggest only one stable climate-vegetation state in the Amazon.

Introduced invasive species can also act as a trigger for dramatic changes in ecosystem structure, function, and delivery of services. (See Chapters 3, 4, and 11.) In marine systems, species are commonly brought into new areas through ballast water discharges from ships, and they sometimes establish in new areas through outcompeting native species for food and space. One example is the rapid and irreversible change in the Black Sea, where the carnivorous ctenophore *Mnemiopsis leidyi* caused the loss of 26 major fisheries species and has been implicated (along with other factors) in subsequent growth of the anoxic "dead zone." (See Chapter 19.)

Certain kinds of human activity can lead directly to largely irreversible changes—the most obvious being habitat loss from conversion to urban environments, tourist resorts, ports and harbors, reservoirs, and agricultural lands. Habitat loss results in loss of not only the ecosystem services provided by the affected habitat, but often also the services provided by associated habitats. For instance, development of a port in an estuary may prevent people from obtaining food from the estuary and at the same time affect nearby fisheries whose target species depend on the estuary for nursery habitat. Even minor losses in species or habitat extent may reduce the capacity of ecosystems for adjustment to changing environments, with consequences for ecosystem function, services, and human-well being. (See Chapter 11.)

Finally, technological advances and other changes in drivers can have nonlinear impacts. For instance, societies moving from subsistence harvesting to harvesting with improved technology can cause very sudden and large changes in the rate of resource exploitation. These jumps in exploitation rates often pass the threshold for sustainability and result in crashes of harvested populations, such as fish stocks. The changes in drivers are also, in effect, irreversible, since a return to previous, low-tech methods is unlikely.

Another driver with a potentially disproportionate effect on environmental degradation and loss in services is human migration. This outcome can occur when in-migrants originate from culturally or ethnically different groups than local residents and have neither the same vested interests in environmental protection nor societal self-regulatory mechanisms, as do local communities. Such effects of migration are often not captured in assessments of population impact on environment, since migration, and especially internal migration, is often difficult to monitor and rarely shows up in population census data.

28.7 Are There Parts of the World in Which Recent Declines or Stagnation in Human Well-being Can Be Attributed to Changes in Ecosystem Services?

This assessment shows that global environmental change is highly variable among the world's regions. Some trends and their impacts become apparent only when the scale of analysis shifts from the global to regional and local scales. This section details some of the major findings emerging from the assessment at these lower scales and illustrates the needs to look at ecosystem changes at multiple scales.

Population growth rates are now declining nearly everywhere in the world, but with substantial regional differences. Substantial population growth is still expected in sub-Saharan Africa, South Asia, and the Middle East over the next few decades. The share of the global population represented by North America and Europe is expected to decline from 17% to 10%, while Africa's share is expected to increase from 13% to 23%. Urban populations are growing three times as fast as the population as a whole, creating ecological and socioeconomic problems in cities and surrounding hinterlands. Most of this growth will occur in developing countries. The most critical environmental effects, meanwhile, are local, such as unsafe water supply and indoor air pollution, where residents are also drawing down ecosystem services at ever-greater distances.

The trend toward an increasing proportion of urban dwellers can also most easily be seen on continental and regional scales. Over the past 50 years, there have been relatively modest increases in the proportion of the population living in urban areas in Europe (from 52% to 73%) and North America (64% to 77%). But both the absolute numbers and the percentages have increased dramatically in the developing regions of Africa (from 15% to 37%), Asia (17% to 38%), and Latin America and the Caribbean (42% to 75%). By the year 2000, Asia had 195 cities of more than a million inhabitants (up from 31 in 1990) out of a global total of 388 such cities. Asia also had 45 of the 100 largest cities in the world, while Europe had 15, North America 13, and Latin America 17. (See Chapter 27.)

Global agriculture has registered many successes for the provisioning of food from the world's ecosystems, but again a regional perspective reveals problems among generally favorable aggregate trends. Farmers in some of the world's poorest countries and other resource-poor regions have not shared in the yield increases over the past several decades. Per capita food output has actually declined in sub-Saharan Africa.

Meanwhile, policy distortions and market failures are important problems contributing to the highly variable pattern of food provisioning and food security. OECD countries provide extensive subsidies to their agricultural sectors and also protect them through tariffs, quotas, and export subsidies. The worldwide consequences of these institutional arrangements have been lower prices for internationally traded commodities, higher tax bills, and the overuse of agricultural inputs, such as fertilizers, with associated consequences on ecosystems. (See Chapters 12, 19, and 20.)

Despite widespread increases in the use of fertilizers in other parts of the world, sub-Saharan Africa stands out as a particular problem area where declining soil fertility is a principal constraint for sustaining food production and where soil nutrient stocks are being used unsustainably and fertilizer application remains low. (See Chapter 26.) Meanwhile, rising populations, declining use of fallow, the cultivation of fragile lands, and limited conservation investments are all apparent in many developing regions.

Although there is substantial reason to believe that the world in the coming decades can produce sufficient food to feed its growing population, important regional issues exist in the global pattern of cultivated land. Many regions have experienced declines in the area of cultivated lands over the last several decades, as described earlier. Due partly to increased competition for alternative land uses and to reduced availability of suitable land (particularly outside the tropics), there is declining potential for further expansion of agricultural lands; future increasing agricultural productivity in many parts of the world is likely to come largely from the intensification of the management of existing cultivated lands. (See Chapters 8 and 26.)

Access to sufficient clean fresh water is a problem at a global scale, but also one with a strong regional component. The essential functions of clean water are several: maintaining human and environmental health; supporting essential economic production, such as agriculture, energy, and industry; diluting and transporting wastes; and contributing to religious and cultural activities. (See Chapters 7, 15, 17, 20, and 26.) Despite their critical importance, these freshwater services are under threat throughout the world, and the world's poor people, concentrated in developing countries, are at particular risk. In the mid-1990s, some 80 countries with 40% of the world's population were already suffering from serious water shortages. North Africa and the Middle East, in particular, face great pressure and demand on already overstressed water resources. Azerbaijan, Egypt, and Libya, for example, were already using 55%, 110%, and 770%, respectively, of their sustainable water supplies in the early 1990s.

Water pollution is exacerbating local water scarcity in many parts of the world and is expected to accelerate in coming decades. In developing countries, 90% of sewage continues to be discharged into rivers, lakes, and coastal areas. In Africa, where such problems are particularly intense, major pollution sources include fecal contamination and toxic pollution from cities, industrial centers, and mining sites. (See Chapters 7 and 15.) It is clear, meanwhile, that environmental water is often the loser worldwide, for water needs also to be left in rivers and lakes to maintain the health of ecosystems and fisheries, which are already under heavy pressure from population and economic growth. (See Chapter 20.)

Differential vulnerability to environmental change and poverty also reveal strong regional and local variability. (See Chapter 6.) In the face of general global food availability and the progress in reducing the incidence of famine, many developing countries are experiencing declines in agricultural production and food security, especially among small-scale farmers, isolated rural populations, and those living on marginal lands. The global trends in natural disasters reveal that Asia is disproportionately affected, with more than 70% of all lives lost from natural disasters occurring there. (See Chapters 6 and 16.) In China alone, floods affect more than 100 million people on average annually.

Sea level rise from climate change poses risks for low-lying coastal areas throughout the world (see Chapters 19 and 23), but particularly vulnerable are the small islands of the Pacific, coral reefs, and the deltas of such areas as Egypt and Bangladesh. And the Intergovernmental Panel on Climate Change has concluded that the adverse impacts of ongoing and future climate change will occur largely in the developing countries already beset by poor sanitation, water stresses, financial pressures for needed development programs, and poor health and inadequate medical services.

28.8 What Are the Most Critical Gaps in Knowledge and the Most Crucial Research Needs?

There are many limitations on the scientific community's ability to provide a comprehensive judgment about the conditions and trends in ecosystems and the services they provide. Although it is certain that human well-being is affected by changes in the provision of ecosystem services, the details of that relationship remain difficult to untangle except in the simplest cases, such as the ability of ecosystems to provide food to increasing numbers of people. This section categorizes the main types of uncertainties that limit the ability to synthesize the results presented in the individual chapters on systems and services. Two major needs are focused on: data and information, and processes and understanding.

28.8.1 Data and Information

The most basic limitation is that there are many important features of today's world for which no information is available, much less the high quality, well-documented, and comparable information that is necessary to understand crucial problems. For example, we have relatively little replicable data on forest extent that can be tracked over time. Methods of measuring forest extent vary from country to country, and in spite of large efforts by international agencies to harmonize the information, the ability to document changes in this is surprisingly poor for much of the world.

A similar situation exists for cropland, where methodological issues and significant data gaps cloud the picture of cropland conversion and the use of cropland over time in most regions. The global distribution of wetlands remains unknown, as does the actual current distributions of many important plant and animal species, much less their changes over time.

All these gaps in information result in significant constraints on documenting the trade-offs between provisioning and non-provisioning services. While there is high certainty in some cases relating to large-scale trends such as climate change, species losses, and land degradation, the weakness in documentation and information on regional trends remains a serious handicap. Interestingly, local data and information can in turn be of extremely high quality, in part because the scales of measurement are more amenable to traditional sampling technologies and methods. However, the ability to generalize from local information to regional and global information is limited.

28.8.2 Processes and Understanding

The ability to provide a clear picture of the trade-offs among ecosystem services, and therefore information that is relevant to the continued management of ecosystems for human well-being, is also constrained by limits in understanding of the relevant processes and underlying relationships. For example, while it has become much clearer over the past decade that biodiversity is important for ecosystem functioning, there is limited understanding of the ways in which biodiversity regulates ecosystem functioning at local and regional scales, and there is intrinsic difficulty in predicting unexpected, accelerated, and some times irreversible changes triggered by alterations of local and regional biodiversity. The response of ecosystems to changes in the availability of important nutrients, including carbon, especially through increasing atmospheric pathways is not broadly understood and cannot be deduced strictly through model simulations.

One of the most critical needs for further information is an improved understanding of the factors governing the capacity of ecosystems to provide services. Documenting threshold changes in ecosystems and understanding the structural and dynamic characteristics of systems that lead to threshold and irreversible changes is clearly important in this respect and is currently not well understood. Equally important is the development of both conceptual and quantitative models that can begin to give both scientific and policy communities advance warning of when the capacity of systems is beginning to be eroded or thresholds are likely to be reached, so that action may be taken before significant adverse trade-offs have occurred.

Table 28.2 on page 838 synthesizes some of the main recommendations for data and information on particular ecosystems and services that are the most important ones for building the capacity to forecast changes in ecosystem services. The table identifies a selection of the critical issues to be resolved by further research, why those issues are important, and what processes or questions are important to understand in terms of those issues. Finally, the minimum data and information that will be required to address the issues raised are identified.

Table 28.2. Critical Issues Requiring Research and Data Collection to Forecast Significant Impacts of Ecosystem Change on Human Well-being. This list is intended to highlight the most critical issues and does not identify many other important research and data needs.

Which ecosystems and services most critically require research and data collection to forecast significant impacts on human well-being?	Why is the issue critical?	What do we need to know?	What types of data are required?
Drylands in all semiarid areas	direct dependence of poor on ecosystem services and coping capacity during times of stress; intensifying use for rangeland and cropland	Where is productivity of drylands declining from intensifying use? What are the feedbacks from intensifying rangeland and cropland on soil fertility, climate regulation, and access to water? Where and how is human well-being changing in response to changes in productivity?	indicators of land productivity; indicators of human well-being attributable to changes in land productivity
Coastal and marine systems in all parts of the world	recipient of nutrients from food production systems; importance for fisheries	Where is nutrient input and overharvesting affecting fisheries? Where are declining fisheries affecting access to protein?	nutrient inputs; trends in fish populations
Tropical forests	most significant repository of biodiversity, with high cultural value and potential implications for ecosystem function; rapid conversions expected to continue; non-timber forest products can be major contributor to household food, medicine, traditional livelihoods	Where is habitat loss causing declines in biodiversity? What are the effects of habitat loss on species and populations over what time scales?	indicators of habitat extent and quality, indicators of biodiversity
Boreal forest	acceleration of natural disturbances (e.g., pests and fire)	What drivers are most important for accelerating disturbance regimes? What are anticipated responses to climatic changes?	information on interaction of disturbance regimes and global change
Inland waters	water is basic societal and biological need; human health and economic development issue; direct provision of food	What are contemporary and historical patterns of water infrastructure, use, and supply? What is the access of humans to surface and groundwater sources? Sustainability of fisheries?	basic surface hydrography and well-log data from around the world; extent of fisheries; water quality data
Polar systems	most sensitive to climate change; potentially significant feedbacks to climate regulation; importance of traditional livelihoods	How are polar systems responding to climate change? How does the climate regulation function of polar systems change in response to climate change?	species composition; changes in hydrology and trace gas fluxes' rate and extent of change in permafrost and peat
Food and cultivated systems	cultivated systems occupy a large global area; food provision critical for human well-being; large changes in ecosystem states and services due to provision of food	What are the trade-offs in other services inherent in different management practices? What is the overall sustainability of current fisheries management?	contemporary simultaneous data on outputs and other services from different cultivation and grazing systems
Emergence of disease related to ecosystem change	potentially large implications for human health	Which types of ecosystem changes trigger the emergence of disease? Which types of diseases and which ecosystems are potentially the most significant?	occurrences of diseases related to ecosystem change

Climate change	? 5	↑ 5	↑ 5

Figure 4.16. Major Anthropogenic Variables Acting as Drivers of Change on Different Scales of Ecological Organization or Biodiversity Levels. Color=degree of driver impact on ecological scale (red=maximum impact followed by orange, then yellow); ↑=upward trend of driver impact on ecological scale; 1 to 5=degree of impact reversibility (5=least reversible); Shading=degree of certainty based on expert knowledge (dark shading=least certain); ?=information on trends unknown. Impact indices were based on a year 2010 timeframe.

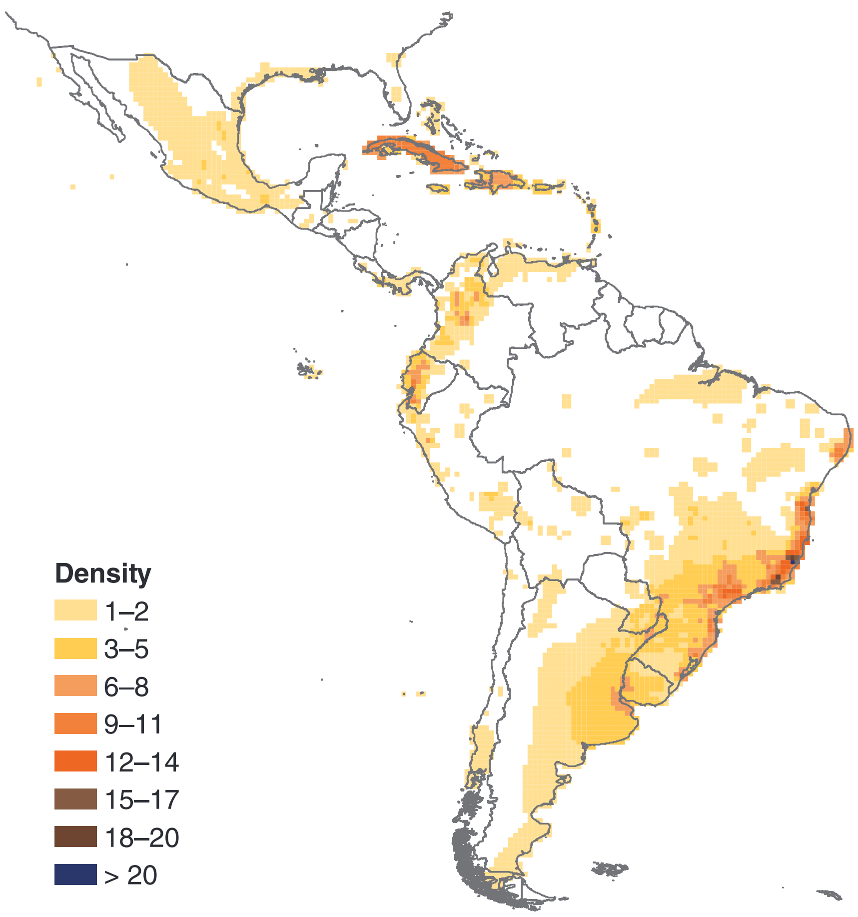

Figure 4.18. Density Map on Extent to Which the Ranges of Threatened Bird Species Have Contracted in Central and South America. The color scale indicates the number of threatened bird species that used to occur in a pixel, but now no longer do so. (BirdLife International 2004a; unpublished data from BirdLife's World Bird Database)

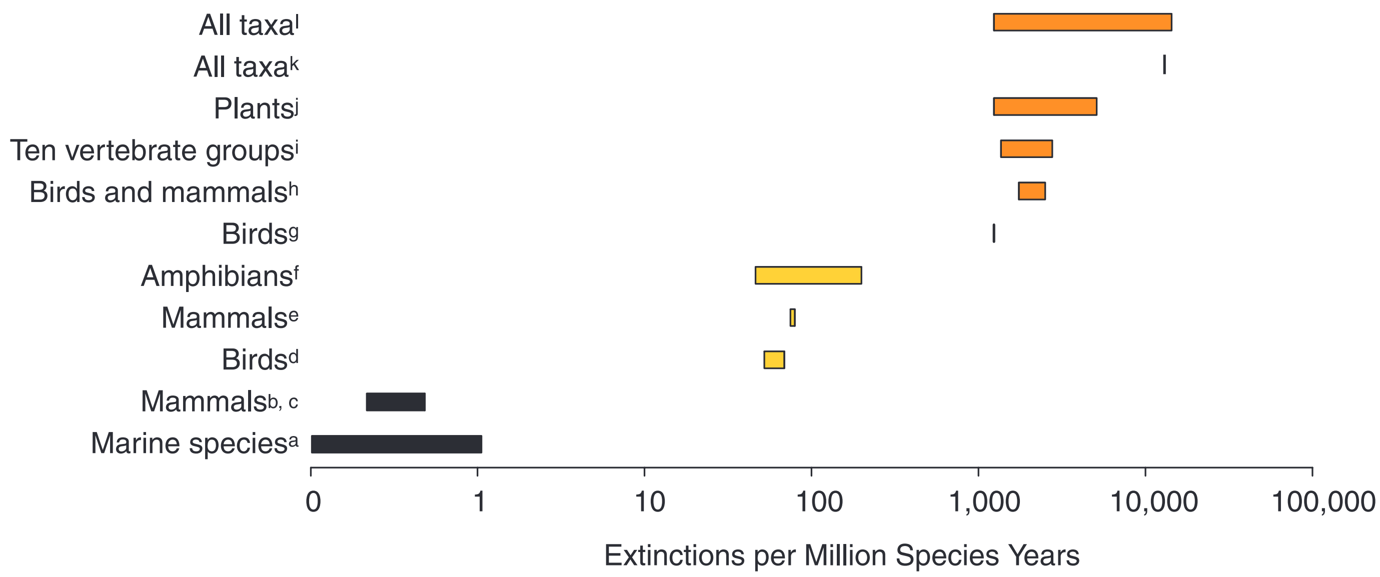

Figure 4.22. Background and Contemporary Extinction Rates. Background extinction rates are in black, extinction rates based on observed extinctions over the past 100 years are in yellow and estimated contemporary extinction rates using a number of different approaches are in orange. Based on background extinction rates from the fossil record: [a]May (1995), [b]Alroy (1998) (lower estimate of 0.21), [c]Foote (1997) (higher estimate of 0.46). Observed extinctions over the past 100 years: [d], [e], [f]Baillie et al. (2004). Projections based on threatened species: [g]Pimm and Brooks (1997), [h]Smith et al. (1993) (also uses recently extinct species), [i]Mace (1994). Plant extinctions using species-area curve with assumptions about habitat loss from agricultural/urban expansion and from climate change: [j]MA *Scenarios*, Chapter 10. Increased energy consumption: [k]Ehrlich (1994). Species-area relationship from deforestation rates: four studies in [l]Reid (1992).

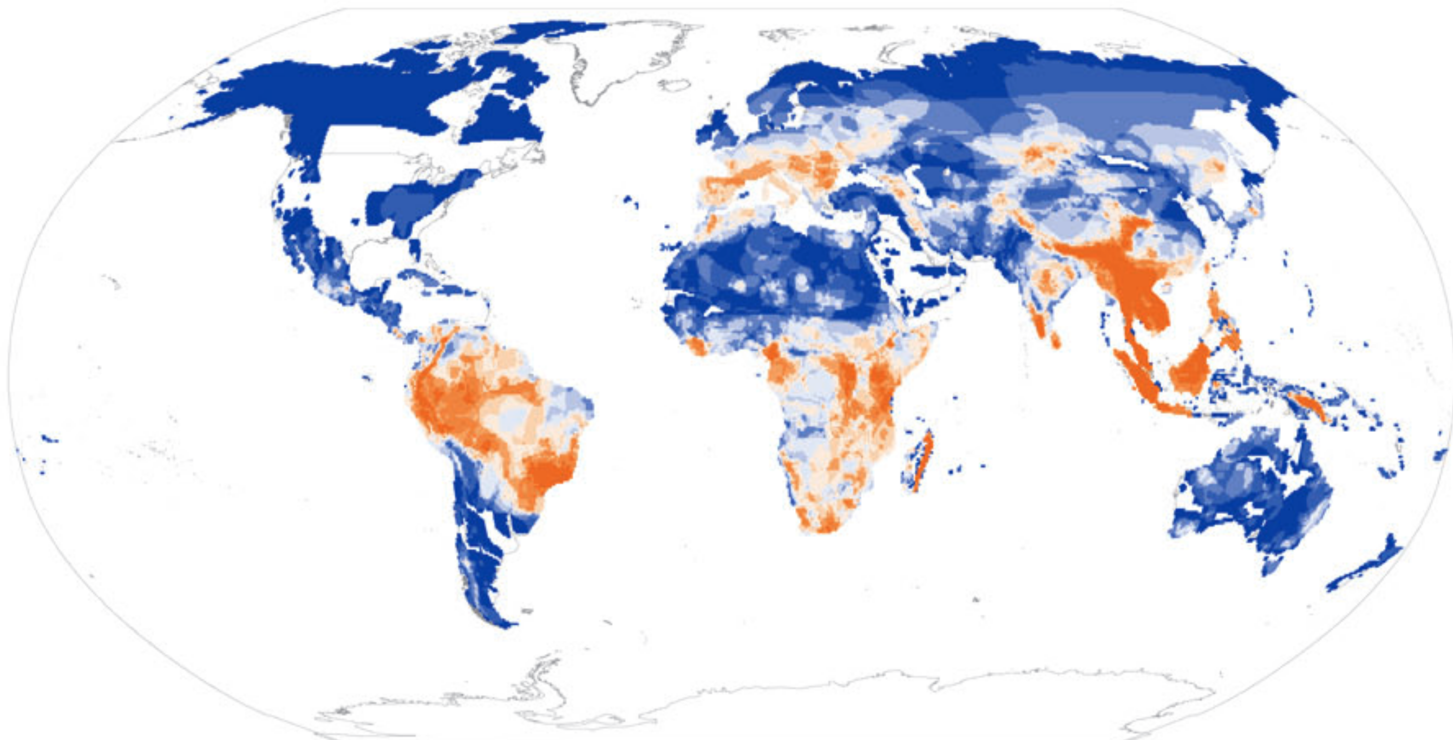

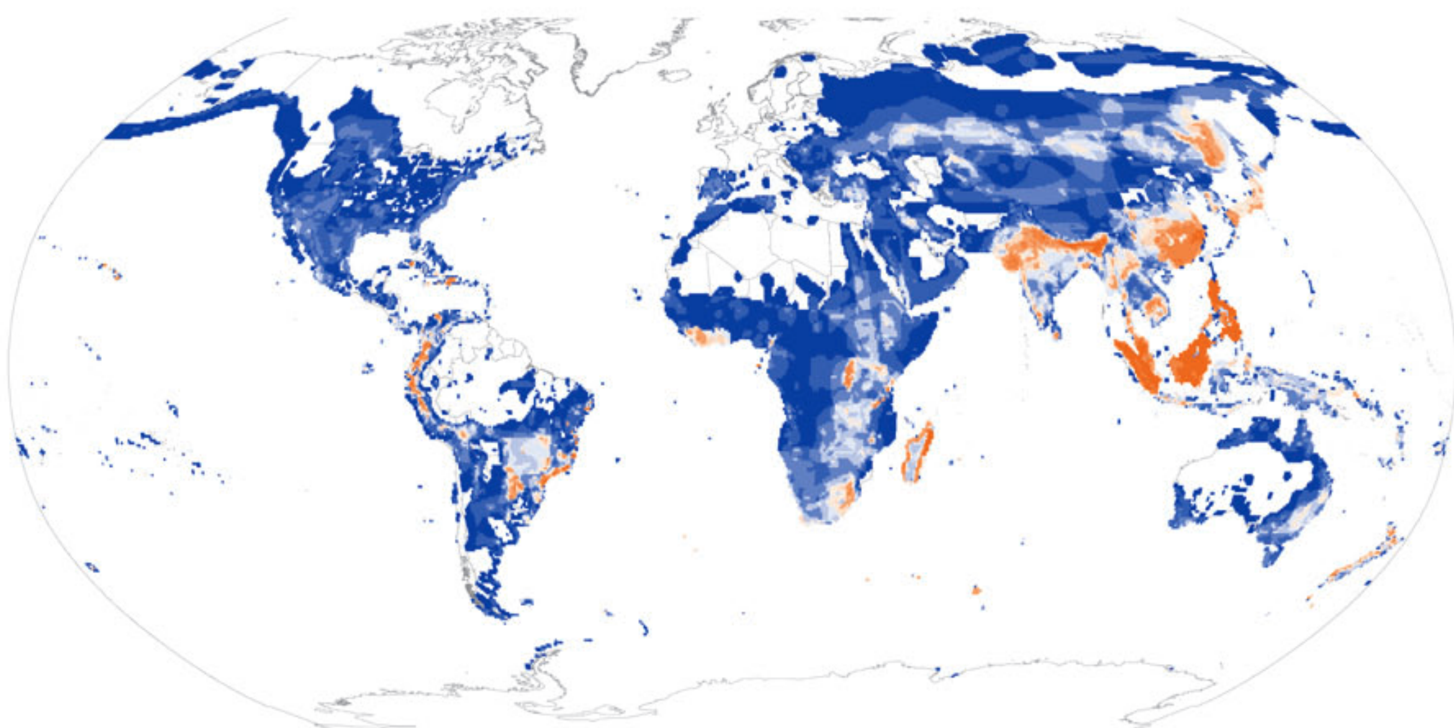

Figure 4.25. Density Distribution Map of Globally Threatened Mammal and Bird Species Mapped at a Resolution of 1/4 Degree Grid Cell. N = 1,063 mammals and 1,213 birds. Dark orange colors correspond to higher richness, dark blue colors to lower richness. Maximum richness equals 25 for mammals and 25 for birds. Color scale based on 10 equal-area classes. (Baillie et al. 2004)

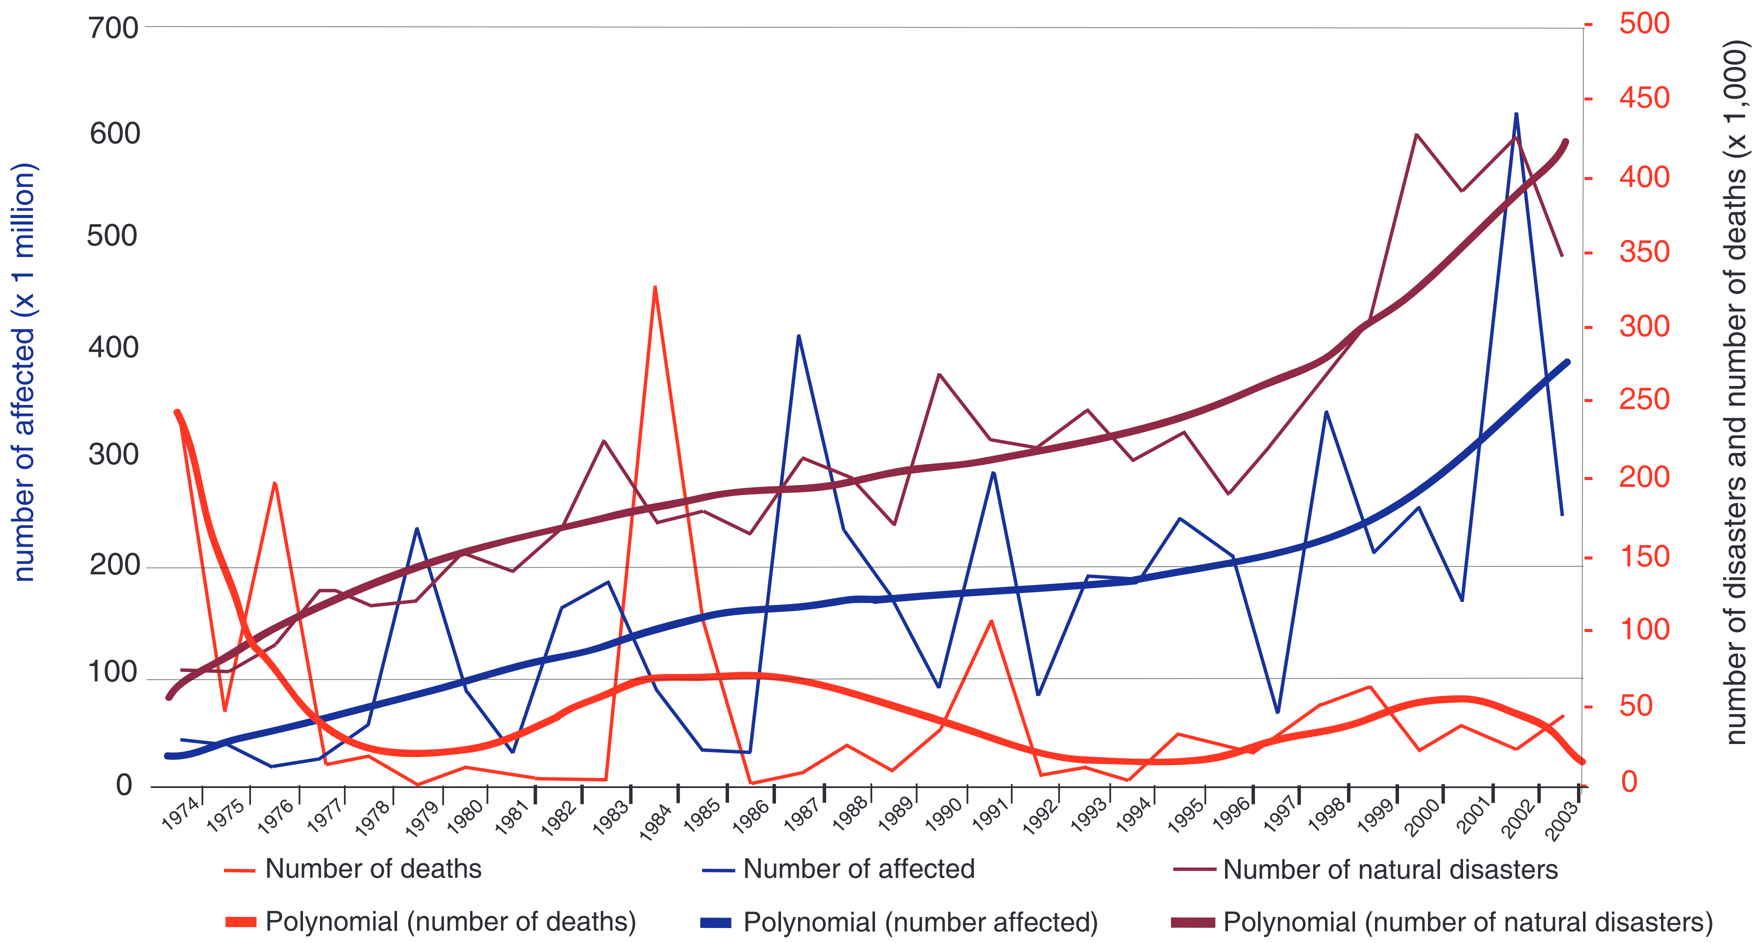

Figure 6.3. Polynomial Trends in the Numbers of Natural Disasters, Persons Killed, and Persons Affected, 1974–2003 (CRED 2003)

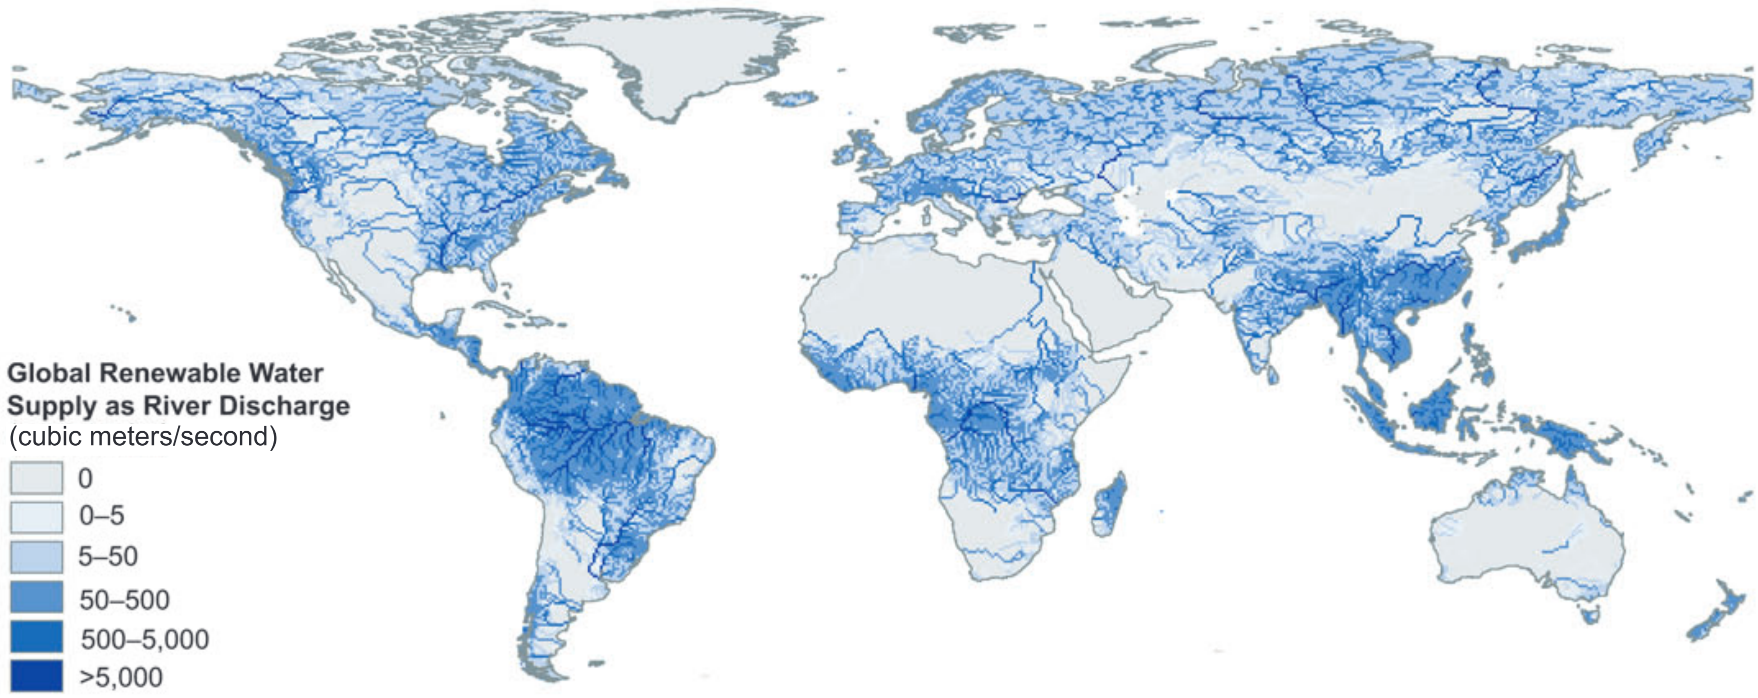
	Reasons for Concern				
Global warming ° C	**I: Global food production**	**II: National agricultural economies and market trade**	**III: Effects on natural resource base**	**IV: Food security among vulnerable livelihoods**	**V: Impacts of large-scale droughts and floods**
6	Increased potential for shortfalls	Large increases in trade and dependence on imports			
5			Widespread increase in desertification	Increased variability and costs in some regions threaten food security	Potential for large-scale, prolonged events to trigger migration and economic collapse
4	Increased risks in periods of adverse weather	Risks to economies with existing stresses (water shortages, high temperatures)			
3			Increased competition for water, depleted surface water	Regional risks are significant for many livelihoods	Prolonged events create serious economic and societal crises
2	Little threat to global food supply	Some risk to small economies, e.g., small island states			
1			Locally significant water conflicts; widespread soil degradation	Some livelihoods already in crisis	Prolonged events have significant costs at present
0 (present)		Underdevelopment prevalent in LDCs			

Figure 6.6. Climate Change Risks for Agricultural Systems. The five "Reasons for Concern" follow the IPPC's template from the Third Assessment Report's Summary for Policymakers (IPPC 2001). (Downing 2002)



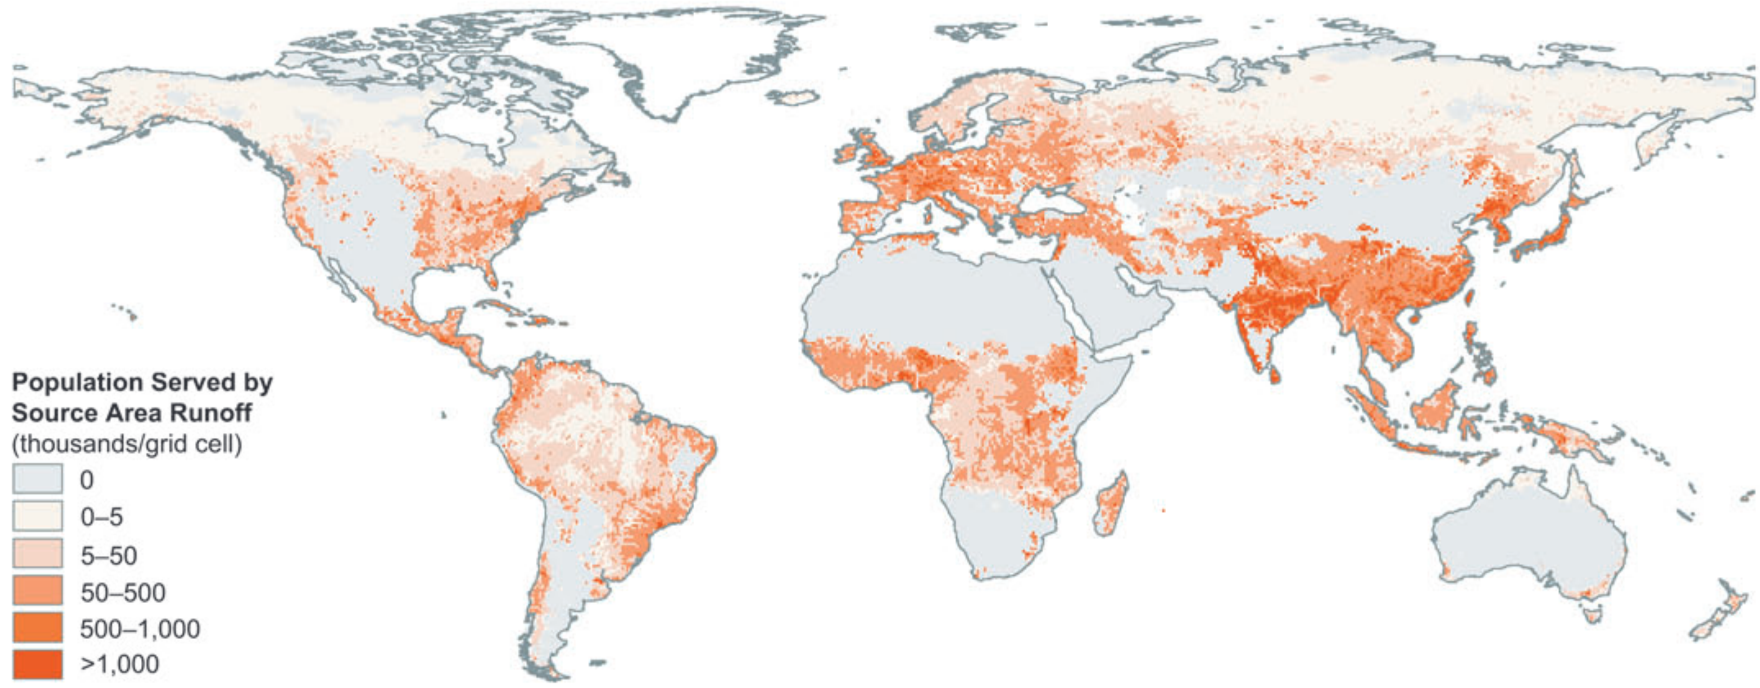


Figure 7.1. Global Renewable Water Supply as River Discharge and Populations Dependent on Accessible Runoff at Point of Origin. River flows, or total blue water (B_t) is that water passing through 50 km x 50 km grid cells. The top map depicts the global renewable water supply. The bottom map depicts total renewable blue water that is accessible to humans (B_a). Due to their remoteness, some high runoff-generating regions (e.g., Amazonia) fail to support significant populations and are effectively inaccessible. Populations served by nonrenewable groundwater or desalinization are not shown. Table 7.2 gives aggregated regional summaries of the geographic distributions shown here. (Dividing by 31.7 converts values in the top map into units of cubic kilometers per year.)

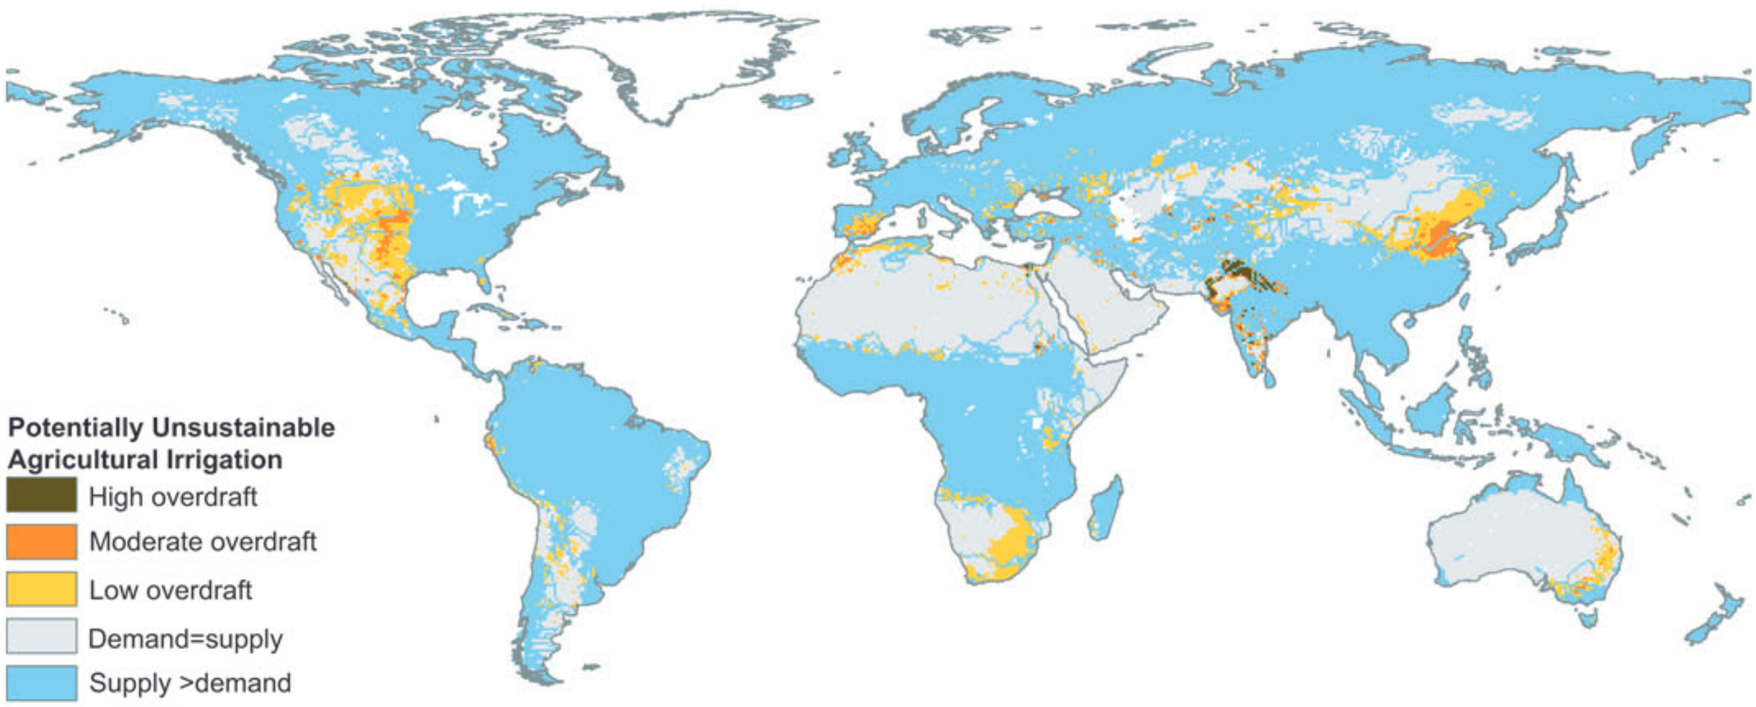

Figure 7.3. Contemporary Geography of Non-sustainable Withdrawals for Irrigation. The following divisions based on calculated consumptive use by crops were used: High overdraft: <1 km³/yr; Moderate: 0.1–1 km³/yr; Low: 0–0.1 km³/yr. All estimates made on ca. 50 km x 50 km resolution grids. The map indicates where there is insufficient fresh water to fully satisfy irrigated crop demands. The imbalance in long-term water budgets necessitates diversion of surface water or the tapping of groundwater resources. The areas shown with moderate-to-high levels of non-sustainable use occur over each continent and are known to be areas of aquifer mining and/or major water transfer schemes.

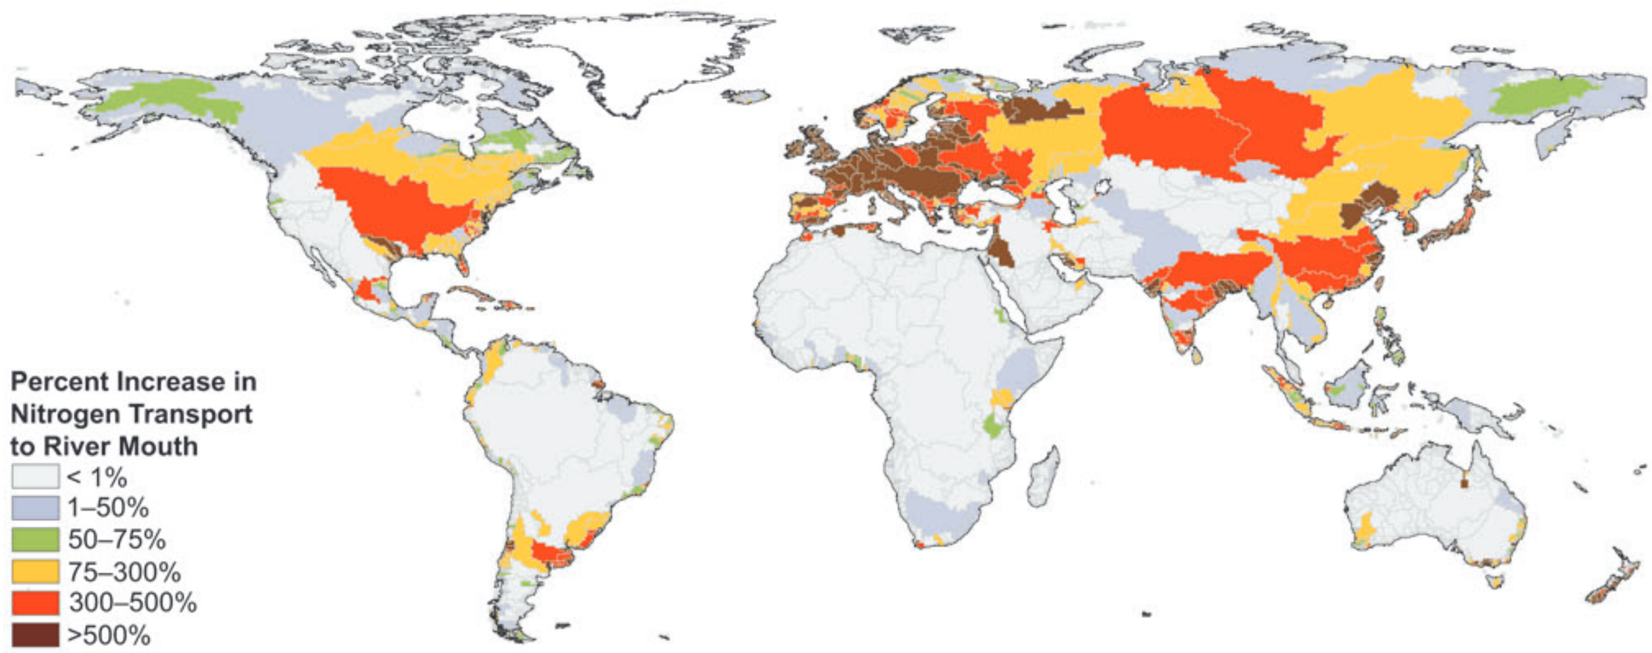

Figure 7.5. Contrast between Mid-1990s and Pre-disturbance Transports of Total Nitrogen through Inland Aquatic Systems Resulting from Anthropogenic Acceleration of This Nutrient Cycle. While peculiarities of individual pollutants, rivers, and governance define the specific character of water pollution, the general patterns observed for nitrogen are representative of anthropogenic changes to the transport of waterborne constituents through inland waterways. Elevated contemporary loading to one part of the system (e.g., to croplands) often reverberate through other parts of the system (e.g., coastal zones), exceeding the capacity of natural systems to assimilate additional constituents. (Green et al. 2004)

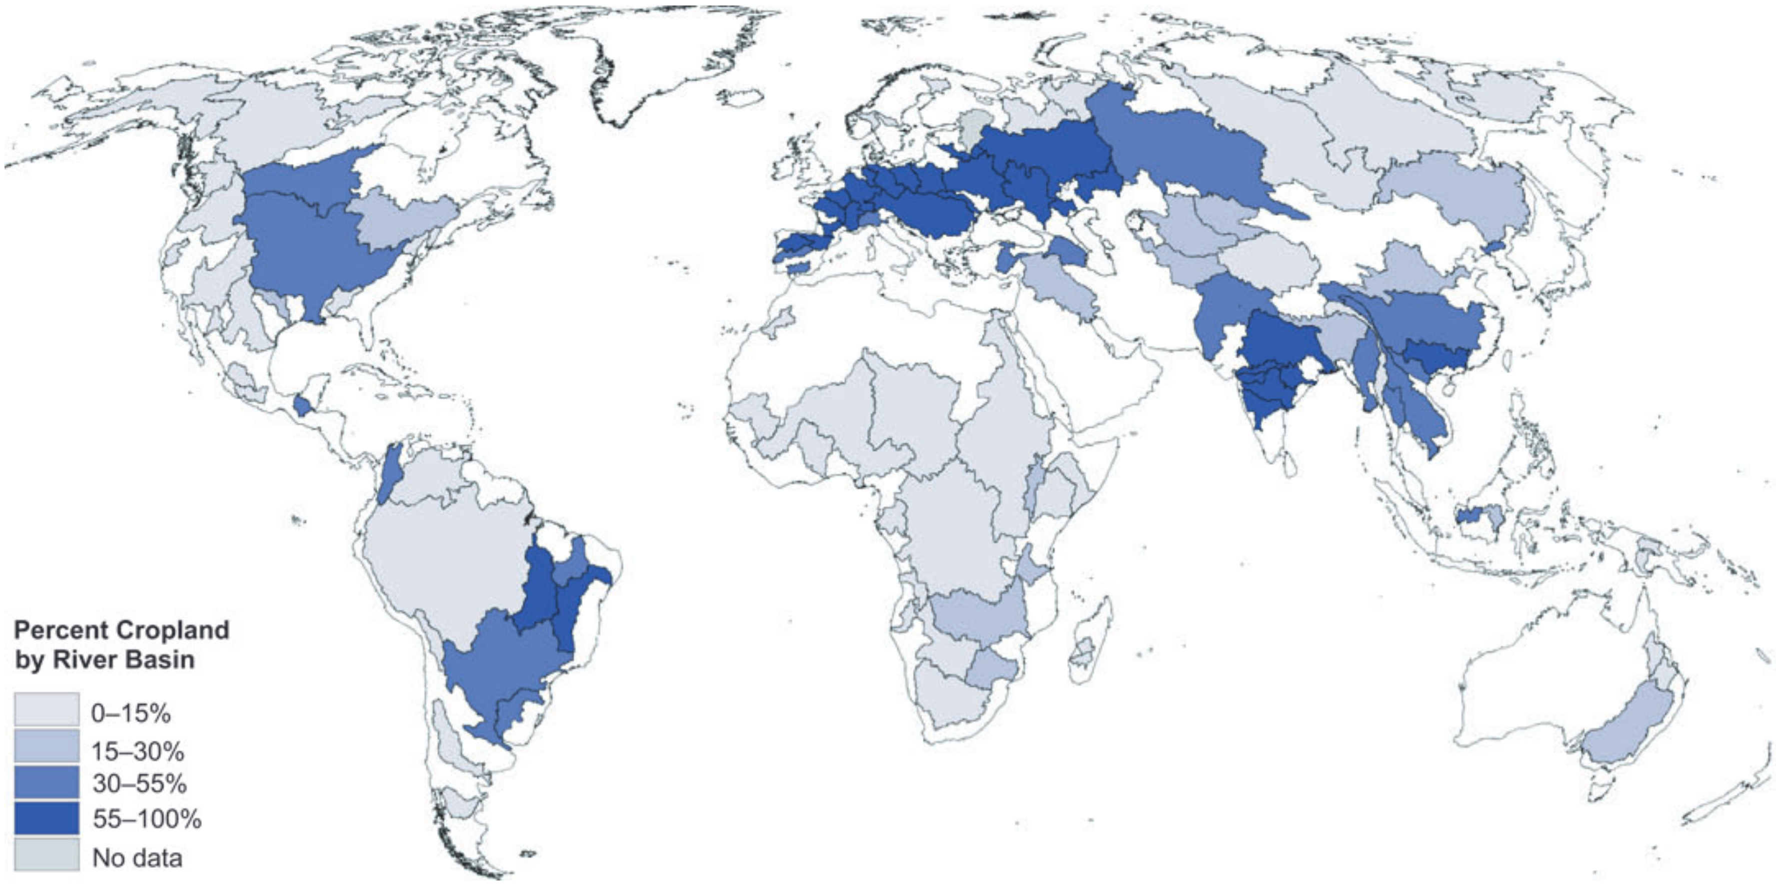

Figure 7.10. Percentage of Cropland Area by River Basin. Cropland areas exclude those with more balanced mosaics of cropland and natural vegetation. (Revenga et al. 2000)

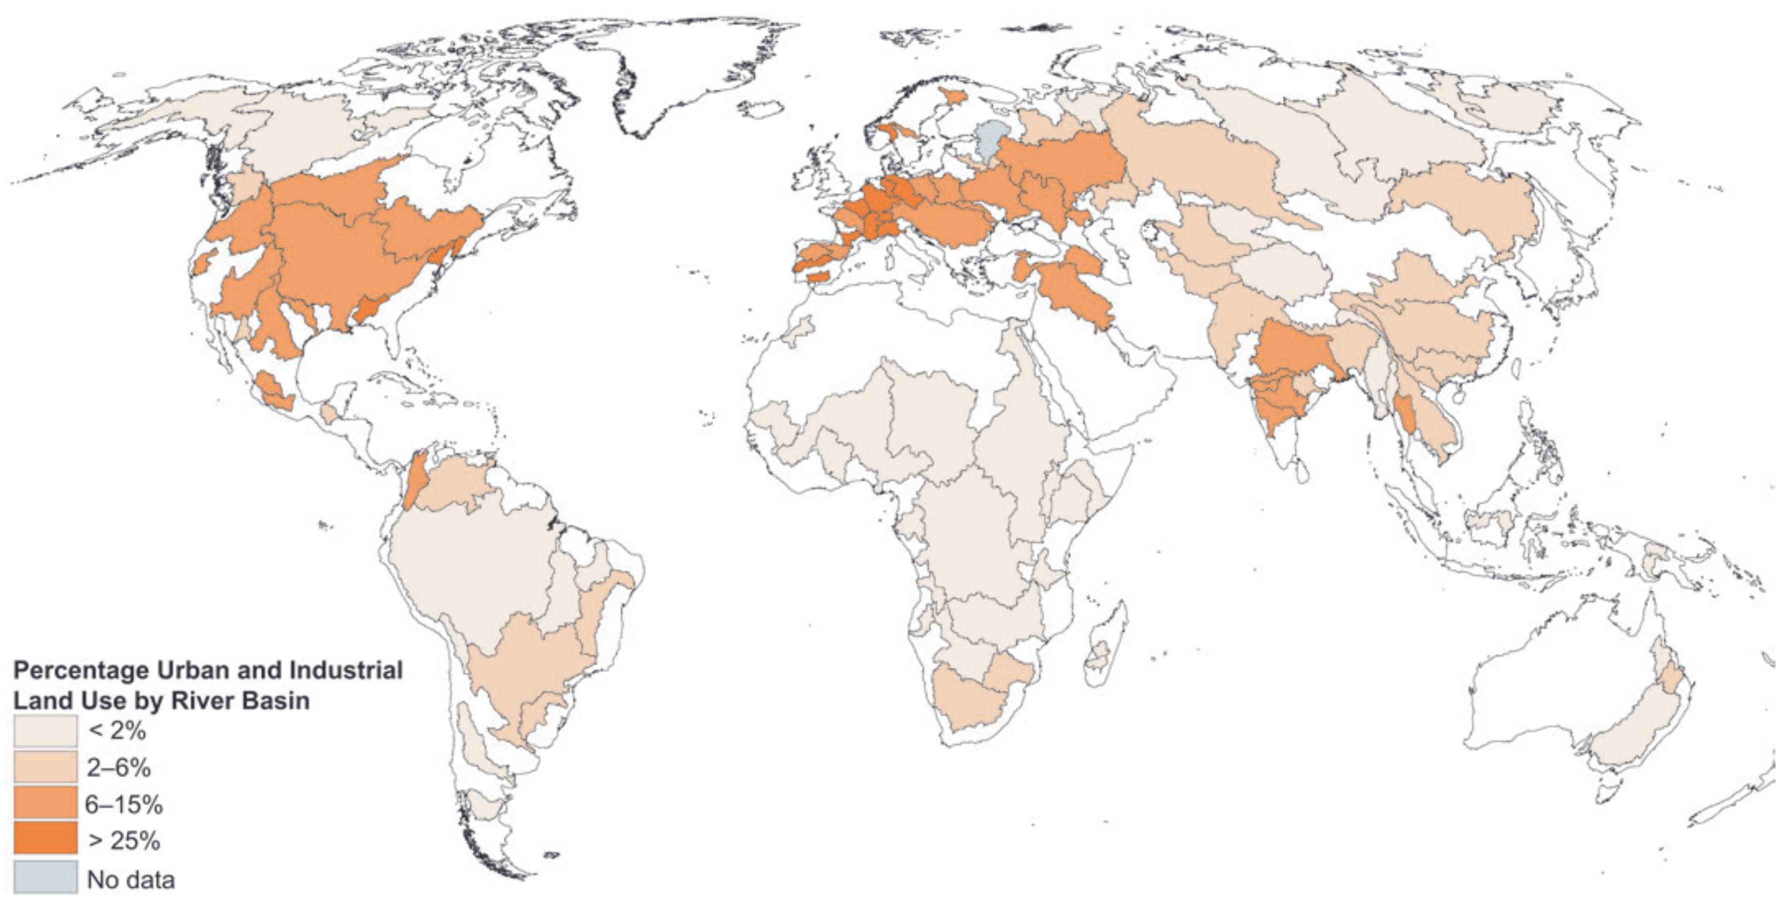

Figure 7.11. Percentage Urban and Industrial Land Use by River Basin (Revenga et al. 2000)

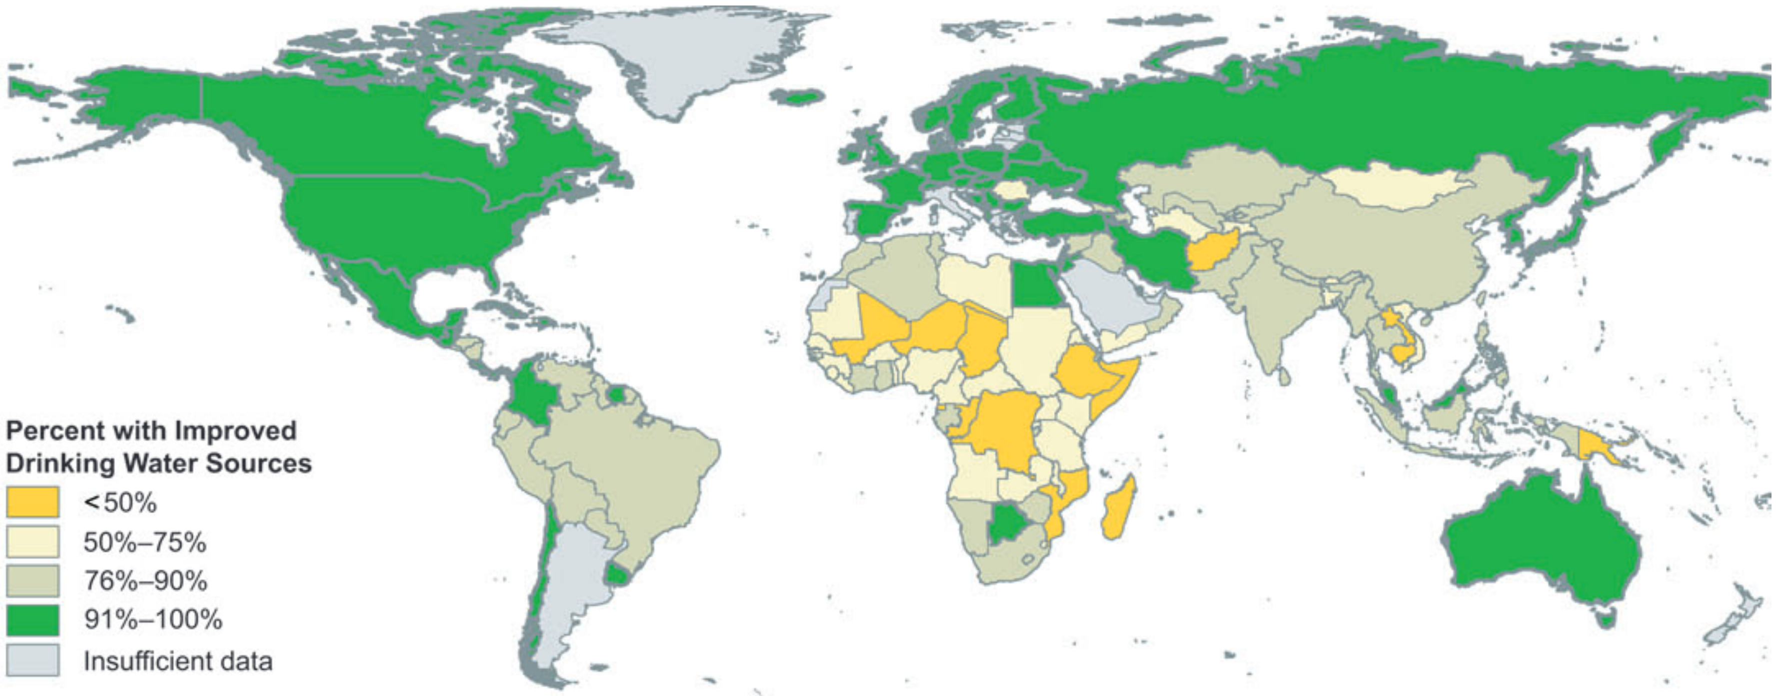

Figure 7.13. Proportion of Population with Improved Drinking Water Supply, 2002 (WHO/UNICEF 2004)

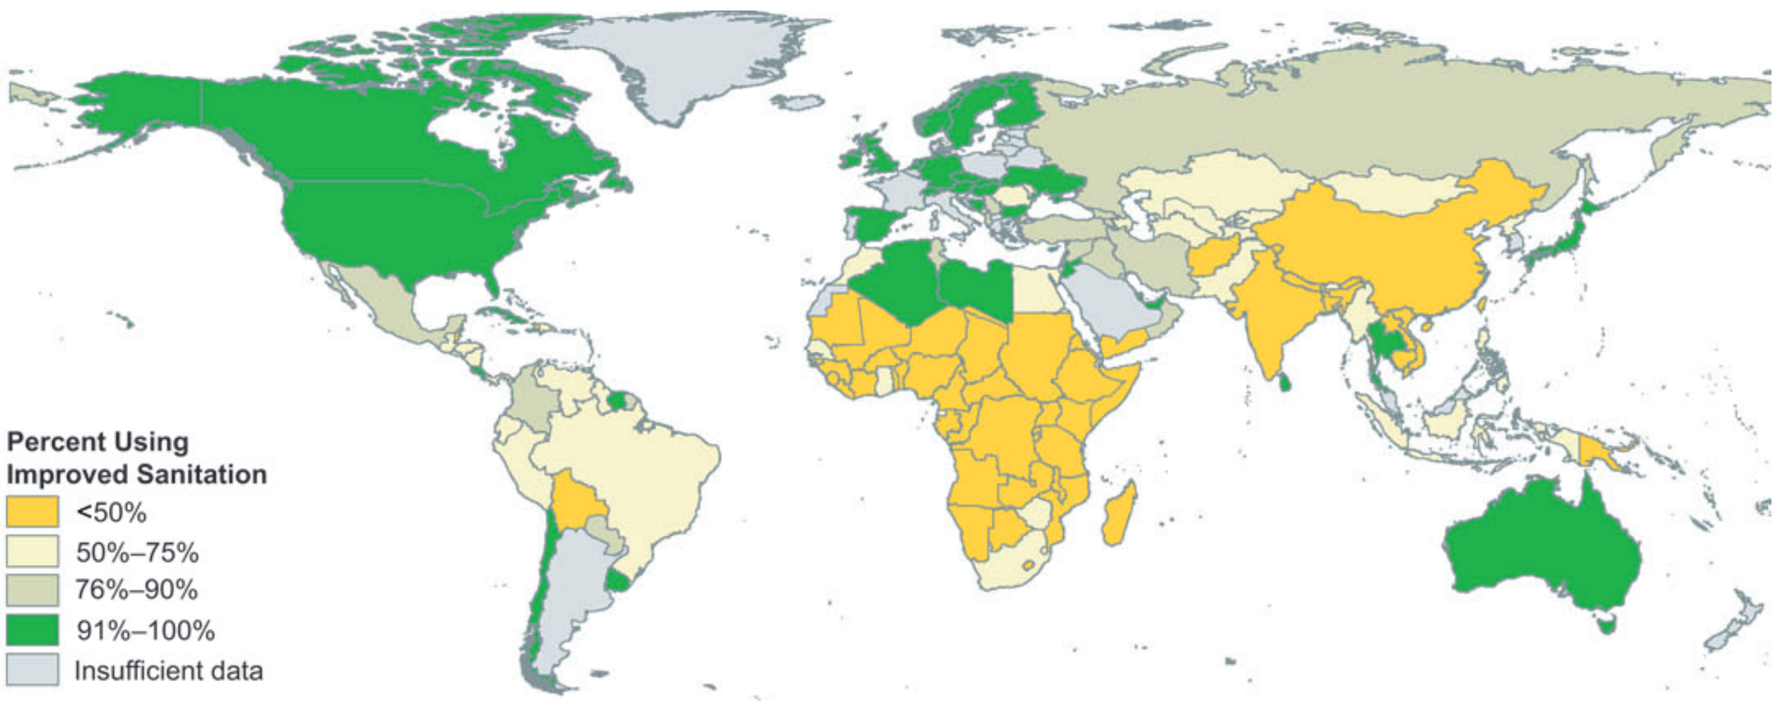

Figure 7.14. Proportion of Population with Improved Sanitation Coverage, 2002 (WHO/UNICEF 2004)

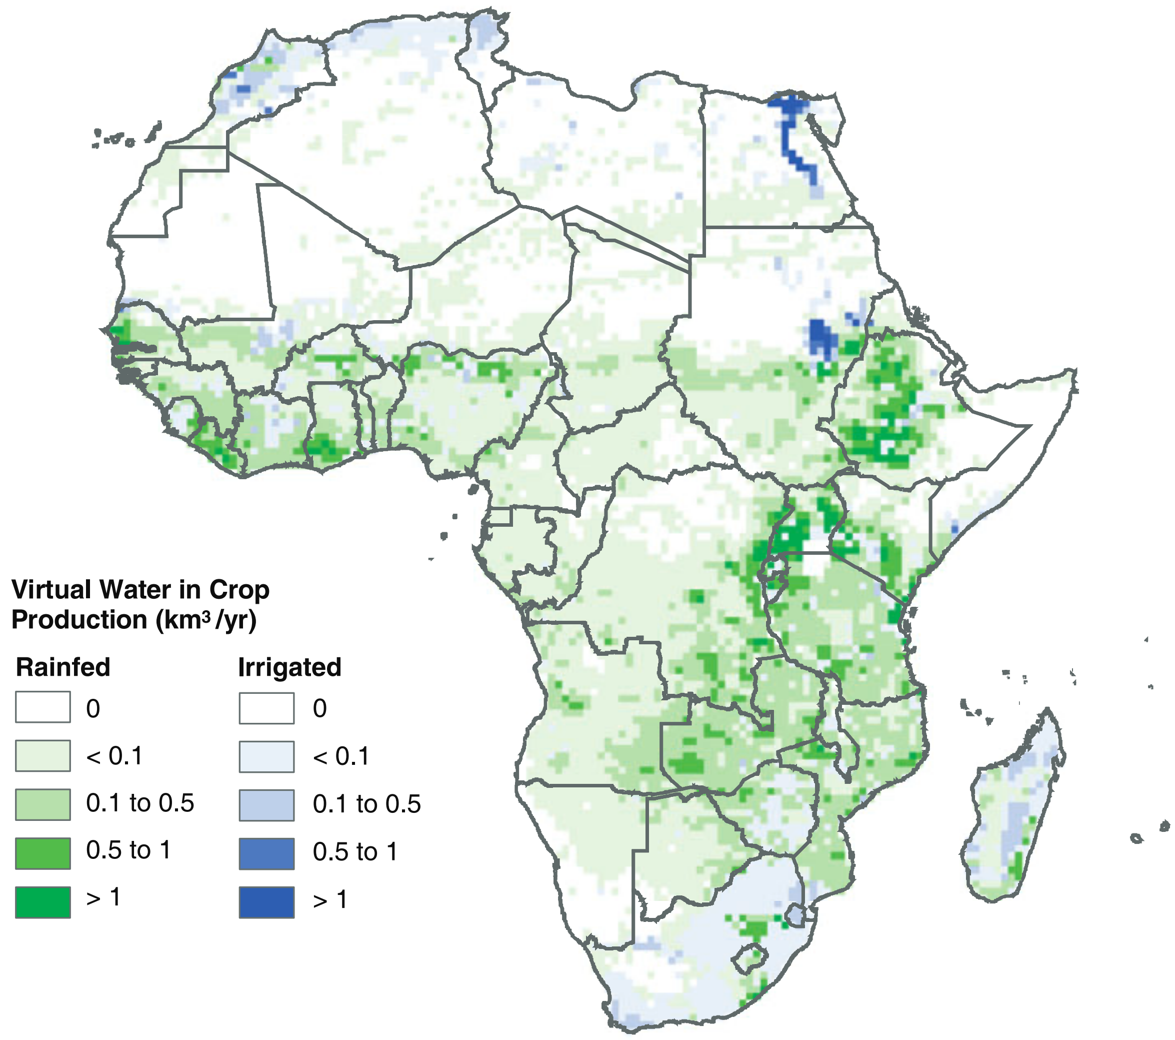
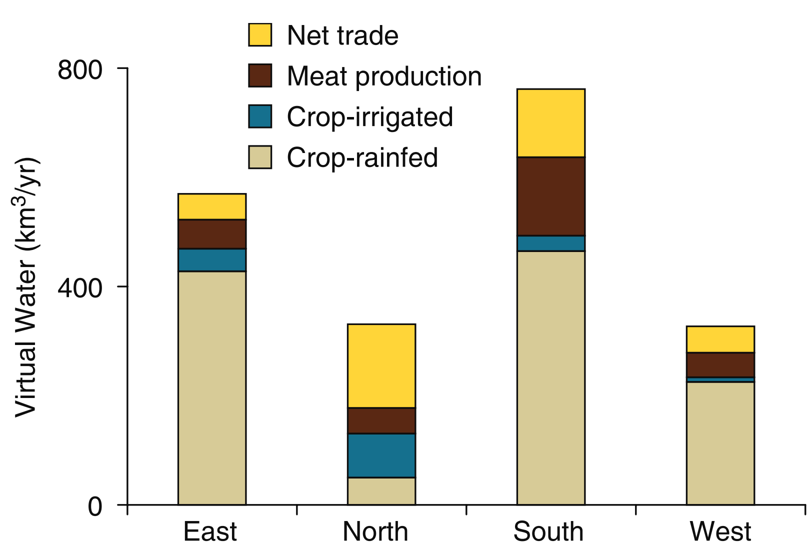


Virtual Water for Africa (km^3/yr)

	Crops [1]	Meat [2]	Total
Production	1326	289	1615
Percent of AET [3]	9%	2%	11%
Imports	404	21	425
Exports	50.5	0.3	50.8
VW Balance	1680	309	1989

[1] VW in crops = AET over rainfed cropland +PET over irrigated cropland.
[2] VW in meat = VW in feed/fodder + 30% AET over grazing land.
[3] AET = actual evapotranspiration; percent relative to continental total.

Box 7.4 Figure A



Box 7.4 Figure B

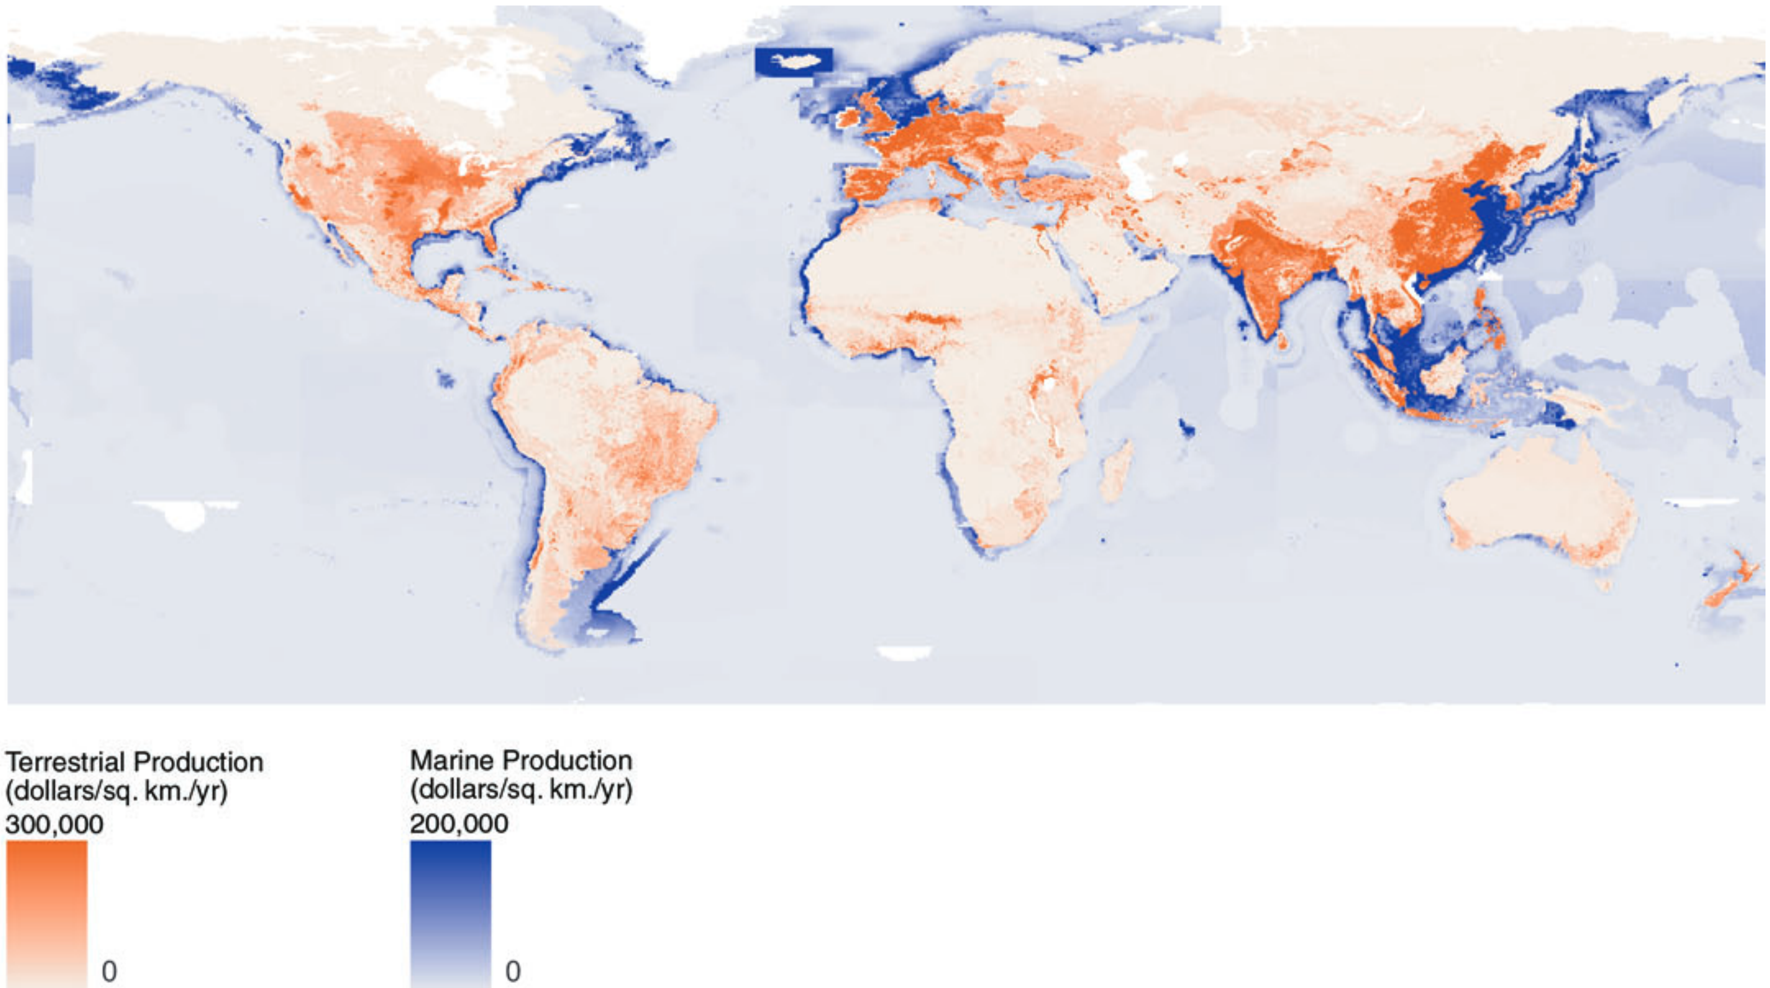


Figure 8.2 Spatial Distribution of Value of Food Production for Crops, Livestock, and Fisheries, 2000. The map shows the approximate value of production in year 2000 using FAOSTAT (2003) production data for all food crops and livestock products weighted by a set of 1989–91 global average commodity prices denominated in International US dollars. These prices are used by FAO to compute its Production Indices. The image was constructed from a composite rainfed-irrigated cropland surface using the global 1992–3 cropland map of Ramankutty and Foley (1998) intersected by the global irrigation map of Doell and Siebert (1999). Crop production was allocated by country in proportion to the share of each 100 km^2 occupied by rainfed and irrigated agriculture assuming irrigated agriculture is, on average, twice as productive as rainfed agriculture. Livestock production was allocated across a global pasture dataset (Foley et al. 2003) by country, assuming production was distributed into each pixel in proportion to its area of pasture/rangeland.

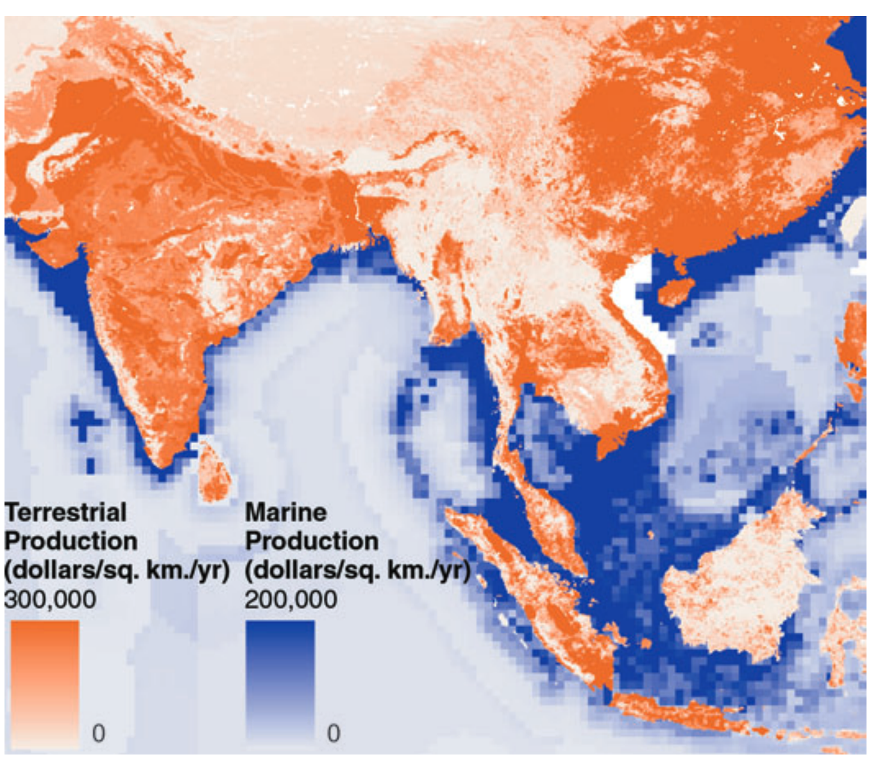

Figure 8.3 Spatial Distribution of Food Production in Parts of Asia for Crops, Livestock, and Fisheries, 2000. This map shows a detail of Figure 8.1. Notice the high value of food production—both marine and terrestrial—in coastal areas.

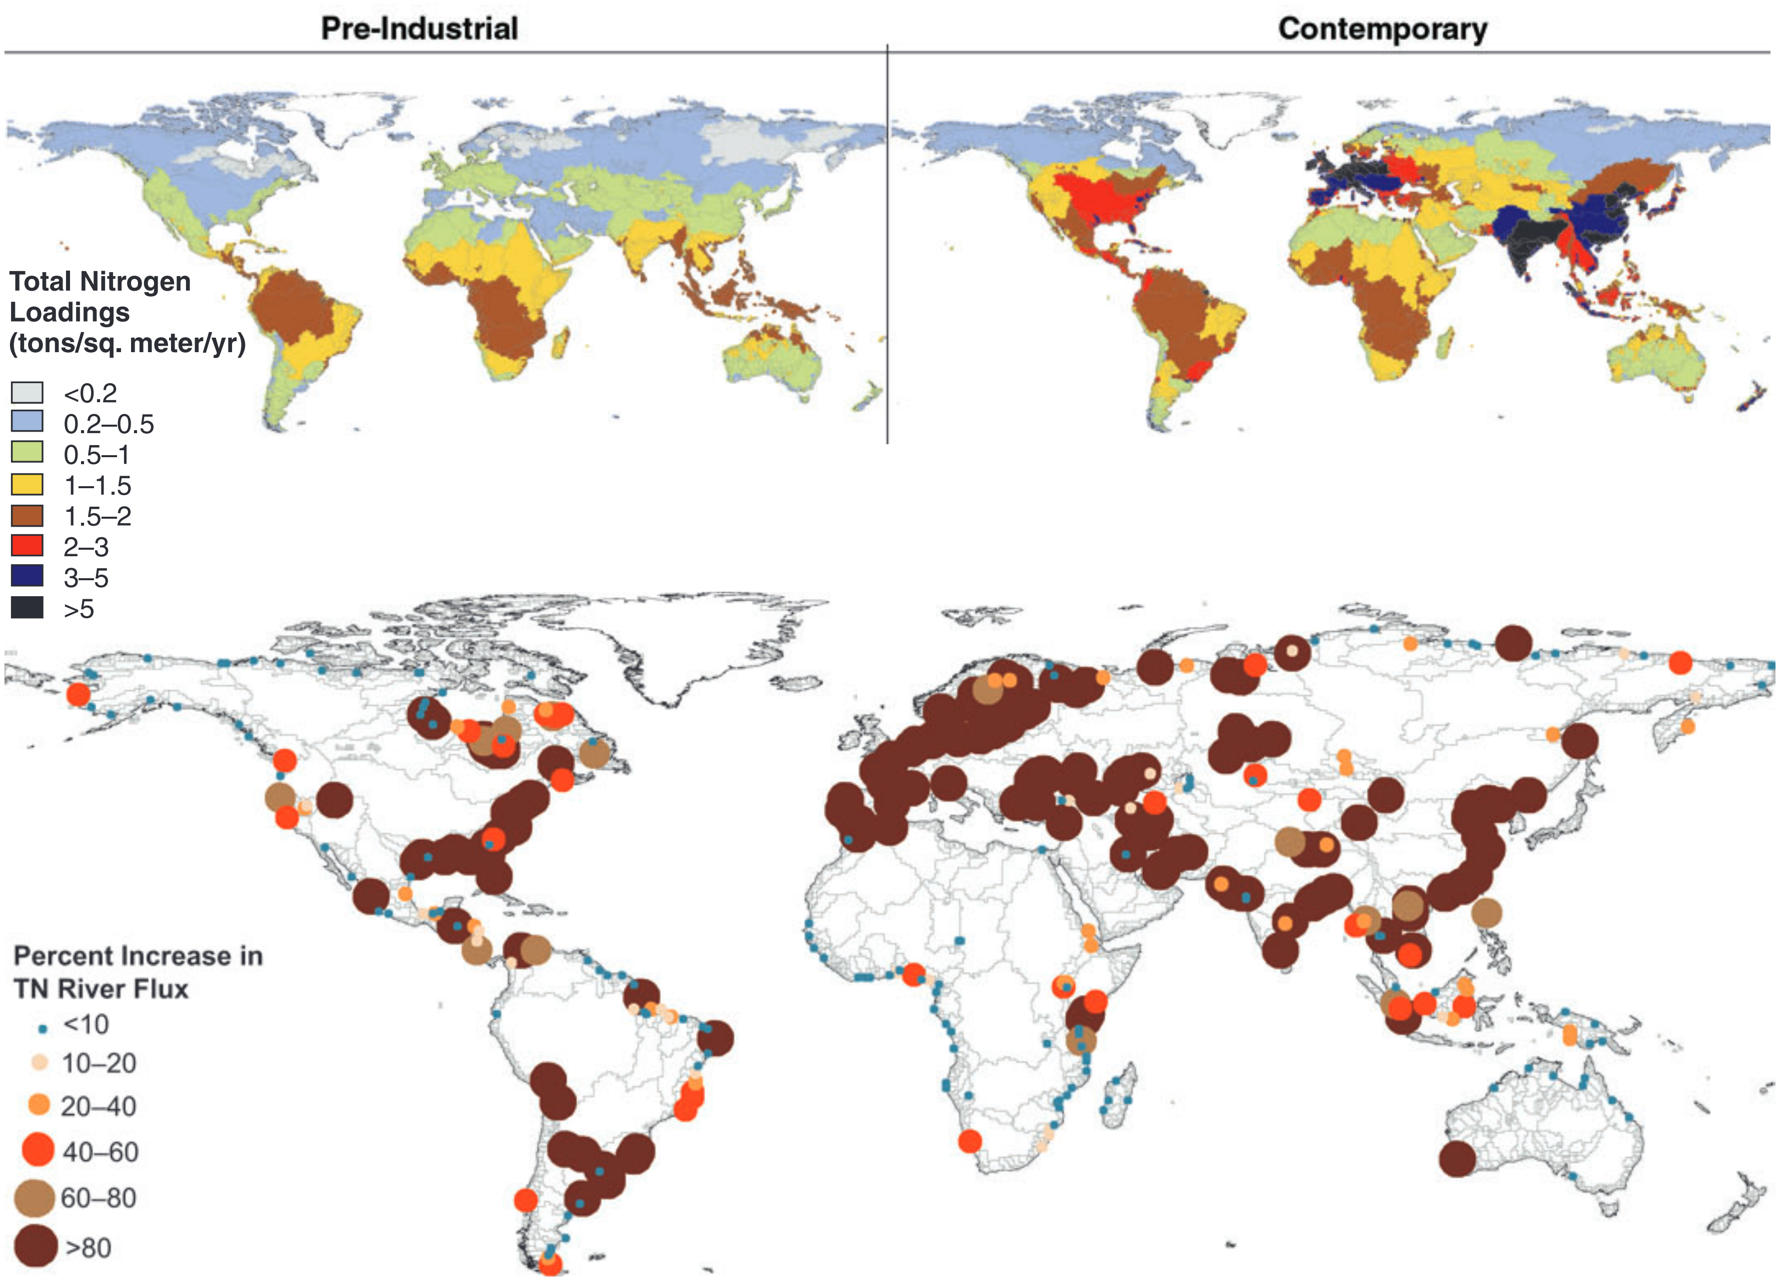

Figure 12.3 Contrast between Contemporary and Preindustrial Loadings of Easily Transported Nitrogen onto Land Mass of Earth and Geography of Relative Increases in Riverborne Nitrogen Fluxes Resulting from Anthropogenic Acceleration of Cycle. Contemporary time is from the mid-1990s. While the peculiarities of individual pollutants, rivers, and governance define the specific character of water pollution, the general patterns observed for nitrogen are representative of anthropogenic changes to the transport of waterborne constituents. Elevated contemporary loadings to one part of the system (e.g., to croplands) often reverberate to other parts of the system (e.g., coastal zones), exceeding the capacity of natural systems to assimilate additional constituents. (Green et al. 2004)

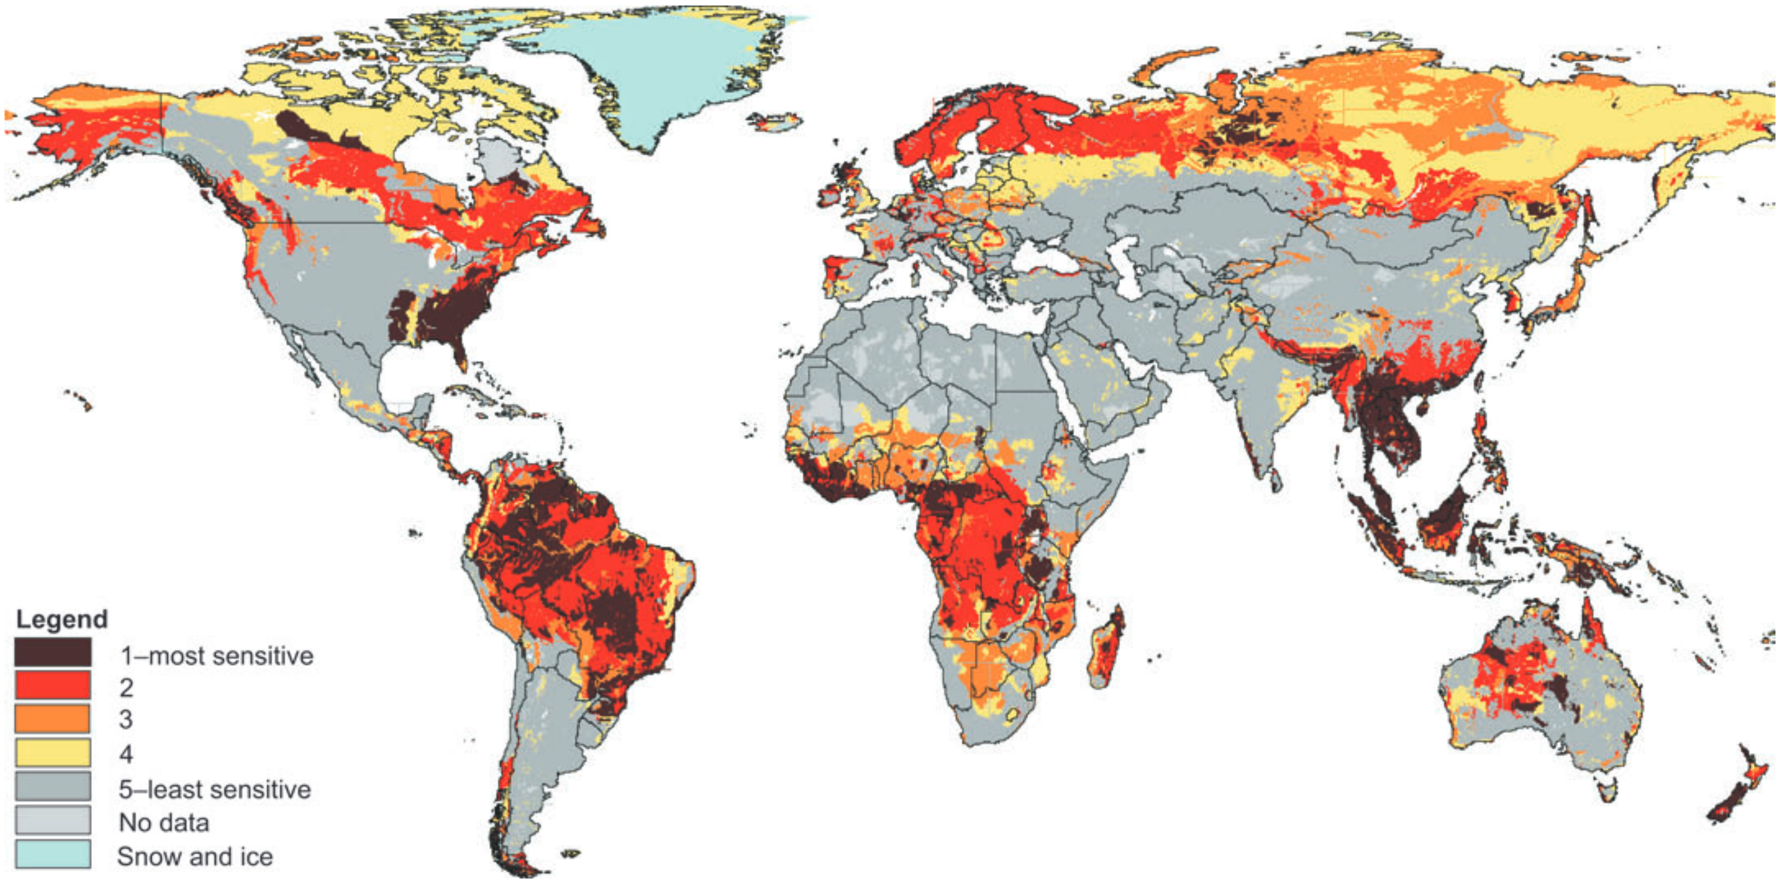

Figure 12.6 Global Map of Soil Sensitivity to Acidic Inputs from Atmospheric Sulfur and Nitrogen Deposition. This map shows the ability of the soil to buffer acid deposition. Problems of acidification are most likely to arise where high projected rates of deposition coincide with high sensitivity—for instance, in Southeast Asia. (Kuylenstierna et al. 2001)

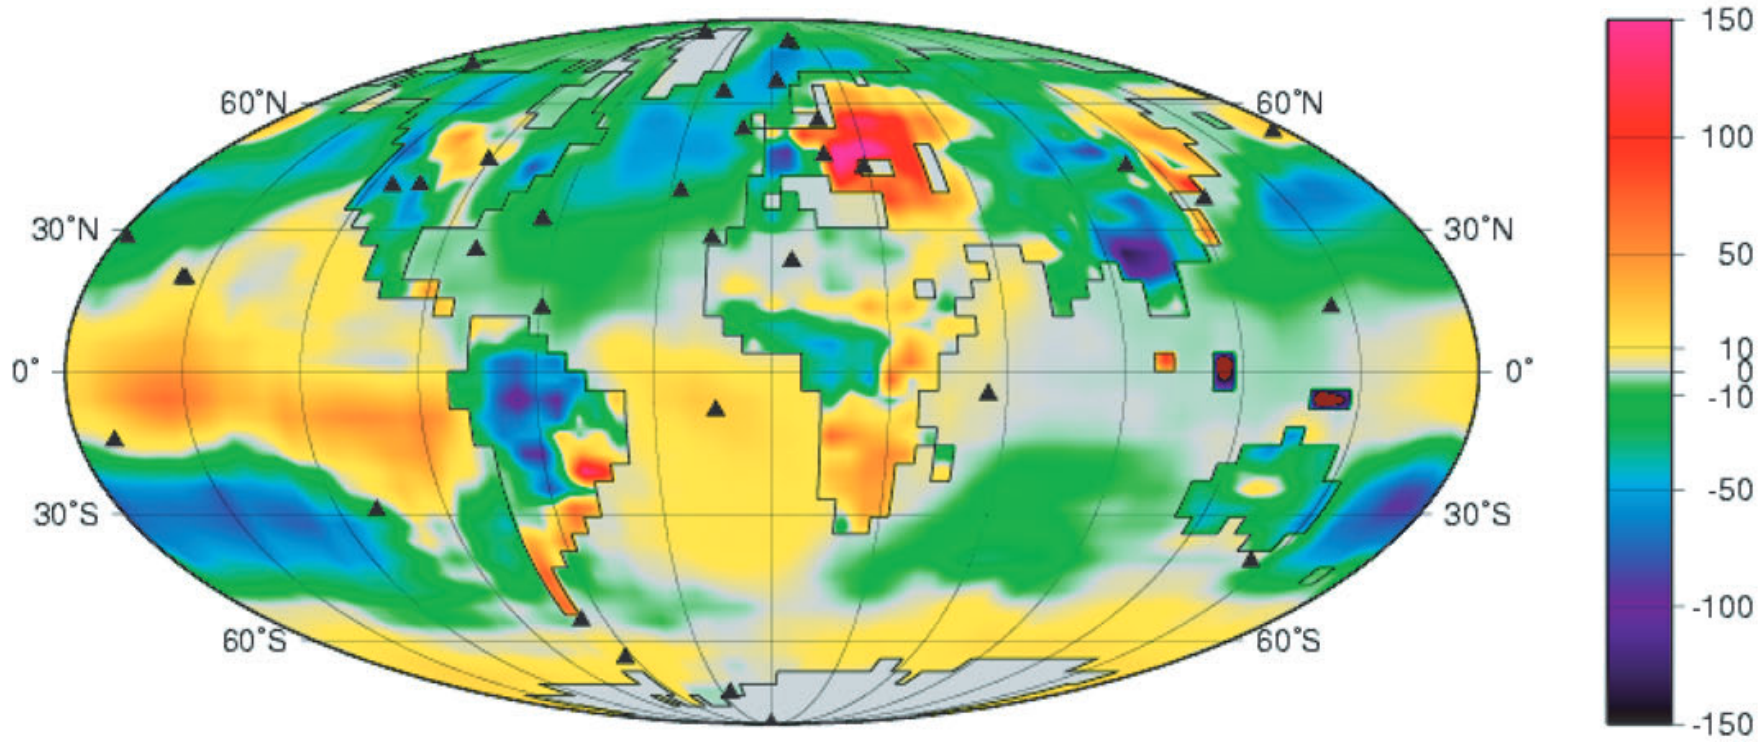
Modeled Map of Carbon Dioxide Sources and Sinks, Excluding Fossil Fuels



Modeled Map of Carbon Dioxide Sources and Sinks, Including Fossil Fuels

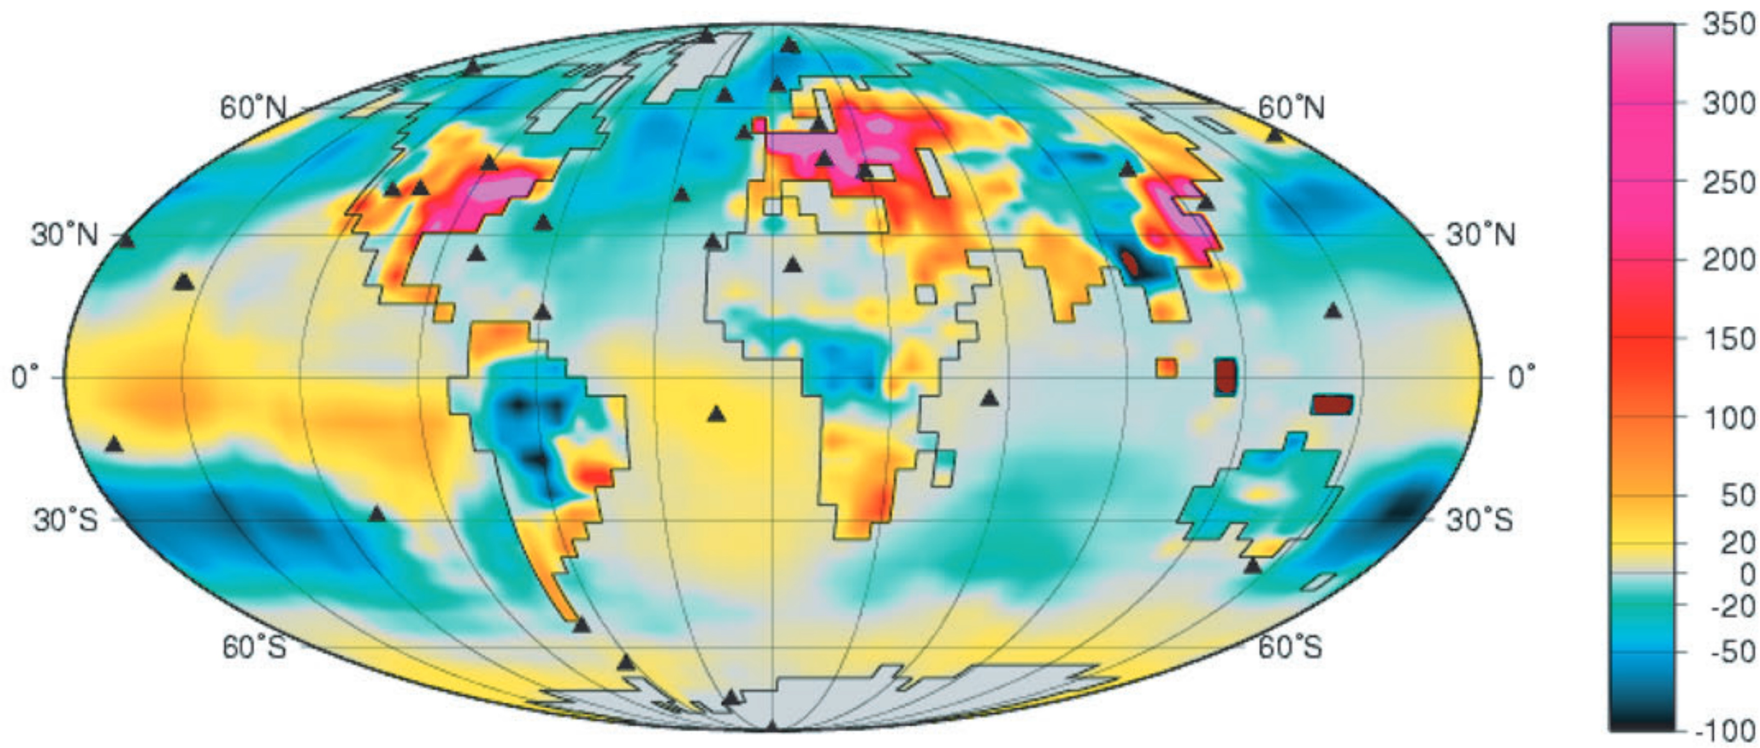


Figure 13.5 Maps of Carbon Dioxide Fluxes Estimated from Atmospheric Measurements, July 1995 to June 2000 (in gC/m²/year) (Rödenbeck et al. 2001). The spatial allocation of sources and sinks of CO_2 is derived from measurements of atmospheric concentrations from a network of sites over the globe using a technique known as inverse modeling. This technique gives the sum of all fluxes. Positive numbers denote a source into the atmosphere; negative numbers denote a sink from the atmosphere. The magnitude and spatial allocation of fluxes is very sensitive to the number of measuring sites and the time period of the analysis. The top figure is the total flux excluding fossil fuel emissions to highlight the terrestrial vegetation fluxes. The bottom figure includes fossil fuel emissions; therefore land areas appear to be sources or smaller sinks.

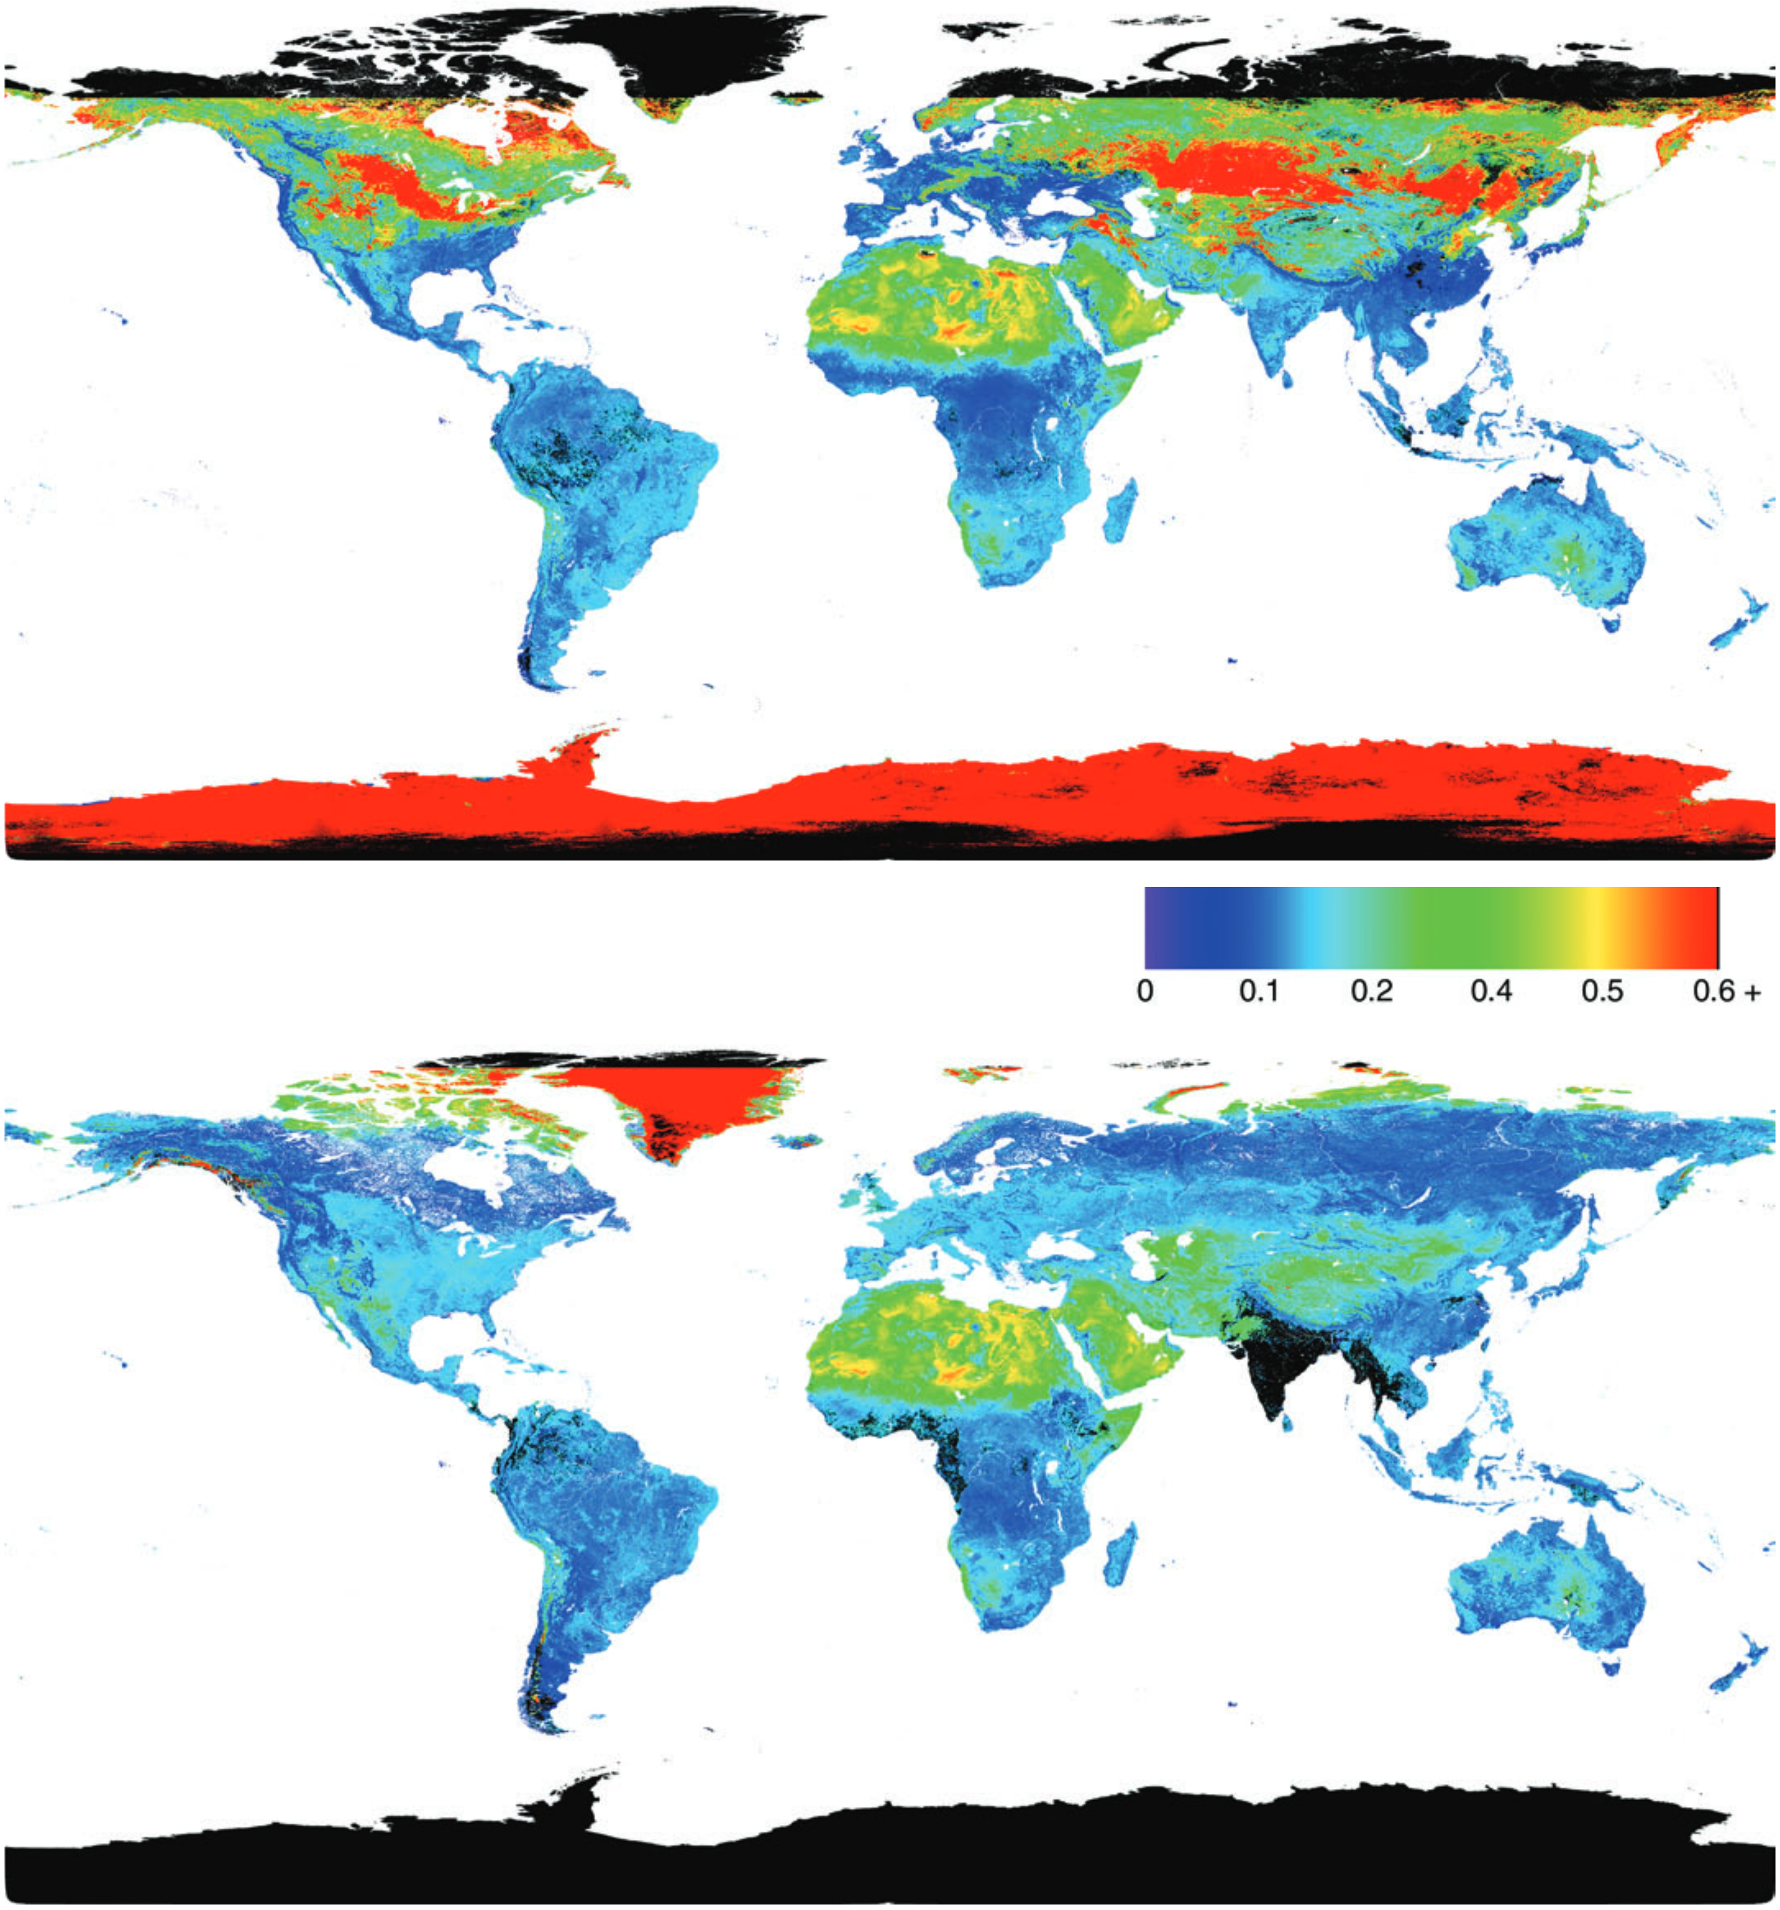

Figure 13.8 Map of Land Surface Albedo Captured by the MODIS Satellite Instrument (Schaaf et al. 2002; Lucht et al. 2000). Albedo is the fraction of solar radiation reflected back into the atmosphere from Earth's surface. Higher albedo means that more energy leaves the planetary boundary layer (net cooling of the atmosphere). Regions where there were no data available, e.g., due to clouds, are indicated by black. The top figure is of data sampled in January 2001. In the northern areas during the winter season, snow albedo is very high (up to 0.8, red). The boreal forest belt can be clearly seen in blue and green since trees mask snow, reduce albedo, and warm the surface air during the snow season. The bottom figure is of data sampled in June 2001. In comparison with January 2001, the northern land areas have a much lower albedo due to the absence of snow. In this map, the area with the highest albedo (up to 0.5, green and yellow) is the Sahara desert. High albedo in this region suppresses rainfall during the summer rain season.
