Re: Comments on Northwest Forest Plan Amendment Draft Environmental Impact Statement

Regional Forester Buchanan and Regional Forester Eberlien,

Central Oregon LandWatch submits these comments in response to the Draft Environmental Impact Statement ("DEIS") for the Northwest Forest Plan Amendment ("Amendment"), which was published in the Federal Register on November 15, 2024.

Central Oregon LandWatch ("LandWatch") is a conservation organization which has advocated for preservation of natural resources in Central Oregon for over 35 years. With over 950 members in Central Oregon, LandWatch has a long history of protecting the forests and streams in and around the Deschutes National Forest and other lands managed under the Northwest Forest Plan ("NWFP"). LandWatch's members and supporters live in Central Oregon, including on lands adjoining the Deschutes National Forest, and recreate in the Crescent, Fort Rock and Sisters Ranger Districts. They hunt, fish, take photographs, view wildlife, hike, drive, and engage in other recreational activities on National Forest lands, generally, and on lands within the boundary of the NWFP area specifically.

LandWatch's comments are focused on the NWFP area east of the Cascade Crest and primarily within the Deschutes National Forest, an extremely varied Central Oregon landscape ranging in elevation from 10,358 feet to 2,900 feet, and encompassing a broad spectrum of wildlife, plant groups, forest composition types, and fire regimes. Notably, it contains areas considered "dry forest," as well as areas of "moist forest" or mixed moisture composition.

Recent forest management projects on the Deschutes National Forest are often framed in terms of "forest restoration," with a narrow purpose and need centered reducing fuels and mitigating the perceived threat of extreme wildfire behavior.[1] The over-reliance on fuels-centric projects, however, is leading to an artificial ceiling on forest restoration efforts, the misapplication of treatments in the context of place, and increasing controversy in the Central Oregon region related to the management of National Forest lands.

[1] Examples include: Green Ridge Landscape Restoration; Cougar Rock Restoration Project; West Bend Vegetation Management Project.

While there is broad consensus that some ponderosa pine and dry-mixed coniferous forests under the NWFP are in a degraded state, defining the purpose and need for restoration is not without controversy; the when, where, why, and how to restore forest ecosystems east of the Cascades continues to be highly debated in scientific, public, and policy forums. The Forest Service's often narrow focus on reducing fuels to restore forest condition fails to address the full suite of factors that have fundamentally changed disturbance regimes and degraded forests. Further, a fuels-centric approach has significant tradeoffs for fish and wildlife, plant community pattern and composition, and is unlikely to meaningfully influence the 2 percent of fires that burn most forested acres.

In updating the NWFP, LandWatch continues to urge the Forest Service to consider establishing forest plan standards and other sideboards that help re-calibrate forest management and restoration projects east of the Cascades—especially where projects propose to address large-scale risks such as wildfire—and embrace a more balanced forest management framework that centers on ecological restoration and drivers of degradation. This framework should limit large tree logging, grazing, and road networks, reintroduce keystone species such as beaver, and balance the benefits of fire against its continued exclusion.

The United Nations Convention on Biodiversity has defined ecological restoration as:

> the process of managing or assisting the recovery of an ecosystem that has been degraded, damaged or destroyed as a means of sustaining ecosystem resilience and conserving biodiversity. Degradation is characterized by a decline or loss of biodiversity or ecosystem functions. Degradation and restoration are context-specific and refer to both the state of ecosystems and to ecosystem processes.[2]

Similarly, Stine et al. (2014) defined ecological restoration as:

> the process of assisting the recovery of an ecosystem that has been degraded, damaged, or destroyed. Ecological restoration focuses on re-establishing the composition, structure, pattern, and ecological processes necessary to facilitate terrestrial and aquatic ecosystem sustainability, resilience, and health under current and future conditions.

Recalibrating forest management to lead with ecological restoration is necessary to facilitate terrestrial and aquatic ecosystem resilience and health under current and future conditions. Further, by taking a more balanced approach to fuels management, restoration efforts can better address ecological concerns related to forest ecosystem structure, process, pattern, and composition, improve forest resiliency in the face of climate change, and decrease the level of controversy around federally managed public forests.

LandWatch appreciates the Forest Service's stated goal of implementing NWFP updates that reflect evolving social and ecological realities. However, the alternatives presented in the DEIS ultimately fail to lead with ecological integrity and resilience and largely propose to perpetuate a counter-productive fuels-

[2] UN Conference of the Parties to the Convention on Biological Diversity (2016). Ecosystem restoration: short-term action plan. https://www.cbd.int/doc/decisions/cop-13/cop-13-dec-05-en.pdf.

centric approach to forest management east of the Cascades.

In amending the NWFP, LandWatch urges the Forest Service to consider a more balanced approach to forest management and restoration that builds upon the core tenets and purpose of the 1994 plan, while beginning to rectify the exclusion of Tribes in the original NWFP. To that end, our comments focus on strengthening key management standards and sideboards around four themes: 1) ensuring that fuels-reduction efforts and timber harvest do not further degrade ecological integrity, wildlife habitats, and other key forest values; 2) meaningfully including Tribes, establishing co-stewardship, and respecting sovereignty; and 3) safeguarding mature and old-growth forests while improving our understanding of forest treatment outcomes in a changing climate.

The DEIS fails to offer a suite of updates that would cohesively solve any of these key social-ecological concerns, and fails to uphold the 1994 NWFP's original purpose, need, and spirit, which is a disservice to the communities and wildlife habitats in and around the NWFP planning area.

I. AMENDMENT PURPOSE AND NEED

The DEIS states that the purpose of the Amendment is:

> to amend, all or part of 17 national forest land management plans, as amended, within the NWFP area to establish new or modify existing plan components to better enable the Forest Service to meet the original intent of the 1994 NWFP to conserve mature and old-growth ecosystems and habitat for the conservation of northern spotted owl and other Endangered Species Act (ESA) listed and non-listed species, protect riparian areas and waters, and provide a sustainable supply of timber and non-timber forest products. (DEIS at 1-4)

The DEIS describes the need for the NWFP Amendment process as "driven by evolving ecological understandings and the need for the Forest Service to adapt their management strategies to current and future challenges" (DEIS at 1-5). This need comprises five key focus areas: (1) wildfire resistance and resilience; (2) climate change adaptation; (3) conserving and recruiting mature and old-growth ("MOG") forests, ensuring habitat for species dependent on MOG systems, and supporting biodiversity; (4) Tribal inclusion and incorporating Indigenous Knowledge into project planning and implementation; and (5) supporting the economic sustainability of communities near the NWFP planning area through a "predictable supply" of timber and non-timber products (DEIS at 1-5).

The purpose and need ostensibly align with the intent of the 1994 NWFP while acknowledging the need to adapt to shifting climatic, ecological, and social conditions and to include Tribes in NWFP development and implementation. However, the analysis contained within the DEIS fails to demonstrate that any of the Alternatives—including and especially the Proposed Action Alternative—would meet all of these needs. Instead, the DEIS continues to focus largely on logging to achieve unfounded fuels treatment targets, with no compelling evidence of the co-benefits to long-term wildfire resilience, climate change adaptation, mature and old-growth stands, threatened and endangered ("T&E") species, biodiversity, or local

economies. In fact, the DEIS repeatedly acknowledges the potential for the Alternatives to result in habitat degradation and fails to make the case that forest and non-forest products from the NWFP area will be a vital part of sustaining local communities. The DEIS also presents alternatives that would fail to uphold Tribal treaty rights, meaningfully include Indigenous knowledge, or guarantee Tribal co-management.

Ultimately, the proposed approaches in each of the Alternatives are inadequate to meet the Amendment's stated purpose and need. In other words, the DEIS fails to articulate a rational connection between the facts found and the conclusion made.[3]

II. INADEQUATE RANGE OF AMENDMENT ALTERNATIVES

Despite a vast, interconnected set of issues and goals identified in the purpose and need, the DEIS fails to evaluate a reasonable range of alternatives to fulfill the intent of this complex Amendment in accordance with the National Environmental Policy Act ("NEPA").[4]

In the DEIS, the Forest Service only analyzes four alternatives, including a No Action Alternative ("Alternative A"), a Proposed Action ("Alternative B"), and two action alternatives. By contrast, the 1994 NWFP considered and analyzed ten alternatives that covered a broad range of possible approaches to achieving the NWFP's original purpose and need. Even within the four alternatives, with regard to key issues such as age thresholds for logging late-successional and old-growth ("LSOG") stands, there are functionally only two alternatives. Of the four alternatives presented in the Amendment DEIS, the key proposed management thresholds and objectives for LSOG in dry forest Late-Successional Reserves ("LSR") and Matrix are the exact same in Alternatives A and C; the proposed thresholds in Alternatives B and D are also identical to one another. Effectively, this means that the Forest Service only analyzed two alternatives connected to one of the NWFP's core issues: conservation of mature and old-growth trees.

Courts have previously determined that where the Forest Service considered only a no-action alternative (in this DEIS, Alternative A and the identical Alternative C), and "two virtually identical alternatives" the agency "failed to consider an adequate range of alternatives."[5] Although there is no NEPA requirement for the minimum number of considered alternatives, an EIS that considers only two reasonable alternatives will rarely satisfy the statute's "hard look" standard.[6]

NEPA requires federal agencies to include a detailed statement on "a reasonable range of alternatives to the proposed agency action," and Forest Service regulations require an EIS to "document the examination of reasonable alternatives to the proposed action," which "should meet the purpose and need and address one

[3] *Mtr. Vehicle Mfrs. Ass'n v. State Farm Mut. Auto. Ins. Co*., 463 U.S. 29, 43 (1983) (The agency must "articulate a satisfactory explanation for its action including a rational connection between the facts found and the choice made.")
[4] 42 U.S.C. § 4332(2)(H)
[5] *Muckleshoot Indian Tribe v. U.S. Forest Serv.*, 177 F.3d 813 (9th Cir. 1999)
[6] *Native Ecosystems Council v. U.S. Forest Serv.*, 428 F.3d 1233 (9th Cir. 2005)

or more significant issues related to the proposed action.[7] To amend the NWFP in line with the DEIS's purpose and need, and comply with federal law, the Forest Service must analyze alternatives encompassing a range of additional potential activities, standards, guidelines, and desired conditions. For example, the Forest Service did not consider any alternatives that would eliminate commercial logging, eliminate salvage logging, emphasize managed wildfire, or holistically prioritize habitat conservation and restoration for the suite of important forest species beyond northern spotted owl. The Forest Service also did not consider a set of alternatives that would equally uphold Tribal treaty rights, ensure Tribal inclusion, establish durable co-stewardship, and elevate Indigenous Knowledge. Instead, the three action alternatives manufacture a trade-off between actively managing forests and fulfilling the agency's trust responsibilities.

At minimum, the Forest Service should have included at least one alternative considering and analyzing the following for the treatment of dry forests and/or forests east of the Cascades:

- Maximizing recruitment and retention of mature and old-growth trees and forests by only harvesting trees younger than 80 years.
- Mechanical treatment methods that only use thinning from below.
- Retaining all trees greater than or equal to 20 inches diameter at breast height ("DBH").
- Eliminating post-fire salvage logging.
- Prioritizing gappy-patchy-clumpy forest composition outcomes to support wildlife habitat needs, and in alignment with site-specific local information about best ecological practices.
- Retention of known migration corridors for terrestrial wildlife species, such as mule deer and elk. This would include considering an alternative to retain 20-40% cover in all known corridors as indicated by GPS collar data, mapped Oregon Department of Fish and Wildlife ("ODFW") Priority Wildlife Connectivity Areas ("PWCA"), or equivalent data-driven information.
- An alternative that does not contain arbitrary targets for the number of acres treated per decade. Treatment acreages should be site-specific, project-level decisions.

III. MEANINGFUL PUBLIC REVIEW AND INFORMED AGENCY DECISION-MAKING

a. Incomplete and Inaccurate Environmental Baseline

The Forest Service did not provide sufficient data regarding the baseline conditions in the NWFP area to support its conclusions. NEPA's primary purposes are to ensure fully informed decision-making by the agency and to provide for public participation in the environmental analysis and decision-making process.[8] To achieve these purposes, NEPA requires every federal agency to prepare an EIS for "all major Federal actions significantly affecting the quality of the human environment."[9] An EIS shall "provide full and fair discussion of significant environmental impacts and shall inform decisionmakers and the public of the

[7] 42 U.S.C. § 4332(2)(H); 36 C.F.R. § 220.5(e)
[8] 36 C.F.R. § 220.5(e)
[9] 42 U.S.C. § 4332(2)(C)

reasonable alternatives which would avoid or minimize adverse impacts or enhance the quality of the human environment."[10]

To comply with NEPA's "hard look" mandate, an agency must maintain inventories or otherwise collect and disclose information about the resources it manages so that an adequate baseline exists to evaluate the environmental impacts of a proposed action.[11] Without establishing the baseline conditions in the Project area before the action begins, "there is simply no way to determine what effect the [action] will have on the environment and, consequently, no way to comply with NEPA."[12]

Among other missing, incomplete, or inaccurate elements of the DEIS baseline, the Forest Service failed to adequately include or consider:

- **Barriers to Tribal stewardship, including cultural burning**. Despite the centrality of Tribal inclusion to this Amendment process, with cultural burning and beneficial fire at its core, the DEIS does not account for the existing bureaucratic and structural barriers to Indigenous fire use. The DEIS also does not disclose how and where beneficial fire use and other Indigenous stewardship practices will be applied, nor how these will supplant the existing fire suppression paradigm.
- **Methodological and spatial information on forest and forest treatment types.** The definitions of "dry" and "moist" forest provided in Appendix F and the guidelines for distinguishing between these forest types under FORSTW-ALL-GDL provide only the vaguest level of insight into the potential treatment approaches that might be employed under the Amendment (DEIS at A1-15). The process for determining dry or moist forest classifications remains unclear, which makes the coarse-resolution interactive map of dry and moist forest types nearly meaningless in assessing potential impacts of each alternative. The DEIS also lacks any mapping of past burn and vegetation removal areas, which would necessarily inform any analysis of potential impacts to dry and moist forest types.
- **Baseline in formation on eastside forest vegetation treatments and effectiveness monitoring.** The Forest Service failed to disclose and analyze data on vegetation treatment implementation and outcomes over the first 30 years of the NWFP. This data is critical to inform management in the future, and should necessarily inform priority actions for achieving desired ecological conditions.
- **Species distributions and statuses.** While the DEIS extensively lists various Threatened and Endangered Species that may occur within the NWFP area (DEIS at 3-52 to 3-55), it does not include baseline information on how the first 30 years of the NWFP has impacted these species in terms of population, distribution, or habitat. Instead, Section 3.5 only offers descriptions of habitat types and vegetation associations and incorporates by reference more detailed accounts of only a handful of species. Appendix C, the Draft Biological Evaluation ("BE"), lists 776 species that may

[10] Id.
[11] See *Neighbors of Cuddy Mountain v. U.S. Forest Serv.*, 137 F.3d 1372, 1379-80 (9th Cir. 1998).
[12] *Half Moon Bay Fishermans' Marketing Ass'n v. Carlucci,* 857 F.2d 505, 508 (9th Cir. 1988); see also *Am. Rivers v. FERC,* 201 F.3d 1186, 1195 & n.15 (9th Cir. 2000) (noting that an accurate and complete baseline against which to compare potential effects of reasonable alternatives is "critical" to the NEPA process).

be in the NWFP area, along with their associated habitat types, but does not provide any spatial information on their likely habitat distributions to compare to proposed treatments (DEIS at C-12 to C-57). For all but 9 of these species, the BE determines that the action alternatives will have "No Impact" or "May Impact Individuals or Habitats" (DEIS at C-8). However, without any spatial data or underlying analysis to reach those conclusions, this offers no meaningful information to decision-makers or the public.

- **Baseline conditions for Northern Spotted Owl habitat.** Given the NWFP's intent to protect and increase habitat for Northern Spotted Owl ("NSO"), it is imperative that the Forest Service disclose and analyze baseline conditions for NSO dispersal, nesting, roosting, and foraging habitats, all of which are central to determining suitable forest management approaches. This is particularly crucial in light of the emerging impacts of climate change and barred owl population expansion on NSO.
- **The NWFP's contributions or impediments to climate adaptation.** The DEIS lists carbon stocks by National Forest (DEIS at 3-87) and lists treatment acreages (DEIS at 3-93),[13] but does not attempt to analyze or quantify how existing or proposed management would influence any part of the NWFP area's capacity to adapt to climate change.
- **Wildfire, fuels treatment, and suppression history within the NWFP area.** The DEIS centers wildfire as a threat to communities and timber resources and especially highlights the need for fuels treatments in dry forests, yet does not analyze the specific histories of wildfires, logging, restoration work, or suppression activities that might influence shifting fire regimes or management decisions.
- **Impacts to aquatic and riparian ecosystems.** Although the DEIS does not propose changes to the Aquatic Conservation Strategy ("ACS"), it also contains no information on past or potential impacts to riparian and aquatic systems within the NWFP area. The proposed increases in logging, including in Riparian Reserves, will inherently affect aquatic ecosystems above and beyond the status quo. It is incumbent upon the Forest Service to fully study and disclose how the various alternatives could impact riparian and aquatic habitats.
- **Roads, routes, and trails.** The DEIS does not disclose or consider temporary and system road networks, ML 1-5 road densities, user created roads, trail networks, and other relevant data on existing roads and trails.

b. Failure to Disclose, Analyze, and Consider the Reasonably Foreseeable and Cumulative Effects of the Proposed Amendment

The agency must disclose, analyze, and consider the reasonably foreseeable[14] and cumulative effects[15] of a proposed action. NEPA's "action-forcing" procedures also require that an agency takes a "hard look" at the

[13] Without more information on forest composition or geography, acreage is a relatively meaningless proxy for carbon stores (M.E. Harmon, Deschutes Collaborative Forest Project presentation, February 13, 2025).
[14] 42 USC § 433(2)(C)
[15] 36 C.F.R. § 220.4(f)

environmental consequences of its proposed action in advance of a final decision.[16]

The DEIS fails to provide adequate information, evidence, and analysis for the public to assess the potential outcomes of the proposed alternatives. Instead, it relies on simply listing potential actions and biological resources, physically describing geographic areas, and summarizing research without connecting findings to the impacts of the NWFP itself. From these lists and descriptions, the DEIS then offers subjective assessments of potential effects without any data or evidence, nor any information about past and present project implementation within the NWFP area (See relevant discussion in DEIS Chapter 3, at 3-1 to -164). The DEIS also fails to consider the cumulative effects of other land management agency actions, such as the secession of 2.6 million acres of Bureau of Land Management ("BLM") land from the NWFP, which has resulted in increased logging of key resources formerly within the NWFP planning area. The Forest Service must consider and disclose the cumulative and reasonably foreseeable effects of increased logging on all federal ownerships as part of the FEIS. Similarly, the Forest Service must account for changes in the federal forest management policy landscape. The DEIS consistently defers to the National Old-Growth Amendment ("NOGA")—which was withdrawn in the final days of the Biden Administration—for meaningful protections of mature and old-growth trees. The FEIS must account for the reasonably foreseeable effects of NOGA's withdrawal and must adequately protect mature and old-growth trees and forests in the NWFP area in the absence of NOGA.

Concerningly, and as discussed further in sections below, the DEIS also fails to consider the direct, indirect, and cumulative impact of new roads. Roads are necessary to implement any of the alternatives, and to achieve the proposed dramatic increases in treatment acreages. Road construction, therefore, is a connected action that must be considered as part of the NWFP Amendment NEPA review.[17]

The Forest Service's failure to sufficiently disclose, analyze, and consider the direct, indirect, and cumulative effects of the Amendment violates NEPA and is arbitrary, capricious, an abuse of discretion, not in accordance with, and without observance of procedure required by law.[18] Additionally, the Forest Service has failed to demonstrate compliance with the 2012 Planning Rule and the National Forest Management Act.[19]

i. Simply Listing All Relevant Actions is Not the Same as Cumulative Effects Analysis

The DEIS particularly lacks adequate information on cumulative effects to allow for meaningful public review and an informed decision. The cumulative impact or effect from an action means "effects on the environment that result from the incremental effects of the action when added to the effects of other past, present, and reasonably foreseeable actions…Cumulative effects can result from actions with individually minor but collectively significant effects taking place over a period of time.[20] Accordingly, "[i]n a

[16] *Robertson v. Methow Valley Citizens Council*, 490 U.S. 332, 350–51 (1989).
[17] 40 C.F.R. § 1501.3(b)
[18] 5 U.S.C. § 706(2).
[19] 36 C.F.R. Part 219; 16 U.S.C. § 1600 *et seq.*
[20] 36 C.F.R § 220.4(f)

cumulative impact analysis, an agency must take a 'hard look' at *all* actions" that may combine with the action under consideration to affect the environment.[21]

"Simply listing all relevant actions is not sufficient."[22] Rather, "some quantified or detailed information is required. Without such information, neither the courts nor the public . . . can be assured that the [agency] provided the hard look that it is required to provide."[23] To be useful to decision makers and the public, a cumulative impact analysis must include "some quantified or detailed information; . . . general statements about possible effects and some risk do not constitute a hard look absent a justification regarding why more definitive information could not be provided."[24]

Except for minimal considerations of cumulative effects in Section 3.8 (See DEIS at 3-99, "Issue 7 – Sustainability of Regional Communities"), which extends its analysis into 72 "NWFP-socioeconomic region counties" (despite the NWFP area only intersecting 54 counties across Washington, Oregon, and California), the DEIS fails to address cumulative effects. For the other six key issue areas, the DEIS merely offers the types of "general statements about possible effects and some risk" that courts have deemed insufficient to constitute a "hard look." Section 3.9, "Cumulative Effects" (DEIS at 3-156) spends four pages listing other land management agencies and types, then simply enumerates some actions connected to each of the seven key issue areas. For each issue area, the DEIS presents no "quantified or detailed information" before drawing conclusions about action alternatives respective unspecified cumulative effects. For example, Section 3.9.2.2, "Issue 2 – Forest Stewardship," lists potential activities that other agencies could carry out, suggests that agencies may work together cooperatively, and then concludes "[t]he cumulative effects of the proposed action alternatives as they relate to forest stewardship would be expected to be overall beneficial when combined with other reasonably foreseeable future actions" (DEIS at 3-162). This does not constitute any analysis of the cumulative effects of forest stewardship activities and is so vague that it offers no insight to agency decision-makers or the public.

The Forest Service must revise and add to the DEIS's cumulative effects summaries to include detailed descriptions of past and present project activities that have altered the planning area (*i.e.*, the time, type, place, and scale). For example, the cumulative effects analysis should include consideration of:

- Past thinning and forest restoration projects;
- Past maintenance, construction, and temporary construction of roads, routes, and trails;
- Past wildfires and suppression activities;
- Recreation impacts;
- The combined effects of past thinning projects and recreation opening up the forest to higher levels of disturbance that impact wildlife habitats.

[21] *Te-Moak Tribe of W. Shoshone of Nev. v. U.S. Dep't of Interior*, 608 F.3d 592, 603 (9th Cir. 2010) (emphasis added).
[22] *Great Basin Res. Watch v. Bureau of Land Mgmt.*, 844 F.3d 1095, 1104 (9th Cir. 2016)
[23] *Neighbors of Cuddy Mountain v. U.S. Forest Serv.*, 137 F.3d 1372, 1379 (9th Cir. 1998).
[24] *Ocean Advocates v. U.S. Army Corps of Eng'rs*, 402 F.3d 846, 868 (9th Cir. 2005) (quoting *Neighbors of Cuddy Mountain*, 137 F.3d at 1379–80).

Only after analyzing these additional cumulative effects can the Forest Service fully understand and disclose the reasonably foreseeable effects of each alternative on each resource type n the NWFP.

IV. ECOLOGICAL AND CULTURAL ISSUES

a. Incorporation of Indigenous Knowledge and Increased Tribal Engagement

Central Oregon, including those lands managed by the Forest Service, are the original homelands of the Wasq'u (Wasco) and Tana'ma (Warm Springs) Tribes. The Klamath and Molalla tribes—among others—have also traditionally frequented this area, as have the Nama (Paiute), who were eventually forcibly relocated to the Warm Springs Reservation by the United States government. What we now know as Central Oregon are the ceded lands of the Confederated Tribes of Warm Springs (Wasco, Warm Springs, and Northern Paiute), where they reserve the right to hunt, fish and gather.

LandWatch supports amending the NWFP in a way that recognizes the role Indigenous peoples have played in stewarding forest landscapes, including those east of the Cascades, since time immemorial (Kimmerer & Lake, 2001; Steen-Adams et al., 2019). The final decision must ensure that Tribal inclusion, Tribal sovereignty, and Indigenous knowledge remain central to National Forest management, which should be conducted in co-stewardship with Tribal nations.

Here, LandWatch reiterates some of the key requests by the NWFP Federal Advisory Committee ("FAC") and the Northwest Forest Plan Just Futures Collaborative to ensure Tribal sovereignty. We recognize that these groups represent a subset of Tribal views, and we defer locally to the goals, approaches, ideas, and understandings of the Tribes whose lands are now considered part of the Deschutes National Forest.

i. Tribal Consultation is Required

Irrespective of the selected Amendment alternative or final Record of Decision, the Forest Service is legally obligated to consult early and often with Tribal governments to ensure that Indigenous people's interests and knowledge are brought forward in the planning process and that land use allocations do not conflict with landscapes of cultural significance or Tribal treaty rights. Given this, the No Action Alternative (Alternative A) is not a legitimate option, since it would continue to represent a NWFP devoid of Tribal input and would not rectify the Forest Service's long-term exclusion of Tribes, rejection of Indigenous Knowledge, and dereliction of its trust responsibilities.

ii. Strengthen and Retain All Tribal Inclusion Plan Components

The alternatives in the DEIS arbitrarily partition Tribal inclusion plan components and force a manufactured decision between upholding Tribal sovereignty and advocating for approaches that prioritize ecological landscape function over commercial logging. Given the primary of Tribal inclusion, Indigenous knowledge, co-stewardship, and trust responsibilities in this Amendment, the Tribal inclusion plan components warrant

consideration and adoption irrespective of the timber and restoration targets set in the updated NWFP.

We urge the Forest Service to retain all Tribal inclusion plan components present in Alternative B. Similarly, we urge the Forest Service to adopt Tribal inclusion measures only present in Alternative D—which particularly focus on first foods—into the Record of Decision. The Forest Service should also change all Forest Stewardship Potential Management Approaches (TRIBAL-FORSTW-ALL-PMA) to be standards so that they become enforceable, meaningful sideboards for Tribal inclusion.

iii. Address the Impacts of Tribal Exclusion

The DEIS does not fully confront the causes or consequences of Tribal exclusion—and by extension, fire exclusion—within the NWFP area. Echoing a request by the NWFP Just Futures Collaborative, we ask that the final Record of Decision better account for the role the Forest Service and the 1994 NWFP have played in perpetuating this exclusion by including the FAC's full Tribal Inclusion recommendations (NWFP Just Futures Collaborative at 2).

iv. Indigenous Knowledge Must be Central to the Amendment and Its Implementation

Although the DEIS presents alternatives that would substantially improve tribal inclusion and incorporation of Indigenous knowledge in the NWFP, its underpinning analyses include relatively little Indigenous science and knowledge. The alternatives also lack sideboards for ensuring that Indigenous knowledge will be a core part of any project-level assessment within the NWFP area. The FAC, which included members and representatives from a wide geographic range of Tribes in the NWFP area, offered extensive recommendations for objectives, standards, and guidelines that would better protect Indigenous sovereignty by consistently incorporating Indigenous knowledge in project planning and implementation. The proposed action (Alternative B) includes standards that protect Indigenous knowledge and require closer collaboration with Tribes (e.g., TRIBAL-COSTW-STD-01 and TRIBAL-IK-STD), but the final standards should go further to recognize Indigenous knowledge as a key basis for the development of any project.

For example, FAC recommendation 1-50, which is a Potential Management Approach for Tribal Forest Stewardship (see TRIBAL-FORSTW-ALL-PMA), should be an enforceable standard or guideline in the Final Decision: "Management activities shall consider Indigenous and western scientific research and ethnographic research related to relevant Tribal cultural land-use activities and interests when analyzing project effects. Ensure that no adverse effects are caused to any Treaty and other Tribal Rights, sacred places, practices, or elements of the landscape identified as culturally important to relevant Tribes" (FAC Recommendations at 15; DEIS at A1-8).

v. Remove Structural Barriers to Cultural Fire and Other Reserved Treaty Rights

While including cultural burning, prescribed fire, and managed wildfire to the DEIS alternatives represents an important shift in the NWFP's approach to wildfire and forest management, the DEIS does not account for the structural and bureaucratic barriers that currently limit cultural burning and Tribal-led prescribed

fire. Nor does the DEIS adequately include Tribal cultural objectives—rather than western silvicultural objectives—of forest stewardship. Rather than simply acknowledging beneficial fire, the Forest Service must analyze and disclose how it will ensure that beneficial fire use will be a meaningful part of implementing the amended NWFP. Similarly, the Forest Service must analyze and disclose spatial information indicating where beneficial fire may be used within the NWFP area and must also adopt policies that further clarify how and when prescribed fire and cultural burning will be employed. These additional analyses will provide necessary sideboards to ensure that fire inclusion—a critical part of Tribal inclusion—will occur in practice.

b. Forest Stewardship

The alternatives presented in the DEIS all substantially decrease protections for mature and old-growth trees in all forest types, while also proposing silvicultural treatment approaches that would prove counter to forest resilience, habitat, and climate goals and may also inhibit Tribal sovereignty.

i. Standards and Guidelines in Dry Forest Types

1. Decreased Protections for Mature and Old-Growth Trees

LandWatch is concerned by the proposal for reduced protections for mature and old-growth trees in both Late-Successional Reserves ("LSR") and Matrix in all alternatives. In Alternatives B and C, this change would allow harvest of trees up to 150 years old in dry LSR and trees established after 1850 in dry matrix (DEIS at 3-25). In Alternative D, trees and stands established after 1850 could be harvested in both dry LSR and dry matrix. For trees in the matrix under Alternatives B and C, the arbitrary proposed age thresholds contain significant exceptions for undefined "restoration" and to "reduce wildfire risks," while also substantially reducing protections for 936,000 acres within the NWFP area (DEIS at 3-29). Alternative D, meanwhile, guarantees that trees established after 1850 can never age into protection, which directly contradicts the NWFP's intent to conserve mature and old-growth forests and habitat. In dry forest LSR, this amounts to an estimated additional 1.23 million acres of potential treatment. Adding to the concern, these increased age thresholds would also apply to riparian forests in LSR (DEIS at 3-37). The DEIS does not offer any evidence or analysis to support these age threshold changes in any forest types, beyond vague assertions that the thresholds will help "address the need…for mature and old-growth forest conservation, while balancing for other priorities" (DEIS at 3-24).

The Forest Service has also precluded any meaningful public analysis of the impacts of these proposed changes, since the DEIS does not adequately define or quantify "dry forest" or "moist forest," so it is not clear exactly how or where these revised standards and guidelines ("S&Gs") would apply. It is important to note that forests east of the Cascades are dynamic and encompass a continuum of moist and dry forest types. For example, on the Deschutes National Forest, Sisters Ranger District, some of the best owl habitat is within the wet mixed conifer (referred to as "PST") Plant Association Group (PAG).[25] These areas are

[25] Green Ridge Landscape Restoration Project, Wildlife Report, EA, p. 38

not dry forests, but the lack of clarity around forest type definitions raises concerns that forest types like the PST PAG may be inappropriately managed.

The DEIS further prevents clear assessment by presenting a table summary of "Current and proposed LSOG management thresholds for conservation by alternative" (Table 3-2, DEIS at 3-25) that contains different information about age thresholds for harvest in various LUAs than the narrative descriptions of "Effects on late-successional and old-growth in dry forests in LSR and MLSA" (DEIS at 3-28 and 3-29) and "Effects on late-successional and old-growth in dry forests in Matrix" (DEIS at 3-30). Whereas Table 3-2 describes the age threshold for dry forest LSR and Matrix in Alternative C as being the same as Alternative A (80 year threshold), the narrative descriptions of Alternative C treatments in dry forest Matrix and LSR describe the threshold as 150 years, or identical to Alternative B. This type of confusing discrepancy renders it impossible to understand the intended goals or likely outcomes of the various Amendment alternatives.

Beyond the confusion and uncertainty introduced by the proposed decrease in protections for mature and old-growth forests, each of the alternatives would pose substantial threats to wildlife that depend on mature and old-growth habitat, as well as on the broader ecosystem integrity of forests east of the Cascades, which already have a deficit of large, old trees (Buotte et al., 2020; Mildrexler et al., 2020). The Forest Service has failed to disclose and consider the cascading impacts to threatened, endangered, and sensitive species that would result from its proposed actions in all dry forest LUAs. Relatedly, there is a significant contradiction between the Forest Service saying, on the one hand, that the Amendment will not cause "substantial adverse impacts" to any species (DEIS at 1-7), while allowing considerably more logging of mature and old-growth forests, and by extension eliminating suitable ecological conditions for multiple listed species and species of conservation concern.

2. Standards to Protect Large, Mature, and Old-Growth Trees and Forest Types

Instead of allowing increased logging of mature and old-growth forests and trees, the Amendment should include a standard that meaningfully protects all large, mature, and old-growth trees across the entire NWFP area, including in areas the Forest Service has determined to be at risk of large-scale disturbance. This type of standard would require managing NWFP area forests, and particularly dry forests, to maximize the recruitment and retention of mature and old-growth trees and stands. Such a standard is critical for forests and surrounding communities to receive the full benefits of healthy mature and old-growth forests.[26]

The best available science is clear that protecting mature and old growth forest conditions is essential to mitigating the impacts of climate change (Hudiburg et al., 2009; Law et al., 2018, 2022; Mildrexler et al., 2020), providing clean and cool water for fish, wildlife, and growing communities, and providing refuge for wildlife and people alike (Brandt et al., 2014). In fact, two of the architects of the original NWFP have called for an end to all logging of mature and old growth trees within the NWFP planning area.[27] As the

[26] 36 C.F.R. § 219.13(b)(6); 36 C.F.R. § 219.9(b)
[27] Guest Column: Protect older natural forests in the western Cascades (2021). *The Register-Guard*. Accessed February 14, 2025.

Federal Register Notice ("FRN") for the NWFP Amendment states, "[p]rotecting and enhancing biodiversity of mature and old growth ecosystems is a central tenet of the NWFP, and the 2012 Planning Rule's focus on ecosystem integrity emphasizes this priority. Mature and old growth ecosystems are critical components of biodiversity and provide carbon storage" (88 FR 87396). In considering management east of the Cascades, this central tenet must lead the development of all management actions, and the retention of all large trees should be part of all projects, which none of the DEIS alternatives guarantee.

Protecting mature and old growth trees on forests east of the Cascades does not prevent the Forest Service from implementing projects to address fuel concerns in forests where frequent fire was historically common. Large trees are not driving concerns related to fuel loading or the risk of large-scale disturbance. Removing small trees, including via methods such as thinning from below, can achieve fuels management objectives without logging large trees.

3. Removal of Risk Reduction Guideline in LSR

The shift from a guideline based on reducing risk of major disturbances in LSR east of the Cascades to a set of geographically undefined age thresholds is especially antithetical to the original intent of the NWFP. The 1994 NWFP defines LSR as forests containing mature and old-growth age classes of trees, and describes creating LSR with "an objective to protect and enhance conditions of late-successional and old-growth forest ecosystems, which serve as habitat for late-successional and old-growth forest related species including the northern spotted owl."[28] LSR, as such, is intended to mature into our future old-growth forests and treatments are only allowed in very specific, very limited circumstances. This is further emphasized by another 1994 NWFP LSR description: "these reserves represent a network of existing old-growth forests that are retained in their natural condition with natural processes, such as fire, allowed to function to the extent possible" (NWFP at B-4). Further, the Forest Service concedes "[LSR] forest communities are the result of a unique interaction of disturbance, regeneration, succession, and climate *that can never be recreated in their entirety through management*. The structure, species composition, and function of these forests are, in their entirety, not fully understood" (NWFP at B-5; emphasis added).

As such, the 1994 NWFP set guidelines that focused on young and plantation stand management to reduce the risk of catastrophic fire, with narrow exceptions for treatments in older LSR:

> While risk-reduction efforts should generally be focused on young stands, activities in older stands may be appropriate if: (1) the proposed management activities will clearly result in greater assurance of long-term maintenance of habitat, (2) the activities are clearly needed to reduce risks, and (3) the activities will not prevent the Late-Successional Reserves from playing an effective role in the objectives for which they were established. (NWFP at C-13)

[28] NWFP- *Standards and Guidelines for Management of Habitat for Late-Successional and Old-Growth Forest Related Species Within the Range of the Northern Spotted Owl- Attachment A to the ROD for Amendments to Forest Service and Bureau of Land Management Planning Documents Within the Range of the Northern Spotted Owl,* https://www.fs.usda.gov/Internet/FSE_DOCUMENTS/stelprd3843203.pdf, p A-1, B-1

Although this guideline may have ultimately placed too much emphasis on fire suppression, it also supported a management direction more focused on disturbance regimes and successional processes that could have been further enhanced in this DEIS through Tribal inclusion and beneficial fire use. Instead, the DEIS seemingly abandons the understanding of LSR as communities that cannot result purely from silvicultural prescriptions. Simultaneously, it fails to correct the 1994 NWFP's omission that Indigenous cultural burning was central to the development of the late-seral, mature, and old-growth conditions that provide for habitat, ecological function, and cultural needs.

Further, removing the three exception factors outlined in the 1994 guideline for risk-reduction treatments in older LSR threatens to undermine the purpose of the NWFP and its ability to protect the ecological integrity of east side forests. The three factors are important sideboards for guiding informed project development, and the DEIS fails to demonstrate how the removal of mature trees (up to 150 years in dry LSR) will reduce risks and support long-term habitat maintenance for NSO and other species. Logging large trees conflicts with the purpose of the original NWFP, exacerbates large tree structure scarcity problems, and provides little if any benefit to reducing the risk of large-scale disturbance events.

ii. End All Salvage Logging

The science has long been clear that there is no ecological reason to conduct salvage logging operations (Brown et al., 2004; Noss et al., 2006). The Forest Service should end salvage logging in all LUAs, including on both dry and moist forest types east of the Cascades. In not including a DEIS alternative without salvage logging, the Forest Service failed to consider reasonable Amendment alternatives.

Research has found that the detrimental effects of salvage logging can include increased fine fuels, decreased tree regeneration (Donato et al., 2006), soil compaction (Jennings et al., 2012), impaired water quality (Emelko et al., 2011), increased fuel loading (Donato et al., 2013), and altered bird nesting (Hutto & Gallo, 2006; Kronland & Restani, 2012), among other impacts. Salvage logging also has negative climate consequences: standing dead trees that remain post-fire continue to store substantial carbon (Harmon et al., 2011; Powers et al., 2013). The USFS literature review by Nemens et al. (2019) that the DEIS relies on to substantiate its commitment to salvage harvest specifically highlights each of these impacts. Yet, the DEIS insists there remains an open "public and scientific debate on the economic and accelerated forest development benefits of postfire harvest of fire-killed trees," despite not seriously analyzing any benefits beyond timber outputs (DEIS at 3-32). If any debate exists, it is around the tradeoffs between selling post-fire logged trees and ecologically degrading burned areas. The Forest Service uses this idea of a "debate" to justify including salvage logging in all alternatives, with no quantified analysis of the specific impacts to the NWFP area, nor any consideration of a no-salvage alternative.

Alternative C places the greatest restrictions on salvage logging, prohibiting its use in moist LSRs and limiting dry forest salvage for "protection of critical infrastructure, and along existing system roads" (FORSTW-ALL-DRY-STD-03-C; see DEIS at 2-20). We contend that this type of "salvage" would be better classified as hazard tree felling, and that this standard should be strengthened to only allow hazard tree felling within a specified narrow distance of roads or other infrastructure, which would retain

significant habitat benefits while removing hazards to humans and infrastructure.

iii. Setting Unsubstantiated Treatment Targets is Arbitrary and Capricious

Under the proposed action, the DEIS sets a target of logging one third of all dry forests in the NWFP area within 15 years of Amendment approval—790,000 to 964,000 acres every 15 years, not including acres of salvage logging (DEIS at 3-33). From an ecological, cultural, and climatic perspective, this is a completely arbitrary target that will also fail to meet fire resilience objectives. The DEIS lacks a rationale for why logging as much as four times more per decade than the current NWFP would achieve any of the DEIS's intended outcomes beyond potentially—though by no means certainly, given the depressed state of eastside timber markets—increasing decadal MMBF sales.

For all "dry forest" LUAs, the Forest Service proposes to conduct all logging projects and achieve timber production objectives using "ecological forestry methods," which the DEIS defines in Appendix F:

> Ecological forestry utilizes ecological models from natural forest systems as a basis for managing forests. It incorporates principles of natural forest development, including the role of natural disturbances, in the initiation, development, and maintenance of forests and forest landscape mosaics. Most importantly, ecological forestry recognizes that forests are ecosystems with diverse biota, complex structure, and multipole functions, and not simply collections of trees valuable primarily for the production of wood. In doing so it seeks to maintain the fundamental capacities (integrity) of the forest ecosystems to which it is applied (DEIS at F-2, citing Franklin et al., 2018).[29]

The stated structural complexity and biodiversity outcomes of "ecological forestry methods" are promising in a vacuum, but this definition offers no clarity as to how, where, or over what time scales the Forest Service might employ these methods. The vague concept of ecological forestry is especially concerning considering the arbitrary logging treatment acreage targets set by the DEIS. To truly achieve ecological outcomes and support natural disturbances as described the above definition, the Forest Service should lead with ecological forestry methods, which in turn should dictate the number of acres requiring treatment. As it stands, the DEIS has the order of operations reversed by starting with decadal treatment acreage targets, which will inevitably result in conflicts between timber production and the conditions dictated by ecological forestry modeling outputs. Without clearer methodology sideboards, this conflict will likely prioritize timber over any commitment to forest ecosystem diversity or structural complexity.

c. Fire Resistance and Resilience

Fire is a key ecological driver in Central Oregon forests, having shaped forest structure, process, pattern, and composition for millennia. There is little controversy over whether a lack of fire in forest communities that historically experienced frequent, low to mixed severity fires—such as lower elevation ponderosa pine

[29] This reference lacks a bibliographic entry in the DEIS, which makes it difficult to determine what, precisely, the Forest Service intends to cite. Presumably, the reference is to the 2018 textbook "Ecological Forest Management" by Jerry F. Franklin, K. Norman Johnson, and Debora L. Johnson.

and dry-mixed coniferous forests—has fundamentally transformed and contributed to the degradation of many of these forest ecosystems (Brown et al., 2004; Haugo et al., 2015; Noss et al., 2006). While public perception is often that too much of our forests are burning in the modern era, western forests continue to be in a fire deficit (Hessburg et al., 2021; Parks et al., 2015) and modern fire suppression efforts effectively put out 97-98 percent of all fire starts (Dombeck et al., 2004; Hessburg et al., 2021; North et al., 2015). The two percent of fires that escape suppression efforts are most often driven by extreme fire weather and account for 97 percent of all firefighting costs and area burned (Calkin et al., 2005; Hessburg et al., 2021).

The past century and a half of fire exclusion and suppression is also a direct result of Tribal exclusion from public lands. Indigenous peoples in the Pacific Northwest have practiced cultural burning since time immemorial, including east of the Cascades in what is now the NWFP area (Kimmerer & Lake, 2001; Steen-Adams et al., 2019). These practices were eliminated and criminalized as settler colonists began occupying the West and the Federal government dispossessed Tribes of land and culture (Long et al., 2021).

Changes in fire frequency and extent are just one of a suite of factors that have profoundly influenced forest ecosystems east of the Cascades. The transformation and degradation of lower elevation pine dominated forests and watersheds has primarily been driven by logging of large fire-resistant trees,[30] extensive road building, fire exclusion, and livestock grazing (Brown et al., 2004; Stine et al., 2014). The combination of these "drivers of degradation" have culminated in dramatic impacts to forest ecosystems, playing a leading role in the biodiversity crisis and the loss or near loss of multiple keystone species. Though the challenges related to addressing these drivers of degradation are large, each is fundamentally a resource management decision that can be changed, mitigated, or prohibited all together through this amendment

i. Fire inclusion is a necessary cultural and ecological practice

Mature and old-growth forests and trees have historically been an outcome—though not necessarily a direct objective—of Indigenous fire use, which helped maintain overall forest structure and biodiversity and eliminated smaller fine fuels on many forested landscapes (Long et al., 2021). By extension, the NWFP Amendment must include Indigenous cultural and prescribed burning as a critical management approach for supporting holistic forest function, particularly in fire-dependent forests east of the Cascade Crest. Cultural burning may support forest biodiversity and specialized habitat needs at a finer scale than is possible merely through frequent, low-severity wildfire (Long et al., 2021). Cultural burning—in combination with wildfire regimes—also supports the availability of First Foods, browse and forage for game species, and basketry materials (Anderson & Lake, 2016; Marks-Block et al., 2019, 2021; Steen-Adams et al., 2019).

The FEIS must retain cultural burning and other Indigenous stewardship elements to ensure that Indigenous fire practices are recognized as both vital and distinct from Western prescribed burning. Fuels reduction must not be the sole purpose of beneficial fire use in the Amendment. Protecting and prioritizing Indigenous

[30] Despite the ecological impacts, large tree logging continues to occur on the Deschutes National Forest: Group sounds alarm over plan to cut big, old trees near Bend - OPB (2022).

fire practices will help restore not only an ecological fire regime, but also a cultural fire regime across the NWFP area.

ii. Standards and Guidelines for Community and Infrastructure Protection

Despite the ostensible goal of enhancing community wildfire protection, the DEIS fails to take a hard look at the robust science around home hardening, defensible space, and human ignition prevention as the most effective ways to protect built infrastructure and people from wildfire damage (Cohen, 2000; Syphard et al., 2014). Rather, the Forest Service continues to rely on a wildfire management approach that "inverts" the wildfire problem by basing prevention strategies on the misguided idea that forests encroach on communities, rather than recognizing the reality that communities encroach on forests (Calkin et al., 2023).

Insofar as the DEIS devotes attention to community protection, the Guidelines for Fire Resilience under the proposed action specifically give primacy to fuels treatments (*i.e.*, vegetation removal) over the goals of other important ecological S&Gs. Guideline FIRE-ALL-GDL-03, for example, deprioritizes riparian reserve S&Gs in service of near-community vegetation removal: "In community protection areas, fuels treatments should take precedence over riparian reserve standards and guidelines when necessary to meet fire behavior objectives consistent with sustaining long-term aquatic ecosystem function (see DC-01; 1994 NWFP Standards and Guidelines page C-35, FM-01)" (DEIS at A1-26). Similarly, FIRE-ALL-GDL-04 supersedes *all other* S&Gs across all other LUAs in service of vegetation removal: "In community protection areas, fuels treatments should take precedence over other standards and guidelines across the LUAs when necessary to meet fire behavior objectives while meeting the long-term purposes of these LUAs (see DC-01)" (DEIS at A1-26). Meanwhile, "community protection area" is loosely defined as "locations where wildfire risks affect communities, tribal values, and infrastructure. There is significant risk of potential economic loss and public safety concerns posed by a wildfire occurring within this area" (DEIS at F-1). In other words, the Forest Service could determine that a community protection area exists almost anywhere, and accordingly remove vegetation deemed to be "hazardous fuels" at the expense of other important forest values.

Community protection is clearly an important and worthwhile aim of the Amendment, but these "community protection" S&Gs continue to rely on mechanical fuels reduction in wildlands as the primary solution to what is fundamentally a built infrastructure problem (Calkin et al., 2023). While fuels removal will undoubtedly play a role in enabling fire suppression tactics in and near communities, the Forest Service must do more to realistically face this problem by developing S&Gs that elevate the importance of home hardening and defensible space, and that use specific definitions of community risk that incorporate social vulnerability and adaptive capacity in addition to proximity to forests (Lacey et al., 2025).

iii. Standards and Guidelines for Prescribed and Cultural Burning

In amending the NWFP, new S&Gs should require understory burning to be the primary focus of projects proposing to remove small trees. Whether it is the only treatment, or implemented shortly after science-based thinning, carefully applied understory burning provides important ecological benefits, creating

landscape heterogeneity, reducing surface and ladder fuels, lowering stand densities, improving drought resistance of surviving trees, and may be the most appropriate treatment in riparian areas that historically experienced frequent fire (Brown et al., 2004; Kauffman et al., 1997; Knapp & Keeley, 2006; Mildrexler et al., 2023; van Mantgem et al., 2016). These S&Gs should support the use of both prescribed burning and cultural burning as forms of beneficial fire.

iv. Standards and Guidelines for Suppression Activities

Neither the existing NWFP nor the proposed Amendment alternatives include S&Gs for management during fire suppression. Given the DEIS's focus on refining and updating management guidance to address wildfire concerns—especially east of the Cascades—the Amendment should provide additional clarity around what actions are allowed during suppression activities, particularly in mature and old-growth forests.

For example, additional clarity is needed around how, when, and whether the Forest Service builds fuel breaks as part of suppression activities. The Forest Service should consider S&Gs that clearly define when and where fuel breaks are appropriate. Where fuel breaks are deemed necessary to suppression efforts, new S&Gs that provide clarity around how they are implemented will greatly reduce negative outcomes. For example, S&Gs around the development of gappy, patchy, clumpy fuel breaks and shaded fuel breaks where all large trees are retained would mitigate the potential ecological impacts of suppression activities.

The Forest Service should also develop S&Gs that account for emerging research indicating that wildfire management decisions—including using managed wildfire for resource benefit—are likely to result in better ecological outcomes and reduced high-severity fire when compared to mechanical management approaches (Furniss et al., 2024). Relatedly, the Forest Service should consider and adopt an alternative that includes S&Gs to more cautiously employ suppression tactics, given the evidence that intensive suppression leads to an increased proportion of high-severity, uncontrollable, and dangerous wildfires on forest landscapes, a phenomenon termed "suppression bias" (Kreider et al., 2024). Concerningly, the DEIS ties itself explicitly to the Wildfire Crisis Strategy, which implies continued primacy of fuels removal and fire suppression that will further entrench suppression bias without thoughtful S&Gs in place.

S&Gs for suppression activities will assist the Forest Service in fully meeting the original purpose of the NWFP, including conserving and mitigating impacts to mature and old-growth ecosystems, NSO and other species habitats, and riparian areas.

d. Biological Resources – Ecological Integrity and Habitat Protection

i. Standards and Guidelines to Protect the Ecological Integrity of Forests

The Forest Service should establish new forest plan S&Gs that protect the ecological integrity of the forest, including key wildlife habitat, under all management scenarios.[31] For example, the Forest Service should

[31] 36 C.F.R. § 219.9(a)(1)

develop and adopt a standard that protects all large (≥20 inches DBH), mature, and old growth trees. Large trees, regardless of species and age, provide critical wildlife habitat (both alive and dead), store the majority of forest carbon, are in a deficit east of the Cascades, and are generally the most fire-resistant trees on the landscape. Logging large trees as part of risk reduction efforts conflicts with the purpose of the original NWFP, exacerbates large tree structure scarcity problems, and provides little if any benefit to reducing the risk of large-scale disturbance events. Further, protecting large trees will reduce the controversy and contentious tradeoffs that surround large tree logging, thus streamlining silviculture prescriptions for LSR stands and improving the public's trust in the Forest Service.

Protecting large trees, landscape heterogeneity, and broader ecosystem integrity will require S&Gs that support the total ecological and cultural function of a landscape, rather than simply its silvicultural composition. While certain place-specific assessments and management approaches are appropriately left to the project level, landscape-scale analysis is still critical to guiding decisions at the National Forest or Ranger District level.

ii. Failure to Assess Aquatic and Riparian Impacts

LandWatch supports leaving the Aquatic Conservation Strategy ("ACS") intact as part of this Amendment process, and the Forest Service should ensure the ACS remains unchanged in the FEIS. However, a lack of change to the ACS direction and approach does not mean that the DEIS alternatives will not have impacts on aquatic and riparian ecosystems. The DEIS improperly dismisses impacts to aquatic and riparian resources from consideration under the premise that "impacts to water resources would not be expected to change under the Proposed Action and action alternatives because the proposed amendment does not modify the framework of the ACS" (DEIS at 1-12). This is flawed, unsubstantiated, and circular reasoning; effectively, the Forest Service claims that because the ACS Standards and Guidelines will remain in place, there cannot be meaningful effects on aquatic and riparian areas. Yet, the proposed action will explicitly increase logging in riparian reserves ("RRs"), and the proposed one million additional annual acres of logging activity will require road construction and maintenance likely to contribute to increased erosion, sedimentation, and other riparian impacts. Furthermore, the DEIS explicitly admits the possibility of impacts to aquatic species in its inclusion of 11 federally listed fish species "potentially affected by the Proposed Amendment Action or Action Alternatives," including multiple culturally important anadromous fish and sucker species (DEIS at 3-54 to 3-55). In relying on faulty logic and neglecting to disclose and consider the impacts of heavier logging in RRs, the Forest Service has failed to take a hard look at the reasonably foreseeable effects of the proposed actions on aquatic and riparian habitats and resources.

Although the DEIS fails to analyze potential impacts to listed fish and other aquatic species, the likely effects of management approaches such as removing large, old trees in RRs are distinct and well-understood. Large trees are integral to a variety of crucial aquatic and riparian ecosystem functions and processes—both as standing trees and downed wood (large woody debris)—such as helping to store sediments and nutrients, shaping channel morphology and instream habitats, supporting groundwater flows, and shading streams (Beschta et al., 1987; Bilby & Ward, 1991; Frissell et al., 2014; Pollock & Beechie, 2014). Removal of large riparian trees under the Amendment will trigger foreseeable adverse effects—both

direct and indirect—to threatened and endangered aquatic species and their habitat, including (but not limited to): Deficits of large woody debris and pool frequency; increases in stream temperature, peak flows, and sediment delivery; decreases in base flows; and reductions in habitat complexity. See the attached expert reports from fisheries biologist Amy Stuart and hydrologist Jonathan Rhodes for additional documentation of the importance of protecting aquatic and riparian systems in forests east of the Cascades.

The Forest Service must disclose and consider riparian and aquatic impacts of the proposed action and alternatives and must adopt an alternative that prevents further degradation of ESA-listed species habitats.

iii. Northern Spotted Owl Dispersal, Nesting, Roosting, and Foraging Habitat

Protecting NSO dispersal habitat is an essential management consideration east of the Cascades, especially as climate change and drought place additional stressors on wildlife species, shifting habitats and forcing species to adapt to survive (Buchanan, 2004). As of 2025, the plight of the NSO is urgent: forest losses and barred owl invasions have caused NSO populations to continue declining, prompting the US Fish and Wildlife Service ("USFWS") to recommend that NSO ESA listing status be changed from "threatened" to "endangered" (Davis et al., 2022).

NSO dispersal habitat is essential in supporting the transience and colonization phases of dispersal, which includes nesting, roosting, and foraging habitat ("NRF"). As research has found, "juveniles strongly select for old forest with closed canopy (>70 percent canopy cover) and large-diameter trees (>20 inch DBH), which are similar forest conditions selected by adult spotted owls for nesting and roosting" (Lesmeister et al., 2018). The same study found that canopy cover of 40% or less is "unlikely to be sufficient to facilitate juvenile movements on the landscape…Stands managed for dispersing spotted owls should be at least 80 percent canopy cover and have large average tree diameter" (Lesmeister et al., 2018). USFWS data collected to complete the 2011 NSO recovery plan further supports these statements, finding that "availability of suitable forest cover was critical for territory acquisition and sustained occupancy by spotted owls," and essential to NSO dispersal and survival (Lesmeister et al., 2018).

Logging one third of all dry forests in the NWFP area within 15 years of Amendment approval would have significant impacts on NSO habitats and raise concerns for dispersing wildlife in the face of climate change. While the acreage targets are framed as measures to improve forest resistance and resilience to fire, and to retain old trees, those outcomes are uncertain, whereas the scale of proposed treatments will directly impact the resilience of NSO by substantially changing habitat conditions.

Despite likely devastating NSO habitat, the proposed large-scale logging in the DEIS is also unlikely to prevent or mitigate fire severity and impacts during the period where fuels on the landscape remain reduced. Research by Baker and Rhodes (2008) demonstrated that the probability of high severity and high-moderate severity fires affecting treated areas in their window of effectiveness was very low, concluding that in "92-98% of treated areas, fuel treatment impacts on watershed processes are not likely to be counterbalanced by a reduction in higher-severity fire" (Baker & Rhodes, 2008). A 28-year study on NSO dispersal also found that while nesting habitat has been lost due to wildfire, very little loss of forest due to wildfire has

actually occurred in the dispersal areas studied (Jenkins et al., 2019).

Dispersal habitat on federal lands has seen a 1% increase since the NWFP was adopted (DEIS at 3-74), but the Forest Service fails to take a hard look at how fuels treatments in dry forests would impact dispersal habitat. The DEIS cites no studies or monitoring reports from projects east of the Cascades—where fuels treatments have specifically been implemented to address the perceived threat of fire—that could provide insights into the implications of the proposed actions on dispersal habitat and, by extension, the ability of species to move and adapt to changing climatic conditions. The DEIS also fails to consider that NSO may be using dry forests more frequently than previously understood, largely due to the threat of barred owls, which are less likely to use dry forests. The level of uncertainty and lack of supporting information on NSO habitat in the DEIS fails to support an informed process, and the Forest Service must account for the best available science on trends in NSO dispersal in the FEIS.

The DEIS states that the Amendment process is "driven by evolving ecological understanding and the need for the Forest Service to adapt their management strategies to current and future challenges" (DEIS at ES-2). To meet future challenges, including changing habitat conditions, wildlife must be able to move and disperse. Yet, the Forest Service fails to analyze any alternative that substantially increases dispersal habitat for NSO or other wildlife species.

iv. Failure to Analyze the Impact of Roads

The DEIS includes roads on the list of "Other Resources Considered or Dismissed," despite acknowledging:

> It is possible that the forest road networks could be affected by project/treatment-specific actions authorized by the proposed amendment. Potential effects to this resource may include the creation of new roads for logging, impacts to existing roads due to management activities, or construction or alteration of forest roads due to forest thinning or prescribed burns. (DEIS at 1-12)

The DEIS then dismisses this as an issue for consideration because "the scope, extent, and location of these effects cannot be determined at this time, and a project/treatment specific evaluation would be required for impacts to individual roads or road networks" (DEIS at 1-12).

The DEIS further goes on to say that:

> [t]he proposed NWFP amendment does not authorize or make any project-level decisions; therefore, the extent and location of project-specific ground-based disturbances (e.g., restoration treatments, prescribed burning, cultural burning, timber harvest, and road construction/reconstruction activities) are not known, nor is it possible to obtain this information at this time. (DEIS at 1-14)

Despite this explanation about why such information cannot be obtained, the DEIS repeatedly discusses restoration treatments, prescribed burning, cultural burning, and timber harvest within the scope of its proposed activities and Alternatives—all of which it acknowledges would require road construction—but

roads themselves remain absent from the analysis.

Extending the logic of excluding roads from the DEIS analysis, any projected timber targets or analyses of resource impacts in the NWFP planning area should have been dropped from consideration due to inability to determine "scope, extent, and location." If treatment acreage targets can be set in the NWFP amendment, there should be some ability to estimate additional road needs, associated potential habitat impacts, and long-term roadway restoration and decommissioning processes.

Road construction and maintenance are connected actions and must be analyzed in the EIS. As discussed previously in this comment, the Forest Service has failed to adequately address connected actions. Here, in order for the Forest Service to proceed with projects to meet the proposed dry forest logging targets outlined under the preferred alternative—logging 790,000 to 964,000 acres every 15 years, not including acres of salvage logging—the Forest Service will first need to conduct road maintenance and construction activities to facilitate logging access. Since increased logging targets and increased road construction and maintenance are necessarily connected, the Forest Service must analyze and disclose the extent, density, and impacts of anticipated road construction under the various alternatives. In particular, the new age thresholds and treatment acreage targets indicate substantially more roads would be necessary in LSR—a reasonably foreseeable effect which the Forest Service fails to address.

The biological impacts of roads are well documented. For example, additional sediment loads in streams over extended periods of time from timber harvest and roads have been known for decades. Bjornn and Reiser (1991) summarized that:

> Sedimentation affects fish habitat quality by increasing fines which embed gravels and substrates. Embedded gravels reduce spawning habitat by making gravel difficult to lift, reduces dissolved oxygen to incubating eggs, and covers rearing fish. Turbidity affects fish production by reducing production of aquatic insects and plankton, and foraging efficiency of fish. Sediment fills interstitial spaces between rocks in the substrate, reduces habitable area in streams, and when it exceeds 20 percent of the total area on the substrate, can smother fish and frog eggs and increase mortality.

May and Lee (2004) found that "increases in coarse sediment supply can be associated with sharp reductions in salmonid habitat and productivity" and reported that streams with discontinuous flow caused by sediment increases reduced survival by crowding fish into smaller areas with reduced food availability. The additional bedload of both fine sediments and coarser sediment delivered to streams fills in the channel, decreasing pool depth, channel complexity, and changing the channel profile to a shallow, wide profile.

Recent research by Kampf et al. (2021) on intermittent and ephemeral streams indicates that these nonperennial streams drain almost 60% of forested lands and are the primary connectors with aquatic systems. The authors stated that "land uses that modify flow regimes in these streams can affect sediment and organic matter transport and distribution, stream temperature dynamics, and biogeochemical processing" (Kampf et al., 2021). Even selective logging increases fine sediments along with increased water temperatures and these changes in habitat quality are found decades after logging activities have

ceased (Guenther et al., 2014; Kreutzweiser et al., 2005; Miserendino & Masi, 2010).

Upland impacts of roads are well known, too. For example, negative effects of motor vehicle use and roads on wildlife include wildlife mortality, decreased reproductive success, direct and indirect loss of habitat, displacement, and reduced habitat connectivity. These negative impacts are the result of a series of factors, including access for predators and people, fragmentation of habitat patches, behavioral changes in response to human use, increased noise, and physical alteration of habitat. Further, motorized use of roads and routes substantially increases movement rates of wildlife, causing a series of cascading effects including higher stress levels, increased energetic costs, and reduced productivity.

The Forest Service must analyze the impacts of road construction activities as part of the same NEPA, including establishing an accurate baseline of the existing road network within the NWFP area.

v. Exemptions from Survey and Manage Requirements in Alternative D

Eliminating Survey and Manage requirements for "hazardous fuel reduction treatments" within 0.25 miles of communities, as proposed in Alternative D, is arbitrary and antithetical to the purposes of the NWFP (DEIS at 3-81 to 3-82). The DEIS fails to clarify what constitutes a "community" for purposes of hazardous fuels reduction treatments and does not justify the selection of a 0.25-mile buffer. The only reasoning for this set of exemptions seems to be fast-tracking fuels removal, but with no justification as to why this would require an exemption from Survey and Manage requirements, nor how such an exemption would improve community wildfire safety. Under no circumstances should the Forest Service adopt an alternative that would decrease species protection, particularly with no evidence that this approach would increase community safety.

e. Climate Change and Carbon Storage

A need to incorporate considerations around climate change, ecological integrity, and carbon purportedly drove this Amendment process. However, the DEIS neither meaningfully analyzes how the proposed action would impact climate adaptation and carbon storage, nor how the proposed Amendment alternatives would interact with current and anticipated social, ecological, cultural, and economic impacts of climate change. NEPA calls on agencies to "fulfill the responsibilities of each generation as trustee of the environment for succeeding generations,"[32] and the Forest Service has blatantly failed to do so in this DEIS.

i. Climate Adaptation

It is incumbent upon the Forest Service to disclose and consider the climate implications of its management decisions within the Amendment, yet the DEIS contains almost no information on climate change adaptation in NWFP forests. To support an informed process, the DEIS should have incorporated the best available, regionally relevant research, such as the biannually-updated Oregon Climate Assessments[33] and

[32] 42 U.S.C. § 4331(b)(1)
[33] Oregon Climate Change Research Institute released the 7th Oregon Climate Assessment on January 8, 2025.

equivalents from Washington and California as baseline data on climate impacts and adaptation.

Climate change projections—and their implications for adaptation and adaptive management—should be central to any adopted alternative. Only Alternative D explicitly calls for analysis of projected climate impacts on vegetation, but this type of consideration should be present in any adopted alternative in conjunction with the best available science on ecological forest stewardship (DEIS at 2-12). Further, to ensure Tribal inclusion and co-stewardship, the Forest Service must incorporate components from Tribal climate adaptation plans into its FEIS.[34]

ii. Carbon Storage

To the extent that carbon stocks matter to the NWFP Amendment *per se* in the context of climate change, it is as a form of mitigation, with National Forests providing substantial aboveground and belowground carbon sinks. Instead of emphasizing the important role of forest carbon—particularly in mature and old-growth forests—as a climate mitigation strategy, the DEIS offers a faulty and cherry-picked analysis of carbon stocks and storage that over-emphasizes the role of wildfire in forest carbon emissions and uses the concept of "carbon stability" in confusing and irrelevant ways (see DEIS at 3-86 to 3-93).

The over-emphasis on wildfire-induced carbon emissions also omits any comparative analysis between fire-based emissions and carbon storage losses from logging large, old trees. This is a critical omission; since before the development of the 1994 NWFP, research has demonstrated that harvesting old-growth trees and converting forests to be younger and faster-growing will *not* result in decreased atmospheric CO2. Instead, post-logging forest carbon storage is greatly reduced and does not return to old-growth capacity for at least 200 years. This is true even when accounting for ongoing storage in timber products (Harmon et al., 1990). In eastside forests, retention of the largest, oldest trees is especially critical for carbon storage. East of the Cascades, only 3% of remaining trees are considered large (≥21" DBH), but these trees store 42% of aboveground forest carbon (Mildrexler et al., 2020). Larger, older trees in dry forests are also the most fire resistant and resilient.

Given the body of research on fire resilience and carbon storage in dry forests and forests east of the Cascades, it is particularly imperative to protect mature and old-growth trees in both dry forest matrix and LSR. The replacement of the risk-reduction guideline and the increase in harvest age thresholds are in direct conflict with the Amendment's stated goals of enhancing fire and climate resilience. Alternative proposals, such as creating reserves to protect forest carbon and reduce biodiversity loss, should have been considered alongside other carbon factors in the DEIS (Law et al., 2022). Without improved analysis and a more expansive view of forests' roles in both climate adaptation and mitigation, the Amendment will fail to meaningfully incorporate climate change considerations.

[34] The Tribal Climate Change Project maintains a Tribal Climate Change Guide that includes Tribal Climate Adaptation Plans from across the United States, including the Northwest.

V. EFFECTIVENESS MONITORING

Effectiveness monitoring has been part of the NWFP since its inception, under the premise that "[i]nformation gained through monitoring, research, and other sources of information provide a basis for adaptive management and decision-making based on best available scientific information (DEIS at 2-25). This Amendment should therefore update monitoring systems to better reflect the best available science on climate change, fire, habitat connectivity, and old growth forests. Updating these monitoring systems must also incorporate Indigenous knowledge and perspectives to fully inform both ecological and cultural outcomes of management decisions. Fundamentally, quality monitoring is key to adaptive management, which should be central to forest management in the context of climate change.

The Forest Service should consider and adopt new forest plan standards that require effectiveness monitoring for a percentage of all treated stands within a watershed to better understand the outcomes of management. For example, the Forest Service should adopt a standard that requires 15-20% of all treated stands within a watershed to be monitored for the duration of the plan, which could in turn inform adaptive management strategies for future treatment approaches. In addition, effectiveness monitoring should be triggered when a fire occurs within a watershed. Effectiveness monitoring is paramount to assessing whether treatments are attaining project goals, especially as it relates to wildlife habitat and risk reduction. An effectiveness monitoring program must be carefully developed and include a defined framework, with clear process for establishing a monitoring plan, implementation, and inter-disciplinary team review.

As part of an effectiveness monitoring program, the Forest Service must consider and specify how it will sustain monitoring efforts through time, including how efforts will be staffed and funded. The Forest Service should also consider what role local groups can play in assisting in effectiveness monitoring efforts. Harnessing Indigenous and local knowledge based on long-term observations and experiences, including community-based monitoring, can assist the Forest Service in achieving monitoring and adaptive management goals (Keenan, 2015). Tapping local knowledge can also improve agency relationships with the public and provide sustained institutional knowledge for an agency that sees high staff turnover at the forest level. This is especially important now, as the Forest Service is conducting mass firings and significantly impacting the ability of the agency to meet is Forest Plan obligations. The original NWFP was heavy on the promise of monitoring but often failed to deliver in practice. In amending the NWFP, the agency is obligated to recalibrate its monitoring goals and provide the necessary support to follow through.

VI. CONCLUSION

Amending the 1994 NWFP is necessary for the Forest Service to demonstrate its commitment to Tribal inclusion, ecologically sound wildfire management, and adaptive management practices in the context of a rapidly warming climate. We urge the Forest Service to use this opportunity to elevate non-timber interests to holistically manage the 17 NWFP National Forests for the benefit of present and future generations.

Further, Amending the NWFP provides the Forest Service an opportunity to improve public trust and transparency in how our National Forests are managed. The recent trend of transitioning from standards to

guidelines has caused significant concern and increased uncertainty around forest management outcomes, eroding public trust in the Forest Service as an institution. The DEIS largely continues this trend away from standards—and even, in several alternatives, from guidelines—toward ever-greater forest-level discretion. Maintaining and building upon standards, especially for wildlife and ecological integrity, is vital for ensuring transparency around intended project outcomes and management actions. Forest plan standards are a cornerstone to public trust with the Forest Service; further eroding standards will only lead to more conflict and increased public mistrust of the agency.

Thirty years after the NWFP's initial adoption, and in a time of great ecological and social uncertainty, it is time for the Forest Service to update its management approach in the Pacific Northwest to fulfill its responsibilities to the people and species of the region. We urge the Forest Service to adopt a NWFP Amendment that prioritizes Tribal inclusion, supports ecological integrity, protects habitat quality and connectivity, and integrates beneficial fire use at scale.

Thank you for considering these comments. Please retain Central Oregon LandWatch on your list of interested public for this project.

Sincerely,

BEAUTY, BOUNTY, AND BIODIVERSITY: THE STORY OF CALIFORNIA INDIANS' RELATIONSHIP WITH EDIBLE NATIVE GEOPHYTES

by M. Kat Anderson and Frank K. Lake

California supported a great diversity of plants with edible underground storage organs available to Indian tribes. Together, plant foods, fish and meat made up an indigenous diet that was well-rounded, diverse, and relatively secure. The edible underground parts possessed by these plants are classified as bulbs, corms, taproots, tubers and rhizomes, and when conditions turn unfavorable (too cold or too dry), the above-ground stems die back and the underground organs remain alive. Botanists and ecologists call the plants that employ this strategy *geophytes*. Indians often call them Indian potatoes or "root foods" because they are hidden under the ground. Geophytes were an important source of food for indigenous people throughout California.

STAPLE FOOD CROP

In pre-contact California there were dozens of species of geophytes gathered for their edible underground storage organs in multiple plant communities from the salt marshes, to the deserts, to chaparral, to the open understories of coniferous forests and oak woodlands. For example: the Ohlone dug the bulbs of harebell (*Campanula prenanthoides*) in winter and early spring for food in the vicinity of tan oaks; the Wailaki and Pomo harvested the bulbs of the fawn lily (*Erythronium oregonum*) in the openings amongst interior live oaks; and the Kashaya Pomo unearthed the tubers of elegant piperia (*Piperia elegans*) in dry areas between California black oaks. Some of the most important genera gathered by many

TOP: Raw camas (*Camassia* sp.) bulbs and brodiaea (*Brodiaea* and *Triteleia* spp.) corms on a bed of Pacific big leaf maple leaves prior to baking them in an earth oven. Photograph by Frank K. Lake, 2005. • BOTTOM LEFT: A bounty of camas (*Camassia quamash* subsp. *breviflora*) for food. Photograph by Heron Brae, 2012. The camas bulb, found several inches below the earth's surface, is about the size of a large hazelnut, but can grow as large as a walnut. Camas (*C. leichtlinii* subsp. *suksdorfii* and *C. quamash* subsp. *breviflora*) produces few offsets, but Native people note that when dug repeatedly and encouraged, they tend to divide. • BOTTOM RIGHT: Cooked camas (*Camassia* sp.) bulbs and brodiaea (*Brodiaea* and *Triteleia* spp.) corms wrapped in a bed of Pacific big leaf maple leaves after baking them in an earth oven. tribes include *Allium*, *Brodiaea, Camassia, Chlorogalum, Calochortus, Dichelostemma, Lilium, Lomatium, Perideridia, Sanicula,* and *Triteleia.*

Indian potatoes were not only diverse, but also provided a variety of tastes to please the palate from slightly bitter, to mildly nutty, to sweet. They were eaten raw, boiled, baked, or steamed and then mashed, made into cakes similar to a frittata, bread or biscuits. Many of these geophytes were stored in their raw state in great quantities for later cooking and consumption or stored after baking, roasting and/or drying them.

The use of geophytes as part of the regular human diet in California

They will be combined with dried huckleberries and pine nut flour to make pinch cakes. Photograph by Heron Brae, 2013.

TOP: Columbia lily (*Lilium columbianum*) and other lilies have bulb scales which readily separate and scatter in the digging process. The bulbs of this species and at least three other lilies were eaten by California Indian tribes including leopard lily (*L. pardalinum*), alpine lily (*L. parvum*), and Washington lily (*L. washingtonianum*). • BOTTOM: The larger bulbs of checker lily (*Fritillaria affinis*) were roasted in ashes or baked in earth ovens, and mashed and made into cakes by various tribes. It has numerous rice-grain bulblets that scatter when dug. At least three other fritillarias were gathered for food: brown bells (*F. micrantha*), yellow fritillary (*F. pudica*), and scarlet fritillary (*F. recurva*). Photographs by Fred Sharpe, 2007.

is very old. The archeological record shows that geophyte harvesting is at least 10,000 years old on the Channel Islands and that bulbs, corms, and tubers were more or less harvested in most if not all regions of the state during the last several thousand years. This storage organ had its own month in many tribal calendars, denoting a predictable, renewable food source. For example, one of the 12 moons of the Central Pomo year *Putitcda* (our May) meant "edible bulbs ripening." These storage organs also have high nutritional value, containing significant amounts of fiber, and complex carbohydrates.

Before the substantial ecological changes brought by European settlement, many of the geophytes of California had all of the attributes of a staple food crop: they were abundant, widespread, storable, intensifiable, and nourishing. As little as 200 years ago, many areas in California were clothed in geophyte flowers during the spring and summer—purple patches of blue dicks, orange swaths of tiger lily, yellow carpets of common goldenstars, and snowy areas of wild carrots. Early reports suggest that wildflowers with storage organs were much more prevalent historically and gathered in prodigious amounts. As will be discussed, the abundance of edible geophyte populations observed in certain areas around the time of contact (circa AD 1840–1850s) may have been due, in part, to human management of the plants and their habitats.

THE HARVEST

Gathering the edible parts of geophytes, hidden below the surface of the soil, required extraction with a digging stick sharpened to a point. While digging time spanned the whole year, May to late October was the peak season. Harvesting different genera of geophytes differed by tribe and area. For example, among the Karuk, of northwestern California, *Brodiaea*, *Calochortus*, *Dichelostemma*, and *Triteleia* were dug in the spring to summer and *Lilium* species in the fall. Traditional gathering sites were visited annually, and areas were specifically owned and maintained by particular families and passed down intergenerationally.

Despite relatively intensive, annual gathering, populations of geophytes remained robust. This was due in part to the gatherers' awareness of harvesting methods and how they affected the plant's regeneration and the overall health of the habitat. Always thinking about the harvest into the future, tribes made sure that the harvest would help increase future yields.

When indigenous people harvested geophytes, they did more than just retrieve the largest storage organs for consumption. They replanted the smaller bulblets, cormlets, tuber fragments, and bulb scales; they tilled the soil to facilitate the growth of the new plants; weeded non-desired plants; and they scattered the seeds contained within the dried seed pods to enhance reproduction. A grassland or coastal prairie subject to this kind of management might not show overt signs of human manipulation, but the valued foods would likely have broader distributions and higher population numbers than would be the case in the absence of any tribal manage-

UPPER LEFT: Blue dicks has dozens of different names in Indian languages and was probably the most widely eaten geophyte in California. The corms are eaten raw, boiled, or roasted in ashes. Photograph by M. Kat Anderson, 1988. • LOWER LEFT: A single blue dicks plant can produce a large number of both corms and cormlets. This and other underground swollen stems were eaten in great quantity and gathered at the same sites year after year by employing harvesting and management strategies designed to benefit populations and ensure their continuation. One of these techniques was to replant the cormlets after digging, while another is described by Mono elder Melba Beecher to ensure re-seeding: "The bulb [*Dichelostemma capitatum*] is harvested in late summer or early fall when the blooms are gone." Photograph by Kat Anderson, 1992. • RIGHT: Ross Stone, Big Pine Paiute, gathering *nahavita*, also known as blue dicks (*D. capitatum*) corms, a favorite traditional Paiute food on the east side of the Sierra Nevada. Photograph by Bill Helmer, 2005. All of the four other *Dichelostemma* spp. were also dug and eaten by California Indian tribes including fork-toothed ookow (*D. congestum*), firecracker flower (*D. ida-maia*), wild hyacinth (*D. multiflorum*), and twining brodiaea (*D. volubile*).

ment. Many tribal harvesters learned from, or emulated the digging-related disturbances of wildlife, such as gophers or bears.

The harvest of geophytes could be coupled closely with propagation because of the nature of their reproductive adaptations. Evolving in environments in which drought, fire, and herbivory were common, geophytes all developed clonal structures—offsets or propagules in the form of scales, bulbils, bulblets, or cormlets—which if severed or otherwise separated from the parent structure could grow into genetically identical plants. With these adaptations, disturbances, especially herbivory, that might threaten the existence of the parent plant were also likely to separate and disperse

the propagules—thus ensuring the continuation of the genome. In feasting upon these highly nutritious foods, gophers, voles, moles, bears, deer, or elk would simultaneously be acting as predators and dispersers. Native people who exploited geophytes as food were taking advantage of the pre-existing adaptations that made most geophytes excellent subjects for food intensification strategies.

Aerated and loosened with digging sticks, the soil had a higher moisture-holding capacity and became a better environment for seed germination and propagule growth. Native people also managed plant density, preferentially harvesting the densest patches to keep the plants from getting too clumped and thus maximizing production. Perhaps, most importantly, indigenous people made conscious decisions about what to harvest and what to leave behind, based on accumulated knowledge about the plants' reproduction and adaptive traits. In the case of blue dicks, for example, Leah Harper, Nor-Rel-Muk (pers. comm. 2003) explained how she harvested the largest organs and left in the soil the immature ones: "Grandma told us how to take the big bulb and leave the babies. And put them back in."

Ruby Pomona, North Fork Mono, with the edible *tana* or turkey pea (*Sanicula tuberosa*) dug in open black oak and ponderosa pine stands in Sierra National Forest. According to Ruby (pers. comm. 1989), *tana*, as well as a brodiaea with a purple flower, and wild carrot (*Perideridia* spp.), "came up better after a burn." The small tuber was gathered widely by the Mono, Nisenan, Pomo, Salinan, Sierra Miwuk, and Wailaki and it is still relished today and generally eaten raw. Already by 1932, Salinan consultants, Maria and David Mora, relayed to interviewer John P. Harrington that *tr'ôtêmák* (*Sanicula tuberosa*) is "scarce now." Photograph by M. Kat Anderson, 2006. At least two other sanicles were dug for their edible tubers, sharptooth blacksnakeroot (*S. arguta*) and poison sanicle (*S. bipinnata*).

Human geophyte harvesters could also benefit the plants' sexual reproduction by properly timing the harvest. When dug after seeds had matured, this process could facilitate dispersal of the seeds, which were more likely to find safe germination sites in tilled soil. It was a common practice to take this facilitation a step further by placing broken stems with seed pods into the holes before covering them. Undesirable plants were also weeded out to favor geophytes at many gathering sites—thus reducing competition and increasing site productivity.

Through observation and experimentation, Native Americans in California learned a great deal about the ecological requirements of the edible geophytes. The most important conclusion they came to was that fire was good for many of the "root foods," which included checker lilies, leopard lilies, sanicles, and wild carrots, among others. By burning geophyte habitats, Indians could maintain the sunny environments that most required, eliminate competition, reduce accumulated leaf litter and duff, that could block or hinder their emergence each year, and thus enhance reproduction. The results were manifested at both the individual and population levels: individual plants grew more vigorously, producing larger or more numerous underground storage organs, and populations were enlarged rela-

tive to what would have been the case without fire.

In the historical and ethnographic record there are accounts of Indians burning to enhance the geophyte harvest. For example, anthropologist J.W. Duncan equated the Maidu burning of oak areas with motive of fostering more bulbs and greens. Linguist Alice Shepherd (1989:411) recorded for the Wintu: "Where the ground has been burned, wild potatoes grow in bunches and ripen big...They go to find things there." Today Native elders equate productive bulb collection areas with deliberate burning or wildfires.

Because of their underground storage organs, geophytes are well adapted to withstand the effects of fire. Growing deep in soil, the bulbs, corms, and rhizomes are protected and insulated from the heat. Fire benefits geophytes in a number of ways, and are actually dependent on its regular occurrence.

One hypothesis is that for some geophyte species, fire confers its beneficial effects directly to the plants through heat. Their underground storage organs have contractile roots, and thus can pull themselves down deeper in the soil when stimulated by the heat of a fire. When this happens, the scales, bulblets, or cormlets attached to the main "mother" organ are stripped off. While attached, the growth of these clones is suppressed; when separated, they grow into new plants. In this direct way, therefore, fire promotes asexual reproduction and enlargement of population sizes. Geophytes receive

most of the benefits of fire indirectly, however, through fire's effects on the environment or habitat in which they live. Thick layers of leaf litter and duff can inhibit or even prevent geophyte growth. The bulbs remain alive in the soil, but the accumulated dead biomass blocks the heat and light that would stimulate growth, and may even act as a physical barrier for sprouting. In overgrown areas, bulbs can sit in the soil bank for decades without growing. After the leaf litter and other biomass covering the soil are eliminated by fire, however, the plants are able to push through the blackened earth.

When fire reduces duff and litter, the sun can warm the soil thoroughly where the warming effect may increase by the light-absorbing black color of the carbon that results from burning. Such warming is necessary for both vegetative growth and flower bud differentiation, and it also provides the sequence of cold–warm–cold temperatures that most edible geophytes in California need for good bulb development. Warmer soil temperatures in the spring promote more flower buds, and this means more dry fruits with seeds that can grow into new plants. Fire's cleansing properties, are therefore, a mechanism which promotes larger and denser geophyte patches.

Fire also impacts geophytes through its effects on the soil. Burning releases a flush of nutrients, but Indian burning may also have changed the soil's texture or physical properties in ways that benefited geophyte growth and/or facilitated harvest by humans. The bi-product of burning woody material results in the production of charcoal or "biochar" that serves to increase soil porosity, nutrient retention and moisture holding capacity in addition to increasing soil texture complexity. Today, the traditional beneficial uses of biochar are being investigated and technologically developed for modern garden and agricultural uses.

Probably the most important effect of fire on geophytes is to maintain (or increase) the size of the areas in which the environmental conditions are suitable for geophyte

growth. To a great extent, this means simply eliminating or suppressing the growth of plants that compete with geophytes for light. Most edible geophytes require full or partial exposure to the sun to grow and reproduce properly. The flowering and bulbing of wild onions (*Allium* spp.) and wild lilies (*Lilium* spp.), for example, are greatly affected by how much light they receive. In the lily family, low light intensities usually result in flower abortion. The high light requirements of most geophytes are a primary reason for their occurrence in open habitats. When trees or brush encroach on open lands and create unfavorable shaded conditions, camas (*Camassia* spp.), leopard lily (*Lilium pardalinum*), wild onions, and other geophytes remain as a corm and bulb bank in the soil, their growth suppressed. With fire, plants are released from the shaded environments, and grow and flower vigorously. Flowering greatly benefited insects and other pollinators. Botanist Mark Skinner (pers. comm. 2007) said: "Burning definitely encourages (the growth of) many North American *Lilium* taxa. Some are adapted to frequent fires (*L. pyrophilum, L. iridollae, L. catesbaei*), some proliferate after fires (*L. washingtonianum*). I'm sure it's nutrient availability to some degree, but mostly it's light availability that drives that phenomenon."

CONCLUSIONS

Tribal gathering secured huge quantities of subterranean plant parts by revisiting the same traditional gathering sites. Tribal harvesting and management strategies were designed to benefit populations and ensure their continuation with ecological consequences for species, populations, and plant communities. The Native gathering and management systems have been in place long enough to influence what constituted fitness for evolving geophyte species. Over the last two centuries, there has been a general decline in geophyte populations, and today there are numerous rare and endangered geophyte taxa in California; this decline may be tied not only to habitat loss and fragmentation, but also to the termination of the former indigenous disturbance and management regimes under which the geophytes most recently evolved.

While few indigenous people gather or manage root foods today, this is changing. Tribes are renewing their gathering rights and practices, forming new collaborations with land management entities, setting up ethnobotanical gardens, creating their own land trusts, restoring digging, and returning fire to their reservations, rancherias, and other traditional lands. Many tribes are incorporating food security interests with landscape restoration strategies. An example is thinning of dense trees and shrubs and prescribed burning to meet the dual objectives of hazardous fuels reduction and the re-establishment of edible geophytes aligned with broader tribal resource objectives. These efforts are helping to restore the beauty, bounty, and biodiversity of California landscapes.

Fire Probability, Fuel Treatment Effectiveness and Ecological Tradeoffs in Western U.S. Public Forests

Jonathan J. Rhodes[1] and William L. Baker[*,2]

[1]*Planeto Azul Hydrology, PO Box 15286, Portland, Oregon 97293, USA*

Abstract: Fuel treatment effectiveness and non-treatment risks can be estimated from the probability of fire occurrence. Using extensive fire records for western US Forest Service lands, we estimate fuel treatments have a mean probability of 2.0-7.9% of encountering moderate- or high-severity fire during an assumed 20-year period of reduced fuels.

INTRODUCTION

Fuel treatments to reduce fire impacts have been promoted as a public forest restoration priority by policy [1] and the Healthy Forests Restoration Act of 2003. It is difficult to generalize about the effectiveness of fuel treatments under all conditions [2, 3], but treatments are not universally effective when fire affects treated areas [4]. Factors influencing effectiveness include forest type, fire weather [4], and treatment method [5].

However, treatments cannot reduce fire severity and consequent impacts, if fire does not affect treated areas while fuels are reduced. Fuels rebound after treatment, eventually negating treatment effects [3, 6]. Therefore, the necessary, but not sufficient, condition for fuel treatment effectiveness is that a fire affects a treated area while the fuels that contribute to high-severity fire have been reduced. Thus, fire occurrence within the window of effective fuel reduction exerts an overarching control on the probability of fuel treatment effectiveness. The probability of this confluence of events can be estimated from fire records. Although this probability has not been rigorously analyzed, it has often been assumed to be high [7].

The probability of future fire occurrence also abets assessing the ecological risks incurred if fuels are not treated. Therefore, analysis of the likelihood of fire is central to estimating likely risks, costs and benefits incurred with the treatment or non-treatment of fuels.

Assessing fire occurrence and its effect on fuel treatment effectiveness also has merit because treatments can incur ecological costs, including negative impacts on aquatic systems [8], soils [7], and invasion by non-native plants [9, 10]. Here, we use watershed and aquatic systems as a specific context for evaluating tradeoffs involved with treatment and non-treatment of fuels on western public lands. However, the analysis applies to upland ecosystems as well.

The effects of fire on watersheds and native fish vary with several biophysical factors, including watershed and habitat conditions, the condition of affected populations, and fire severity and extent [11]. If treatments reduce the watershed impacts of severe fire, they may provide benefits that outweigh treatment impacts because high-severity fire can sometimes trigger short-term, severe erosion and runoff [12] that can negatively affect soils, water quality, and aquatic populations. However, fuel treatments can also have impacts on aquatic systems. The magnitude and persistence of these treatment impacts vary with treatment methods, location, extent and frequency.

Although some fuel-treatment methods could have lower impacts, ground-based mechanical treatments are often employed because other methods generate activity fuels [7] and are more costly. Ground-based methods and associated machine piling, burning of activity fuels, construction and increased use of roads and landings can increase soil erosion, compact soils, and elevate surface runoff [8, 13, 14]. Although the effects of prescribed fire on watersheds are typically limited and fleeting, it can increase soil erosion and sediment delivery, sometimes significantly and persistently [15], especially if fires escape and burn larger and more severely than planned.

When impacts are extensive, proximate to streams, or in terrain with erosion hazards, treatments can increase runoff and sediment delivery to streams. Road activities that increase sediment production, such as elevated road traffic, often affect stream crossings where sediment delivery is typically efficient and difficult to control [16]. Elevated sediment delivery to streams contributes to water quality degradation that impairs aquatic ecosystems [17].

The extent and frequency of treatments may be significant. Stephens and Ruth [18] suggested treating fuels on 9.4 million ha, or ~53% of USFS lands in the Pacific Northwest and California. Agee and Skinner [7] suggested repeating treatments every 10-20 years, due to transient effects on fuels.

Repeated treatments increase the potential for cumulative effects on aquatic ecosystems due to the persistence and additive nature of watershed impacts over time [19] and may increase the establishment of non-native plants [9]. The chronic watershed impacts from repeated treatments may be more deleterious to native fish than pulsed disturbances from wildfires [8].

Additional degradation of aquatic habitats on public lands may hamper efforts to protect and restore aquatic biodiversity. These habitats are increasingly important as cornerstones for restoring aquatic ecosystems and native fish [14].

Where fuel treatments might incur soil and watershed impacts, the risks from treatment and non-treatment should be assessed [7]. Although the respective impacts of treatments and fire are influenced by numerous factors, the occurrence of fire strongly affects the net balance between costs and benefits. If fire does not affect treated areas while fuels are reduced, treatment impacts on watersheds are not counterbalanced by benefits from reduction in fire impacts.

We provide a framework for quantitatively bounding the potential effectiveness of fuel treatments and the likelihood of fire affecting untreated watersheds, based on the probability of fire and the duration of treatment effects on fuels. This can be used to help statistically estimate the expected value associated with treatments or non-treatment based on the probability of possible outcomes and their associated costs and benefits [20]. Previous assessments of watershed tradeoffs from treatment and non-treatment [21, 22] did not include these in quantifying risk to aquatic systems associated with treatment versus non-treatment of fuels.

We use geographically-explicit data on fire on public lands in the western US to estimate, at a broad-scale, the probability that fuel treatments will be affected by fire during the period when fuels have been reduced. We also estimate the risk of higher severity fire occurring in watersheds if fuel treatments are foregone. These estimates provide a broad-scale bounding of treatment effectiveness and potential return from the fiscal and environmental costs of fuel treatments.

METHODS

The Analytical Model

Our analysis is based on the simple conceptual framework that unless fire occurs while fuels are reduced, fuel treatments cannot affect fire severity. We examine the probability of discrete classes of fire severity because fire impacts on watersheds vary with severity [11]. For instance, lower-severity fire has minimal, transient watershed impacts [11].

Future fire occurrence in specific locations cannot be predicted with certainty, but its probability can be estimated from empirical data. The probability of fire of a particular severity affecting treated areas can be estimated using the standard formula for the probability of an event occurring during a specific time frame:

$$q = 1 - (1 - p)^n \quad (1)$$

where q is the probability that a fire that would be of a specific severity in the absence of treatment occurs within n years, p is the annual probability of fire of a specific severity at the treatment location, and n is the duration, in years, that treatments decrease fuels and can reduce fire severity. In Equation 1, q provides an estimate of the mean fraction of an analysis area likely to burn at a specific severity within a given time frame in the absence of fuel treatments, which also represents the upper bound of potential effectiveness of treatments in reducing fire, since treatments cannot lower fire severity unless a fire occurs.

Both n and p can be estimated from available data. The duration of post-treatment fuel reduction, n, likely varies regionally with factors affecting vegetation re-growth rates, but fuels in western U.S. forests generally return to pre-treatment levels in 10-20 years [3, 7]. To estimate the upper limit of treatment effectiveness, we assume $n = 20$ years. We estimated the annual probability of fire of various severities, p, for each analysis area based on standard methods [23]:

$$p = (F*r)/(A*D) \quad (2)$$

where p is the annual probability of fire of a specific severity, F is total area burned at any severity within the analysis area over the duration of the data record, r is the estimated fraction of F that burned at the specified severity over the analysis area, A is the total analysis area, and D is the total duration of the data record, in years.

We based our estimates of the annual probability of fire on post-1960 fire records rather than reported natural fire return intervals for two primary reasons. First, evidence indicates that natural fire regimes no longer operate in many forests, because of direct fire suppression and indirect changes in fuels from livestock grazing, logging and fire exclusion [24]. Annual burned area has also increased in some forest types, likely due to climatic warming [25]. Recent fire data ostensibly integrate these alterations, reflecting how fires are likely to burn in the near future under current conditions and management. Natural fire return intervals do not capture these alterations. Second, there is considerable uncertainty regarding the accuracy of reported natural fire intervals [23, 24]. However, we stress that our approach can easily accommodate alternate estimates of annual fire probability using more geographically-refined data or where management changes might alter future fire probability.

We confined analysis to USFS lands in 11 western states, the focus for most proposed fuel treatments on public lands. The probability of fire varies geographically with several factors, including weather, ignition, fuels, and forest types. To bracket this effect, we estimated the annual probability of high-severity fire, p, for (*i*) all landcover types and (*ii*) more frequently burning ponderosa pine (*Pinus ponderosa*) forests at the scale of U.S. Forest Service (USFS) administrative regions that are the finest scale at which extensive data allow estimation of fire severity. We focus on high-severity fire, but also analyze fires of broader severity, including (1) either high- or moderate severity and (2) any severity.

Our estimates represent an initial, broad-scale first approximation of the potential of fire to affect areas within a given time frame, based on the assumption that fire and treatments are random. Although fire is not random, data are insufficient to accurately quantify more local patterns. Our approach provides a valid mean result at our scale of analysis, based on data from more than 40,000 fires across the western U.S. Site-specific data could be used in future, local studies where the probability of fire is known to depart considerably from the regional mean. Ideally, fuel treatments may not be randomly located, but instead focused in areas where fire is most likely. However, this is not assured by current policy [26]. Widely used methods for assessing the risk of high-severity fire may have limited accuracy [27].

Therefore, our analysis assumes random treatment location, as a first approximation.

West-Wide Analysis

To provide a broad-scale perspective of potential fuel treatment efficacy, we estimated mean annual probability, *p,* of fire for all USFS lands in the 11 western U.S. states, excluding Alaska, for the entire duration that data on total annual fire area are available (1960-2006). Data on fire area from 1993-2003, reported by agency ownership [28], were used to estimate mean annual fraction of total fire area on USFS lands, which was extrapolated to estimate mean annual fire area on USFS lands from 1960-1993 and 2004-2006, for which fire area data were reported [29], but not by agency ownership. Annual fire area on USFS lands in the 11 western states was assumed proportional to the fraction of total USFS area in these states. Total number of fires on western USFS lands from 1960-2006 is not reported, but based on the foregoing areal partitioning, the fire area data are from several hundred thousand fires on western USFS lands. The estimated annual fire area on these western USFS lands from 1960-2006 was summed to yield *F* in Equation 2.

The fraction of total fire area, *r*, that burned at high severity and high-moderate severity was estimated from data in USFS burned area emergency rehabilitation reports (BAER) for 470 fires in the 11 western states from 1973-1998 in six western USFS regions [30].

Regional Analysis of Fire in Ponderosa Pine

Because ponderosa pine forests are a key forest with more frequent fire, we estimated the mean annual probability of fire by severity in these forests on USFS lands: 1) on a regional basis, in six western USFS regions; and 2) West-wide. We used geographical information system (GIS) data for 40,389 fires in these forests for the entire period of data availability, 1980-2003 (Fig. **1**). Data were in a GIS point dataset, containing burned area for each fire, maintained by the Bureau of Land Management [31] and derived from a systematic National database [32]. We quality controlled these data for our study area, removing a few duplicate records.

A GIS map of ponderosa pine forests was obtained by selecting codes 5-7 (ponderosa pine) in the Westgap map from the GAP program, which includes national vegetation mapping from satellite imagery [33]. A GIS map of U.S. Forest Service regions is from the agency [34]. We converted all maps to Albers projection, Clarke 1866 datum, then used these to extract all fire records (n = 40,389) for ponderosa pine forests on USFS land in the 11 western states. We used USFS maps to subset fires by region, and then: (*i*) areas of individual fires were summed to yield *F* in Equation 2; (*ii*) the GIS was used to obtain *A*, and (*iii*) fire severity data by USFS region from 1973-1998 [30] were used to estimate *r* by severity.

RESULTS AND DISCUSSION

West-Wide Analysis

For the period 1960-2006, an estimated mean of ~220,000 ha, or a decimal fraction of 0.0037 of USFS western lands burned annually at any severity. Despite the approximations involved, our estimate of the mean annual fraction of areas burning at any severity compares reasonably with independent estimates by falling between them. Fire of any severity annually burned a mean fraction of ~0.0014 of the Deschutes National Forest in Oregon, from 1910-2001 [35], and ~0.0046 of 11 national forests in the Sierra Nevada, California, based on data from 1970-2003 [36].

Together with fire severity data [30], our West-wide estimate yields an estimated mean annual probability, *p*, of 0.001 and 0.002 for high- and high-moderate severity fire, respectively (Table **1**). Based on these estimates of *p*, Equation 1 yields a probability, *q*, of 0.020 and 0.042, respectively, for high- and high-moderate-severity fire. Substituting space for time, our results indicate that, on average, approximately 2.0 to 4.2% of areas treated to reduce fuels are likely to encounter fires that would otherwise be high or high-moderate severity without treatment. In the remaining 95.8-98.0% of treated areas, potentially adverse treatment effects on watersheds are not counterbalanced by benefits from reduced fire severity. These results also provide an estimate of the likelihood of high-severity fire affecting forests, if fuels are untreated. On average, over a 20-year period, about 2.0-4.2% of untreated areas would be expected to burn at high or high-moderate severity, respectively.

Using Equation 1, our results indicate that if treatments were repeated every 20 years across all USFS lands in the West, it would take about 720 years (36 cycles of treatments), on average, before it is expected that high-severity fire affects slightly more than 50% of treated areas while fuels are reduced. Treatments would have to be repeated at 20-year intervals for 340 years (17 cycles of treatments) before high-moderate severity fire is expected to encounter more than 50% of treated areas. Even after this duration of repeated treatments, it is likely that almost 50% of treated areas will be cumulatively affected by repeated treatments without compensatory benefits from reduced fire severity.

These West-wide estimates provide perspective, but include forest types, such as subalpine forests, typified by low-frequency, high-severity fire, where fuel treatments are unlikely to encounter fire [4]. Other forests, such as ponderosa pine, burn more often.

Regional Analysis of Ponderosa Pine

For ponderosa pine forests, the probability, *q*, of treated areas being affected within their window of effectiveness varies regionally from 0.020 to 0.040 for high-severity fires and from 0.042 to 0.079 for high-moderate severity fires (Table **1**). As expected, *q* in these forests is higher than for the West-wide analysis of all cover types. The highest probabilities, as expected, are in the Southwest and in the Northern Rockies, with its dry summers (Table **1**).

In these forests with more frequent fire, it is likely that fuel treatments can potentially reduce fire severity on a small fraction of treated areas. The results (Table **1**) indicate that in 92.1-98.0% of treated areas, fuel treatment impacts on watershed processes are not likely to be counterbalanced by a reduction in higher-severity fire.

Across the six regions, treatments would have to be repeated every 20 years for 340 to 700 years (17 to 35 times), on average, before it is expected that high-severity fire affects more than 50% of treated areas during periods of treat-

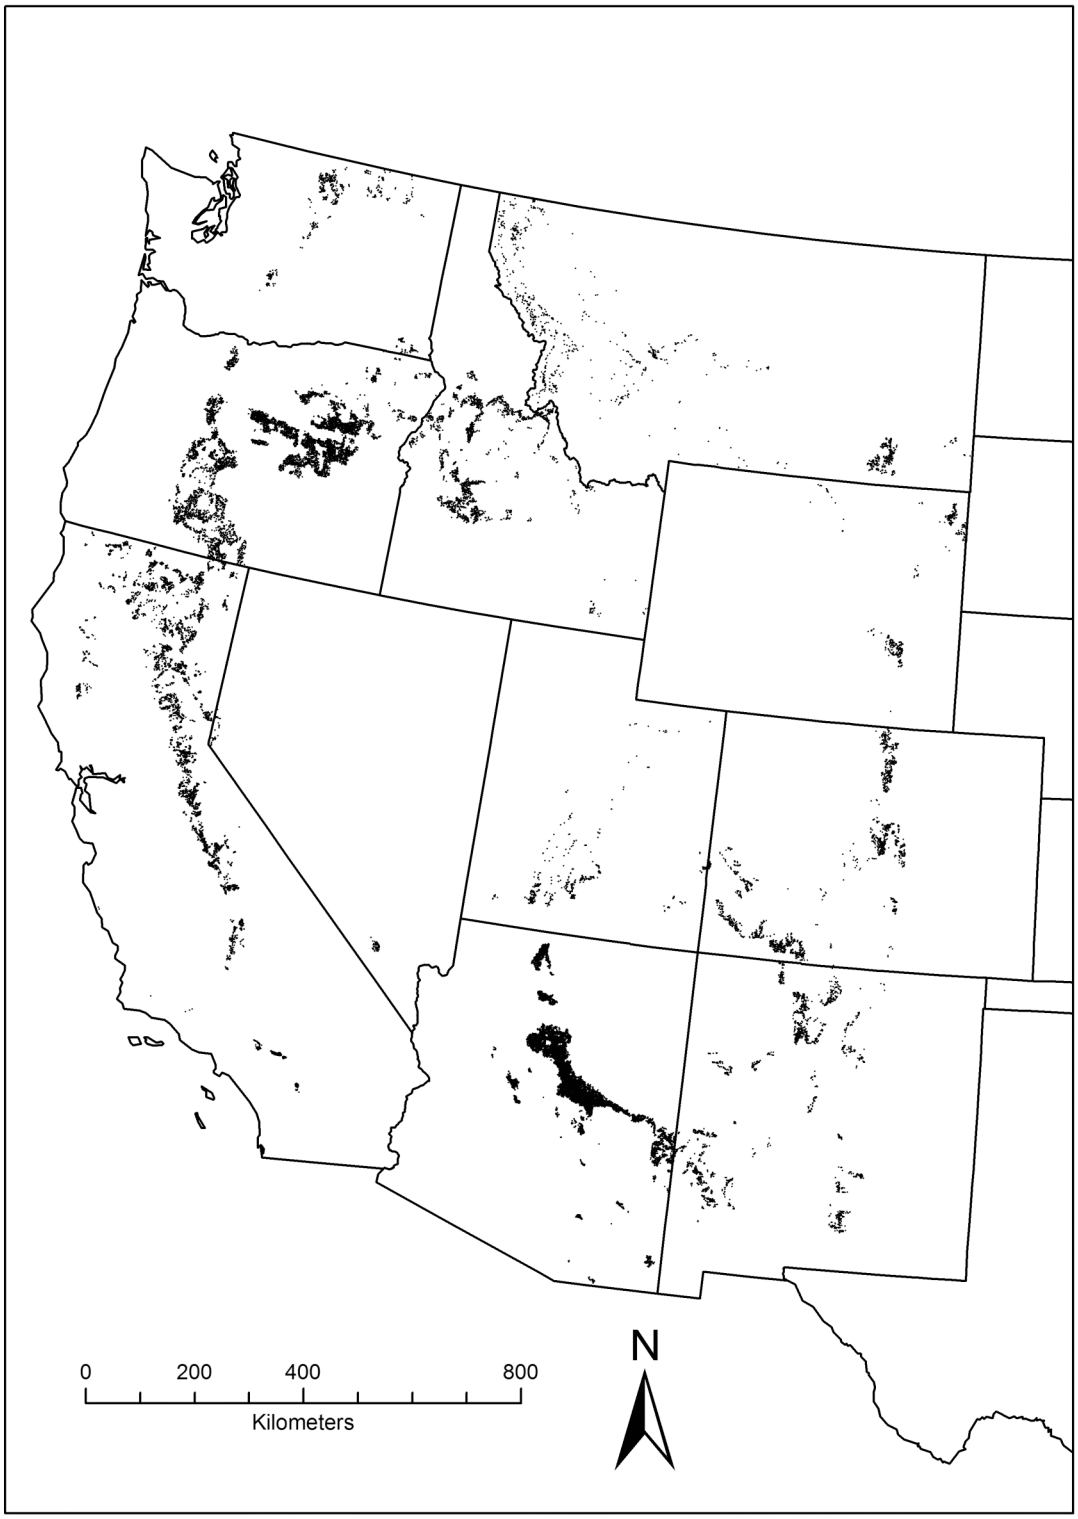

Fig. (1). Ponderosa pine forest fires (n = 40,389) in the western United States from 1980-2003. This is the dataset used in the regional analysis.

ment effectiveness. Treatments would have to be repeated for 180 to 340 years (9 to 17 times) before more than 50% of treated areas are expected to be affected by high-moderate severity fire. On average, these repeated treatments would affect watersheds and, potentially aquatic systems, depending on treatment practices, without providing reduction in fire severity on almost 50% of treated area.

An alternative method for estimating the risk of fire in the absence of fuel treatments is to use the fire rotation rather than mean annual probability of fire. The fire rotation indicates how long it takes, on average, for a particular area to burn one time and how often fire may return to a particular point in the landscape [23]. The fire rotation is calculated by:

$$B = 1/p \quad (3)$$

Table 1. Estimated *p* and *q* for Fires in Ponderosa Pine (PIPO) Forests. Data are Shown for Three Fire Severity Classes by USFS Region, and for All Forests on USFS Lands West-Wide

USFS Region	Any Severity		High-Moderate Severity		High Severity

West-wide: PIPO	0.0054	0.1026	0.0031	0.0602	0.0015	0.0295
West-wide: All types	0.0037	0.0715	0.0021	0.0416	0.0010	0.0203

where B is the fire rotation for fire of a specific severity and p is, again, the mean annual probability of fire of a specific severity.

Based on our analysis, the mean annual probability, p, of high-severity fire in ponderosa pine forests West-wide is 0.0015 (Table **1**), implying a fire rotation, B of about 667 years, varying from 500 to 1,000 years among individual regions. Based on the results in Table **1**, the fire rotation for high-moderate severity fire is about 323 years in ponderosa pine forests West-wide, varying from 244 to 454 years in individual regions, based on data in Table **1**. These results suggest that western ponderosa pine forests are not currently being rapidly burned by high or high-moderate severity fire, counter to other previous work [37].

Relaxing the Assumptions and Some Caveats

In some cases, the occurrence of fire of any severity may be of interest. Such cases include areas where fire of any severity might lead to high-severity fire. In ponderosa pine forests, the probability of fire of any severity encountering treatments within 20 years is approximately 7.15-16.5% across the six regions (Table **1**). Thus, if it is assumed that fuel treatments that encounter fire of any severity might be effective, the results indicate fuel treatments, on average, would not have the potential to reduce fire impacts on aquatic systems in 83.5-92.8% of the area treated. Based on Equation 1 and Table **1**, treatments would have be repeated every 20 years for 80-200 years, on average, before fire of any severity affects more than 50% of the treated areas in ponderosa forests in these USFS administrative regions.

However, the assumption that treatments that encounter low-severity fire convey benefits may not be warranted. Low-severity fires are commonly and easily extinguished under current management whether or not they encounter fuel treatments. Further, low-severity fire has minimal adverse impacts on watershed processes while conveying benefits, including maintenance of forest structure and fuel levels.

Our probabilistic approach does not explicitly address factors that can strongly influence fire area and severity, such as fuel conditions. Although spatially-explicit modeling of fire behavior can directly investigate the effects of such conditions, such models are unlikely to provide accurate estimates of the probability of occurrence of fire of a given severity because a host of other factors that influence fire area and severity cannot be deterministically predicted, including the frequency and location of ignitions and weather conditions during fire. Methods of assessing the risk of high-severity fire that are primarily based on fuel conditions have been shown to be an ineffective predictor of the actual severity at which fires burn [38]. In contrast, extensive recent data from numerous fires, as used in our analysis, does provide a robust estimate of the mean probability of the occurrence of fire of a given severity, because it integrates the many factors that influence fire occurrence and severity.

Our estimates likely represent the upper bound for fuel treatment effectiveness at the scale of analysis. In many cases, less than 4.16-7.86% of treated area is likely to experience high-moderate severity fire during the duration of treatment effectiveness, because q decreases with decreases in n, the duration of treatment effectiveness. This duration is often less than the 20 years assumed in our analysis. In the Sierra Nevada of California, fuels returned to pre-treatment levels within 11 years [39]. At the values of p in Table **1**, reducing n from 20 to 11 years (Eq. 1) reduces the probability that higher-severity fire affects treatments by ~45%.

Moreover, fuel levels rebound after treatment, eventually negating potential treatment effectiveness. If the reduction in effectiveness over time is such that mean effectiveness over the duration, n, is half the initial degree of effectiveness, the probability that fuel treatments reduce high-severity fire is approximately half the value of q for any value of p and n calculated using Equation 1.

Finally, available data indicate that fuel treatments do not always reduce fire severity when fire affects treated areas while fuels are reduced [4]. Our analysis does not address these effectiveness issues. For these combined reasons, Equation 1 likely estimates the upper bound of potential fuel treatment effectiveness in reducing fire impacts on aquatic systems.

Although our analysis focuses on higher-severity fire in bounding the effectiveness of fuel treatments and their net watershed effects, these fires do not have solely negative effects. Higher-severity fire benefits watersheds and aquatic

ecosystems in several ways, including providing a bonanza of recruitment of large wood and pulsed sediment supply that can rejuvenate aquatic habitats and increase their productivity [8, 14]. High severity fire is also a key process for the restoration of structural heterogeneity in forests, which is important for biodiversity [27, 40].

Our analysis intrinsically assumes some degree of climatic stationarity, which may not be warranted. Climatic variability influences the area annually burned in forests [25, 41]. However, the relatively recent fire data used in our regional analysis incorporates recent climatic fluctuation and possibly directional change, which would not be reflected in estimates based on natural fire return intervals. For instance, the data in our analysis of ponderosa pine forests come primarily from years in which annual fire area had increased due to climatic warming [25]. However, the analysis framework is flexible enough to accommodate projected values of the mean annual probability of fire, p, based on forecasts of climatic change or changes in fire management.

Current findings suggest treatment effects on fire severity are mostly confined to treated areas [3], but theory suggests a dense network of treatments might slow fire spread and reduce intensity, yielding a landscape-scale effect on fire severity [42]. However, empirical evidence of severity reduction was seen in the lee of only three of several dozen treatments in two Arizona wildfires [43]. Nonetheless, if dense treatment networks are shown to work in the future, our approach can aid in estimating their costs and benefits, because fire must still affect treated areas while fuels are reduced for networks to reduce fire severity.

CONCLUSIONS

Our analysis provides West-wide and regional first approximation of the likely upper bound of fuel treatment effectiveness. While valid at these two scales, they are not applicable to all smaller analysis areas, due to spatial variation in annual fire probability. However, the framework is flexible enough to allow more spatially explicit analyses of q where local estimates of n and p are available. The framework allows analysis of uncertainty, by using a range of plausible values for n and p. The analysis can also estimate the number of treatments to reach a specified q, abetting estimation of cumulative effects on ecosystems from repeated treatments.

Our approach also provides a method for quantitatively assessing the imminence of high-severity fire effects in the absence of fuel treatments and the degree of urgency of response. Based on available data, these are shown to be much lower than previously estimated in some work [37].

Our results and analyses can improve the assessment of risks to watersheds inherent in the treatment or non-treatment of forest fuels, because it accounts for the probability of fire and the transient nature of fuel treatments. For instance, previous work [22], evaluating treatment and non-treatment impacts, assessed the risks associated with fuel treatments based on the assumption that a single treatment significantly reduces fire risk on all treated areas, subsequently reducing consequent watershed impacts from fire. Other evaluations of these tradeoffs [21] compared the erosional effects of fuel treatments with high-severity fire under the explicit assumption that high-severity fire was inevitable without treatment and the implicit assumption that treatments always reduce or eliminate the potential for high-severity fire. Our analysis indicates that these assumptions are unwarranted and likely mischaracterize the outcomes and associated impacts of treatment options.

The approach can be extended to aid in assessing the risk to other ecosystem elements and processes that may be adversely affected by either fuel treatments or high-severity fire. For instance, non-native vegetation can be influenced by high fire severity [44] and some fuel treatments [10], especially if the treatments are repeated [9].

Even in ponderosa pine forests that burn relatively frequently, our regional analysis indicates that after 17 cycles of treatments, only slightly more than 50% of treated areas could potentially have fire severity reduced, on average. Our results indicate that high-severity fire is far from inevitable in areas left untreated and is, instead, expected to affect only a relatively small fraction of such areas at the broad scale of our analysis. Factoring in the probability of fire, using our framework, can significantly improve the assessments of the risks posed to aquatic systems by treating or not treating forest fuels. Where site-specific data on fire probabilities exist, the framework can be used to help locate treatments where they are most likely to encounter higher severity fire, increasing the likelihood of treatment benefits. In fact, our results indicate that such efforts are crucial.

There are several important factors that influence the aquatic tradeoffs among fuel treatments, fire, and aquatic systems that our framework does not address. Although the probability of outcomes is critical to assessing the expected value of options, the ecological costs of the outcomes of treatment *vs* non-treatment are also important in assessing the expected value of these options. With respect to the aquatic context, there is an ongoing need to fully evaluate tradeoffs such as the severity and persistence of the negative and positive impacts on watersheds and aquatic populations from fuel treatments and higher severity fire [8, 45]. An additional related issue is how effective treatments are when they encounter fire under a broad array of conditions affecting fire behavior [3]. While our analysis does not address these factors, it refines evaluation of net impacts of fuel treatment *vs* non-treatment by providing a framework for estimating the likelihood of fire occurrence in a given time frame.

At the scales of our analysis, results indicate that even if fuel treatments were very effective when encountering fire of any severity, treatments will rarely encounter fire, and thus are unlikely to substantially reduce effects of high-severity fire.

ACKNOWLEDGEMENTS

We thank Susan Goodman of the Bureau of Land Management for compiling and distributing the fire history database, Andrew Westerling for discussion of historical fire history records, the Pacific Rivers Council for funding aspects of the initial research on this topic, and three anonymous reviewers for their helpful comments on the manuscript.

CHAPTER SIX

Stream Temperature and Aquatic Habitat: Fisheries and Forestry Interactions

ROBERT L. BESCHTA, ROBERT E. BILBY, GEORGE W. BROWN, L. BLAIR HOLTBY, and TERRY D. HOFSTRA

ABSTRACT The temperature of water entering a forest stream system typically resembles that of the watershed's subsoil environment. As this water continues to flow down the stream system, seasonal and diurnal water temperatures are strongly influenced by solar radiation. Pronounced differences in stream temperature patterns are evident for streams draining watersheds throughout the Pacific Northwest. Seasonal and diurnal patterns of stream temperature influence a wide range of responses by instream biota. Furthermore, logging activities can initiate pronounced temperature changes by the removal of forest vegetation along channels. Buffer strips of forest vegetation are an effective means of minimizing stream temperature impacts associated with logging. Although direct mortality of fish is probably not a major concern throughout the Pacific Northwest when stream temperatures are altered by management activities, temperature changes can influence rates of egg development, rearing success, species competition, and other factors.

The temperature of water in forest streams is an important factor regulating aquatic life. But until the 1960s, the impact of harvesting on the temperature of forest streams was seldom considered or reported in the literature. Whereas fisheries studies focused on the toxicological effects of high temperature in the laboratory, most watershed studies were concerned with changes in runoff and sediment.

The situation changed dramatically in the early 1960s, especially in the Pacific Northwest. Scientists observed changes in the migration of anadromous fish in the Columbia River because of increases in temperature below dams and the outfall of the Hanford thermonuclear reactor. Conversely, the beneficial impact of dams in reducing water temperature became an issue on the Rogue River in Oregon. Research on the energy balance of large rivers began to provide information about how their temperature was affected by the macro- and microclimatic factors, storage and release from reservoirs, and localized heat inputs.

The Alsea Watershed Study in western Oregon, which began in 1958, was the first detailed study of effects of timber harvesting on the temperature of small, forest streams. Temperature changes were

monitored before and after harvesting, and research on energy balance components provided a basis for understanding why temperature changes occurred. In the late 1960s, high postlogging stream temperatures were a central issue in a harvesting-fisheries controversy over the North Umpqua River in Oregon. This controversy, along with others, was part of a developing environmental awareness and involvement by the public, administrators, and legislators. These concerns also led to major changes in national policy for the USDI Bureau of Land Management and USDA Forest Service and were instrumental in the development of forest practices acts, on a state-by-state basis, for the Pacific Northwest in the early 1970s. These forest practices acts identify management activities intended to prevent significant temperature changes in fish-bearing streams.

The objectives of this paper are to characterize stream temperature regimes in forested ecosystems, to indicate the underlying physical mechanisms of temperature change resulting from the removal of forest canopies over streams, and to identify the various processes by which temperature changes following logging can affect aquatic communities and the production of fish.

STREAM TEMPERATURES AND FORESTED ECOSYSTEMS

The temperature of moisture arriving at a channel is dependent on many factors. In high mountain catchments of the Pacific Northwest, much of the annual precipitation occurs as snowfall, which accumulates on a watershed until sufficient energy is available for snowmelt. Most snowmelt typically occurs during the spring months. However, at lower elevations snowfall accumulations may be relatively transient, and rapid snowmelt can occur during rain-on-snow events. Typically, meltwater (at 0°C) and rainfall (at > 0°C) infiltrate forest soils and then move laterally through relatively porous soils and subsoils toward topographic depressions and stream channels. The pathways by which subsurface flow reaches a channel are highly variable, but when such water eventually enters a defined channel and becomes streamflow, its temperature generally reflects that of the watershed's subsoil environment.

As water flows downstream, its temperature will continue to change as a result of several factors that make up the heat balance of water. The net rate of gain or loss by a stream as it moves through a forest is the algebraic sum of net radiation, evaporation, convection, conduction, and advection (Brown 1983). Net radiation is generally dominated by the amount of direct-beam solar radiation that reaches a stream's surface. Heat gain or loss from evaporation and convection depends on the vapor pressure and temperature gradients, respectively, between the water surface and the air immediately above the surface. Wind speed at the air-water interface is also an important controlling variable. Conduction of heat between the water in the stream and the streambed depends on the type of material that makes up the bed. Bedrock channels are more efficient than gravel-bed channels at conducting heat. Advection is the result of heat exchange as tributaries or groundwater of different temperature mixes with the main streamflow, and can either increase or decrease stream temperature.

Channel characteristics and morphology also influence the amount of heat gain or loss of a stream. The surface area over which energy transfers take place is important: wide streams receive more energy than narrow ones. Discharge is another significant variable: for the same surface area and energy input, the temperature change expected of a high-discharge stream will be less than that of a low-discharge stream. In other words, for a given rate of net input, the change in temperature of a stream is directly proportional to surface area and inversely proportional to discharge.

How do these factors combine to produce temperature patterns for coastal streams in the Pacific Northwest? In winter, solar radiation levels at the stream surface are typically low, regardless of canopy cover. This is the result of a combination of factors affecting the availability of direct-beam solar radiation: short days, low sun angles (this maximizes reflection at the water surface and the shading effects of streamside vegetation and topography), and cloudy weather. During the summer months, when solar radiation levels are greatly increased (higher sun angles, longer days, and clear skies) and stream discharge is low, shading effects of the forest canopy become significant. The seasonal progression of potential direct solar radiation (for clear weather conditions) is shown in Figure 1. Although some losses occur as solar energy is routed through the atmosphere, much of the incoming solar radiation is intercepted by the canopy of streamside vegetation. Net radiation underneath a continuous canopy may be only 15% or less than that of an unshaded stream (Brown 1983) during daytime conditions. Throughout the year, evaoporative and convective transfers of energy are typically low for forested streams, because vapor pressure and temperature gradients close to the water surface are small and wind speeds are usually low. Likewise, conductive heat transfers are usually insignificant (Brown 1969). Because water has a relatively high specific heat, seasonal and daily temperature changes of forested streams are relatively small and gradual.

Seasonal temperature patterns for three small forested streams in the Pacific Northwest are shown in Figure 2. As expected, the watersheds show maximum temperatures occurring in summer and minimums in winter. However, the exact timing and magnitude of seasonal extremes vary. Porcupine Creek, the farthest north of the three, has the greatest range in monthly stream temperatures (nearly 13°C). The timing of summer maximum temperature for these streams follows, by one to two months, the timing of maximum solar radiation (Figure 1). An exception to the cyclical pattern of seasonal temperatures, shown in Figure 2, occurs in streams fed by large springs or groundwater sources. These systems often display a nearly uniform temperature year round, being cooler than other streams in summer and warmer in winter (Minkley 1963).

Characterizing the extent of natural or climatic variability in stream temperatures is an important preliminary step in attempting to document the effects that temperature changes related to logging may have on aquatic communities. If, after logging, stream temperatures lie within the bounds of natural variability, then any effects related to temperature change might be difficult to detect. Furthermore, even if

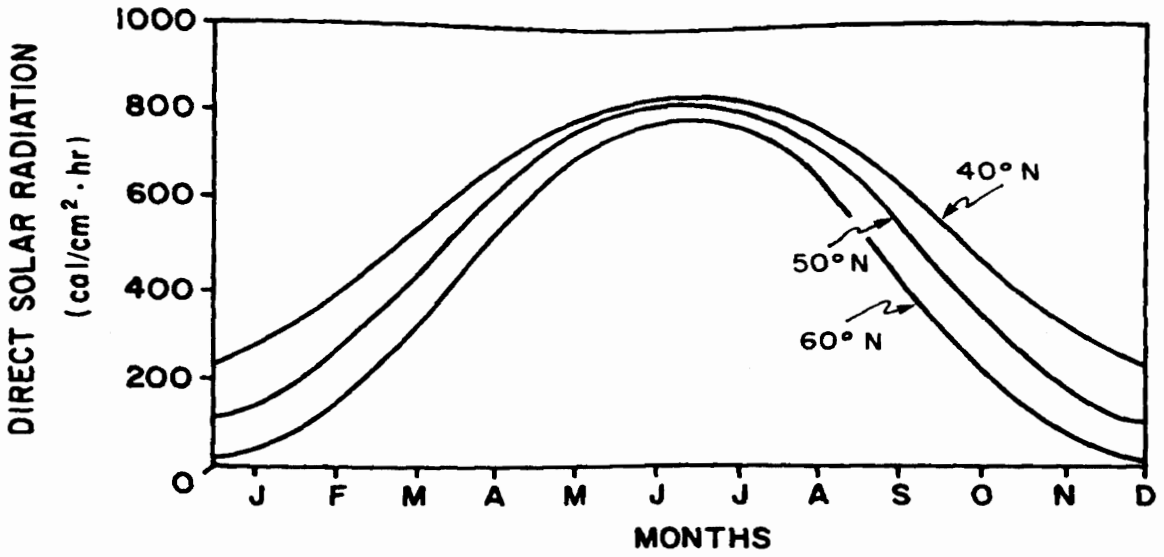

Figure 1. Seasonal pattern of potential direct-beam solar radiation at a stream surface during clear weather (assumed atmospheric transmission coefficient = 0.9) for selected latitudes (Buffo et al. 1972).

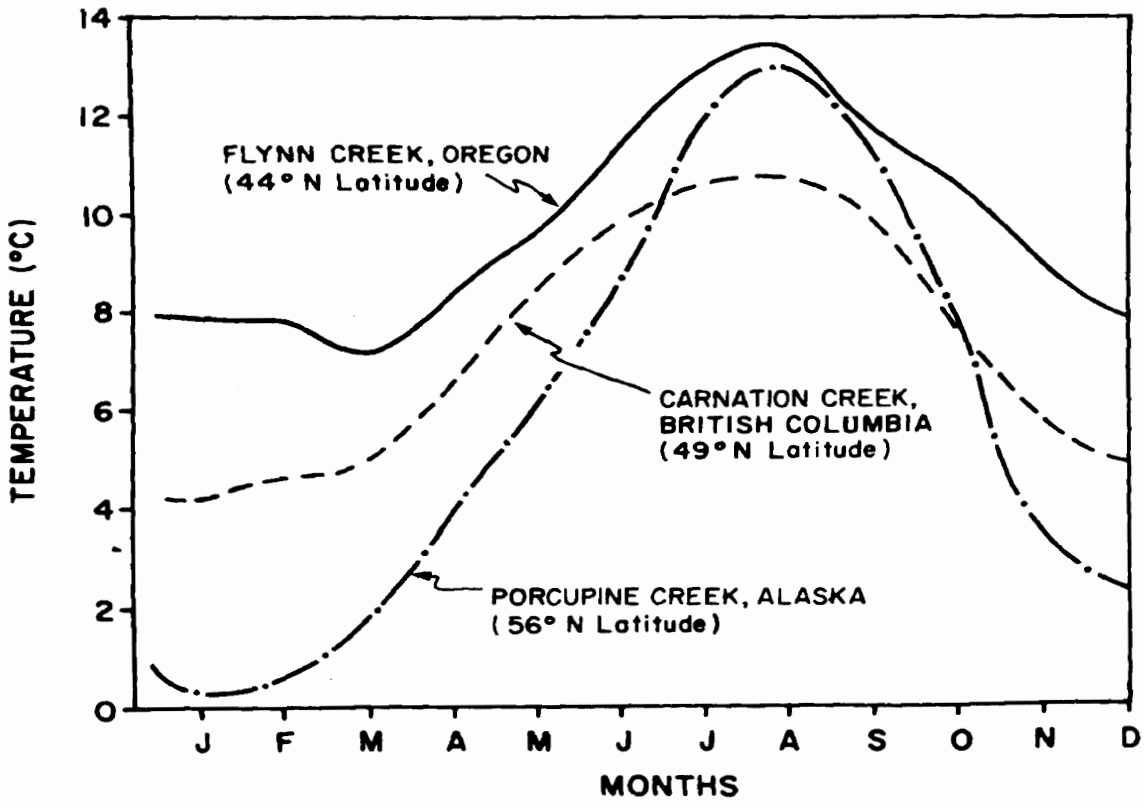

Figure 2. Seasonal temperature patterns for three coastal streams in the Pacific Northwest.

measurable, such effects might be relatively unimportant if they would be expected to result from climatic variability anyway.

The variation in monthly temperature between years can be as much as 4°C during the winter months (December-March) for Porcupine Creek in southeastern Alaska, but year-to-year variations in monthly temperature are generally less than 2°C for other times of the year (Koski 1984). Monthly temperature fluctuations between years generally remain lower than 2°C, regardless of season, at Flynn Creek in the Oregon Coast Range.

Superimposed on the seasonal progression of stream temperatures is a diurnal pattern. Generally, changes in water temperature over the course of a day tend to be greatest during summer, in part because of the relatively low volumes of water flowing in streams at that time of year. Peak daily temperatures are usually achieved during the late afternoon, and minimums just before dawn. Even in midsummer, when large diurnal changes in direct solar radiation occur above the forest canopy, the shading effects of the forest vegetation greatly moderate and reduce the energy exchanges at the stream surface. For example, diurnal temperature variations near the mouth of Carnation Creek (Vancouver Island, British Columbia) average approximately 1.3°C for the months of June, July, and August; maximum diurnal variations for these same months are less than 2.4°C (Holtby and Newcombe 1982). Diurnal variations for a well-shaded coastal Oregon stream were less than 1°C, even during the day of the annual maximum (Brown and Krygier 1970). Streams bordered with relatively low densities of forest vegetation or which have a significant number of natural openings along the channel would be expected to have higher diurnal variations.

A time series of monthly average water temperatures extending from 1923 to 1975 has been reconstructed for Carnation Creek, B.C., using fifty-two years of air temperature records from a nearby permanent weather station (Estevan Point, B.C.) and a regression of air and stream temperatures for the period 1971 to 1984. A temperature record of this duration provides an estimate of the extent to which climatic variability has influenced undisturbed stream temperatures in that region. Historical variability in Carnation Creek stream temperatures has been relatively small. For all months of the year, the average monthly temperature lies within 1°C of the long-term monthly median at least 50% of the time.

Forest streams change temperature in space as well as time, again in response to energy transfers. As stream order increases, so usually does stream width, stream discharge, and the number of tributaries. As width increases, surface area exposed to solar radiation usually increases, because riparian vegetation may shade less and less of the stream surface. On the other hand, discharge also increases in a downstream direction. The balance between these factors ultimately determines the rate of temperature change downstream, especially in summer. For instance, in the tributaries of Carnation Creek, B.C., diurnal ranges during the summer increase in proportion to drainage area and stream width (both correlates of stream surface area), indicating the overriding importance of direct solar radiation during

periods of low discharge indicating the temperature regimes of small streams. During the winter there is no relation between stream surface area and diurnal range; and other factors, principally discharge and elevation, become important determinants of diurnal variation. In large rivers, diurnal temperature fluctuations are generally dampened because of the relatively large volumes of water contained by these systems (Hynes 1970).

Where tributaries join, or enter a main stream, the mixed temperature is the simple resultant of their individual temperatures, weighted by their respective discharges (Brown 1983). Thus a small tributary will produce little change in the temperature of a larger stream unless the small stream's temperature is greatly different. Hence, as stream order increases, the impact on temperature of tributaries entering the main channel generally decreases.

Because much of their flow is derived from forested headwater catchments, rivers in the Pacific Northwest exhibit seasonal temperature patterns similar to those of small forest streams. In Figure 3, average monthly temperatures are illustrated for three rivers across Oregon. Winter temperatures for the Nestucca River in the Oregon Coast Range are similar to those for the smaller Flynn Creek watershed shown in Figure 2. This similarity is primarily a consequence of the combined low net radiation inputs and high streamflows common at that time of year. In summer, monthly temperatures for the Nestucca River average approximately 18°C, or nearly 5 to 6°C warmer than those for the smaller Flynn Creek watershed. These downstream increases in monthly water temperatures during the summer occur primarily from net radiation inputs to the water as it flows through increasingly wider reaches of the stream system. In addition, flows are low at this time of year and serve to magnify the effects of energy inputs.

Winter temperatures for the Nestucca River in the Oregon Coast Range tend to be higher than for Fall Creek and the Umatilla River, located farther east (Figure 3). Fall Creek drains a portion of the western Cascades; the Umatilla River has its headwaters in the Wallowa Mountains of eastern Oregon.

The range of temperatures experienced in coastal streams is relatively low because of the maritime influence of the Pacific Ocean on the coastal climate. Lower winter temperatures occur for rivers draining the Cascades and mountain ranges farther east, where cold water temperatures associated with rainfall or snowmelt and cold nighttime air temperatures (which promote radiational cooling of stream water) are conducive to lower stream temperatures. Monthly temperatures in January for the Umatilla River in eastern Oregon average more than 3°C lower than those of the Nestucca River in the Oregon Coast Range. Downstream changes in water temperature, as water moves from headwater channels toward the mouth of a river system, are also described by Theurer et al. (1985).

Even though general temperature patterns are evident in forest streams, local anomalies may occur. Thermal stratification, while common in lakes, is generally precluded in streams, because of constant

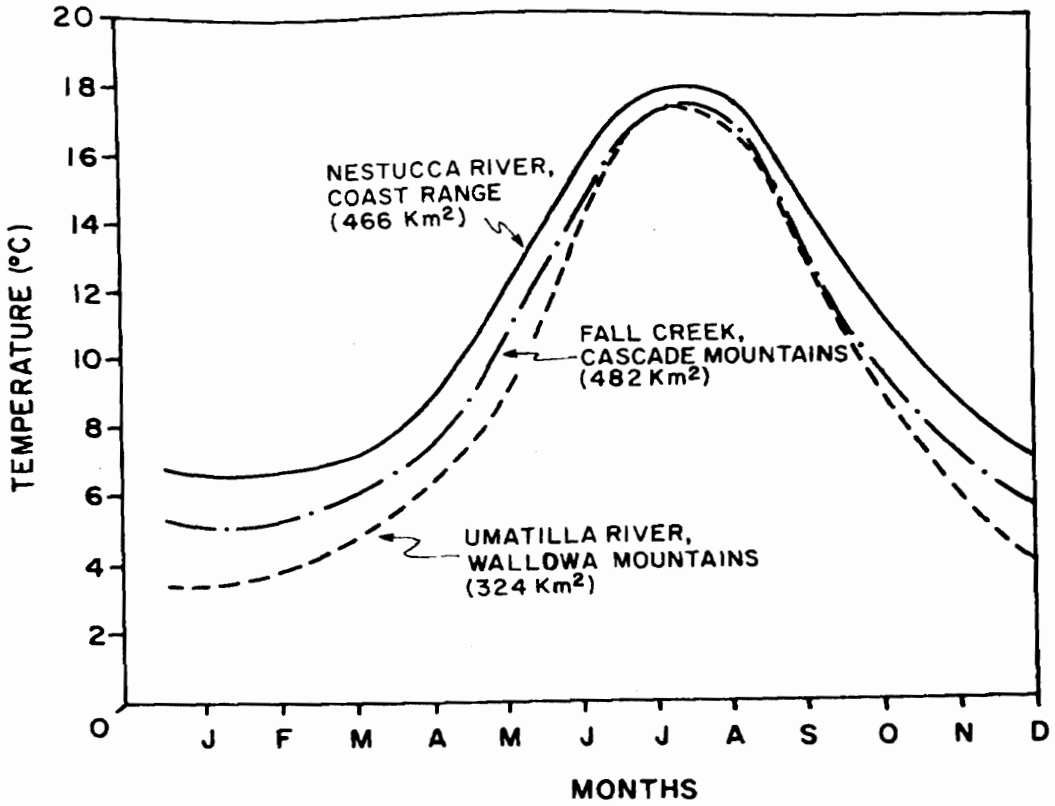

Figure 3. Seasonal temperature patterns for three rivers in Oregon (1965-71).

turbulence of flowing water. However, several studies have shown that water near the bottom of pools is sometimes 5 to 10°C cooler than water near the surface (Keller and Hofstra 1982, Bilby 1984, Keller et al., in press). Cool-water sources usually result from a tributary stream, groundwater, or an upwelling of stream water that has been cooled by flowing through the streambed (Figure 4). The occurrence of these sources seems to be rare, accounting for only 1.6% of the stream surface area of a western Washington stream (Bilby 1984). Where relatively cool water enters a channel, fish and other organisms may find local thermal environments more favorable than surface water temperatures would indicate (Gibson 1966, Keller and Hofstra 1982); however, reduced dissolved oxygen levels associated with cool-water sources may limit their immediate usefulness to instream biota (Figure 5). The occurrence of such phenomena serves as a reminder that generalizations about the thermal environments of forest streams may be misleading.

In summary, the seasonal cycles in the temperatures of streams draining forested watersheds in the Pacific Northwest can be defined on temporal and spatial scales. There are clear seasonal patterns, with low levels of between-year variability. Diurnal variations also follow a predictable pattern and are generally very small. Spatially, there are regular, predictable effects of such variables as latitude, proximity to the ocean, and stream order. Particularly during summer months, however, there appears to be a significant amount of fine-scale heterogeneity

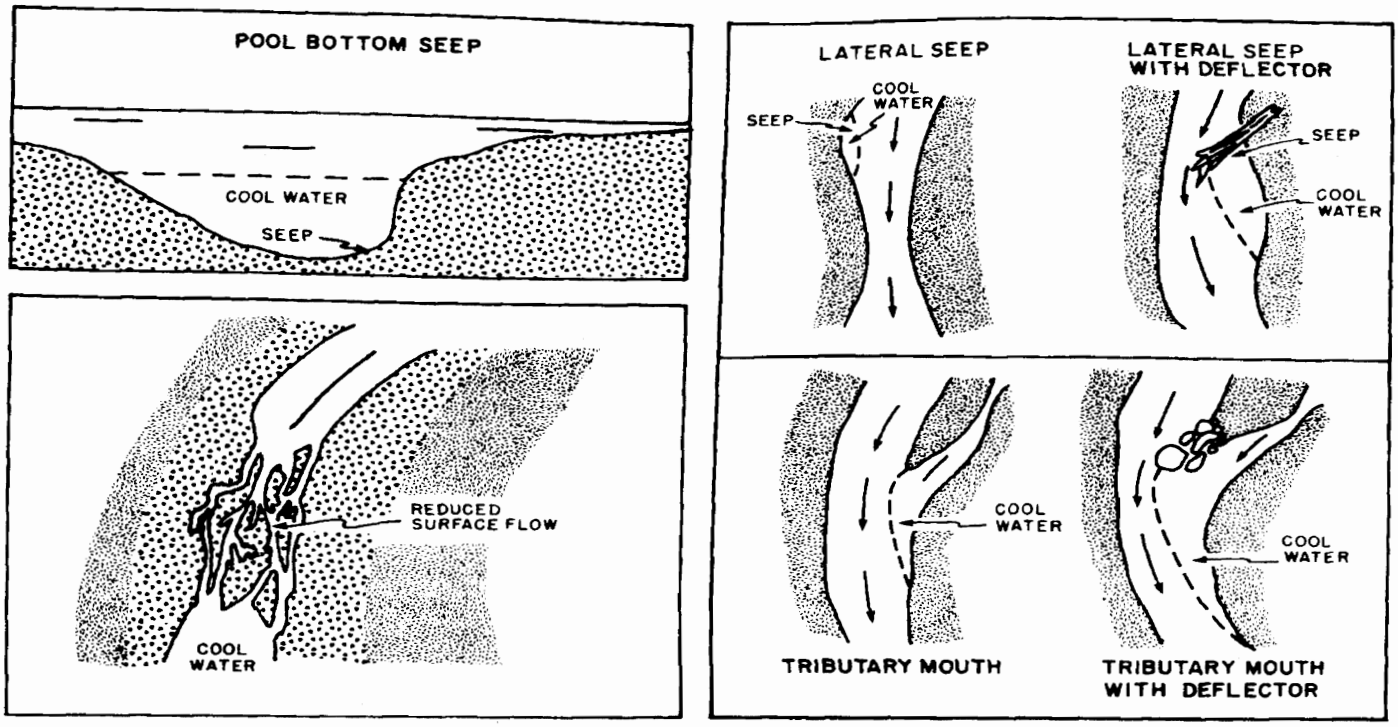

Figure 4. Examples of cool-water sources in mountain streams (from Bilby 1984).

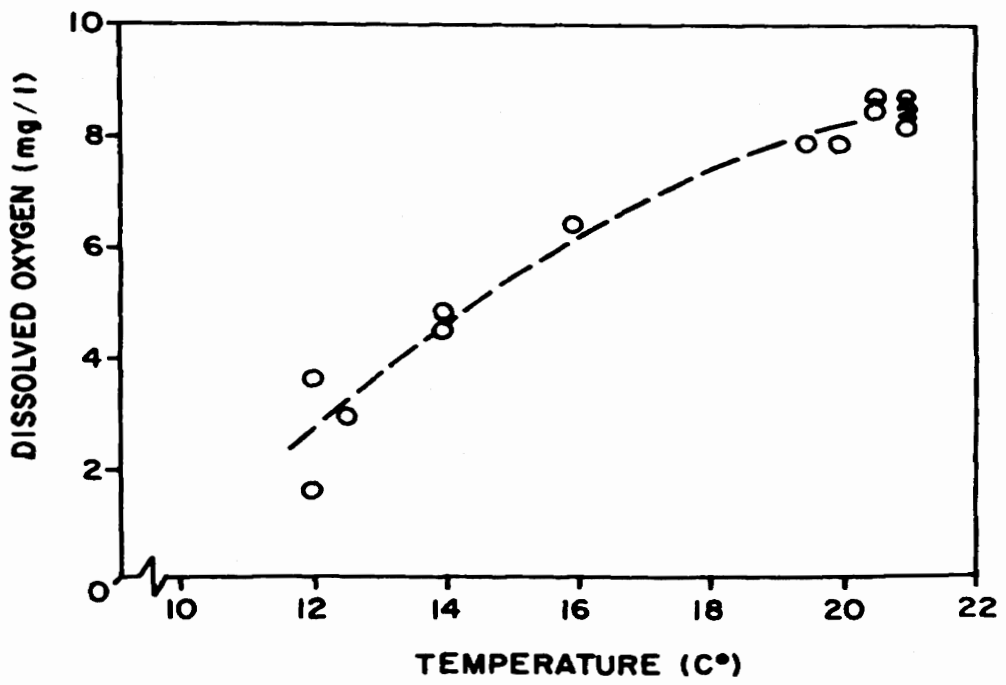

Figure 5. Relation between stream temperature and dissolved oxygen associated with a cool-water source in Redwood Creek, California (from Keller and Hofstra 1982).

in the thermal environment of streams brought about by variations in exposure to solar radiation, flow, channel widths, and the occurrence of cool-water upwelling. Nevertheless, the general temperature patterns represent a characteristic of the aquatic habitat that fish and other organisms must withstand and, perhaps more important, to which they have adapted their life strategies.

EFFECTS OF CANOPY COVER ON STREAM TEMPERATURES

Most stream temperature concerns in forest ecosystems have focused on summertime increases associated with forest harvesting. The energy balance components described earlier also operate for streams from which the canopy is removed. Again, the principal source of energy for heating small streams during summer conditions is incoming solar energy striking the water surface. The more canopy removed, the greater is the exposure of the stream to this heat source. Most of this incoming energy is stored in the stream, and its temperature rises accordingly.

Compared with solar radiation inputs, energy transfers involving convection or evaporation are of much less importance to the thermal regime of exposed mountain streams. Both require wind movement at the stream surface to be effective, in addition to temperature and vapor pressure gradients. Because of normally low wind velocities immediately above the water surface, neither process plays a significant role in controlling the temperature of an exposed stream (Brown 1983). Furthermore, these two processes tend to counterbalance each other. For example, if relatively warm air is present over a stream surface, the heat gain to the stream by convection will tend to be offset by heat loss through evaporation. This is important for several reasons. First, high air temperatures do not cause stream temperature to increase following canopy removal even though daily maximum air temperatures are usually at their highest during clear sunny weather, just as temperatures of streams are. However, the two variables are often highly correlated. Second, once a stream's temperature is increased, the heat is not readily dissipated to the atmosphere as it flows through a shaded reach. Hence, additional energy inputs to small streams can have an additive effect on downstream temperatures.

The net rate of heat exchange (N_h) per unit area of stream surface is shown in the following equation:

$$N_h = N_r + E + H + C \qquad (1)$$

where N_r = net radiation
E = evaporation
H = convection
C = conduction

Although the net radiation term comprises both short- and long-wave components, the shortwave or incoming solar radiation portion is by far the most important factor that changes as a result of canopy reductions, particularly during the summer.

Seasonal and diurnal temperature patterns of exposed streams differ markedly from those of shaded, forest streams. For a channel with a forest canopy shading the water surface, the individual terms on the right-hand side of equation (1) remain relatively small over a 24-hour period, even in midsummer. Hence diurnal temperature fluctuations are also small. However, should the canopy be removed through harvesting activities or natural causes, the net heat gain or loss may be significantly altered.

During winter months, exposed streams may experience lower temperatures when there is no canopy to inhibit energy losses by evaporation, convection, or long-wave radiation from the stream. Long-wave losses are greatest when clear skies prevail, particularly at night. While this phenomenon is not important in coastal streams of Oregon and Washington, where nighttime cloud cover and relatively warm air temperatures are common, it may be important for streams at high elevations in the Cascades and streams farther east, or at northerly latitudes where snow accumulations are insufficient to cover and insulate the channel from energy losses. Because most research studies in the Pacific Northwest have concentrated on evaluating changes in summer stream temperatures, less is known about winter temperature changes, if any, as a result of reductions in canopy cover.

Studies in deciduous forest types of the eastern United States have found relatively small changes in winter stream temperatures due to forest harvesting. In Pennsylvania, changes in winter maximum temperatures ranged from -0.7 to +0.9°C; changes in winter minimums ranged from -1.4 to +1.0°C (Table 1). In West Virginia, complete removal of riparian trees lowered winter stream temperature minimums approximately 2°C (Lee and Samuel 1976). In New Jersey, dormant season stream temperatures remained unchanged following herbicide application to riparian forest vegetation. Results from studies of coastal streams in the Pacific Northwest (Brown and Krygier 1970, Holtby and Newcombe 1982) show little change in winter temperatures following canopy reductions from logging.

During the summer, the amount of direct solar radiation available to a stream whose canopy has been removed is substantial (Figure 6), hence exposed streams may experience large diurnal fluctuations. The extent to which the incoming solar energy increases the temperature of an exposed stream further depends on the surface area of the exposed reach and the stream discharge. Streams with small discharges and large exposed areas inevitably experience the greatest temperature increases (Sheridan and Bloom 1975).

Research associated with a variety of forest types and geographic locations has identified the magnitude of temperature increases to be expected from canopy removal. For summertime conditions in the eastern United States, increases in average maximum temperatures following reductions or removal of forest canopy have generally ranged from 3 to 10°C (Table 1). Minimum temperatures in summer either remained unchanged or were generally limited to increases of less than 1°C.

Table 1. Summary of temperature changes associated with forest management activities and experimental treatments on forest watersheds, eastern United States.

Location	Treatment	Stream Temperature Variables	Temperature Change (°C)	Reference
Georgia	Clearcut with partial buffer strip	Average June-July maximum	+6.7	Hewlett and Fortson (1982)
Maryland	Riparian harvest up to 40 m from channels	Average summer maximum Average summer minimum	+4.4 to 7.6 +0.6 to 1.1	Corbett and Spencer (1975)
New Jersey	Riparian herbicide application	Average summer maximum Average summer minimum Dormant season	+3.3 Unchanged Unchanged	Corbett and Heilman (1975)
North Carolina	Deadened cove vegetation	Average summer maximum	+2.2 to 2.8	Swift and Messer (1971)
	Complete clearcut	Average summer maximum	+2.8 to 3.3	Swift and Messer (1971)
	Understory cut	Average summer maximum	0 to 0.3	
Pennsylvania	Riparian harvest (lower third of slope)	Average summer maximum Average summer minimum	+3.9 Unchanged	Lynch et al. (1975)
	Clearcut with herbicide treatment	Average June-July maximum Average June-July minimum	+10 to 10.5 +1.7 to 1.8	Rishel et al. (1982)
		Average Dec.-Feb. maximum Average Dec.-Feb. minimum	-0.5 to +0.9 -1.4 to +0.2	Rishel et al. (1982)
	Commercial clearcut with buffer strip	Average June-July maximum Average June-July minimum	+0.6 to 1.6 0 to 0.6	Rishel et al. (1982)
		Average Dec.-Feb. maximum Average Dec.-Feb. minimum	-0.7 to +0.9 -0.5 to +1.0	Rishel et al. (1982)
West Virginia	Clearcut	Average summer maximum	+4.4	Kochenderfer and Aubertin (1975)

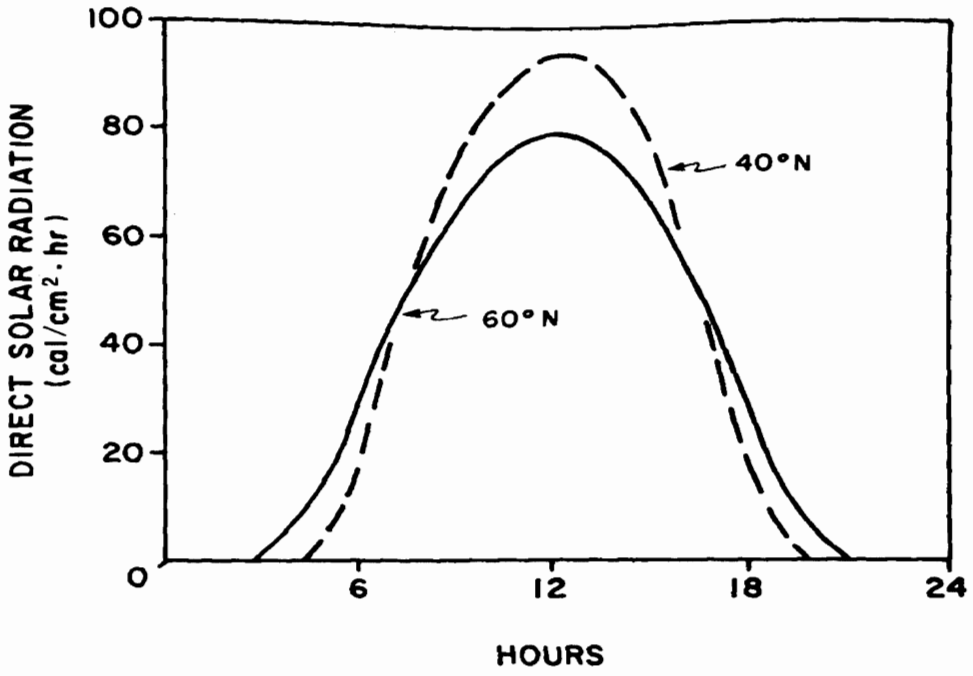

Figure 6. Daily pattern of potential direct-beam solar radiation at a stream surface during clear weather (assumed atmospheric transmission coefficient = 0.9) on June 22, for selected latitudes (Buffo et al. 1972).

For the Pacific Northwest, watershed studies in the Coast Range and the Cascade Mountains of Oregon have shown increases in mean monthly maximum temperatures of about 3 to 8°C (Table 2) following clearcut harvesting. Burning may add another 1°C increase. At Carnation Creek on Vancouver Island, British Columbia, Holtby and Newcombe (1982) found that summer temperature increases due to logging were proportional to the basin area logged. They predicted a 7°C increase in mean summertime water temperature if the entire watershed was clearcut. Studies in the Pacific Northwest also show that the minimum temperatures in summer are much less altered by canopy removal and are generally limited to increases of less than 1 or 2°C.

Concern over altered temperatures after logging streamside vegetation usually focuses on the inevitable increases in maximum temperatures observed during the summer. This focus is very much a result of the toxicological perspective on temperature changes that is prevalent in fisheries research. However, in the majority of cases in the Pacific Northwest, stream temperatures in deforested watersheds, while invariably warmer than they were in the forested state, do not approach the tolerance limits of the resident fish species.

Holtby (1986) compared temperature changes over three biologically interesting periods at Carnation Creek: (1) the winter (October through February), (2) the spring (April and May), and (3) the summer (May through September). Logging-related increases in temperature (as indexed by thermal summations), from 1977 to 1984, averaged 15% (range

	Tractor striped area	Δ Temperature per 100 m of channel	15.8°C/100 m	Brown et al. (1971)

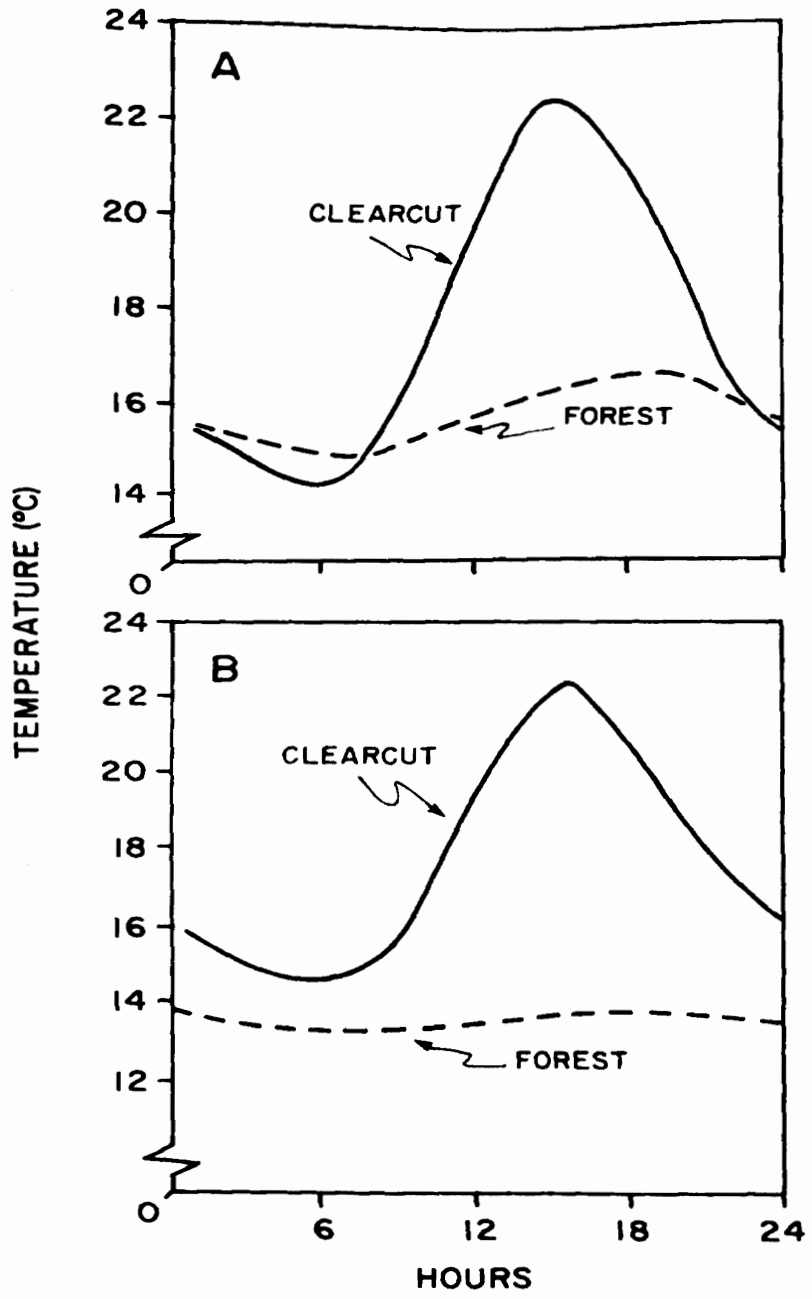

Figure 7. Summertime stream temperatures during clear weather in (A) West Virginia (from Lee 1980), and (B) Coast Range of Oregon (from Brown and Krygier 1967).

of 2 to 32%) during the winter, 27% (range of 18 to 36%) during the spring, and 37% (range of 16 to 56%) during the summer.

The increased exposure of small headwater streams draining clearcuts to incoming solar radiation leads to substantial increases in diurnal fluctuations (Figure 7). In some situations, the diurnal range in midsummer can increase by more than 15°C if the overstory shade is

completely removed (Brown and Krygier 1970, Moring 1975a). In other situations, increases in diurnal ranges have been considerably less. Increases in average diurnal ranges during summer after complete clearcutting along tributaries to Carnation Creek were less than 3°C (Holtby 1986). In the main creek, average diurnal range increased approximately 1°C during the summer. Increased diurnal ranges during most of the winter months were detectable but nevertheless were considerably smaller.

Because direct-beam solar radiation is the primary factor influencing temperature change in summer, the effect of partial canopy removal is directly proportional to the reduction in canopy providing shade to the stream. What this signifies is that leaving buffer strips represents an effective means of preventing temperature change for many mountain streams.

The importance of a buffer strip for preventing increases in stream temperature can be determined by measuring its angular canopy density (ACD). Whereas canopy density is usually expressed as a vertical projection of the canopy onto a horizontal surface, ACD is a projection of the canopy measured at the angle above the horizon at which direct-beam solar radiation passes through the canopy. This angle is determined by the position of the sun above the horizon during that portion of the day (usually between 10 a.m. and 2 p.m. in mid to late summer) during which solar heating of a stream is most significant. Thus ACD can provide a direct estimate of the shading effects of streamside vegetation. Although it is possible for natural forest vegetation to have ACDs of 100%, indicating complete shading from incoming solar radiation, the ACD of old-growth stands in western Oregon generally falls between 80 and 90% (Brazier and Brown 1973, Steinblums et al. 1984). In northern California, Erman et al. (1977) found ACDs to average 75% along undisturbed streams.

The relative degree of shading provided by a buffer strip depends on a range of factors (e.g., species composition, age of stand, density of vegetation). Although buffer-strip width is also important, by itself it is not generally a good predictor of shade protection. Figure 8 illustrates the variability of ACD associated with buffer-strip width for forest stands in the Coast Range and Cascade Mountains of Oregon. Buffer strips with widths of 30 m or more generally provide the same level of shading as that of an old-growth stand.

How can we predict the effect of complete removal of riparian vegetation, partial removal, or a buffer strip on the daily temperature pattern of a stream? The answer is relatively simple: by determining the change in energy available to the stream surface. In summer this means determining how much additional surface will be exposed to direct sunlight during clear weather. This task is comparatively easy when attempting to predict the effect of completely exposing a stream reach that was fully shaded. It is more difficult to predict the change in exposed surface area that will occur following partial removal of the canopy.

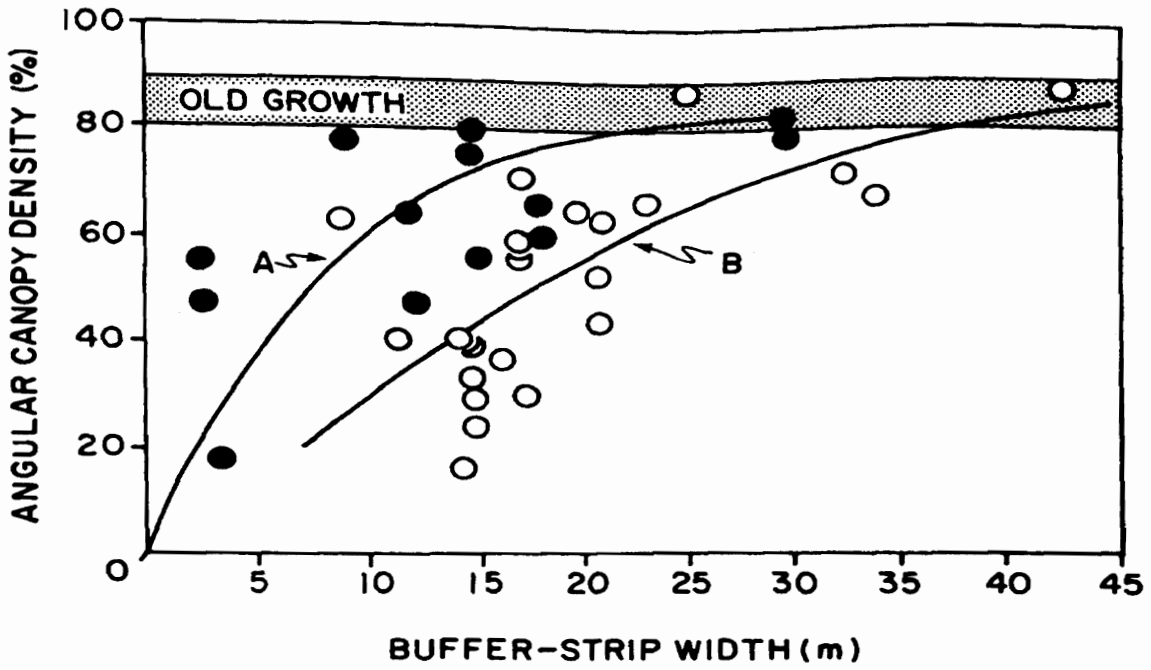

Figure 8. Relation between angular canopy density (ACD) and bufferstrip width in western Oregon. Data for (A) from Brazier and Brown (1973); data for (B) from Steinblums et al. (1984).

Once the surface area A exposed to direct-beam radiation is estimated, the increase in net energy N_h (mostly shortwave solar radiation) can be readily determined from tables and combined with an estimate of stream discharge Q to predict the temperature increase ΔT produced by harvesting:

$$\Delta T = \frac{N_h \times A}{Q} \times 0.000167 \qquad (2)$$

where N_h = net rate of heat added to the stream ($cal/cm^2 \cdot min$)

A = surface area of stream exposed to incoming solar radiation (m^2)

Q = streamflow (m^3/sec)

A detailed description of this predictive technique and the methods for laying out buffer strips to ensure temperature control are given by Currier and Hughes (1980) and Brown (1983).

Equation (2) works well for predicting temperature increases from harvest along short reaches of stream where incident solar radiation is the major contributor to the energy balance. On reaches greater than 1,000 meters, evaporative and conductive energy transfers begin to become significant dissipators of energy and must be accounted for in the prediction. Similarly, the temperature and inflow rate of groundwater must be quantified. These variables add a great deal of

complexity to the prediction (Beschta 1984), making it no longer a simple, easy-to-apply technique. From a practical standpoint, this situation also means that streams exposed over long reaches will not continue heating indefinitely (e.g., Theurer et al. 1985). They will eventually reach an equilibrium temperature as evaporation, convection, conduction, and groundwater inflow balance the incoming radiation load.

What happens to temperature when streams flow from a fully exposed reach into a shaded reach? Will they cool down just as they warmed in the sun? Probably not unless cooler water from a tributary or from subsurface seepage enters the channel. Even though the direct solar radiation may be greatly reduced in the shady reach, it is still greater than long-wave radiation losses from the warm water and is likely to be greater than energy losses from evaporation, convection, or conduction. Thus the water temperature will remain relatively unchanged in the shaded reach unless it mixes with other cooler water within the reach. Management strategies to prevent excessive temperature increases by alternating shaded with unshaded reaches will be effective only if cooler inflows occur within the shaded reaches. Where cooler inflows do not occur, temperature increases from each exposed reach will not decrease appreciably through the shaded reaches, and the result is a "stair-step" temperature increase in the downstream direction (Brown et al. 1971).

Because heat added to a stream is not readily dissipated, temperature increases in small headwater streams can increase the temperature regimes of downstream reaches. The magnitude of downstream effect depends on the relative increase in temperature and amount of streamflow from the exposed tributaries. The mixing of any heated water, from exposed headwater streams, with cooler subsurface seepage or at tributary junctions will moderate the pronounced diurnal temperature increases experienced in an exposed headwater stream. Nevertheless, where extensive reaches of channel have become exposed either as a result of clearcut logging without buffer strips or from sluiced channels due to mass soil failures and debris torrents, a cumulative effect on the downstream thermal regime should be expected. Unpublished data (Beschta and Taylor 1986) for Salmon Creek, a 325 square kilometer drainage in the Oregon Cascades, shows such a cumulative effect. A thirty-year trend of increasing summer stream temperatures has been measured during a period of extensive logging and roading throughout the basin. During the summer, maximum stream temperatures at the mouth of this drainage have increased from 16°C in the mid-1950s to 22°C in the late 1970s; minimum temperatures in summer increased approximately 2°C (from 12 to 14°C) during this same period.

Increased temperatures have also been observed in the Middle Santiam River of the Oregon Cascades as the basin was logged. Logging activities in this basin have been largely limited to areas along the lower 11 km of the river, with areas farther upstream essentially undisturbed. Thus temperature changes downstream of the logged area can be referenced against temperatures of the undisturbed section. Average daily maximum temperatures for the period May to October increased approximately 1°C from 1972 to 1982, apparently as a result

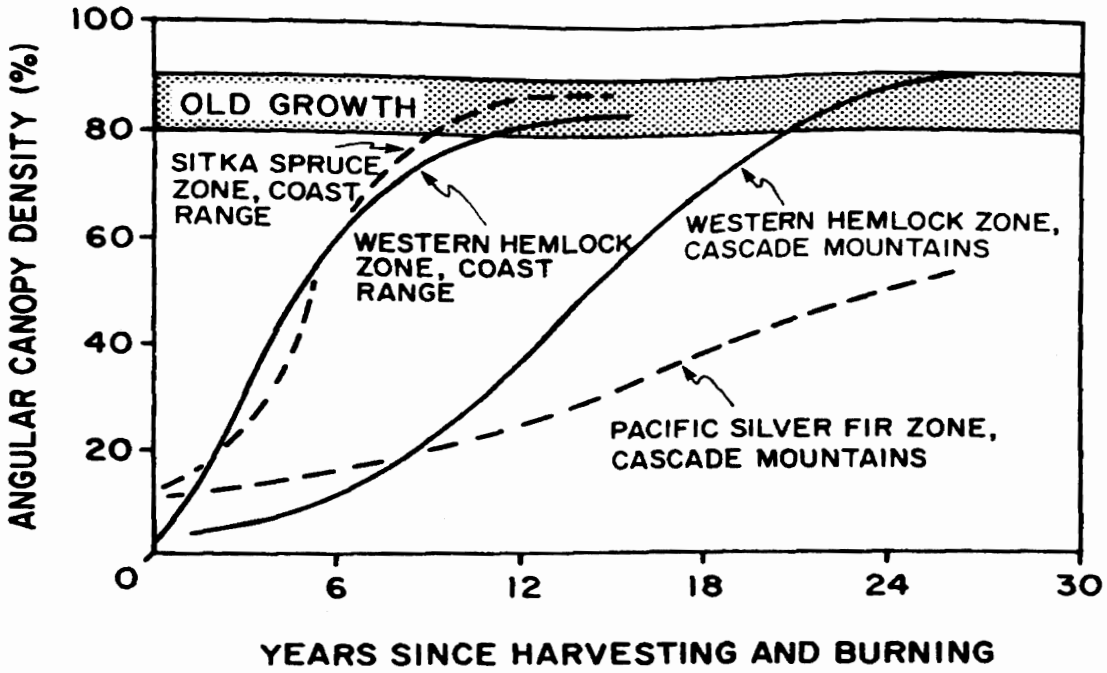

Figure 9. Relation between angular canopy density (ACD) and stand age for vegetation zones in western Oregon (Summers 1983).

of harvest (K. Sullivan, Weyerhaeuser Company, Tacoma, pers. comm.).

When temperature increases are produced by complete or partial exposure of a stream, they will subsequently decline as riparian vegetation returns. The rate of shade recovery depends on streamside conditions and vegetation. Sites in moist coastal ecosystems of the Pacific Northwest recover more rapidly than those in more arid ecosystems; sites at lower elevations more rapidly than those at higher elevations. In western Oregon, Summers (1983) examined sites with small streams that had been clearcut and burned at various times in the past to evaluate the recovery of shade (Figure 9). On the average, 50% of a stream was shaded within about five years of harvesting and burning in the Coast Range, within fifteen years from lower elevations of the Cascades (Western Hemlock Zone), and within twenty-five years for the higher elevations of the Cascades (Pacific Silver Fir Zone). Whereas small streams may be quickly overtopped by brush and effectively shaded from direct-beam solar radiation, larger streams, which require the canopies of tall conifers for shade protection, require longer periods.

Several alternatives are generally available to forest managers to prevent excessive temperature changes in order to avoid potential conflicts with fisheries interests, water quality changes, or other concerns. Where no change in temperature is permitted, a buffer strip is the obvious solution. But where some change in temperature is acceptable following logging, small clearcuts along streams, partial cuts or partial cuts within buffer strips (leaving only that vegetation that

provides shade during a critical time of the year), scheduling of cutting activity over time in a drainage, or some combination of these methods can provide a desired level of temperature protection.

THERMAL EFFECTS ON THE STREAM ECOSYSTEM

Research on the effects of thermal alterations on fish communities falls into three general areas that serve as foci for our discussion: (1) trophic effects (effects of thermal alteration on other components of the community that affect fish), (2) thermal tolerances and preferences of fishes, and (3) fish metabolism, development, and activity.

Trophic Effects

Water temperature changes in mountain streams may not only influence fish populations and productivity but also that of the microbial community, algae, and invertebrates. These latter biotic components form the energy base for fish communities, and changes in these compoents can potentially be translated into impacts on fish through a change in available food. The energy base for stream biota comes primarily from two sources: algal production and terrestrial sources of organic matter (needles, leaves, twigs, etc.) (Fisher and Likens 1973). In most forest streams, the largest proportion of available energy is from terrestrial organic inputs. The nutritional value of this organic matter to animals that ingest it is due largely to an encrusting layer of microorganisms that develops after entry into the stream (Kaushik and Hynes 1971). With increased temperatures, these microflora develop more rapidly and utilize available organic matter at a higher rate (Suberkropp et al. 1975). Rapid decomposition of organic material may promote increased invertebrate production more quickly than in cooler streams, thus leading to additional fish food at an earlier time. However, the organic matter would thus be consumed over a shorter period, so this effect may be transitory.

Where streamside vegetation has been removed, light availability and stream temperatures typically increase. Although Murphy et al. (1981) demonstrated increased stream primary production mainly from increased light availability after canopy removal, it is difficult to separate the influence of light and temperature. Light limitation of aquatic plant production has been demonstrated in several Pacific Northwest streams (Stockner and Shortreed 1978, Rounick and Gregory 1981, Walter 1984). Both increased light and temperature generally cause higher production of stream algae and, in many cases, a change in species composition. Phinney and McIntire (1965) examined the influence of both light and temperature on production of a natural assemblage of periphyton in an artificial stream channel. They found that algae production was higher at 18°C than it was at 8-10°C for all tested light levels. However, the influence of increased light on algae growth in the two channels differed. At 18°C, algal production increased with light intensity up to an intermediate level and decreased at higher illumination. In the cooler channel, algal productivity increased up to the highest light level tested. Kevern and Ball (1965) and Bisson and Davis (1976) also noted a marked increase in periphyton

production in heated stream channels compared with channels exposed to similar light regimes at lower temperatures. In contrast, Stockner and Shortreed (1978) conclude that nutrients and light are important regulators of algal growth in Carnation Creek, B.C., but that temperature does not have an important regulatory effect.

Changes in the taxonomic composition of the algal community in a stream following exposure to direct sunlight have been noted in several studies. In a spring-fed stream where temperature was constant (7°C), but light was experimentally varied through shade manipulation, Busch (1978) found that increased light both altered the species of algae present and caused an increase in algal biomass and invertebrate production. Warren et al. (1960) noted that in Oregon streams filamentous green algae dominated where at least 3% of full sunlight reached the substrate. In shaded stretches, diatoms predominated. Temperature also probably plays a role in this shift from a flora dominated by diatoms to one of green algae. Bisson and Davis (1976) noted a heavy growth of filamentous green algae in their heated channel. Their control channel had far less of this type of algae despite being exposed to similar light levels. The heavy growth of filamentous algae in the heated stream trapped considerable amounts of fine sediment, resulting in a shift in the invertebrate community to one dominated by oligochaete worms. These worms were rarely consumed by fish during this experiment. However, the general significance of such shifts in algal community composition on fish production in mountain streams is not well understood.

The influence of the changes in the energy base on higher tropic levels of the stream after canopy removal is difficult to interpret (Lee and Samuel 1976). Higher production levels of both microorganisms and algae suggest corresponding increases at higher levels of the food chain. However, the faster processing rate of organic matter by microbes coupled with a decrease in the input of leaves, needles, and other organic materials after clearcutting may lead to a scarcity of this material at certain times of the year. For example, Fisher and Likens (1973) found that under natural forested conditions, organic matter of leaf and twig size persisted in a small New England stream for about a year. With the more rapid processing at higher temperature, the residence time of this material in the stream should decrease. Since most terrestrial organic matter enters the stream as a pulse in autumn, an increased rate of processing could reduce summer stocks of this material, hence lowering food supplies for invertebrates dependent on this material. Thus when streams become exposed following removal of riparian vegetation, a short-term increase (from logging slash) followed by a longer term decrease in the availability of terrestrial organic matter may occur. The effect on the invertebrate populations and the extent to which it is offset by greater algal productivity are not known.

Nevertheless, despite the potential for deleterious effects, invertebrate standing crops in headwater streams that drain clearcuts are generally greater than those either in old-growth forests or in second-growth deciduous forests (Hughs 1966, Newbold et al. 1980, Smith 1980, Murphy and Hall 1981, Murphy et al. 1981). It would

appear that the possible deleterious effects of removing riparian vegetation are outweighed by the increased primary production resulting from increased temperatures, light levels, and nutrients.

Invertebrates may be directly influenced by temperature increases, apart from the influence of their food supply. At higher temperatures, invertebrates feed more actively and, as a result, exhibit elevated growth rates (Cummins et al. 1973).

Temperature increases have at times been related to noticeable decreases in invertebrate production. Minshall (1968), studying a spring-fed brook in Kentucky, found a large decrease in both species diversity and numbers of individuals when stream temperature was elevated in a clearcut. However, spring-fed streams, in general, tend to have a constant, cold temperature year round and hence a fauna specialized for these unusual circumstances. This type of system may be especially sensitive to elevated temperatures.

Higher stream temperatures can also cause accelerated development of aquatic insect larvae, leading to early adult emergence (Nebeker 1971a, 1971b, Moore 1980). Salmonid fishes prey heavily on emerging adults, and accelerated insect development may benefit fish by making more food available earlier in the year. However, for most trouts (Salmo spp.) the emergence of fry from spawning gravel and the onset of active feeding coincides with spring and early summer hatches of aquatic insects.

Bisson and Davis (1976), working with two experimental stream channels, one heated about 4°C over the other, reported a reduction in the number of taxa in the heated channel. They also reported that nearly all the species represented in the channels produced higher biomasses in the control stream. There were exceptions to this rule, however, the most notable being a species of oligochaete worm and a snail, both of which exhibited increased production in the channel. Neither species was eaten by the juvenile chinook salmon in the channels, and as a result the increased production was of no benefit to the fish.

Sherberger et al. (1977) indicate that a temperature of at least 28°C was needed to influence mortality in Isonychia, a mayfly, while Hydropsyche, a caddisfly, withstood brief exposures up to temperatures of 26.5°C. Temperatures below the lethal limit did not have an effect on survival. At least in the case of these two invertebrates, lethal levels are above that needed to severely affect salmonids. Thus increased temperatures would probably eliminate the fish before their food resource was affected.

Some invertebrates are able to avoid high summer temperatures, such as those created by canopy removal, by adjusting their life cycle to spend the stressful period in a resistant, resting stage. Macan (1961) demonstrated that the mayfly, Rithrogena semicolorata, emerged earlier in the year in a warm stream than normally seen in cooler waters. The eggs deposited by the adults in spring in the warmed stream remained dormant for a longer period than those in cooler streams,

hatching only when water temperatures decreased in autumn. Many invertebrates, however, such as those that spend one or more years in a larval form, would not generally be able to avoid temperature extremes by using this tactic.

Increased temperatures have been implicated in several studies as leading to increased entry of invertebrates into the drift (Pearson and Franklin 1968, Waters 1968, Bisson and Davis 1976). However, other investigators have not found this phenomenon (Bishop and Hynes 1969, Wojtalik and Waters 1970, Reisen and Prins 1972). The drift reaction of various invertebrates is probably species specific, which would account for the discrepancies noted in these studies. Increased drift rate would make more food available for fish, since drift forms the major food source for salmonids.

The influence of elevated temperatures on salmonid production of natural systems is difficult to delineate because of the variety of other factors concurrently affected. However, more abundant invertebrates have been observed in streams draining clearcuts (e.g., Murphy et al. 1981). Increased algal productivity leading to higher invertebrate production, and consequently to elevated food availability for fish, has been hypothesized as a cause of the frequent observation of increased salmonid production in streams exposed to sunlight (Murphy and Hall 1981, Weber 1981, Hawkins et al. 1983, Bisson and Sedell 1984). The consistency of these observations has led to general acceptance of the hypothesis that salmonid abundance is greater in streams draining clearcuts because there is more available food. Consequently, it is also generally accepted that an understanding of the effects of logging on the entire stream ecosystem is essential if we are to make progress in understanding the narrower problem of logging impacts on fish production.

Thermal Tolerances and Preferences of Fishes

The systematic study of the thermal tolerances and preferences of fishes began in the last century (see Brett 1970). Our understanding has slowly broadened from the concept of a single end point (e.g., a single upper lethal temperature) to a two or three factor concept (the zone of thermal tolerance of Fry 1964, where lethal temperatures are modified by acclimation temperature and exposure) and finally to a multifactorial concept where a multidimensional zone of thermal tolerance is defined by many interacting environmental factors (Brett 1970). Such studies are of necessity conducted under the tightly controlled conditions of the laboratory. The relevant objective of this work is to define for a particular species the boundaries of the thermal habitat. It may then be inferred that any land use activity that drives temperatures outside these boundaries will have deleterious and possibly lethal consequences.

Have any generalities relevant to our general topic emerged from this work? Apparently salmonids are tolerant of the extremes in temperature they are likely to encounter over their life spans and geographic ranges. In particular, the life stages of salmonid species that rear in freshwater seem especially tolerant of extreme high

temperatures (extreme in the sense that most species can tolerate temperatures that are many degrees higher than any they are likely to encounter).

Because fish are cold-blooded, or poikilothermic, the temperature of their external environment dictates their internal temperature, which in turn regulates metabolic rate. Thus changes in water temperature directly influence the physiology and activity of fish. Furthermore, the relative sensitivity of fish to temperature changes depends, to a great extent, on their stage of development.

Early studies evaluated the effects of elevated temperatures on the survival of salmon eggs. For example, Combs and Burrows (1957) examined the influence of various temperatures on the survival of chinook salmon eggs. They found the upper lethal limit to be between 14 and 15.5°C. Similarly, Seymour (1959) reported that chinook eggs would not survive to the stage of vertebral development at temperatures in excess of 16.5°C. Sockeye salmon eggs appear to be even more susceptible to elevated temperatures, as Combs (1965) set the lethal level for development of this species at 13.5°C. Even in cases where temperature elevation is not sufficient to cause direct egg mortality, morphological characteristics of the fish can be altered as a result of high temperature during embryonic development (Orska 1963). Although laboratory studies provide an upper bound on temperature tolerance of eggs and embryos exposed to constant temperatures, the temperature environment in redds may be quite different.

Spawning and egg development in salmonids occurs during the autumn, winter, and spring. In coastal Oregon, Ringler and Hall (1975) found intragravel water temperatures during the time of coho salmon egg incubation in a stream draining a clearcut watershed to be well below those reported to cause developmental abnormalities. In the case of some races of spring-spawning salmonids, egg development may continue into late spring when the possibility of coincident low stream flow and sunny days could produce water temperatures detrimental to the development of the eggs. The extent to which this occurs is unknown. In addition to the influence elevated temperatures may have on egg development, depressed temperatures have been seen to lengthen incubation periods or increase freezing mortalities (Alderdice and Velsen 1978, Reiser and Wesche 1979, Reiser and White 1981). However, the effect removal of streamside vegetation has on minimum stream and intergravel temperatures in winter has generally received little attention (Needham and Jones 1959, Sheridan 1961).

Lethal threshold temperatures for Pacific salmon and steelhead trout have been identified for laboratory conditions (Figure 10), where the fish are held at a given temperature for long periods of time. This situation does not exist under natural conditions (even where temperatures have been elevated because of the removal of streamside vegetation), hence the direct application of laboratory temperature limits to field conditions is tenuous. Streams flowing through clearcut areas may display sizable fluctuations of water temperature over the period of a day, and maximum temperatures may exceed the reported lethal threshold temperatures for a brief time. However, these streams may

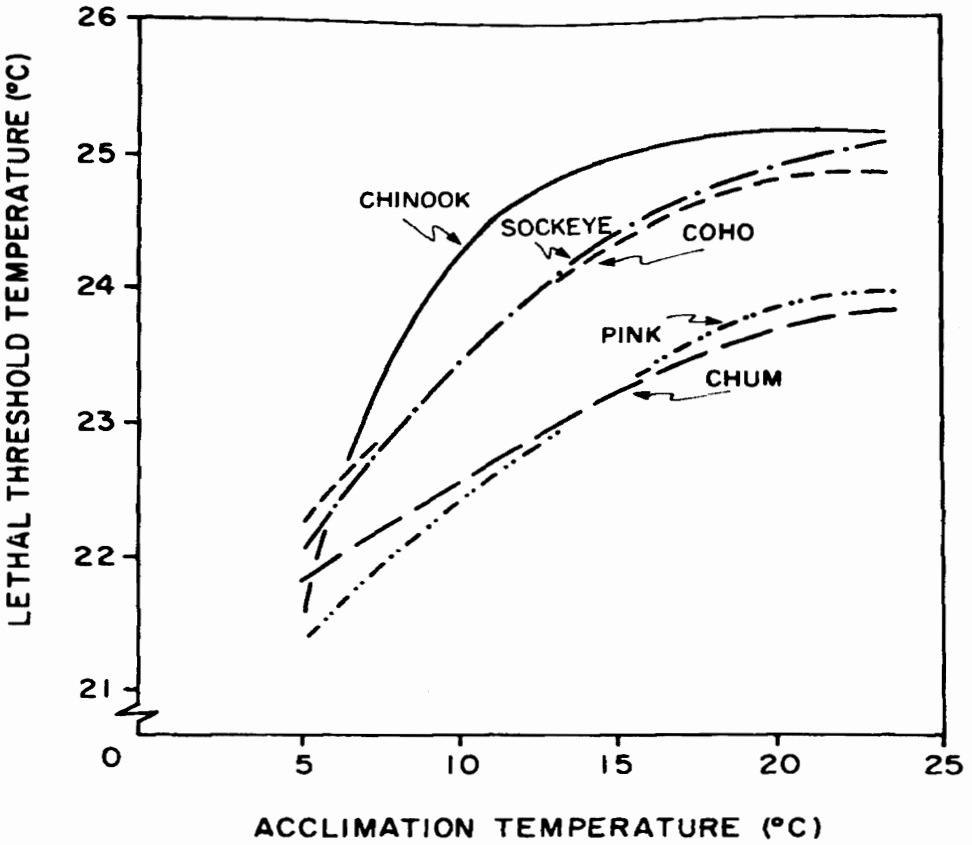

Figure 10. Lethal threshold temperatures for juvenile salmonids (from EPA 1973): chum salmon (Oncorhynchus keta), pink salmon (O. gorbuscha), coho salmon (O. kisutch), sockeye salmon (O. nerka), and chinook salmon (O. tshawytscha).

contain sizable populations of salmonids (Bisson et al. 1985). Apparently fish are able to withstand periodic, short-term exposures to fairly high temperatures with minimal detrimental impact.

The temperature levels preferred by rearing juvenile salmonids have also been evaluated in a number of laboratory studies. Brett (1952) found that the range of greatest preference by all species of Pacific salmon was from 12 to 14°C for acclimation temperatures ranging from 5 to 24°C. Brett (1952) also noted a definite avoidance of water over 15°C. Mantelman (1960) observed that juvenile rainbow trout were most commonly found in water ranging from 13 to 19°C and actively avoid water in excess of 22°C. These preferred temperatures may be exceeded in streams draining clearcut watersheds (Brown and Krygier 1970, Sheridan and Bloom 1975).

Elevated temperatures can also influence salmonid behavior. Upstream movement of adult sockeye salmon and steelhead trout was curtailed in the Columbia River when water temperatures reached 21°C (Lantz 1971). At these times the migrating fish congregated in the mouths of cooler tributaries until water temperatures decreased. Keenleyside and Hoar (1954) reported that both chum and coho salmon

fry exhibited progressively increased rates of downstream migration as water temperature increased. Temperature preferences of fish have been the target of many studies; these have been summarized by Coutant (1977) and Jobling (1981).

For the coho salmon of Carnation Creek there is no evidence that increased summer temperatures (several degrees outside of their probable historical limits) and increased diurnal fluctuations affected fish distributions, at least on a macroscale. The availability of small-scale cover ("fine logging debris") was the important factor in determining the abundance of fry in stream sections whose banks had been completely clearcut, not the increases in stream temperatures in those sections (Scrivener and Andersen 1984).

Larkin (1956) noted that, as a rule, freshwater fish are adaptable to a wide range of environmental conditions and that the outcome of competitive interactions may vary depending on these conditions. A species that is dominant under one set of conditions may not necessarily prevail when conditions differ. Two recent studies have examined the influence of water temperature on interspecific interactions between fish. Reeves (1985) showed that the outcome of interactions between juvenile steelhead trout (age 1+) and the redside shiner (Richardsonius balteatus) was mediated by water temperatures. Water temperatures and the presence of the other species influenced production and activity in laboratory streams and distribution in the field and laboratory. Trout dominated in cool water (12 to 15°C) and shiners in warm water (19 to 22°). Baltz et al. (1982) found that competition between two species of nongame fish was affected by water temperature: one species dominated in cool water and the other in warm. Alteration of the temperature regime may influence not only growth and survival of a given species but also the structure of the fish community.

The development of thermal tolerance criteria in laboratory studies seems to have been markedly unsuccessful in helping understand the effects of logging on fish communities in the Pacific Northwest. To our knowledge, there are no records of elevated temperatures following shade removal that have led to extensive fish kills. An exception is the fish kill observed following a hot slash fire in Needle Branch, Oregon, during the Alsea Watershed Study (J. D. Hall, Oregon State University, Corvallis, pers. comm.). In fact, there is a general tendency for salmonid biomass to be higher in streams draining clearcuts (Burns 1972, Smith 1980, Martin et al. 1981, Murphy and Hall 1981, Holtby and Hartman 1982, Hawkins et al. 1983, Bisson and Sedell 1984, Scrivener and Andersen 1984). While such increases may have been due to many factors, the generality of the observation suggests that temperature increases resulting from clearcut logging do not, by themselves, have significant deleterious effects on salmonid abundance. One reason is that stream temperatures throughout the region seldom exceed, for extended periods, the tolerance limits of the resident salmonid species. The fish themselves also appear to be behaviorally "plastic" and can act to reduce either or both the temperatures they are exposed to and the duration of the exposure. For instance, salmonids appear to seek out cool water regions in streams where temperatures approach and exceed tolerance limits (Gibson 1966, Kaya et al. 1977). Even in studies where

elevated summer temperatures, resulting from streamside disturbance, appear to have precluded salmonids, strong arguments can be made that the temperature effects were indirect. For example, Barton et al. (1985) concluded that the suitability of streams in southern Ontario for trout was characterized by maximum summer temperatures. While the effects of temperatures could have been direct, the authors suggest that elevated temperatures over several decades allowed the successful invasion of warm water competitors of the salmonids, possibly resulting in their competitive exclusion.

Although salmonid populations may respond favorably to opening of the riparian canopy, increased water temperatures, or both, resulting from management activities in these streams, the cumulative effect of these changes on other areas of the watershed has received little or no consideration in the Pacific Northwest. Water temperature in mid-order streams lower in a watershed depends largely on the temperature of water entering from upstream. Mid-order streams are important rearing areas for juvenile anadromous salmonids, especially chinook salmon and >1+ steelhead trout. They also have a more diverse fish community than lower order streams do (Vannote et al. 1980). Changes in environmental conditions may result in a decrease in available habitat for salmonids and alter the outcome of interactions between salmonids and potential competitors. Environmental changes less favorable to salmonids, such as increased water temperature in higher order streams, could offset any increase in abundance or production of anadromous salmonids that might occur from opening the canopy along lower order streams, or could even result in an overall decrease in population.

Temperature Effects on Fish Metabolism, Development, and Activity

The second general approach that has been used to study the effects of thermal change of stream fishes considers the effects of temperatures on metabolism, development, and activity. Within the bounds of thermal tolerance for any species, temperature is an important modifier of metabolism which then acts through numerous pathways to affect development, growth, activity, and reproduction or, more generally, survival and success (Brett 1958, Brett 1970, Lantz 1971). This rather broad field has been reviewed extensively (e.g., Fry 1967, Warren and Davis 1967, Brett 1970).

Except when fish are starving, the response of growth and activity to increasing temperatures is enhancement up to some optimum temperature and them diminution as the optimum is exceeded. In general, the optimal temperatures for growth and activity are similar to those likely to be encountered at a particular stage of the fish. It is also generally the case that the optima are rather broad, especially for species and life stages where the temperatures encountered are wide ranging.

Laboratory studies with salmon and trout at constant temperature levels have generally shown decreased growth with higher temperatures when food was limiting. A fish will not grow until metabolic energy requirements are first met (Warren and Davis 1967), and the metabolic rate increases with temperature. Dwyer and Kramer (1975) examined the

metabolic rate of cutthroat trout at several temperatures. They measured the lowest metabolic rate at 5°C and the highest at 15°C with a decrease in rate at 20 to 24°C. Normally, metabolic rate would be expected to continue to increase as a function of temperature; however, in this experiment the trout held at 20 and 24°C fed very little, and it is likely that the decrease in metabolic rate was brought on by starvation. Wurtsbaugh and Davis (1977) found that maintenance food levels (the amount needed to maintain constant body weight) for rainbow trout were 2.7% of body weight per day at 6.9°C and 7.5% at 22.5°C. Averett (1968) found that juvenile coho salmon required twice the amount of food to grow at 17°C than at 5°C. In many salmonids, however, the dimunution in growth and swimming performance with increasing temperature occurs primarily at temperatures near the lethal thresholds (e.g., Brett 1967, Brett et al. 1969).

Wurtsbaugh and Davis (1977) indicated that if steelhead trout were fed limited amounts of food, growth decreased at higher temperatures. The difference in productivity lessened, however, if the ration was increased. Similarly, the production of coho salmon has been shown to decrease at higher temperatures under conditions of limited food (Iversen 1972). The decreased production in Iversen's (1972) study was attributed to both increased metabolic rate and a reduction in food availability due to a decrease in the invertebrate population in the artificial stream channel in which the experiment was conducted. Bisson and Davis (1976) also reported a decrease in fish production with increased temperature for juvenile chinook salmon. They subjected artificial stream channels to diurnal and annual temperature cycles with one of the channels heated and maintained at a temperature approximately 4°C higher than the control. Production in the cooler channel exceeded that in the heated channel by 100% the first year of the experiment and 30% by the second year. The decreased production in the heated channel was attributed to increased metabolic requirements and reduced food levels.

Fish productivity at elevated temperatures could probably be maintained, provided the food supply increased enough to compensate for increased metabolic requirements. In a study in which water temperature in artificial streams varied daily, production of juvenile steelhead trout (>1+) was two and one half times greater in cooler water (12 to 15°C) than in warmer (19 to 22°C) water (Reeves 1985). One reason for these differences was that fish in the cooler water were able to maintain territories in areas of higher food concentration, which were in areas of greater water turbulence.

Nearly all these studies on the influence of temperature on fish production were conducted in artificial streams. More recent studies of natural streams have not always corroborated the results from artificial channels. Martin et al. (1981) compared a population of cutthroat trout inhabiting a shaded section of stream with fish in a section of stream exposed to direct sunlight. They could find no difference in trout biomass or density between the two sections, although the exposed section had a daily maximum temperature that averaged 2°C higher than the shaded section. However, in a final analysis of the data set, Martin (1985) concluded that in the canopy area with no temperature change,

density increased. In the open area where temperature increased, growth increased but density did not. Some studies of salmonid populations in streams exposed to sunlight have reported increases in production. For example, Murphy and Hall (1981) reported higher salmonid biomass in streams exposed to sunlight than in streams flowing through old-growth forest in Oregon. The temperature increases in the exposed streams were slight, ranging from 0.1 to 1°C, thus the fish biomass increase is probably attributable to factors other than increased temperature. Bisson and Sedell (1984) also reported higher salmonid biomass in streams draining clearcut areas than in shaded systems in southwestern Washington, but these authors did not monitor stream temperatures.

While the growth efficiency of salmonids is theoretically highest at low temperatures, activity of fish in cold water is at a minimum and feeding rates are correspondingly depressed. Thus optimum growth usually occurs at some intermediate temperature where activity levels are high enough to ensure active feeding, and metabolic conversion efficiencies are also relatively high. "Optimum" stream temperatures for various stages of development and species of fish are shown in Table 3.

The relation between increases in diurnal variations and growth rate is unknown. For some species, increases in diurnal variation might be beneficial. Biette and Green (1980) have demonstrated for sockeye salmon that temperature fluctuations, resulting from diurnal migrations throughout the thermoclines of stratified lakes, are associated with growth increases at low, and therefore realistic, ration levels. In contrast, Edwards et al. (1979) have shown for brown trout that increases in diurnal temperature fluctuations with constant mean temperatures result in diminution in growth. As noted earlier, streams often contain pockets of water cooler than the ambient stream (Keller and Hofstra 1982, Bilby 1984). These areas have been seen to be used by salmonids during times of stressful temperatures (Gibson 1966, Kaya et al. 1977), and may in part be responsible for the presence of salmon and trout in streams that occasionally attain very high temperatures (Bisson et al. 1985). However, the potential for this mechanism to assist in reducing thermal impacts to fish may be limited by the relative scarcity and, potentially, low oxygen concentration of cool-water areas (Bilby 1984).

Temperature is known to affect other physiological processes. For instance, as temperatures increase, diseases often become more virulent. The higher susceptibility to disease is brought on by a combination of higher metabolic rates and elevated levels of physiological stress. Ordal and Pacha (1963) and Parker and Krenkel (1969) report that a large number of common diseases of salmonids, including kidney disease, furunculosis, vibrosis, and columnaris, become more virulent as temperature increases. Nakatani (1969) found that columnaris became well established in salmonids at temperatures of 17 to 18°C under crowded conditions. When temperatures reached 21°C, the disease killed most of the infected individuals. Chinook and coho salmon and steelhead trout, infected with furunculosis, a bacterial infection, were held at temperatures ranging from 3.9 to 20.5°C (Groberg et al. 1978). At temperatures below 10°C, mortality of the fish ranged from 2 to 26% of

Table 3. Water temperature criteria, in degrees Celsius, for fish in western North America.

Species	Upstream Migration	Spawning	Incubation	Juvenile Rearing		
				Preferred	Optimum	Upper Lethal
Chinook	---	5.6-13.9	5.0-14.4	7.3-14.6	12.2	25.2

the infected fish. However, at 20.5°C, 93 to 100% of the infected fish died within two to three days. These investigations were conducted under conditions of constant temperature and high population densities. As with much of the temperature research, it is difficult to transfer work done in a controlled environment to a situation in the field. The virulence of various fish diseases under conditions of varying temperatures and relatively low population densities has seldom been examined.

An exception to the general rule of increased disease virulence with increased temperature was noted by Bisson and Davis (1976). They found a reduced infection rate of juvenile chinook salmon by the trematode parasite (Nanophyetus salmicola) for fish held in water 4°C warmer than a control. This seems to represent an instance where the infecting organism is less tolerant of temperature elevation than the host.

It is generally accepted that the temperature regime is one habitat component to which fish populations are locally adapted (Ricker 1972). For instance, Leggett and Carscadden (1978) demonstrated for the anadromous American shad (Alosa sapidissima) that the principal factor determining interpopulation differences in reproduction strategies was the variability in thermal regimes of the natal streams. Since developmental and metabolic rates in fish are highly dependent on temperature, variations in temperature lead to variation in the timing of such life history events as emergence and migrations. In lakes of the Fraser River drainage, interannual variations in sockeye salmon smolt sizes that are not accounted for by density appear determined by the length of the growing season, which, in turn, is determined by temperatures around the time of emergence (Goodlad et al. 1974).

Temperature variations around the time of smolt migration have been shown to be the principal source of interannual variability of Atlantic smolt migration timing in Norway (Jonsson and Ruud-Hansen 1985). Thedinga and Koski (1984) have shown, in their studies of the coho salmon of Porcupine Creek, Alaska, that variations in the timing of smolt outmigrations can have deleterious impacts on marine survival.

Since the timing of life history events is an adaptation to local conditions, it can be expected that changes in those environmental conditions, such as changes in temperature regimes caused by logging, may reduce the fitness of affected populations, with deleterious consequences to production (Leggett and Carscadden 1978). The possible effects of altering events such as fry emergence and smolt and adult migration have been mentioned in the context of logging effects (Narver 1972, Moring 1975b, Holtby and Newcombe 1982, Hartman et al. 1984), but with the exception of research at Carnation Creek, B.C., there has been little systematic study.

In a recently completed study, Holtby (1986) attempted to assess the effects of temperature on the timing of life history events of a population of coho salmon in a small coastal stream (Carnation Creek). Temperature-related impacts on this fish population were seen to bring about a series of changes: (1) logging-related (58%) and climate-related (42%) increases in late winter temperatures accelerated fry emergence (Holtby and Newcombe 1982, Tschaplinski and Hartman 1983); (2) increased length of growing season, resulting from earlier emergence, led to increased fry size entering their first winter (Hartman et al. 1984); (3) increased fry size led to higher overwinter survival (Holtby and Hartman 1982); (4) higher overwinter survival and size led to increased numbers and sizes of 1+ smolts; and (5) seaward migration of the smolts in spring was accelerated by seven to ten days.

The impacts of temperature increase on the freshwater phases of the coho population generally suggest increased production of smolts. However, earlier release to the sea of hatchery-stock coho smolts has been linked to decreased marine survival (Bilton et al. 1982). Therefore, the benefits that resulted from changes in smolt size and numbers following logging (Figure 11) may be substantially or wholly offset by increased saltwater mortality attributable to earlier migration.

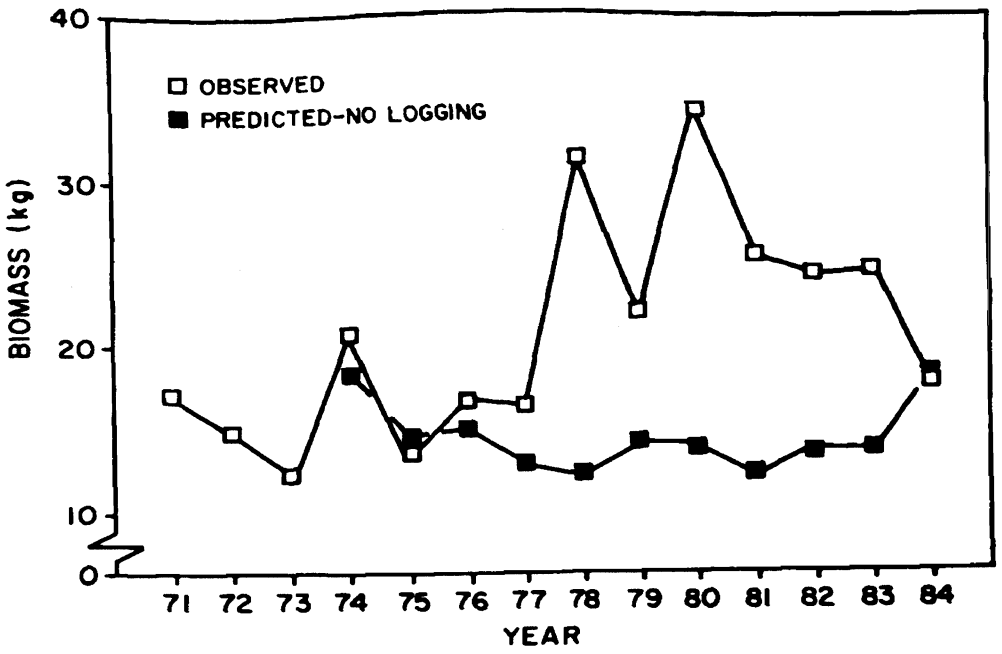

Figure 11. The combined weight of coho salmon smolts produced by Carnation Creek, B.C. Logging began in the winter of 1975-76 and was largely complete in those areas of the watershed immediately surrounding anadromous salmon habitat by the summer of 1979. The line of predicted smolt output assumes that temperature changes associated with logging did not occur (Holtby 1986).

Several important points emerge from the studies at Carnation Creek, B.C. First, the alteration in the timing of life history events due to temperature changes may significantly affect fish production. Second, temperature effects are not necessarily confined to the stream, but ultimately may affect returns of adults to the stream. Third, the temperature changes that resulted in effects on fish production were relatively small and clearly not life threatening changes that occurred in the winter and spring. The much larger thermal effects of logging that were observed during the summer had no detectable effects on coho smolt production.

SUMMARY AND CONCLUSIONS

Stream temperatures in forested watersheds in the Pacific Northwest can be characterized as (1) predictable along such various spatial scales as latitude, elevation, and stream order, (2) predictable on temporal scales such as season and day, and (3) of low variability both between years and within days. It has been repeatedly demonstrated that removal of riparian vegetation alters stream temperature regimes. In coastal streams, where prolonged periods of below zero temperatures are rare, removal of riparian vegetation invariably results in increased mean and maximum stream temperatures and increased diurnal ranges. Over a sufficiently long period, effects of streamside

logging on thermal regimes can be detected throughout the year, and not just in the summer as is the general perception. In regions where winter temperatures are below freezing, the removal of riparian vegetation may result in the depression of stream temperatures and greater periods of freeze-up, but such situations have been little studied.

For a given stream, the magnitude of the temperature increase after streamside logging is proportional to the increase in exposure of the stream to incoming solar radiation, or, conversely, to the amount of shade reduction. Thus buffer strips (composed of vegetation not susceptible to blow down) are an effective means of providing shade and preventing temperature changes. The exact configuration and width of such buffer strips can be highly variable and site specific. In western Oregon, it appears that buffer strips 30 m or more in width along small streams provide approximately the same level of shading as an old-growth forest. More important, an understanding of the energy transfer influencing stream temperature permits the dimensions of streamside logging to be controlled to produce the desired effects on stream temperatures, ranging upward from no effects at all.

There are many reasons why the observed logging-related temperature increases have not had significant deleterious effects on resident salmonids. Among these are (1) the wide thermal tolerances of the freshwater forms of most of the resident salmonid species, (2) the natural diurnal cycling of stream temperatures, which limits exposure to maximum temperatures, (3) the occurrence of localized cool-water sources, which fish seem readily able to locate and utilize, (4) the inability to extrapolate tolerance limits determined under homogeneous laboratory conditions to the spatially and temporally complex thermal environments of streams, and (5) the ability of fish to migrate to other locations or to curtail activities temporarily when temperatures become stressful. Although increased summer temperatures remain a concern to fisheries managers, it appears that fish are generally able to tolerate such increases without major adverse impacts on growth or mortality.

Because of the extensive geographical range of salmonids, the effects of temperature on these fish should be viewed in a regional context. In at least some regions of the Pacific Northwest, concern over the lethal effects of elevated summer temperatures in small streams draining deforested watersheds is unwarranted. This is certainly the case in the low elevation, coastal streams of British Columbia and Washington. However, in other regions of the Pacific Northwest, increased temperatures from logging may remain a significant concern. For example, in southern areas (southern Oregon and northern California) and areas east of the Cascade Mountains, increased temperatures due to logging may have a greater impact on fish populations than in areas of cooler climate, because of ambient water temperatures. Unfortunately, for most of these areas little information is available that might demonstrate the influences increased water temperatures have on fish populations.

Temperature is clearly an important component of the habitat of many stream organisms, including the fish, and most organisms respond

to the changes in stream temperatures caused by streamside logging. But because temperature is only one of several closely interconnected physical factors that are affected simultaneously by streamside logging, it is questionable whether our understanding of the impacts of logging on fish production can be increased by trying to study the effects of temperature in isolation.

Increased temperatures following logging, together with increased light levels and increased nutrient concentrations, often lead to general increases in productivity in the trophic levels that form the basis of fish production. Increased temperatures, light, and nutrients all play a role. Temperature directly affects development rates of fish; in some systems, the temperature increases lead to earlier emergence, longer growing seasons, and increased survivals at critical times in the life histories of fish. Increased temperatures also directly affect metabolism and activity levels of fish.

The apparent generality of enhanced fish production after streamside logging could be an artifact of geographically limited data or a "coastal rain-forest" perspective. For instance, there is relatively little known about the effects of logging on stream temperatures and fish production in areas where streams freeze in the winter. In such regions, production "bottlenecks" might occur during the winter period of low flows and freezing temperatures. Slight changes in stream exposure might cause decreased stream temperatures, and, coupled with other physical effects of logging such as channelization and decreased pool depths, could conceivably decrease winter habitat for fish and decrease production (Bustard 1985). Under such circumstances, enhanced summer production would be essentially nullified by worsened winter conditions.

The same streamside activities that lead to changes in temperature and light levels precipitate other changes in the stream (Bisson et al., Everest et al., Swanson et al., and Sullivan et al., in this volume). Streamside logging has often been associated with changes in sedimentation, bank stability, channel morphology, large woody debris, and other factors that ultimately alter the productive capacity of a stream for fish. Where sources of large organic debris have been removed, the effects of streamside logging on the physical configuration of the stream can extend for decades.

There are many promising areas for research on the impacts of streamside management on fisheries. There is a great need to develop empirical predictors of the productivity gains to be had from controlled streamside disturbance (In what situations should the streamside be left unaltered? If there are productivity gains to be had, how can streamsides be managed to maximize those benefits?). A great deal has yet to be learned about the processes governing the productivity of salmonids in the diverse stream types and climatic zones in the region. This knowledge is essential if the riparian zone is to be successfully managed. A technological challenge lies in the development of techniques that maximize the beneficial effects while minimizing or mitigating deleterious impacts.

Considering the productivity gains that may be had by judicious streamside treatments, it seems to us an overly conservative view to eliminate all forest management activity in the riparian zone. However, much remains to be discovered before managers can abandon their cautious stance on streamside logging. Therein lie the challenges for joint fisheries-forestry research.

ACKNOWLEDGMENTS

Bilby, R. E., and J. W. Ward. 1991. Characteristics and function of large woody debris in streams draining old-growth, clear-cut, and second-growth forests in southwestern Washington. Can. J. Fish. Aquat. Sci. 48: 2499–2508.

Amount of large woody debris (LWD) surveyed in 70 stream reaches flowing through old-growth, clear-cut, and second-growth forests decreased with increasing stream size for all stand types but was greatest at old-growth sites. Average piece volume was larger at old-growth sites than at other stand types in streams >10 m wide, but no differences were seen in smaller streams. Scour pools accounted for 90% of the wood-associated pools at second-growth and clear-cut sites but only 50% at old-growth sites, which contained more pools than other stand types, particularly for larger streams. Pool size was similar for all stand types in smaller streams, but averaged 10 m^2 in streams >10 m wide at old-growth sites and 4 m^2 for other stand types. Pool size was similar for all stand types in smaller streams. Sediment and fine organic matter retained by woody debris decreased with increasing stream size for all stand types, but old-growth sites contained greater amounts of both materials than other stand types. The frequency of pool formation, the type of pool formed, and sediment accumulation were influenced by the amount of fine debris associated with LWD. Changes in LWD amount, characteristics, and function occurred very rapidly following removal of streamside vegetation.

Les quantités de gros débris ligneux (GDL), étudiées dans 70 tronçons de cours d'eau s'écoulant dans de vieilles forêts, des forêts coupées à blanc et des forêts de seconde venue, ont diminué en fonction de l'augmentation de la taille des cours d'eau dans tous les types de peuplements, mais ce sont les vieilles forêts qui ont donné lieu aux quantités de GDL les plus importantes. Le volume moyen des débris présents dans les cours d'eau d'une largeur supérieure à 10 m a également été plus grand dans les vieilles forêts que dans les autres sites, mais dans le cas des cours d'eau plus étroits, on n'a pas observé de différence entre les trois types de peuplements. Les zones calmes d'affouillement représentaient plus de 90 % des zones calmes formées par les débris de bois dans les forêts de deuxième venue et les forêts coupées à blanc, mais seulement 50 % dans les vieilles forêts, qui comptent un plus grand nombre de zones calmes que les autres types de peuplements, surtout en ce qui a trait aux cours d'eau plus larges. La taille des zones calmes dans les petits cours d'eau était semblable dans tous les types de peuplements, alors que dans les cours d'eau de plus de 10 m de largeur, elle était en moyenne de 10 m^2 dans les vieilles forêts et de 4 m^2 dans les autres peuplements. Les sédiments et les matières organiques fines retenus par les débris ligneux ont diminué en fonction de l'augmentation de la largeur du cours d'eau dans tous les sites; toutefois, les vieilles forêts contenaient de plus grandes quantités de ces deux matériaux que les autres sites. La quantité de débris accompagnant les GDL a influé sur la fréquence de formation des zones calmes, le type de zones calmes et l'accumulation de sédiments. Des modifications de la quantité de GDL ainsi que de leurs caractéristiques et de leur rôle sont apparues très rapidement après l'élimination de la végétation riparienne.

Large woody debris (LWD) controls many of the structural and functional properties of smaller streams in forested areas (Bilby and Likens 1980; Harmon et al. 1986; Bisson et al. 1987; Bilby and Ward 1989). Wood affects channel form through the formation and stabilization of pools, waterfalls, and gravel bars (Heede 1972; Bilby 1981; Lisle and Kelsey 1982; Lisle 1986). LWD influences sediment routing through the formation of depositional sites and the creation of waterfalls, which reduce the efficiency of downstream transport of particulate materials (Heede 1972; Swanson and Lienkaemper 1978; Beschta 1979; Bilby 1981; Megahan 1982). A large proportion of the standing stock of particulate organic matter in streams is often associated with LWD (Naiman and Sedell 1979; Bilby and Likens 1980). Wood also provides habitat for some invertebrates (Benke et al. 1984) and fishes (Bustard and Narver 1975; Bisson et al. 1982; Tschaplinski and Hartman 1983; Dolloff 1986; Elliott 1986; McMahon and Hartman 1989).

Features of the stream channel and the bordering riparian vegetation influence the amount and function of LWD. Channel size affects both wood amount and the relative influence of LWD on channel features (Swanson et al. 1976; Bilby 1979; Long 1987; Bilby and Ward 1989). Density of streamside trees is positively correlated with LWD amounts in some systems (Long 1987; Bilby and Wasserman 1989). Morphology of the bed may also influence LWD amount (Bilby and Wasserman 1989). Susceptibility of riparian trees to windthrow can play

For personal use only.

a major role in determining quantities of LWD in streams (Lienkaemper and Swanson 1987; Robison and Beschta 1990).

Various management activities in and adjacent to the channel have also influenced LWD amounts and characteristics in Pacific Northwest streams. Removal of wood from rivers for navigation or to provide upstream access for anadromous fishes has greatly reduced LWD amounts in some systems (Sedell and Luchessa 1982; Bilby 1984). Use of splash dams for log transport, a practice which was used widely in the Pacific Northwest until the 1950s, also reduced wood amounts in many streams (Wendler and Deschamps 1955). Removal of streamside timber during logging occurred until the early 1980s in the Pacific Northwest. While this practice no longer occurs, there are many streams where amount of LWD and the composition and structure of the riparian vegetation were influenced as a result of this activity.

Several conceptual models of the influence of streamside timber removal on amount of LWD have been developed (Swanson and Lienkaemper 1978; Likens and Bilby 1982; Grette 1985; Murphy and Koski 1989). In general, these models predict a decrease in LWD over time as a result of decay of wood present in the channel prior to disturbance coupled with decreased input from the riparian area.

Relatively few data have been collected to validate these models. Comparisons of the amount of LWD in streams flowing through old-growth and previously logged forests in several areas in the Pacific Northwest have verified the decrease in wood after removal of the streamside vegetation (Grette 1985; Long 1987). Some information is also available on the influence of stream size and channel characteristics on the rate of change in LWD amount after removal of streamside vegetation (Long 1987; Murphy and Koski 1989). However, little is known about the changes in the characteristics of pieces of LWD or their function over time after removal of streamside vegetation or the rate at which these changes occur. The purpose of this study was to compare LWD abundance, characteristics, and function in streams bordered by forests of differing ages: old-growth forest, recently clear-cut areas, and 40- to 60-yr-old second-growth forest. Comparison of the three stand age-classes provides an indication of the rate at which changes in LWD occur following timber removal from the riparian area.

Description of Study Sites

Measurements of LWD abundance, characteristics, and associated channel features were made on 70 stream reaches in southwestern Washington. All sites were located in the foothills of the Cascade Range or the Willapa Hills. Streams ranged from second order to fifth order with drainage areas from 0.4 to 137 km^2. Bankfull channel widths ranged from 3.1 to 23.5 m. All stream reaches surveyed drained watersheds underlain with volcanic bedrock (Huntting et al. 1961).

One of the most important factors in selection of the sites was the condition of the vegetation adjacent to the surveyed reach. Three stand-age classes were examined: (1) undisturbed, old-growth forest, (2) clear-cut to the channel's edge within 5 yr of the survey, and (3) second-growth forest which had been clear-cut to the edge of the channel 40–60 yr prior to our survey. The clear-cut and second-growth classes had been logged only once.

Sites where factors other than stream size and vegetative characteristics of the riparian zone were likely to have influenced LWD were not surveyed. Stream reaches which had been splash dammed at some time in the past were excluded (Wendler and Deschamps 1955). In addition, streams flowing through clear-cut areas which exhibited evidence of post-harvest channel cleaning were avoided, although selective removal of merchantable wood from the stream during or after logging could not be detected. We also avoided reaches which showed evidence of being influenced by landslides or debris torrents during the recent past.

Mean annual precipitation at the sites varied from 180 to 280 cm, primarily as a result of changes in elevation (Sternes 1969). However, all sites were located within 100 km of one another and thus were likely exposed to a relatively similar history of high discharge events, which play a major role in determining LWD distribution (Bilby 1984; Lienkaemper and Swanson 1987).

Methods

Aerial photographs were utilized to identify streams bordered by appropriate forest conditions. These sites were then examined on the ground to determine if they met the criteria outlined above. Once sites were located, watershed area above the surveyed reach was determined from U.S. Geological Survey topographic maps (scale 1:62500). Additional detail on the techniques employed in this study may be found in Bilby and Ward (1989).

We defined LWD as any piece of wood larger than 10 cm in diameter and 2 m long. Organic material not qualifying as LWD by this definition was considered fine organic debris.

All pieces of LWD within the bankfull channel of the surveyed stream reaches were measured with the exception of those pieces which were either floating free in the channel or resting in an unstable position atop a LWD accumulation. These pieces were considered to have a minimal impact on the channel form or stream function and thus were omitted. However, these pieces were rare and nearly all pieces meeting our size criteria were included in the survey.

We attempted to measure at least 50 pieces of wood at each study site. However, LWD was rare at some of the sites and riparian stand conditions changed before 50 pieces were encountered. Due to our criterion of 50 pieces of LWD per site, the length of stream channel surveyed varied with changing LWD abundance, ranging from less than 100 m to nearly 1.5 km.

Characteristics of the LWD pieces which were measured included diameter, taken at the center of the piece, length in and out of the channel, and the species of tree that produced the piece. Advanced decay prevented identification of species for about 10% of the surveyed pieces. Channel characteristics associated with LWD which were measured included surface area of pools, surface area of sediment accumulations, height of waterfalls, and volume of fine organic debris (organic material less than 10 cm in diameter and 2 m in length, including twigs, leaves, needles, etc.).

Average size of LWD pieces was compared between sites with a debris volume index (Bilby and Ward 1989). This variable was calculated by determining the geometric mean diameter and geometric mean total length (both in and outside the channel) for debris pieces in each surveyed reach. Frequency distributions of LWD diameters and lengths were skewed heavily towards smaller size classes; thus, a geometric mean was used to calculate average values for these variables (Bilby and Ward 1989). The debris volume index is the volume of a cyl-

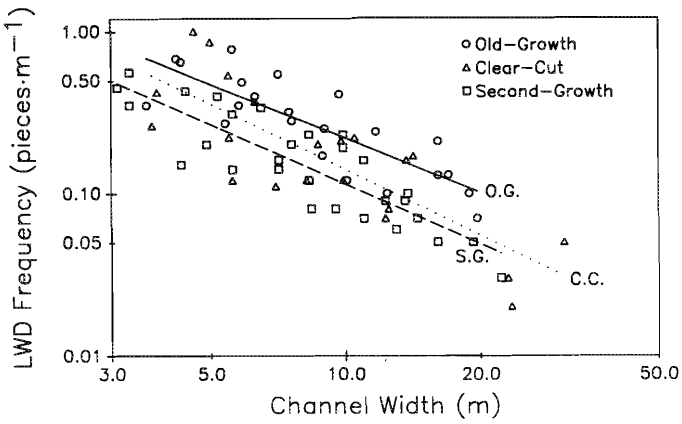

FIG. 1. Relationship between numbers of pieces of LWD per length of surveyed channel and channel width for the three stand-age classes (O.G. = old-growth, C.C. = clear-cut, S.G. = second-growth). There are significant differences among the slope values (ANOVA; $p < 0.05$). Equations for the regressions are as follows: old-growth, $\log_{10}$ LWD frequency $= -1.12 \log_{10}$ channel width $+ 0.46$ ($r^2 = 0.69$); clear-cut, $\log_{10}$ LWD frequency $= 1.35 \log_{10}$ channel width $+ 0.50$ ($r^2 = 0.66$); second-growth, $\log_{10}$ LWD frequency $= -1.23 \log_{10}$ channel width $+ 0.28$ ($r^2 = 0.75$).

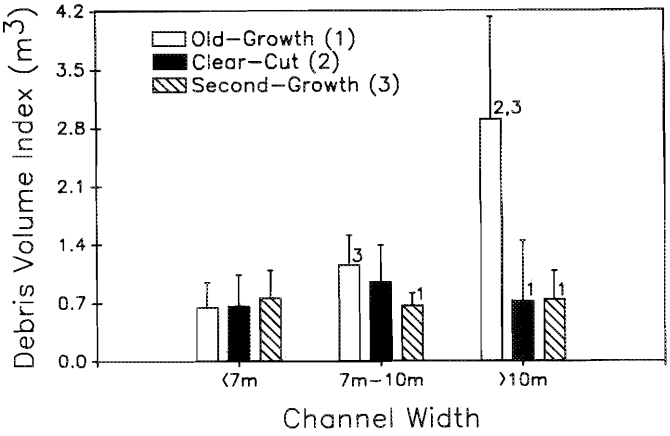

FIG. 2. Comparison of debris volume index (see text for definition) between stand-age classes for channels <7, 7–10, and >10 m wide. Numbers above the bars indicate significant differences from other stand-age classes (t-test; $p < 0.05$).

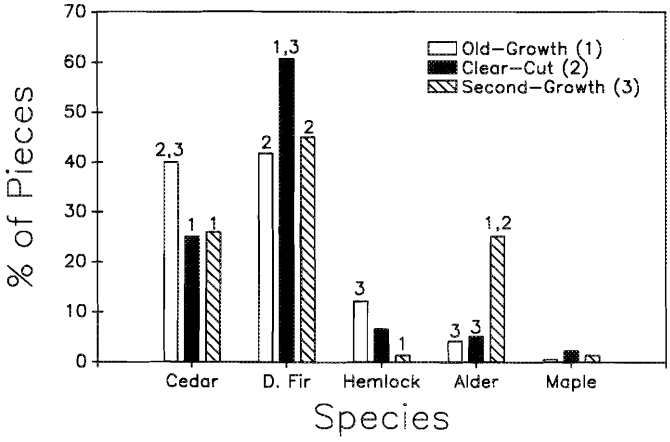

FIG. 3. Species distribution of pieces of LWD in the three stand-age classes. Values significantly different (t-test; $p < 0.05$) from corresponding values for different stand-age classes are denoted with a number above the bar. Cedar = western redcedar (*Thuja plicata*), D. Fir = Douglas fir (*Pseudotsuga menziesii*), Hemlock = western hemlock (*Tsuga heterophylla*), Alder = red alder (*Alnus rubra*), Maple = bigleaf maple (*Acer macrophyllum*).

inder with dimensions equal to the geometric mean diameter and length for each reach.

LWD-associated pools were assigned to one of four classes based on their morphology and method of formation (Bisson et al. 1982). The four classes we recognized were scour pools, plunge pools, backwater pools, and dammed pools.

The influence of fine organic debris on LWD function was examined by comparing the proportion of pieces of LWD retaining large amounts of fine debris (≥ 0.5 m^3) associated with pools, waterfalls, and sediment accumulations with the proportion of pieces of LWD retaining lesser amounts of fine debris associated with these channel features. The same comparison was made between the different pool types to determine if the presence of fine debris favored the formation of certain kinds of pools.

The amount, characteristics, and function of LWD change with changing stream size (Bilby and Ward 1989). Thus, stream size had to be considered in comparing LWD features and function between the three stand-age classes. Because of the variation in precipitation between the study sites, channel width, rather than watershed area, was used as an index of relative stream size.

Regression of LWD features or function against channel width was used for some of the analyses in this study. In cases where regression techniques were not used, streams were segregated into three channel-width classes: <7 m, 7–10 m, and >7 m. There were about an equal number of sites in each stream-size class for each stand-age class. Statistical comparisons of percentage values between stand-age classes and stream-size classes were made using a t-test for equality of two percentages (Sokal and Rohlf 1969).

Results

Abundance, Size, and Species

LWD abundance decreased with increasing stream size for all three stand-age classes (Fig. 1). However, old-growth sites had more wood than similarly sized streams at second-growth or clear-cut sites (t-test; $p < 0.05$). The frequency of LWD pieces in clear-cut and second-growth sites was 59 and 50%, respectively, of that measured in old-growth sites for streams at 15 m wide. In channels 5 m wide, LWD frequency in clear-cut and second-growth sites was 77 and 56%, respectively, of that seen at old-growth sites.

Debris volume index increased with increasing stream size at the old-growth sites (Fig. 2). However, no relationship between piece size and stream size was observed for clear-cut or second-growth sites. The debris volume index for old-growth sites was about four times greater than the other two stand-age classes for streams >10 m wide (ANOVA; $p < 0.05$). LWD piece size was also significantly greater at old-growth sites than at second-growth sites in channels 7–10 m wide. No statistical differences in piece size were observed between stand-age classes for streams <7 m wide.

There were significant differences between stand-age classes in the species distribution of the LWD (Fig. 3; t-test; $p < 0.05$).

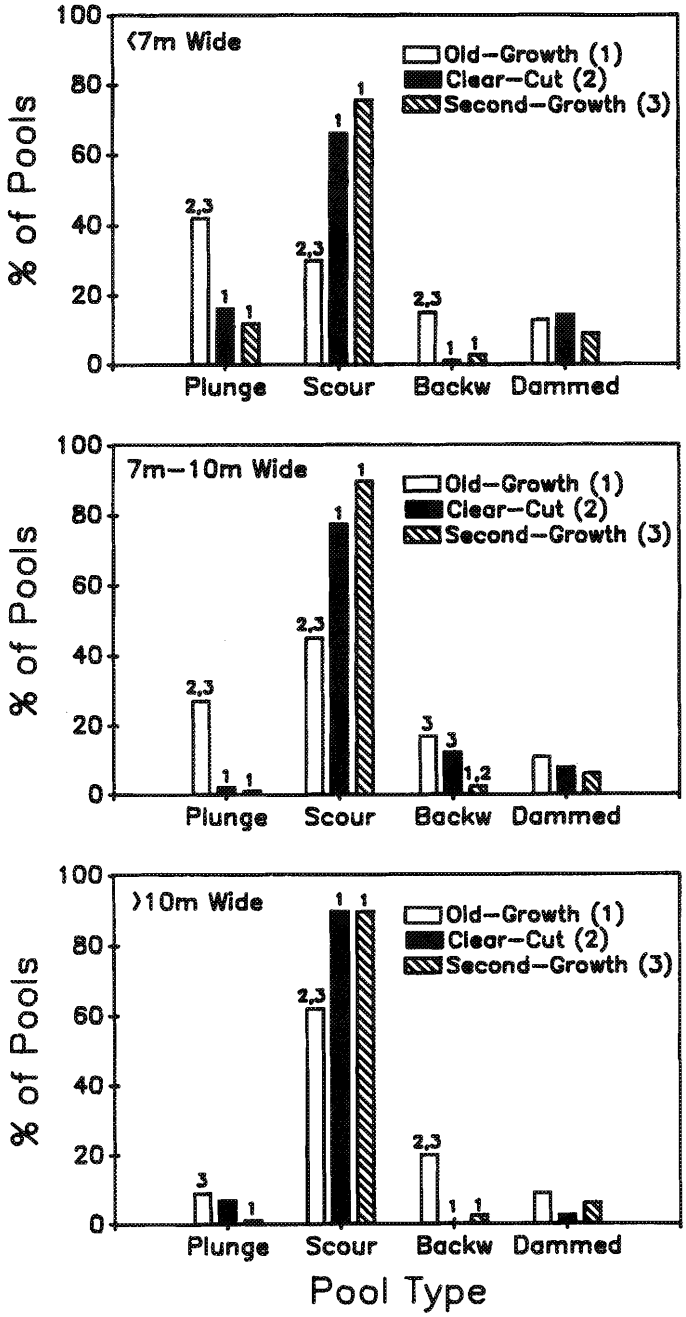

FIG. 4. Distribution of pool types for the three stand-age classes in each of the channel-width classes. Values significantly different (t-test; $p < 0.05$) from corresponding values for other stand-age classes are denoted with a number above the bar.

Western redcedar accounted for 40% of the debris pieces in the old-growth systems but contributed significantly lower proportions of LWD to clear-cut and second-growth sites. Douglas fir, the most commonly encountered species in all stand-age classes, contributed significantly more pieces of LWD in clear-cut systems than in the other two stand-age classes. The proportion of western hemlock was relatively low and progressively decreased from old-growth to clear-cut to second-growth sites. Red alder contributed significantly more pieces of LWD to second-growth sites than to old-growth or clear-cut sites. No differences were observed by stand-age class in the proportion of LWD contributed by bigleaf maple.

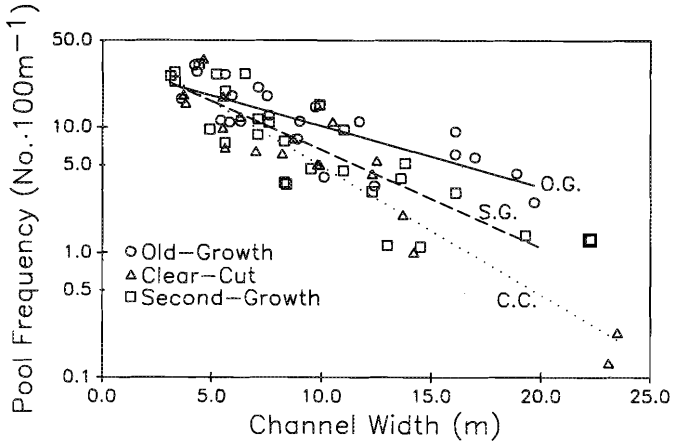

FIG. 5. Relationship between channel width and frequency of LWD-associated pools for the three stand-age classes (O.G. = old-growth, C.C. = clear-cut, S.G. = second-growth). There are significant differences among the slope values (ANOVA; $p < 0.05$). Regression equations are as follows: old-growth, $\log_{10}$ pool frequency $= -0.05$ channel width $+ 1.49$ ($r^2 = 0.64$); clear-cut, $\log_{10}$ pool frequency $= -0.10$ channel width $+ 1.71$ ($r^2 = 0.90$); second-growth, $\log_{10}$ pool frequency $= -0.08$ channel width $+ 1.59$ ($r^2 = 0.70$).

However, this species did not produce more than 5% of the wood in any of the stand-age classes.

Pools

The frequency of occurrence of different types of pools associated with LWD changed with stand-age class and stream size (Fig. 4). Pool types were the most diverse in streams bordered by old-growth forest. In these systems, scour pools increased and plunge pools decreased in abundance with increasing stream size (t-test; $p < 0.05$). Scour pools occurred significantly more frequently in clear-cut and second-growth systems than at old-growth sites for all three stream-size classes and were the predominant pool type in all stream-size classes at clear-cut and second-growth sites. Plunge pools formed by LWD were significantly more common at old-growth sites than at second-growth sites for all stream-size classes and at clear-cut sites in streams <7 m wide.

Backwater and dammed pools formed by LWD occurred less frequently than other pool types in all stand-age classes (Fig. 4). Backwater pools were more common at old-growth sites than at second-growth sites for all stream-size classes and at clear-cut sites for streams <7 m wide and >10 m wide (t-test; $p < 0.05$).

Frequency of LWD-associated pools decreased with increasing stream size for all three stand-age classes (Fig. 5) but was significantly greater at old-growth sites than at the other two stand-age classes (t-test; $p < 0.05$). Pool frequency was most similar among stand-age classes in smaller streams. Differences increased with increasing stream size, and frequency of pools associated with LWD in old-growth sites was more than twice that of second-growth sites and three times that of clear-cut sites for streams 15 m wide.

Surface area of debris-associated pools was not significantly different among the stand-age classes for streams <7 m wide or 7–10 m wide (Fig. 6). However, average pool surface area was significantly greater in streams >10 m wide at old-growth sites (t-test; $p < 0.05$), averaging more than twice the area of pools in clear-cut and second-growth systems.

Can. J. Fish. Aquat. Sci. Downloaded from www.nrcresearchpress.com by University of British Columbia on 01/24/13

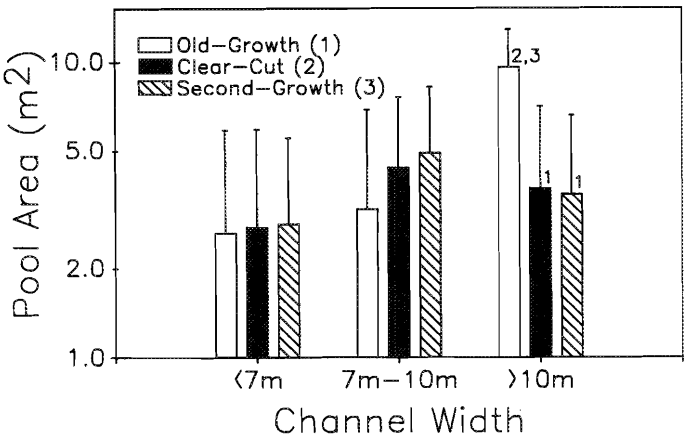

FIG. 6. Comparison of average surface area of scour pools between stand-age classes for different channel widths. Error bars indicate standard deviation. Values significantly different (t-test; $p < 0.05$) from corresponding values in other stand-age classes are denoted with a number above the bar.

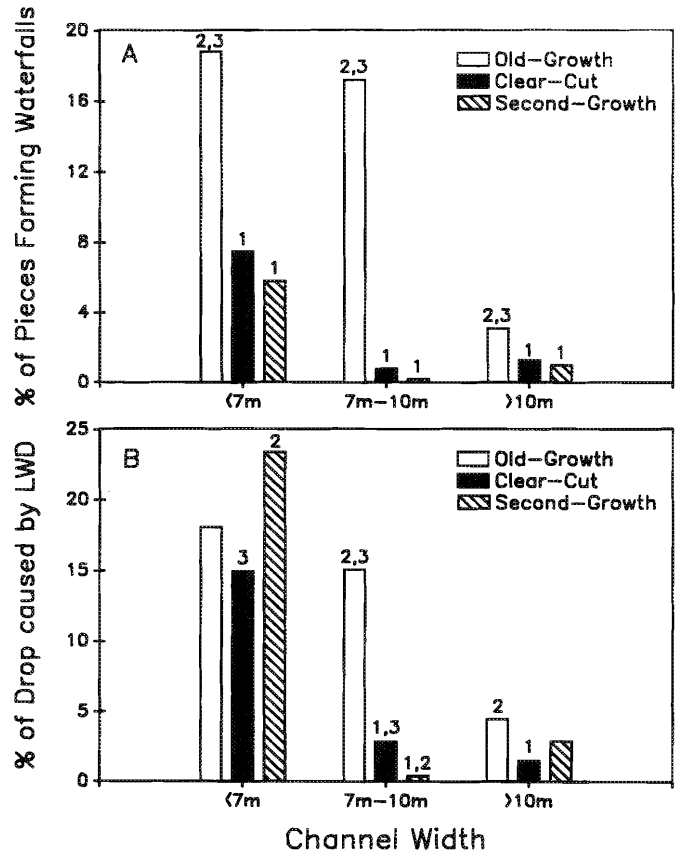

FIG. 7. (A) Proportion of pieces of LWD forming waterfalls and (B) proportion of the total drop in elevation of the surveyed stream sections accounted for by the summed height of LWD-formed waterfalls for the three age classes for each channel-width class. Values significantly different (t-test; $p < 0.05$) from corresponding values in other stand-age classes are denoted with a number above the bar.

Waterfalls

The proportion of pieces of LWD forming waterfalls was significantly greater at old-growth sites than at the other two stand-age classes for all stream-size classes (Fig. 7A; t-test; $p < 0.05$). The proportion of pieces forming waterfalls was greater in streams <7 m wide than in larger systems for all three stand-age classes (t-test; $p < 0.05$).

The proportion of the drop in elevation of a stream reach accounted for by summing the heights of waterfalls formed by LWD decreased with increasing stream size (Fig. 7B). Old-growth sites displayed a greater cumulative elevation drop caused by LWD than the other stand-age classes in streams 7–10 m wide and greater than the clear-cut sites in channels >10 m wide (t-test; $p < 0.05$).

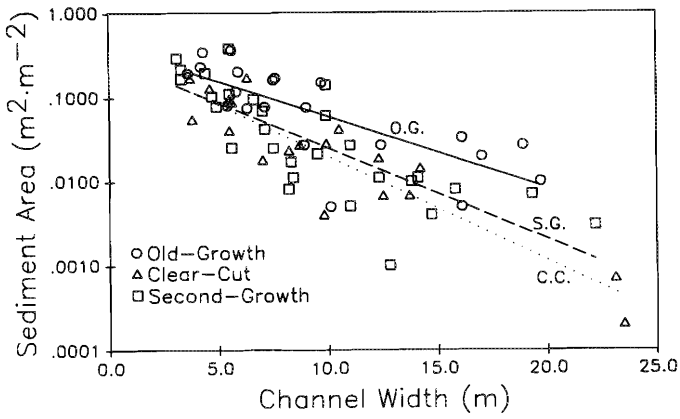

FIG. 8. Relationship between channel width and the surface area of the streambed occupied by LWD-associated sediment accumulations for the three stand-age classes (O.G. = old-growth, C.C. = clear-cut, S.G. = second-growth). There are significant differences among the intercept values (ANOVA; $p < 0.05$). Regression equations are as follows: old-growth, $\log_{10}$ sediment area = -0.08 channel width $- 0.38$ ($r^2 = 0.53$); clear-cut, $\log_{10}$ sediment area = -0.12 channel width $- 0.47$ ($r^2 = 0.84$); second-growth, $\log_{10}$ sediment area = -0.11 channel width $- 0.53$ ($r^2 = 0.62$).

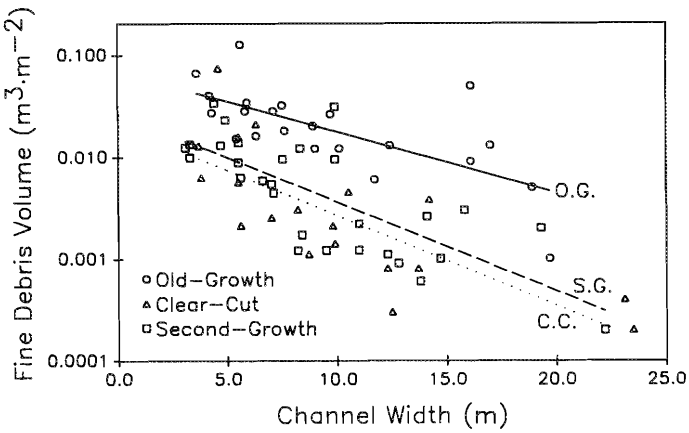

FIG. 9. Relationship between channel width and volume of fine debris associated with LWD for the three stand-age classes (O.G. = old-growth, C.C. = clear-cut, S.G. = second-growth). There are significant differences among the intercept values (ANOVA; $p < 0.05$). Regression equations are as follows: old-growth, $\log_{10}$ sediment volume = -0.06 channel width -1.16 ($r^2 = 0.48$); clear-cut, $\log_{10}$ volume = -0.09 channel width -1.70 ($r^2 = 0.59$); second-growth, $\log_{10}$ volume = -0.09 channel width -1.57 ($r^2 = 0.57$).

Sediment

Proportion of the streambed covered by sediment stored by LWD decreased with increasing stream size for all three stand-

Can. J. Fish. Aquat. Sci. Downloaded from www.nrcresearchpress.com by University of British Columbia on 01/24/13
For personal use only.

TABLE 1. Proportion of pieces of LWD retaining <0.5 and ≥0.5 m^3 of fine debris associated with pools. Values are significantly different for all stand-age classes (*t*-test; $p < 0.05$).

	Pieces of LWD retaining <0.5 m^3		Pieces of LWD retaining ≥0.5 m^3	
	% forming pools	*N*	% forming pools	*N*
Old-growth	21	881	60	221
Clear-cut	28	858	82	51
Second-growth	39	1346	89	95

age classes (Fig. 8). Area of LWD-associated sediment was greater at old-growth sites than at the other two stand-age classes for all stream sizes (*t*-test; $p < 0.05$). Differences in this variable among the stand-age classes increased with stream size, with an estimated 16, 8, and 9% of the bed surface covered with LWD-associated sediment in channels 5 m wide at old-growth, clear-cut, and second-growth sites, respectively, compared with 2.5, 0.5, and 0.7% in channels 15 m wide.

Fine Organic Debris

The volume of fine organic debris per square metre of channel surface area decreased with increasing stream size for all stand-age classes (Fig. 9), but more fine debris was retained by LWD at old-growth sites than at the other two stand-age classes (*t*-test; $p < 0.05$). Volume of fine organic debris stored by LWD in channels 5 m wide was estimated at 0.035, 0.007, and 0.010 $m^3 \cdot m^{-2}$ at old-growth, clear-cut, and second-growth sites, respectively. The corresponding values for a 15-m-wide channels were 0.0087, 0.0010, and 0.0013 $m^2 \cdot m^{-3}$, respectively.

Fine Organic Debris and LWD Function

Differences between stand-age classes in the frequency of debris-associated pools (Fig. 5) were partly due to a greater amount of fine debris at old-growth sites, although the relative abundance of LWD also was an important factor. In all stand-age classes, pools were associated with pieces of LWD retaining ≥0.5 m^3 of fine debris significantly more frequently than with LWD retaining <0.5 m^3 of fine debris (Table 1; *t*-test; $p < 0.05$). About 20% of the pieces of LWD at the old-growth sites had fine debris accumulations ≥0.5 m^3 compared with 6% at clear-cut and 7% at second-growth sites.

The increased diversity of pool types observed at the old-growth sites may have been related to the large amount of fine organic debris at these sites (Table 2). Plunge and dammed pools were associated with accumulations of fine debris ≥0.5 m^3 significantly more frequently than scour pools in all three stand-age classes (*t*-test; $p < 0.05$). Both plunge pools and dammed pools tend to be formed by obstructions that completely span the channel (Bilby and Ward 1989). Fine debris fills in the gaps in the framework provided by the LWD, resulting in more efficient blockage of stream flow. Since larger fine debris accumulations were rare at clear-cut and second-growth sites (Table 1), it is not surprising that plunge pools were rare and scour pools comprise the vast majority of pools in these systems.

Amount of fine organic debris associated with LWD also may have influenced the formation of depositional sites. LWD with fine debris accumulations ≥0.5 m^3 retained sediment significantly more frequently than LWD pieces with less fine debris (Table 3; *t*-test; $p < 0.05$). Thus, accumulations of sediment associated with LWD were more frequent at old-growth sites due to both high levels of LWD and large amounts of fine debris.

TABLE 2. Proportion of the different pool types associated with fine debris accumulations ≥0.5 m^3. Significant differences between pool types within a stand-age class are indicated with a letter (*t*-test; $p < 0.05$; s = scour pools, p = plunge pools, b = backwater pools, d = dammed pools).

Discussion

Effect of Riparian Timber Harvest on LWD

Reduction in LWD amount and piece size as a result of timber harvest has generally been assumed to occur gradually due to a decrease in LWD input coupled with decomposition of material in the channel. However, our data indicate that many changes in LWD abundance, characteristics, and function occur during or shortly after timber harvest. During the 5-yr period separating our old-growth and clear-cut sites, wood amount decreased, average piece size in channels >10 m wide decreased, and the species mix of the LWD changed. It is unlikely that these changes could be attributed solely to decomposition of residual LWD and reduced LWD input over this short time period. The decrease in abundance of large, redcedar logs between the old-growth and clear-cut sites suggests that selective removal of this material from the channel during or shortly after logging may have been a factor in the reduction in LWD. Salvage of redcedar after timber harvest is a common practice in the Pacific Northwest. Removal of LWD from streams also has been shown to destabilize wood remaining in the channel (Bilby 1984), thus promoting flushing of wood downstream and contributing to the decrease in LWD amount. Selective removal of larger logs from channels may also be partly responsible for the lack of relationship between stream size and debris volume index at clear-cut sites. However, since no records of wood salvage from stream channels are kept, the extent to which this practice occurred on our study sites cannot be determined.

Changes in LWD characteristics from the clear-cut to second-growth conditions likely reflect decomposition of residual wood in the channel coupled with reduced input and a change in the composition of the riparian vegetation. The progressive decrease in western hemlock abundance with time after harvest

TABLE 3. Proportion (%) of the pieces of LWD containing fine debris accumulations ≥0.5 and <0.5 m^3 associated with depositional sites. Pieces of wood with large fine debris accumulations are significantly more likely to be associated with areas of deposited sediment in all cases (*t*-test; $p < 0.05$).

	Channel width					
	<7 m		7–10 m		>10 m	
	≥0.5 m^3	<0.5 m^3	≥0.5 m^3	<0.5 m^3	≥0.5 m^3	<0.5 m^3
Old-growth	69.0	30.1	63.8	20.1	36.9	11.9
Clear-cut	60.0	19.7	66.7	16.5	46.2	17.2
Second-growth	64.7	36.9	57.5	20.9	58.1	18.3

indicates elimination of this species from the system without replacement. Since hemlock is less decay resistant than many other conifer species, reduction in its abundance should occur relatively rapidly. The increase in red alder debris in streams in second-growth sites is due to the abundance of this species at the second-growth sites.

There were very large differences between stand-age classes in the amount of fine debris stored by LWD, with old-growth sites containing more fine debris than the other two stand-age classes. Three factors contributed to the large amount of LWD-associated fine debris at the old-growth sites: abundant LWD to retain fine organic matter, a high rate of input from the terrestrial system (Gregory et al. 1987), and high proportions of debris from decay-resistant coniferous trees (Harmon et al. 1986). In contrast, the clear-cut sites have less LWD, very low contributions of organic matter from the terrestrial system, and a high proportion of material from deciduous trees or herbaceous vegetation, which decomposes rapidly. The second-growth sites have conditions intermediate to the two other stand-age classes, with little LWD and inputs of relatively easily decayed terrestrial debris (primarily red alder litter).

Differences between the three stand-age classes in certain characteristics and functions of LWD are accentuated in larger streams. Average piece size, pool frequency, and average pool area exhibit less difference in smaller streams than in larger systems. Differences by stand-age class in the amount of sediment accumulated by LWD or amount of fine organic matter associated with wood are less affected by stream size. In general, however, changes in LWD features and function after timber harvest of streamside vegetation tend to be most pronounced in larger streams.

Changes in LWD over Time

Models of changes in LWD abundance following removal of riparian trees have assumed a relatively slow decline caused by decomposition of residual in-channel wood. Swanson and Lienkaemper (1978) hypothesized that relatively little change in pre-harvest levels of LWD in Pacific Northwest streams would occur for 50 yr due to slow decomposition of pre-harvest LWD. A model by Grette (1985) proposed a linear decline in LWD amount with time, at a rate of slightly less than $1\% \cdot yr^{-1}$. Input of LWD from the deciduous riparian vegetation resumes approximately 40 yr after harvest, but is insufficient to offset decomposition, leading to LWD amounts 50 yr after harvest of approximately 75% of the old-growth level. Murphy and Koski (1989) suggested a faster rate of decline for southeastern Alaska streams, with larger pieces of LWD being eliminated at the rate of $1–3\% \cdot yr^{-1}$, depending on characteristics of the channel.

None of these models, however, accurately predicted the patterns of change in LWD abundance reported here. Using the regressions developed from our data for LWD frequency (Fig. 1) and average debris volume index (Fig. 2), we estimated wood volume in streams 5, 10, and 15 m wide for each stand-age class (Fig. 10A). The regressions in Fig. 5, 8, and 9 were used to calculate pool frequency, area of sediment accumulations, and volume of fine organic material (Fig. 10B, 10C, 10D). Three channel widths were examined, since mean LWD piece size is influenced by stream size (Bilby and Ward 1989) and, as a result, has an influence on input and elimination rate (Likens and Bilby 1982; Murphy and Koski 1989). We have assumed that our clear-cut sites were all 5 yr post-harvest and the second-growth sites were all 50 yr post-harvest.

Total volume of LWD per 100 m of channel decreased 22% from old-growth levels 5 yr after harvest and 35% after 50 yr in streams 5 m wide (Fig. 10A). The magnitude of decrease became progressively greater with increasing channel width, with a depression in LWD volume of 47 and 86% in channels 10 and 15 m wide, respectively, 5 yr after harvest. The very large drop in volume in the larger streams is an indication of the decrease in both piece frequency and piece size. LWD volume decreased 71 and 94% from old-growth levels in channels 10 and 15 m wide, respectively, 50 yr after logging. The rate of decrease in LWD abundance between our old-growth and second-growth sites is comparable with that reported in other studies (Grette 1985; Murphy and Koski 1989). However, our data showed that the majority of this decrease occurred within the first 5 yr after harvest.

Pool frequency in channels 5 m wide is only slightly greater at old-growth sites than at clear-cut and second-growth sites (Fig. 10B). However, in 10- and 15-m-wide streams, pool frequency decreased by more than 50% in the 5 yr after harvest and then changed relatively little over the next 45 yr. Estimated decreases in sediment stored by LWD over time were greater than 50% for all three sized streams, with nearly all the change occurring shortly after timber harvest (Fig. 10C).

Fine debris volume decreases at a much greater relative rate than LWD following removal of the streamside vegetation (Fig. 10D). Fine debris was reduced by about 90% within 5 yr of harvest, regardless of stream size. Little change in the amount of stored fine debris occurred between 5 and 50 yr post-harvest.

Management of Riparian Areas

Pacific Northwest states and provinces have recently instituted regulations or guidelines requiring retention of standing trees along stream channels during timber harvest to provide a source of future LWD. In Washington, from 50 to 200 trees

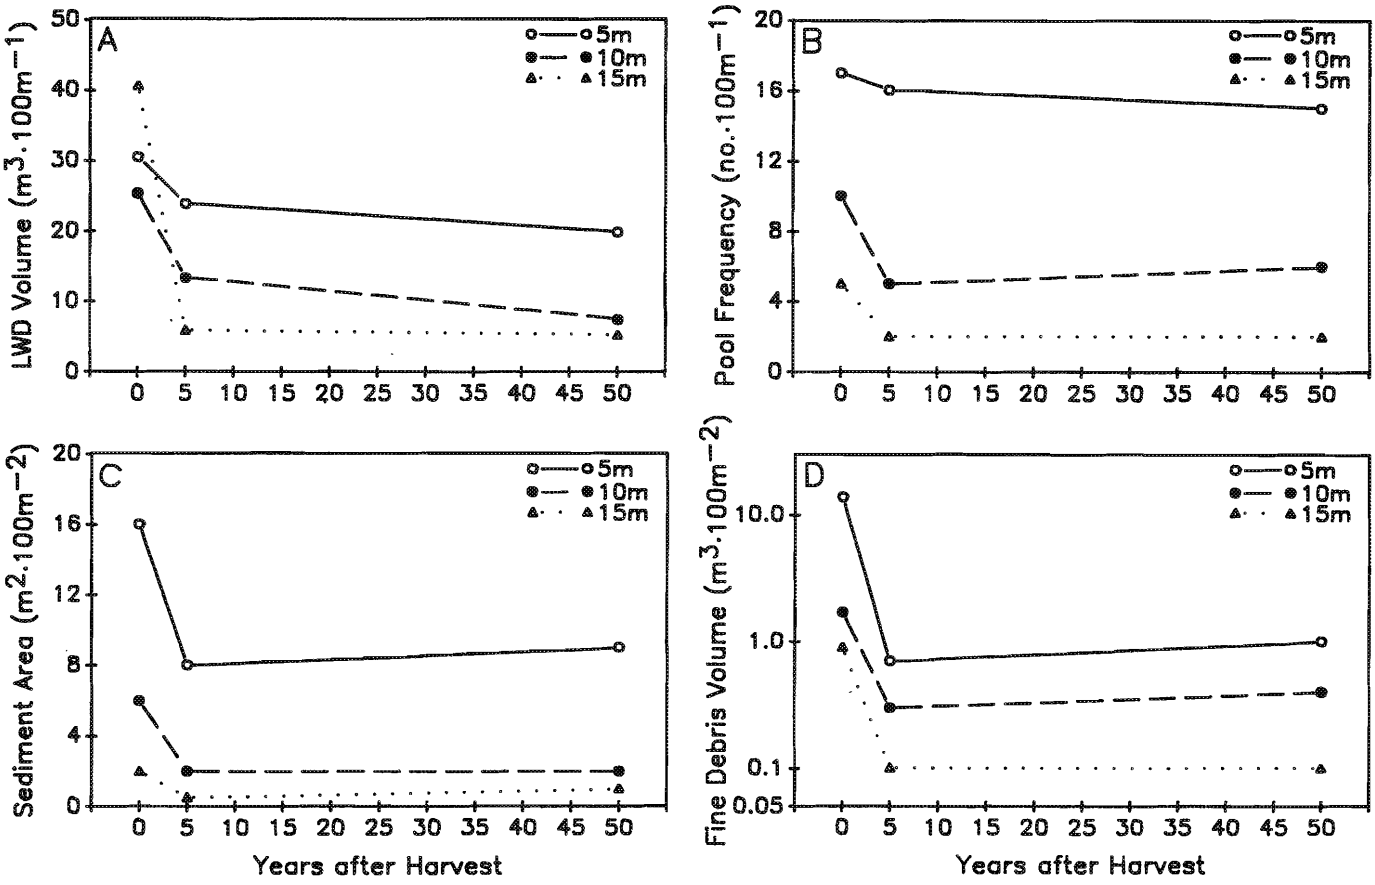

FIG. 10. Changes in LWD abundance and function with time after timber harvest for streams of three different widths. (A) Volume of LWD per length of channel; (B) pool frequency; (C) area of sediment accumulated by LWD; (D) volume of fine organic matter.

per 300 m of stream length must be retained after timber harvest, varying as a function of channel width (Bilby and Wasserman 1989). The width of the protected area also varies with stream size, ranging from 8 to 30 m on either side of the channel. Thus, the patterns of change in LWD abundance and function seen in this study resulted from timber harvest practices that are no longer in use. However, until the early 1980s, the trees along many streams were removed during timber harvest. The effect of this practice was the creation of riparian stands composed largely of red alder. Our data indicate that riparian zones with this type of vegetative composition (our second-growth sites) may not supply sufficient LWD, especially to larger streams. Also, the rapidly decomposing fine organic matter produced by deciduous vegetation is less effective at influencing channel structure than that from coniferous trees. Encouragement of conifer growth in riparian zones dominated by red alder may help alleviate some of these problems.

The vegetative and structural diversity of alder-dominated riparian stands may be increased by active management. Planting of conifer seedlings in riparian areas might be successful if the proper conditions for survival and growth can be created (Emmingham et al. 1989). Clearing small areas of riparian vegetation would be necessary in most cases to provide the conditions required by shade-intolerant conifer species, such as Douglas fir. Control of understory vegetation for several years could also be necessary. Release of suppressed conifers already present in the riparian area by removing the overstory is another possible option (Ferguson and Adams 1980).

The influence of fine organic debris on LWD function also suggests that vegetative characteristics of the riparian zone should be considered when selecting locations for stream habitat enhancement projects that include placement of wood. Our study indicates that LWD placement in streams would achieve improved results if conducted on a site receiving large inputs of fine coniferous debris.

Acknowledgments

We thank J. Heffner and W. Stonecypher for assistance with the field surveys. Helpful comments on the manuscript were provided by P. Bisson, J. Rochelle, K. Sullivan, D. Mumper, D. Wilbur, and two anonymous reviewers.

Chapter 4

Habitat Requirements of Salmonids in Streams

T. C. Bjornn and D. W. Reiser

Habitat needs of salmon, trout, and char in streams vary with the season of the year and stage of the life cycle. The major life stages of most salmonid species are associated with different uses of fluvial systems: migration of maturing fish from the ocean (anadromous fishes), lakes, or rivers to natal streams; spawning by adults; incubation of embryos; rearing of juveniles; and downstream migration of juveniles to large-river, lacustrine, or oceanic rearing areas. We present information from the literature and from our own research on the range of habitat conditions for each life stage that allow the various species to exist. When possible, we attempt to define optimum and limiting conditions. Anadromous salmonids of the Pacific drainages of North America are our primary focus, but we have included information on other salmonids to illustrate the ranges of temperature, water velocities, depths, cover, and substrates preferred by salmon, trout, and char in streams. The scientific names of species identified by common names here are listed in the book's front matter.

Upstream Migration of Adults

Adult salmonids returning to their natal streams must reach spawning grounds at the proper time and with sufficient energy reserves to complete their life cycles. Stream discharges, water temperatures, and water quality must be suitable during at least a portion of the migration season. Native stocks of salmon, trout, and char that have evolved in stream systems with fluctuations in flow, turbidity, and temperature have often developed behaviors that enable survival despite the occurrence of temporarily unfavorable conditions. Native salmonids usually have sufficient extra time in their maturation, migration, and spawning schedules to accommodate delays caused by normally occurring low flows, high turbidities, or unsuitable temperatures. When upstream migration is not delayed, the fish in some stocks that migrate long distances arrive in the spawning areas 1–3 months before they spawn. Some stocks of fish that migrate short distances may not move into natal streams until shortly before spawning, but they must often wait in the ocean, lake, or river for flows or temperatures in the spawning streams to become suitable.

The flexibility in maturation and migration schedules observed in many stocks of native salmonids is not unlimited and has evolved for the specific environment

Influences of Forest and Rangeland Management on Salmonid Fishes and Their Habitats
American Fisheries Society Special Publication 19:83–138, 1991

TABLE 4.1.—Water temperatures (Bell 1986) and depths and velocities (Thompson 1972) that enable upstream migration of adult salmon and trout.

Species of fish	Temperature range (°C)	Minimum depth (m)	Maximum velocity (m/s)
Fall chinook salmon	10.6–19.4	0.24	2.44
Spring chinook salmon	3.3–13.3	0.24	2.44
Summer chinook salmon	13.9–20.0	0.24	2.44
Chum salmon	8.3–15.6	0.18	2.44
Coho salmon	7.2–15.6	0.18	2.44
Pink salmon	7.2–15.6	0.18[a]	2.13
Sockeye salmon	7.2–15.6	0.18	2.13
Steelhead		0.18	2.44
Large trout		0.18	2.44
Trout		0.12	1.22

[a] Estimate based on fish size.

of each stock. Natural or human-caused changes in the environment can be large enough to prevent fish from completing their maturation or migration to spawning areas; the proportion affected depends on the extent of the change. Transplanted stocks of fish may be less successful than native stocks in reproducing themselves if they do not possess the flexibility in migration timing required in their new environment.

Temperature

Salmon and trout respond to stream temperatures during their upstream migrations. Delays in upstream migration because natal streams were too warm have been observed for sockeye salmon (Major and Mighell 1966), chinook salmon (Hallock et al. 1970), and steelhead (Monan et al. 1975). Bell (1986) reported that Pacific salmon and steelhead have migrated upstream at temperatures between 3 and 20°C (Table 4.1).

Streams can be too cold as well as too warm for upstream-migrating salmonids. Cutthroat and rainbow trout have been observed waiting for tributaries to warm in spring before entering them to spawn. Adult steelhead that return from the sea in summer and autumn, and then spend the winter in inland rivers before spawning the following spring, overwinter in larger rivers downstream from their natal streams because the smaller headwater streams are often ice-choked during winter. We believe adult steelhead overwinter in the larger rivers because survival is higher there and the slightly higher temperatures in the rivers enable timely maturation (Reingold 1968).

Stream temperatures can be altered by removal of streambank vegetation, withdrawal and return of water for agricultural irrigation, release of water from deep reservoirs, and cooling of nuclear power plants. Unsuitable temperatures can lead to disease outbreaks in migrating and spawning fish, altered timing of migration, and accelerated or retarded maturation. Most stocks of anadromous salmonids have evolved with the temperature patterns of the streams they use for migration and spawning, and deviations from the normal pattern could adversely affect their survival.

Dissolved Oxygen

Reduced concentrations of dissolved oxygen (DO) can adversely affect the swimming performance of migrating salmonids. Maximum sustained swimming speeds of juvenile and adult coho salmon at temperatures of 10–20°C were reduced when DO dropped below air-saturation levels, and performance declined sharply when DO fell to 6.5–7.0 mg/L, at all temperatures tested (Davis et al. 1963). Swimming performance of brook trout declined similarly (Graham 1949). Low DO may also elicit avoidance reactions (Whitmore et al. 1960; Hallock et al. 1970), and may halt migration. Hallock et al. (1970) observed that adult migration ceased when DO fell below 4.5 mg/L, and did not resume until it exceeded 5 mg/L. Minimum DO recommended for spawning fish (at least 80% of saturation, and not even temporarily less than 5.0 mg/L) should provide the minimum needs of migrating salmonids.

Turbidity

Migrating salmonids avoid waters with high silt loads, or cease migration when such loads are unavoidable (Cordone and Kelley 1961). Bell (1986) cited a study in which salmonids did not move in streams where the suspended sediment concentration exceeded 4,000 mg/L (as a result of a landslide). Timing of arrival at spawning grounds by chinook salmon that migrate upstream during snowmelt runoff can vary by a month or more, depending on the concentration of suspended solids in rivers along their migration route (Bjornn 1978). In the lower Columbia River, the upstream migration of salmon may be retarded when secchi disk readings are less than 0.6 m (Figure 4.1).

High turbidity in rivers may delay migration, but turbidity alone generally does not seem to affect the homing of salmonids very much. In studies after the eruption of Mount St. Helens in 1980, Whitman et al. (1982) found that salmon preferred natal stream water without volcanic ash in an experimental flume, but that they recognized their natal streams despite the ash and attempted to ascend them. Quinn and Fresh (1984) reported that the rate of straying of chinook salmon to the Cowlitz River Hatchery was low and unaffected by the 1980 eruption, but that many coho salmon in the Toutle River, the Cowlitz River tributary most affected by the eruption, did stray to nearby streams in 1980 and 1981. Olfaction is a primary sense salmonids use for homing during upstream migration (Hasler and Larsen 1955; Hasler et al. 1978). Each stream may have a unique bouquet, and the extent to which that bouquet can be altered—by the addition of exotic chemicals, trans-basin diversions, and unnatural suspended sediments—without affecting the homing of salmonids is not known.

Barriers

Waterfalls, debris jams, and excessive water velocities may impede migrating fish. Falls that are insurmountable at one time of the year may be passed by migrating fish at other times when flows have changed. Stuart (1962) determined in laboratory studies that leaping conditions for fish are ideal when the ratio of height of falls to depth of pool below the falls is 1:1.25 (Figure 4.2). Given suitable conditions, salmon and steelhead can get past many obstacles that appear to be barriers. Both Jones (1959) and Stuart (1962) observed salmon jumping over

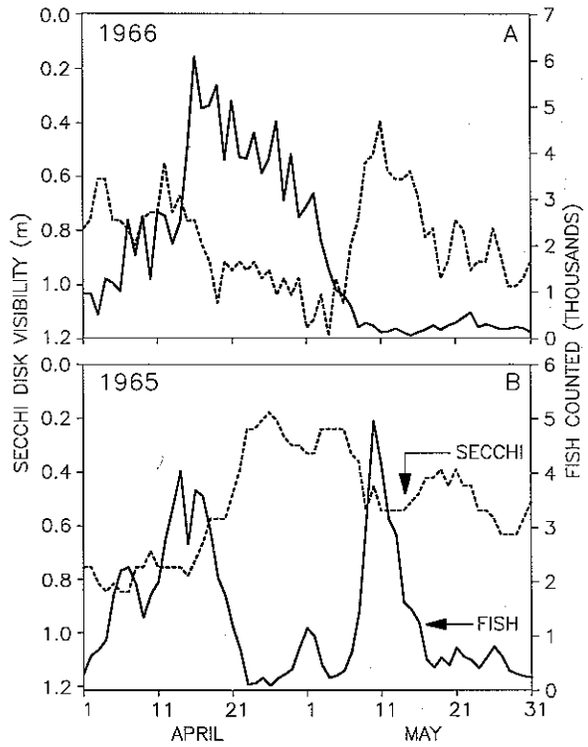

FIGURE 4.1.—Secchi disk visibility (broken line) and number of chinook salmon adults (solid lines) migrating up the Columbia River past Bonneville Dam during April and May of 1965, when high turbid flows interrupted the migration, and of 1966, when turbidities were low and the timing of migration was normal.

obstacles 2–3 m in height. Powers and Orsborn (1985) analyzed barriers to upstream-migrating fish in terms of barrier geometry, stream hydrology, and fish capabilities. They reported the abilities of salmon and trout to pass over barriers depended on the swimming velocity of the fish, the horizontal and vertical distances to be jumped, and the angle to the top of the barrier (Figure 4.3). Reiser and Peacock (1985) computed maximum jumping heights of salmonids on the basis of darting speeds; these heights ranged from 0.8 m for brown trout to more than 3 m for steelhead (Table 4.2).

The swimming abilities of fish are usually described in three categories of speed: cruising speed, the speed a fish can swim for an extended period of time, usually ranging from 2 to 4 body lengths/s; sustained speed, the speed a fish can maintain for a period of several minutes, ranging from 4 to 7 body lengths/s; and darting or burst speed, the speed a fish can swim for a few seconds, ranging from 8 to 12 body lengths/s (Watts 1974; Bell 1986; Table 4.2). According to Bell (1986), cruising speed is used during migration, sustained speed for passage through difficult areas, and darting speed for escape and feeding. Water velocities of 3–4 m/s approach the upper sustained swimming ability of large fish like salmon and steelhead.

Debris jams, whether natural or caused by human activities, can prevent or delay upstream migration. Chapman (1962b) cited a study in which a 75% decrease in number of spawning salmon in one stream was attributed to blockage by debris. On the other hand, many debris jams can be easily passed by fish and they often form pools and provide cover for fish. Removal of debris barriers

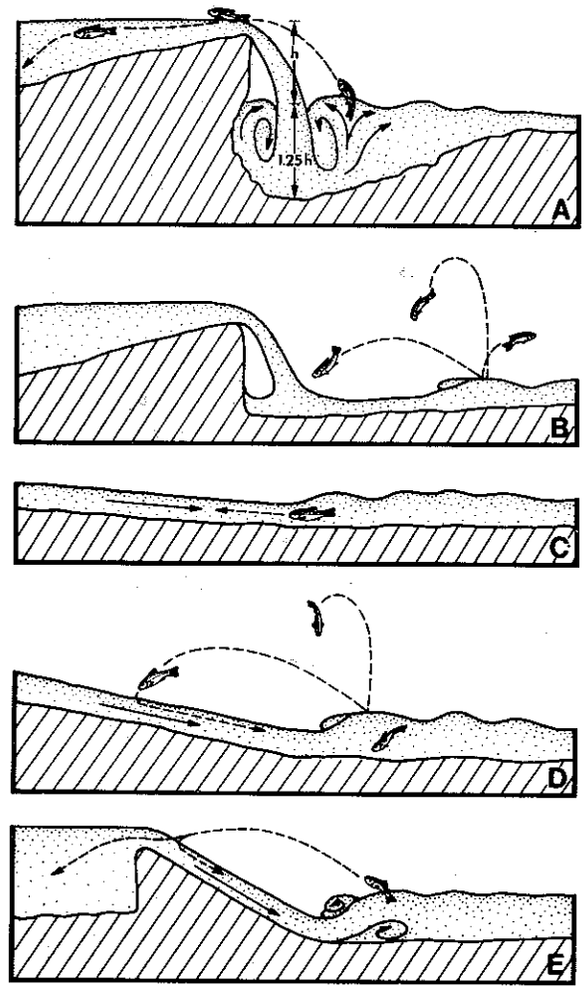

FIGURE 4.2.—Leaping ability of salmonids. (From Eiserman et al. 1975, diagrams drawn after Stuart 1962). (A) Falling water enters the pool at nearly a 90° angle. A standing wave lies close to the waterfall, where fish can use its upward thrust to leap the falls. Plunge-pool depth is 1.25 times the distance (h) from the crest of the waterfall to the water level of the pool. (B) The height of fall is the same as in A, but pool depth is less. The standing wave is formed too far from the ledge to be useful to leaping fish. (C) Flow down a gradual incline is slow enough to allow passage of ascending fish. (D) Flow over an incline steeper than fish can negotiate. Fish may even be repulsed in the standing wave at the foot of the incline. They sometimes leap futilely from the standing wave. (E) A shorter barrier with outflow over a steep incline may be ascended by some fish with difficulty.

should be done with care to avoid sedimentation of downstream spawning and rearing areas and loss of hydraulic stability.

Streamflow

Fish migrating upstream must have streamflows that provide suitable water velocities and depths for successful upstream passage. A variety of techniques have been used to estimate the flows required for migrating fish. Baxter (1961) reported that salmon needed 30–50% of the average annual flow for passage through the lower and middle reaches in Scottish rivers and up to 70% for passage up headwater streams. Thompson (1972) developed a procedure for estimating minimum flows required for migrating fish on the basis of minimum depth and maximum velocity criteria (Table 4.1) and measurements in critical stream reaches, usually shallow riffles. Stream discharges that provide suitable depths and velocities for upstream passage of adults can be estimated by the techniques he described (Thompson 1972):

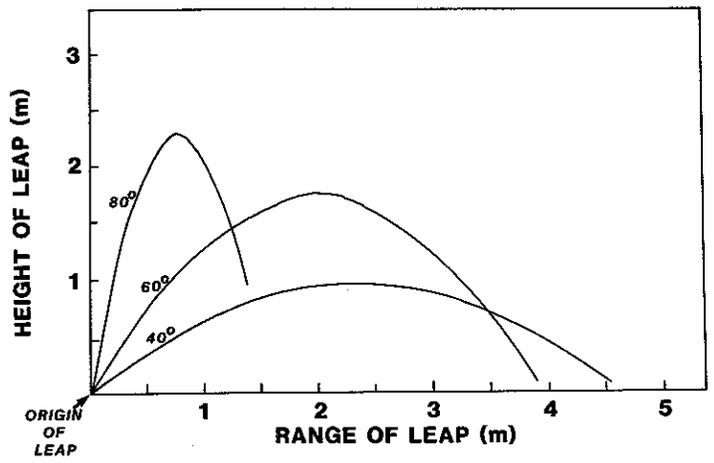

FIGURE 4.3.—Leaping curves for chinook, coho, and sockeye salmon swimming with a maximum burst speed of 6.8 m/s and jumping at various angles. (Adapted from Powers and Orsborn 1985.)

> . . . shallow bars most critical to passage of adult fish are located and a linear transect marked which follows the shallowest course from bank to bank. At each of several flows, the total width and longest continuous portion of the transect meeting minimum depth and maximum velocity criteria are measured. For each transect, the flow is selected that meets the criteria on at least 25% of the total transect width and a continuous portion equaling at least 10% of its total width.

The mean selected flow from all transects is recommended as the minimum flow for passage.

Sautner et al. (1984) reported that passage of chum salmon spawners through sloughs and side channels of the Susitna River, Alaska, depended primarily on water depth, length of the critical stream reach, and size of substrate particles. Fish could successfully pass any stream reach of reasonable length if the depth was greater than 0.12 m when substrate particles averaged larger than 7.6 cm in diameter, or if the depth was greater than 0.09 m when particles were less than 7.6 cm.

TABLE 4.2.—Swimming (Bell 1986) and jumping abilities (Reiser and Peacock 1985) of average-size adult salmonids.

Taxon	Swimming speed (m/s)			Maximum jumping height (m)
	Cruising	Sustained	Darting	
Chinook salmon	0–1.04	1.04–3.29	3.29–6.83	2.4
Coho salmon	0–1.04	1.04–3.23	3.23–6.55	2.2
Sockeye salmon	0–0.98	0.98–3.11	3.11–6.28	2.1
Steelhead	0–1.40	1.40–4.18	4.18–8.08	3.4
Trout	0–0.61	0.61–1.95	1.95–4.11	
Brown trout	0–0.67	0.67–1.89	1.89–3.87	0.8

Spawning

Substrate composition, cover, water quality, and water quantity are important habitat elements for salmonids before and during spawning. The number of spawners that can be accommodated in a stream is a function of the area suitable for spawning (suitable substrate, water depth, and velocity), area required for each redd, suitability of cover for the fish, and behavior of the spawners. Cover is important for species that spend several weeks maturing near spawning areas.

The amount of suitable stream substrate for spawning varies with the size (order) of the stream and species of salmonid using it, as Boehne and House (1983) learned from study of two coastal and two Cascade Range watersheds in Oregon. First-order streams (small headwater streams without tributaries) were not used by salmonids. Less than half the second-order streams (streams resulting from the junction of two or more first-order streams) were used by salmonids; those that were contained nonanadromous cutthroat trout. Most of the third-order streams (steams resulting from the junction of two or more second-order streams) in the coastal watersheds, but only 37% of those in the Cascade Range drainages, were used by cutthroat trout. The larger anadromous steelhead, coho salmon, and chinook salmon spawned in a few third-order streams, but most were found in fourth- and fifth-order streams. As stream order increased, gradient decreased but stream length, width, and depth increased. The amount of spawning gravel per kilometer of stream was greatest in fourth-order coastal watersheds and fifth-order Cascade Range watersheds. Platts (1979b) found similar relations between stream size (order) and use of the streams by fish in an Idaho drainage.

Streamflow

Streamflow regulates the amount of spawning area available in any stream by regulating the area covered by water and the velocities and depths of water over the gravel beds. D. H. Fry (in Hooper 1973) summarized the effect of discharge on the amount of spawning area in a stream.

> As flows increase, more and more gravel is covered and becomes suitable for spawning. As flows continue to increase, velocities in some places become too high for spawning, thus cancelling out the benefit of increases in usable spawning area near the edges of the stream. Eventually, as flows increase, the losses begin to outweigh the gains, and the actual spawning capacity of the stream starts to decrease. If spawning area is plotted against streamflow, the curve will usually show a rise to a relatively wide plateau followed by a gradual decline.

Relations between flow and amount of suitable spawning area have been assessed or predicted by methods based primarily on measurements of water depths and velocities in areas with suitable substrate. Collings (1972, 1974) used a process of depth and velocity contouring to determine the area suitable for spawning at a given discharge. Thompson (1972) quantified the width of the stream at cross-channel transects on spawning bars that met minimum criteria of depth (18 cm) and velocity (0.3–3.0 m/s) at different flows. When measurements have been taken over a wide range of flows, a graph can be plotted of flow versus suitable spawning areas (Figure 4.4) or usable width (Figure 4.5). A method

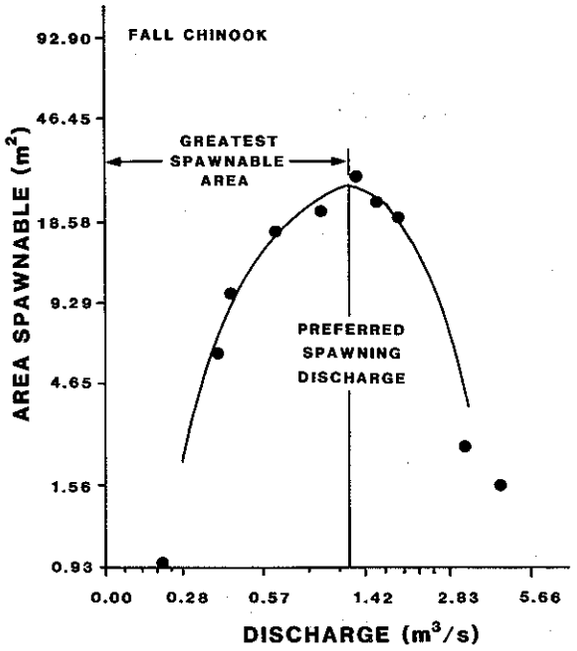

FIGURE 4.4.—Usable-area technique for selecting preferred spawning discharge, North Nemah River. (From Collings 1972.)

similar to that used by Waters (1976), termed the instream flow incremental methodology (IFIM), was developed by U.S. Fish and Wildlife Service personnel to estimate the amount of suitable habitat (for spawning, in this instance); the method relates variations in a stream's water velocity, depth, substrate, and other variables to use of the stream by fishes (Stalnaker and Arnette 1976b; Bovee 1978, 1982, 1986; Bovee and Milhous 1978; Trihey and Wegner 1981). An IFIM analysis results in an index of suitable habitat (weighted usable area, WUA) for a range of streamflows (Figure 4.6). Wesche and Rechard (1980) and EA Engineering, Science and Technology, Inc. (1986) reviewed and evaluated a variety of methods that could be used for estimating the quantity and quality of spawning habitat for salmonids.

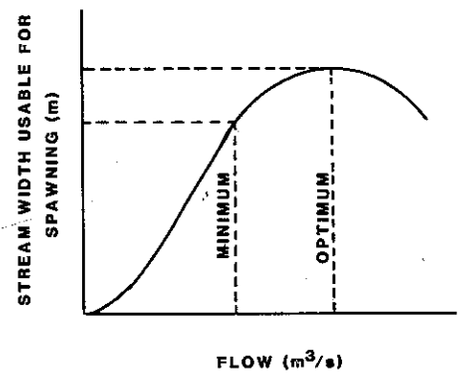

FIGURE 4.5.—Usable-width technique for determining spawning flow. (From Thompson 1972.)

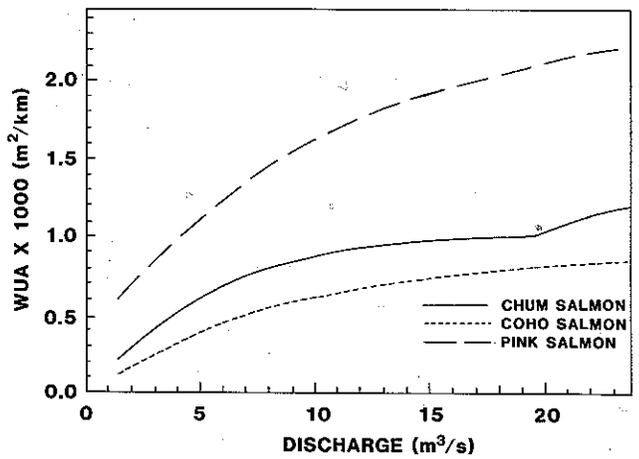

FIGURE 4.6.—Relation of available chum, coho, and pink salmon spawning habitat (weighted usable area, WUA) to streamflow, Upper Tunnel Creek. (From Reiser and Ramey 1984.)

Temperature

Timing of salmonid spawning has likely evolved in response to water temperatures in each stream before, during, and after spawning, and, in some streams, to the occurrence of flows that allow upstream migration of maturing adults. Salmonids have spawned when water temperatures have ranged from 1.0 to 20.0°C, but the favorable range of temperatures for spawning is much narrower (Table 4.3). In British Columbia (Shepherd et al. 1986b), salmon were observed spawning over a wide range of temperatures, but most of the pink, chum, and

TABLE 4.3.—Recommended temperatures for spawning and incubation of salmonid fishes (Bell 1986).

Species	Temperature (°C)	
	Spawning	Incubation[a]
Fall chinook salmon	5.6–13.9	5.0–14.4
Spring chinook salmon	5.6–13.9	5.0–14.4
Summer chinook salmon	5.6–13.9	5.0–14.4
Chum salmon	7.2–12.8	4.4–13.3
Coho salmon	4.4–9.4	4.4–13.3
Pink salmon	7.2–12.8	4.4–13.3
Sockeye salmon	10.6–12.2	4.4–13.3
Kokanee	5.0–12.8	
Steelhead	3.9–9.4	
Rainbow trout	2.2–20.0	
Cutthroat trout	6.1–17.2	
Brown trout	7.2–12.8[b]	

[a] The higher and lower values are threshold temperatures beyond which mortality increases. Eggs survive and develop normally at lower temperatures than indicated, provided initial development of the embryo has progressed to a stage that is tolerant of cold water.

[b] From Hunter (1973).

sockeye salmon spawned in water of 8–13°C, chinook salmon in water of 10–17°C, and coho salmon in water of less than 10°C (mode, 5–6°C).

Each native fish stock appears to have a unique time and temperature for spawning that theoretically maximizes the survival of their offspring. Temperatures before and during spawning must allow the spawners to survive and deposit their eggs, but temperatures during incubation of the embryos (which regulates timing of juvenile emergence from the redd) may be the primary evolutionary factor that has determined the time of spawning (Heggberget 1988). In the case of fall spawners, newly spawned embryos must reach a critical stage of development before the water becomes too cold (Brannon 1965), and emergence of fry must occur at a suitable time during the following spring (Sheridan 1962a; Miller and Brannon 1982; Godin 1982; Burger et al. 1985; Heggberget 1988). Spring spawners must not spawn before the water has warmed sufficiently to permit normal development of embryos, but there may be a survival advantage for the fish to spawn as early as possible to allow the offspring to emerge and grow before the onset of winter. Support for the latter hypothesis can be found in Idaho streams, where steelhead usually spawn before the peak of the snowmelt runoff in spring (thereby risking destruction of their redds by the high flows) rather than after the peak, which would delay the emergence of their offspring until late summer.

Areas with upwelling groundwater have been selected as spawning areas by salmonids such as chum salmon, brown trout, and brook trout (Benson 1953; Bakkala 1970; Witzel and MacCrimmon 1983; Vining et al. 1985). Use of areas with groundwater flow may have survival advantages if the water quality (suitable temperatures and dissolved gases, and lack of damaging heavy metals and sediments) in such areas is more suitable than in areas without groundwater.

Space

The amount of space required by salmonids for spawning depends on the size and behavior of the spawners and the quality of the spawning area. Large fish make large redds; tolerance of nearby fish varies by species; and poor-quality spawning areas may force females to make several redds. Redds range in size from 0.6 m^2 to more than 10 m^2 for anadromous salmonids, and from 0.09 m^2 to 0.9 m^2 for smaller nonanadromous trout and salmon (Table 4.4).

Many salmonids prefer to spawn in the transitional area between pools and riffles (Hazzard 1932; Hobbs 1937; Smith 1941; Briggs 1953; Stuart 1953). Tautz and Groot (1975) reported that chum salmon spawned in an accelerating flow, such as that found at a pool–riffle transition. By placing crystals of potassium permanganate on the gravel surface, Stuart (1953) demonstrated the presence of downwelling currents in these transitional areas (Figure 4.7) and noted that the gravel there was easy to excavate and relatively free of silt and debris. Vaux (1962, 1968) reported that downwelling currents normally occurred in areas where the streambed was convex (such as the pool–riffle transition), and upwelling currents occurred in concave areas (such as the downstream end of a riffle).

The density of redds in streams depends on the amount of stream area suitable for spawning, the number and size of spawners, and the area required for each redd. In two Lake Michigan tributaries with alternating pool–riffle habitat, the densities of spawning chinook salmon ranged from about 80 to 250 fish per hectare of stream area (Carl 1984). The average velocities at the preferred spawning sites in the two streams

TABLE 4.4.—Average area of salmonid redds and area recommended per spawning pair of fish in channels.

Species	Average area of redd (m^2)	Area recommended per spawning pair[a] (m^2)	Source
Chinook salmon	9.1–10.0		Neilson and Banford (1983)
Spring chinook salmon	3.3	13.4	Burner (1951)

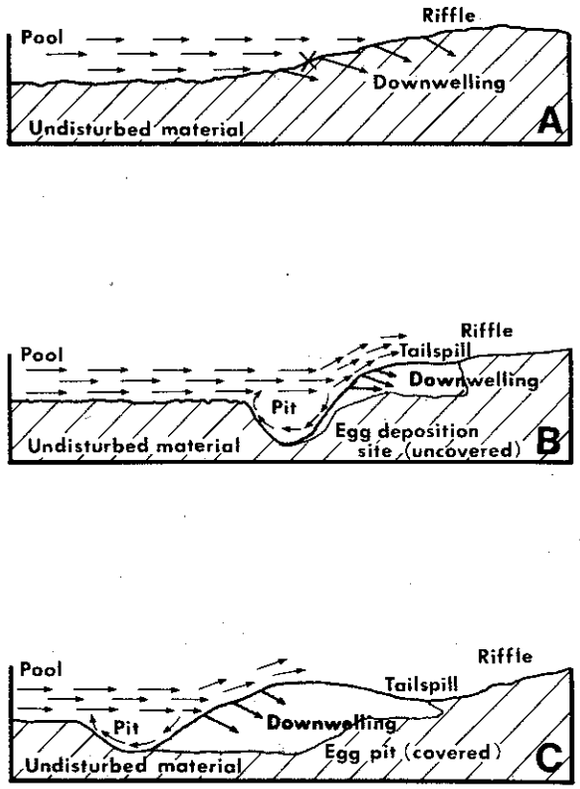

FIGURE 4.7.—Longitudinal sections of a spawning area. (From Reiser and Wesche 1977.) (A) Convexity of the substrate at the pool–riffle transition induces downwelling of water into the gravel. The area likely to be used for spawning is marked with a ×. (B) Redd construction results in negligible currents in the pit (facilitating egg deposition) and increased currents over and through (downwelling) the tailspill. (C) Egg-covering activity results in the formation of a second pit upstream, which may also be used for spawning. Increased permeability and the convexity of the tailspill substrate induces downwelling of water into the gravel, creating a current past eggs. The current brings oxygen to the eggs and removes metabolic wastes.

were 0.42 m/s and 0.50 m/s—similar to those reported by Burner (1951) in the Toutle River, Washington. In the Nechako River, British Columbia, Neilson and Banford (1983) reported that the area of chinook salmon redds averaged 9.1 and 10.0 m^2 and that densities were 1 redd per 235 m^2 and 1 per 112 m^2 in two areas with water depths of at least 0.45 m (the shallowest water in which redd construction was seen). Water depth in the deepest part (pit) of 47 completed redds was 0.46–1.20 m (mean, 0.87 m). Water velocity over the pit of the redds was 15–100 cm/s (mean, 56 cm/s). In a small Oregon coastal tributary, coho salmon constructed 1.7 redds per female and produced a density of 194 redds per hectare of stream (R. A. House, U.S. Bureau of Land Management, unpublished data).

The number of redds that can be built in a stream depends on the amount of suitable spawning habitat and the area required per spawning pair of fish (Reiser and Ramey 1984, 1987; IEC Beak 1984; Reiser 1986). The area suitable for spawning (defined by water depth, velocity, and size of substrate) is usually less than the total area of gravel substrate in the stream, and spatial requirements for each spawning pair may exceed the area of a completed redd. Surface areas of redds can be readily measured, but the spatial requirement for each spawning pair may require additional information such as area of suitable spawning habitat, number of spawners in a given area, and the size and behavior of spawners. Burner (1951) suggested that a conservative estimate of the number of salmon a stream could accommodate could be obtained by dividing the area suitable for spawning by four times the average area of a redd.

In an Oregon stream, gravel substrate made up 25% of the total stream area, but only 30% of that gravel substrate was suitable for spawning by coho salmon (R. A. House, unpublished data). The main stem of the Tucannon River in southeastern Washington contained nearly 200,000 m^2 of gravel substrate (D. W. Kelley and Associates 1982); however, only a small fraction of the river bed was suitable for anadromous fish spawning in the judgment of one of us (T.C.B.), who surveyed 9,000 linear meters of the river and estimated that 3,200 salmon or steelhead redds could be constructed without serious superimposition of redds. If the total area of gravel substrate in the stream (200,000 m^2) had been divided by the average size of salmon or steelhead redds (about 5 m^2), the capacity of the river would have been erroneously estimated to be about 40,000 redds. If Burner's (1951) formula (four times the average redd area) had been used, the estimate would be about 10,000 redds. Much of the river was unsuitable for spawning because water depths and velocities were outside the range acceptable to spawning salmon.

Water Depth and Velocity

Preferred water depths and velocities for various spawning salmonids have been determined from measurements of water depth and velocity at redds (Cope 1957; Sams and Pearson 1963; Orcutt et al. 1968; Thompson 1972; Hooper 1973; Hunter 1973; Smith 1973; Reiser and Wesche 1977; Reiser and White 1981a; Neilson and Banford 1983; Shepherd et al. 1986b). Water depths measured at redd sites varied with species and size of fish and ranged from 6 to 300 cm. In general, the water was at least deep enough to cover the fish during spawning; large salmon required 15–35 cm and smaller trout 6–10 cm (Table 4.5). Many fish spawned in water deeper than necessary to submerge them, but it is not known if the fish preferred the greater depths or were merely using what was available. Water

TABLE 4.5.—Water depth, velocity, and substrate size criteria for anadromous and other salmonid spawning areas.

Species	Depth (cm)	Velocity (cm/s)	Substrate size (cm)	Source
Fall chinook salmon	≥24	30–91	1.3–10.2[a]	Thompson (1972)

velocities at the redd sites ranged from 3 to 152 cm/s, but most were from 20 to 100 cm/s (Table 4.5).

Measurements of depth and velocity were usually taken at the upstream edge of the redd because that point most closely approximated conditions before the redd was constructed and reflected the depths and velocities selected by the fish. Two locations in the water column have been used for making estimates of preferred velocity: 0.6 × depth from the surface to the streambed, and nose velocity (which approximates the location of the fish close to the bed surface). Most velocity criteria have been developed for 0.6 × depth. The ranges of preferred depths and velocities have been defined in a variety of ways. Thompson (1972) used the depths and velocities within a 90–95% confidence interval. Hunter (1973) used the middle 80–90% of the measurements. Smith (1973) used a two-sided tolerance limit within which there was 95% confidence that 80% of the measurements would occur within a normal distribution. Others have simply listed the ranges of depth and velocity measured.

More recently, investigators have developed a series of index curves to depict the suitability of selected variables for different species of fish and life history stages (Figure 4.8). Such curves, used primarily in IFIM, have usually been developed from empirical measurements of depth, velocity, and substrate at the redd site. The curves were based on the assumption that fish select areas in a stream with optimal combinations of physical and hydraulic conditions. The development and limitations of these types of curves were discussed by various investigators (Bovee and Cochnauer 1977; Waters 1976; Baldridge and Amos 1982; Bovee 1982, 1986; Theilke 1985; EA Engineering, Science and Technology, Inc. 1986).

Substrate

The suitability of gravel substrate for spawning depends mostly on fish size; large fish can use larger substrate materials than can small fish. Bell (1986) stated that substrate for anadromous salmon and trout should range from 1.3 to 10.2 cm

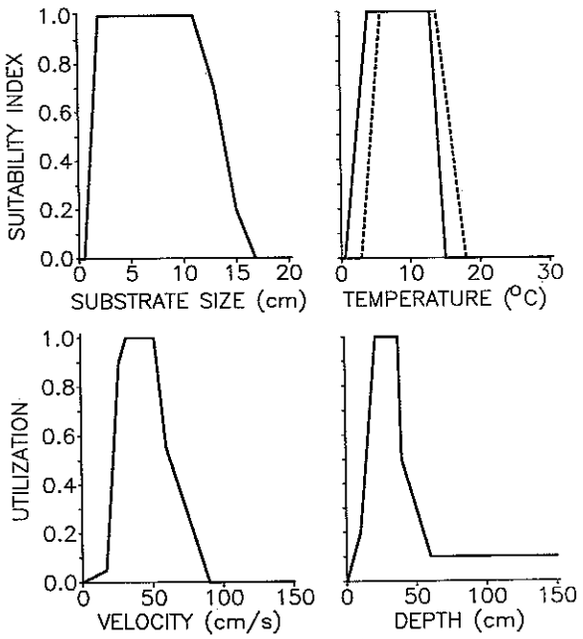

FIGURE 4.8.—Suitability index curves for average substrate particle size and temperature, and use curves for mean current velocity in the water column and water depth, in a spawning area used by chinook salmon. Solid line indicates spawning, dashed line incubation. (Redrawn from Raleigh et al. 1986.)

in diameter (Table 4.5). For smaller fish, other investigators have recommended that the materials not exceed 5.2 or 7.6 cm, depending on size of the fish. The criteria presented above are in general agreement with the sizes of substrate particles found in redds (Orcutt et al. 1968; Hooper 1973; Hunter 1973; Smith 1973; Reiser and Wesche 1977). Salmon have been observed spawning in areas with substrate particles larger than 30 cm, but most often in areas where the majority of particles were smaller than 15 cm (Shepherd et al. 1986b).

To determine the composition of substrate used by salmonids, investigators have collected substrate samples from active redds or known spawning areas and graded them through a series of sieves (Burner 1951; Cope 1957; Warner 1963; Orcutt et al. 1968; Hunter 1973; Reiser and Wesche 1977; Tagart 1976; Corley and Burmeister 1979; Huntington 1985). In such studies, various techniques have been used for the collection of substrate materials (McNeil and Ahnell 1964; Tagart 1976; Walkotten 1976; Platts and Penton 1980; Lotspeich and Everest 1981) and for their characterization (Platts et al. 1979b; Lotspeich and Everest 1981; Shirazi and Seim 1981; Tappel and Bjornn 1983). The particle makeup of redds or spawning areas has been characterized by the proportions within specified size ranges (Tappel and Bjornn 1983), the geometric mean particle diameter (dg: Shirazi and Seim 1981), and the Fredle index (Fi: Lotspeich and Everest 1981).

Substrates used in artificial spawning channels represent the particle sizes best suited for selected species in the judgment of those who designed the channels. Gravel from 2 to 10 cm in diameter was used in the Robertson Creek (British Columbia) spawning channels for pink, coho, and chinook salmon (Lucas 1960). Gravel from 0.6 to 3.8 cm was used in the Jones Creek (British Columbia) spawning channel for anadromous fish (MacKinnon et al. 1961). The Tehama–Colusa spawning channels in California, designed primarily for chinook salmon,

contained gravel 1.9–15.2 cm in diameter (Pollock 1969). Bell (1986) stated that, in general, up to 80% of the substrate in artificial spawning channels should be gravel with diameters of 1.3–3.8 cm; the balance should be of sizes up to 10.2 cm.

Cover

Cover for salmonids waiting to spawn or in the process of spawning can be provided by overhanging vegetation, undercut banks, submerged vegetation, submerged objects such as logs and rocks, floating debris, deep water, turbulence, and turbidity (Giger 1973). Cover can protect fish from disturbance and predation and also can provide shade. Some anadromous fish—chinook salmon and steelhead, for example—enter freshwater streams and arrive at the spawning grounds weeks or even months before they spawn. If the holding and spawning areas have little cover, such fish are vulnerable to disturbance and predation over a long period. Nearness of cover to spawning areas may be a factor in the selection of spawning sites by some species. In three studies, for example, brown trout selected spawning areas that were adjacent to undercut banks and overhanging vegetation (Johnson et al. 1966; Reiser and Wesche 1977; Witzel and MacCrimmon 1983).

Incubation

Although incubation is inextricably tied to spawning, the habitat requirements of embryos during incubation are different from those of spawning adults and thus warrant a separate discussion. When an adult fish selects a spawning site, it is also selecting the incubation environment. Successful incubation of embryos and emergence of fry, however, depend on many extragravel and intragravel chemical, physical, and hydraulic variables: DO, water temperature, biochemical oxygen demand (BOD) of material carried in the water and deposited in the redd, substrate size (including the amount of fine sediment), channel gradient, channel configuration, water depth (head) above the redd, surface water discharge and velocity, permeability and porosity of gravel in the redd and surrounding streambed, and velocity of water through the redd. Chapman (1988) reviewed the literature and discussed the primary factors involved in the incubation of salmonid embryos.

The relations between number of spawners, eggs deposited in redds, and juveniles that emerge from the redds take a variety of forms, depending on the species, life history, stream, and incubation conditions. The number of eggs deposited may increase linearly with the number of spawners as long as the amount of suitable spawning area is not limiting, but level off when suitable habitat becomes in short supply. Usually the number of fry emerging is directly related to the number of eggs deposited; if these two numbers are plotted against each other, differences in the linear slope between areas or streams probably reflect differing qualities of the incubation environment. Some species such as pink or chum salmon occasionally aggregate in extraordinarily large numbers on limited spawning grounds; if redds are superimposed and high egg densities result in oxygen depletion and poor incubation conditions, the number of emerging fry could be inversely related to the number of spawners.

Substrate

Streambed particles in the redd at the end of spawning, and organic and inorganic particles that settle into the redd and surrounding substrate during incubation, affect the rate of water interchange between the stream and the redd, the amount of oxygen available to the embryos, the concentration of embryo wastes, and the movement of alevins (especially when they are ready to emerge from the redd). During redd construction and spawning, the spawners displace streambed particles, deposit eggs and sperm in one or several pockets (Hawke 1978; Chapman 1988), and then cover the embryos with hydraulically displaced particles. During this process, fine sediments and organic materials in the stream substrate tend to be washed downstream; consequently the redd environment is as favorable for the embryos immediately after construction as it will ever be. Conditions for embryos within redds may change little or greatly during incubation depending on weather, streamflows, spawning by other fish in the same area at a later time, and fine sediments and organic materials transported in the stream.

Redds may be disturbed by late-spawning fish constructing redds, or by floods that displace the streambed containing the redd. Redds that remain intact during incubation may become less suitable for embryos if inorganic fine sediments (Figure 4.9) and organic materials are deposited in the interstitial spaces between the larger particles. The fine particles impede the movement of water and alevins in the redd, and the organic material (or the microbe community on it) consumes oxygen during decomposition; if the oxygen is consumed faster than the reduced intragravel water flow can replace it, the embryos or alevins will asphyxiate.

The redd construction process reduces the amounts of fine sediments and organic matter in the pockets where eggs are deposited (McNeil and Ahnell 1964; Ringler 1970; Everest et al. 1987a). If fine sediments are being transported in a stream either as bedload or in suspension, some of them are likely to be deposited in the redd. The amount of fine sediment deposited and the depth to which it intrudes depend on the size of substrate in the redd, flow conditions in the stream, and the amount and size of sediment being transported (Cooper 1965; Beschta and Jackson 1979). In general, intrusion into the redd increases as particle size decreases. When fine sediments are large relative to the spaces (pores) between gravel particles in the redd, they may only settle into the surface layer of the redd, where they can block other sediments from the deeper egg pockets (Hobbs 1937; Beschta and Jackson 1979; Chapman 1988). Under certain conditions, a layer of fine sediments may form above the egg pocket during redd construction or later. Such a layer can be beneficial (if it prevents deposition of fine organic or inorganic materials in the pocket), detrimental (if it impedes emergence of the alevins), or both. Deposition of fine sediments in redds may reduce survival more if it occurs early rather than late in the incubation period (Wickett 1954) because young embryos take up oxygen less efficiently than advanced embryos (Shaw and Maga 1943; Reiser and White 1988).

Depth of the egg pockets below the surface of the streambed varies with the size of fish and the size of streambed material. Large fish like chinook salmon may dig as deep as 43 cm below the streambed surface, but average pocket depths are in the 20- to 30-cm range (Hobbs 1937; Hawke 1978; Chapman 1988). The egg pockets of smaller fish tend to be closer to the streambed surface. Hawke (1978)

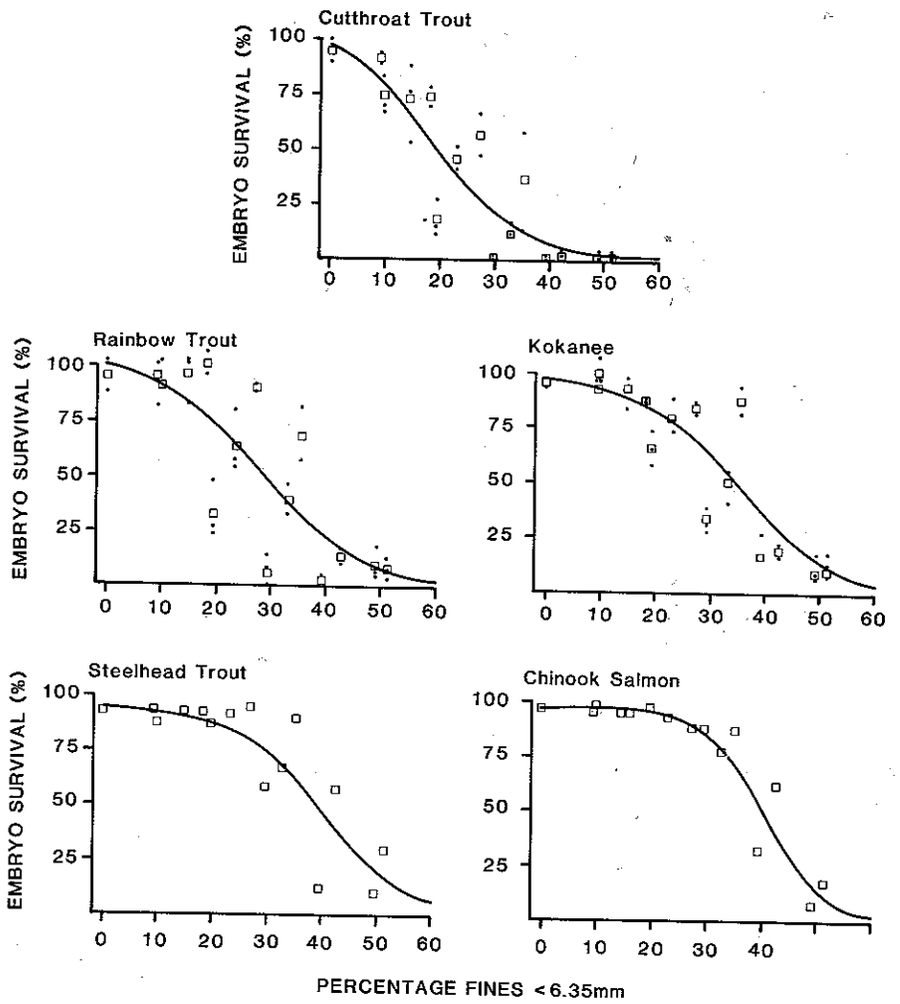

FIGURE 4.9.—Relation between embryo survival and percentage of substrate particles smaller than 6.35 mm for several salmonid species. Chinook salmon and steelhead data are from Tappel and Bjornn (1983); the others are from Irving and Bjornn (1984). Curves were fitted to the data by exponential equations. Squares indicate mean values and dots denote individual replicates.

and Everest et al. (1987a) found that the eggs tended to be near the bottom of the pocket and adjacent to the undisturbed streambed at the bottom of the redd.

During incubation, sufficient water must circulate through the redd as deep as the egg pocket to supply the embryos with oxygen and carry away waste products. Circulation of water through redds is a function of the porosity (ratio of pore space to total volume of redd) of the particles in the redd, hydraulic gradient at the redd, and temperature of the water. Porosity is highest in newly constructed redds and declines during the incubation period as the interstitial spaces acquire fine sediments. The hydraulic gradient through a redd is enhanced by the mounded tailspill created during construction (Figure 4.7). Permeability (ability of

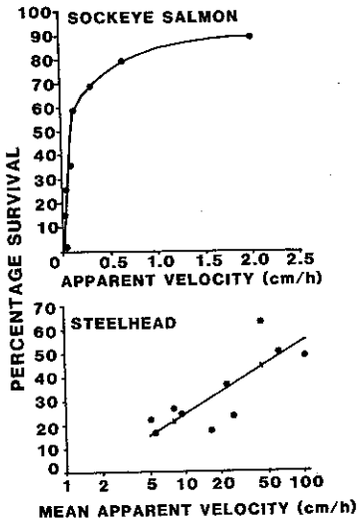

FIGURE 4.10.—Relations between rate of flow of water through a gravel bed and the survival of eyed sockeye salmon eggs (redrawn from Cooper 1965) and steelhead embryos (from Coble 1961).

particles in the redd to transmit water per unit of time) and apparent velocity (volume of water passing through a given area of redd per unit of time) are two commonly used measures of the suitability of a redd for successful incubation of salmonid embryos (Wickett 1954, 1958; Pollard 1955; Terhune 1958; Coble 1961; Vaux 1968). When the permeability and apparent velocity of water in the redd have been too low, reduced embryo survival has been measured for sockeye salmon (Pyper in Cooper 1965), steelhead (Coble 1961), chinook salmon (Gangmark and Bakkala 1960), pink salmon (Wickett 1958), and coho salmon and steelhead (Phillips and Campbell 1961). Survival of embryos decreases as apparent velocities (an indication of the amount of DO reaching the embryos) decrease (Figure 4.10).

Interchange of water between a stream and its streambed particles (Figure 4.7) has been repeatedly demonstrated (Stuart 1953; Sheridan 1962b; Vaux 1962; Cooper 1965). Sheridan (1962b) showed that groundwater in salmon spawning areas in southeast Alaska contains little oxygen, and that the oxygen content of intragravel water decreases with gravel depth. He concluded that the major source of oxygen in intragravel water was the interchange of that water with the surface flow. Cooper (1965) used dyes to demonstrate the influence of streambed configuration on intragravel flow patterns (Figure 4.11). Wells and McNeil (1970) attributed the high intragravel DO in Alaskan pink salmon spawning beds to high permeability of the substrate and to stream gradient. McNeil and Ahnell (1964) reported high permeabilities (>24,000 cm/h) in salmon spawning areas when sands and silts smaller than 0.84 mm made up less than 5% of the particles, and lower permeabilities (<1,300 cm/h) when they made up more than 15%. In sloughs of the Susitna River in central Alaska, Vining et al. (1985) noted that DO concentrations in intragravel water were consistently lower than in surface waters; in the main channel, however, differences in DO concentrations between surface and intragravel waters were slight.

Apparent velocity of water in redds may increase or decrease with the depth (and quantity) of the surface water (Reiser and White 1981a). Early evidence of

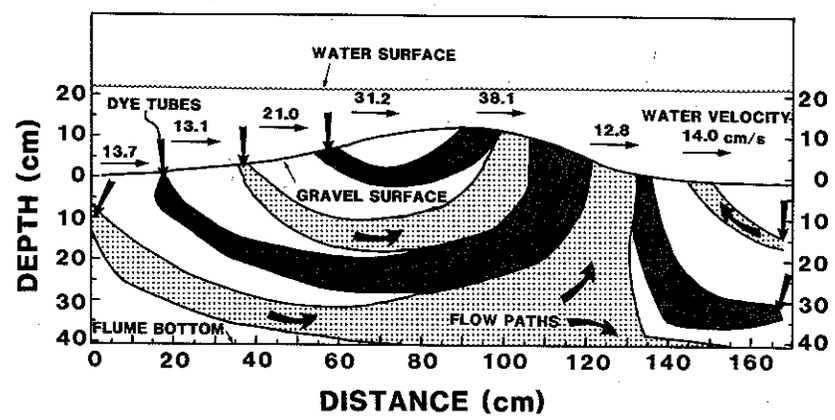

FIGURE 4.11.—Water flow through homogeneous gravel in a flume with a surface similar to that of a new salmon redd. Shadings indicate dispersions of injected dyes. (Redrawn from Cooper 1965.)

this was reported by Wickett (1954), who found a direct relation between gage-height readings in a stream and subsurface flow. Chapman et al. (1982) also observed decreases in apparent velocity when flow decreased from 1,982 to 1,019 m^3/s in the Columbia River.

Salmonid embryos have survived dewatering of redds when the dewatering occurred before hatching, temperatures were kept within a suitable range, fine sediment concentrations did not impede air flow, and humidity was maintained near 100% in the redds (Reiser and White 1981b, 1983; Becker et al. 1982; Stober et al. 1982; Becker and Neitzel 1985; Neitzel and Becker 1985). In a moist environment, unhatched embryos are able to get the oxygen they need from air in the redds (Figure 4.12). Several examples have been reported. Hobbs (1937) found that 80% of the brown trout eggs he observed were still alive in redds that had had no surface flow for 5 weeks, and Hardy (1963) found similar results in brown trout redds after 2–5 weeks of dewatering. Chinook salmon embryos survived in redds that had been dewatered for 3 weeks (Hawke 1978). Steelhead and chinook salmon embryos tolerated 1–5 weeks of dewatering (water flowed through the gravel 10 cm below the eggs) with no significant reduction in survival to hatching, alevin quality, growth rate, or quality of emerged fry (Reiser and White 1983). Survival through hatching of dewatered eggs of chinook, chum, pink, and coho salmon and steelhead was high during a study by Stober et al. (1982). Chinook salmon embryos survived 24 h of dewatering when relative humidity was kept at 100%, but all died if humidity was lowered to 90% (Neitzel and Becker 1985).

In streams with substantial groundwater inflows, DO concentrations and flow patterns of intragravel water may not relate in the usual way to substrate composition and permeability (Hansen 1975; Sowden and Power 1985). Upwelling areas are reportedly favored for spawning by chum, sockeye (Lister et al. 1980; Wilson 1984; Vining et al. 1985), and pink salmon (Krueger 1981). Embryo incubation is improved because upwelling reduces the chances that embryos will become dewatered or frozen, provides a stable incubation environment, and increases the water exchange rate past the embryos, thereby enhancing the

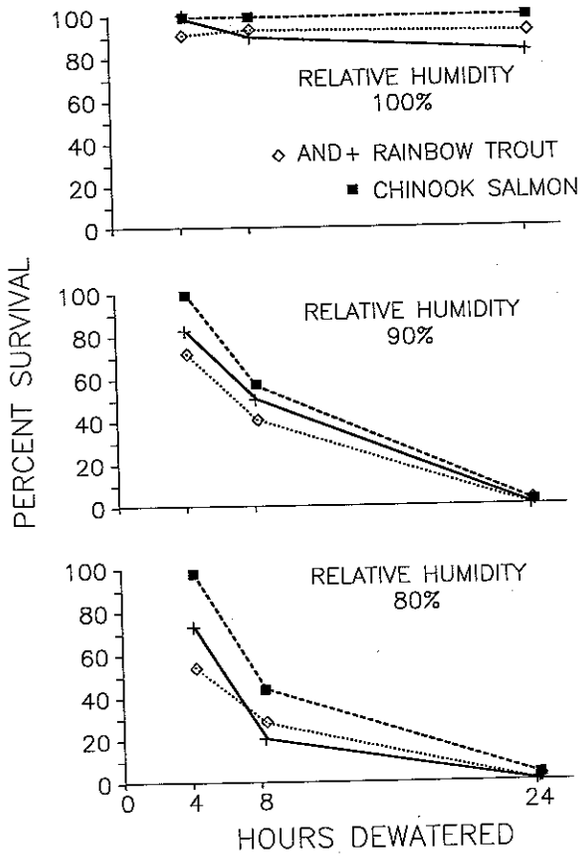

FIGURE 4.12.—Percent survival for dewatered embryos of rainbow trout and chinook salmon under conditions of reduced relative humidity. (From Becker et al. 1986.)

replenishment of DO (if the upwelling water has sufficient amounts) and removal of metabolic waste (Vining et al. 1985).

Egg densities in natural redds are relatively low compared to those in artificial culture facilities; they typically do not affect embryo and alevin survival unless the incubation environment is of marginal quality. If a large chinook salmon deposited 5,000 eggs in a single redd that covered 10 m^2, the density in that redd would be 500 eggs/m^2. However, the density in the actual egg pocket or pockets would be higher, perhaps as high as 2,000–5,000 eggs/m^2 if most of the eggs were deposited in one or two pockets. McNeil (1969) reported that production of pink salmon fry approached 500 fry/m^2 of spawning area when egg deposition was 2,000–3,000 eggs/m^2. In shallow matrix incubators, Kapuscinski and Lannan (1983) found that chum salmon could be incubated at densities as high as 43,000 eggs/m^2 without sacrificing quality of the fry produced.

Once incubation is complete and the alevins are ready to emerge from the redd and begin life in the stream, they must move from the egg pocket up through interstitial spaces to the surface of the streambed. Nunan and Noakes (1985) concluded that emergence of salmonid alevins was a response primarily to gravitational cues rather than to light or intragravel water flow. Emergence can be a problem if the interstitial spaces are not large enough to permit passage of the alevins. In laboratory studies, alevins of chinook salmon and steelhead (Bjornn

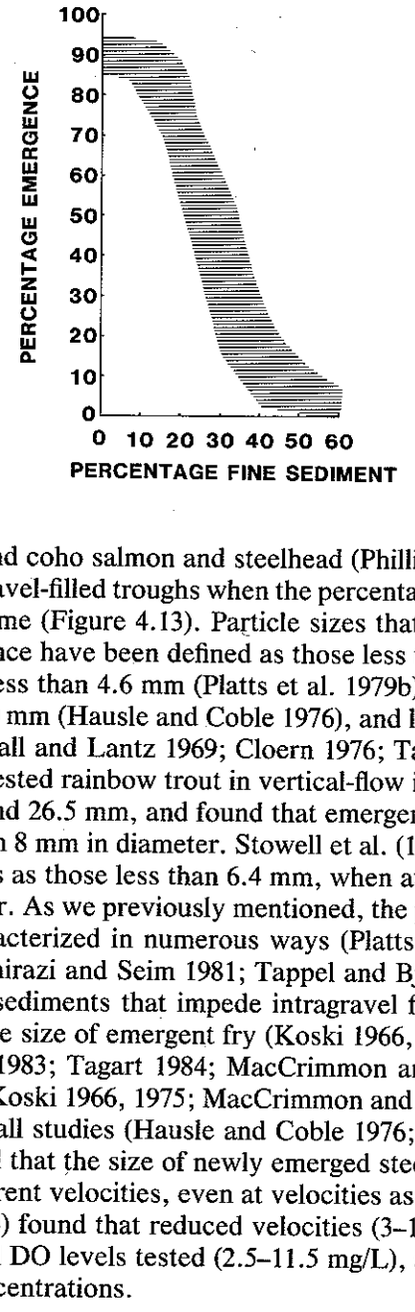

FIGURE 4.13.—Percentage emergence of swim-up fry placed in gravel–sand mixtures in relation to the percentage of sediment smaller than 2–6.4 mm in studies by Bjornn (1968), Phillips et al. (1975), Hausle and Coble (1976), and McCuddin (1977). The stipled area includes data from eight tests on brook trout, steelhead, and chinook and coho salmon.

1968) and coho salmon and steelhead (Phillips et al. 1975) had difficulty emerging from gravel-filled troughs when the percentage of fine sediments exceeded 30–40% by volume (Figure 4.13). Particle sizes that reduce embryo survival and impede emergence have been defined as those less than 6.4 mm (Bjornn 1968; McCuddin 1977), less than 4.6 mm (Platts et al. 1979b), less than 3.3 mm (Koski 1966), less than 2.0 mm (Hausle and Coble 1976), and less than 0.84 mm (McNeil and Ahnell 1964; Hall and Lantz 1969; Cloern 1976; Tagart 1976). Witzel and MacCrimmon (1981) tested rainbow trout in vertical-flow incubators filled with particles of 2, 4, 8, 16, and 26.5 mm, and found that emergence was impeded when particles were less than 8 mm in diameter. Stowell et al. (1983) defined the harmful size range of particles as those less than 6.4 mm, when at least 20% were less than 0.84 mm in diameter. As we previously mentioned, the particle size composition of redds can be characterized in numerous ways (Platts et al. 1979b; Lotspeich and Everest 1981; Shirazi and Seim 1981; Tappel and Bjornn 1983).

Fine sediments that impede intragravel flow and alevin movements may also affect the size of emergent fry (Koski 1966, 1981; Phillips et al. 1975; Tappel and Bjornn 1983; Tagart 1984; MacCrimmon and Gots 1986) and the time of emergence (Koski 1966, 1975; MacCrimmon and Gots 1986), but such effects were not seen in all studies (Hausle and Coble 1976; McCuddin 1977). Silver et al. (1963) reported that the size of newly emerged steelhead and chinook salmon depended on apparent velocities, even at velocities as high as 740–1,350 cm/h. Shumway et al. (1964) found that reduced velocities (3–10 cm/h) resulted in decreased size of fry at all DO levels tested (2.5–11.5 mg/L), and that hatching was delayed at low DO concentrations.

Dissolved Oxygen

Critical concentrations of DO that barely satisfy respiratory demands have been experimentally determined for salmonid embryos at different developmental stages (Table 4.6). Alderdice et al. (1958) found that embryos generally were most sensitive to hypoxial conditions during the early stages of development, when they had received 200–390 temperature units (a temperature unit is one degree

TABLE 4.6.—Critical levels of dissolved oxygen (DO; minimum that satisfies respiratory demand) for salmonid embryos at various stages of development.

Species	Stage of development	Age (d)	Critical DO (mg/L)
Chum salmon (Wickett 1954)	Pre-eyed	0	0.72
	Pre-eyed	5	1.67

above zero for one day). Wickett (1954) showed that larval development during the early stage of development depended wholly on diffusion for satisfying oxygen requirements. Once the circulatory system is functional, oxygen transfer to the embryo becomes more efficient.

Embryos may survive when DO concentrations are below saturation (but above the critical level), but their development often deviates from normal. Doudoroff and Warren (1965) found that when DO was below saturation throughout development, embryos were smaller than usual and that hatching was either delayed or premature. Alderdice et al. (1958) showed that low DO concentrations in the early stages of development of chum salmon delayed hatching and increased

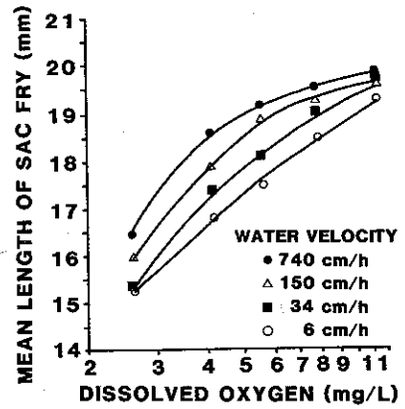

FIGURE 4.14.—Relation between mean length of steelhead sac fry when hatched and dissolved oxygen concentration at which the embryos were incubated, for several water velocities during incubation and a temperature of 9.5°C. (From Silver et al. 1963.)

TABLE 4.7.—Characteristics of sockeye salmon alevins at hatching after embryos were incubated in water at three oxygen concentrations. (From Brannon 1965.)

the incidence of morphological anomalies. Silver et al. (1963) reported that newly hatched steelhead and chinook salmon alevins were smaller and weaker when they had been incubated as embryos at low and intermediate DO concentrations than when they were incubated at higher concentrations (Figure 4.14). Shumway et al. (1964) found that reduced DO lengthened the incubation period of coho salmon embryos, which hatched into smaller alevins than normal. Brannon (1965) found differences in length and other anatomical features among newly hatched sockeye salmon fry that had developed at three DO levels (Table 4.7); however, weights of the emergent fry were similar among treatment groups.

In field studies, survival of steelhead embryos (Coble 1961) and coho salmon embryos (Phillips and Campbell 1961) was positively correlated with intragravel DO in redds (Figure 4.15). Phillips and Campbell (1961) concluded that intragravel DO must average 8 mg/L for embryos and alevins to survive well. Stober et al. (1982) and Fast and Stober (1984) reported that newly hatched alevins in the gravel are able to detect oxygen gradients and migrate to areas containing more DO.

Intragravel DO concentrations are functions of many factors: water temperature, surface and intragravel water interchange, apparent velocity of water flow in

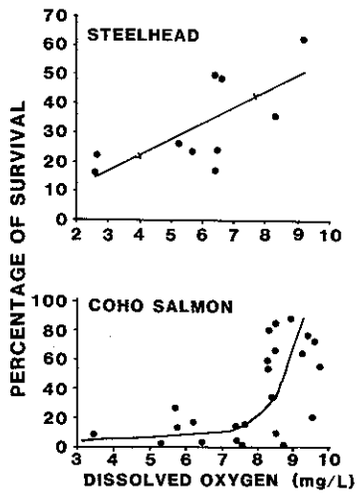

FIGURE 4.15.—Relation between dissolved oxygen concentration and survival of steelhead embryos (from Coble 1961) and coho salmon embryos (Phillips and Campbell 1961) in natural redds.

the redd, permeability of the substrate, and oxygen demand of organic material in the redd, among others. Hall and Lantz (1969), Ringler and Hall (1975), and Moring (1975a) reported that intragravel DO concentrations were reduced in some Oregon streams after adjacent areas had been logged. They attributed such reductions to elevated stream temperatures after removal of the riparian canopy and to increased concentrations of fine sediment that reduced substrate permeability and apparent velocity. Tagart (1976) and Reiser and White (1981b) found direct relations between DO and permeability and inverse relations between DO and percentage of fines in stream substrates. Coble (1961) generalized his experience with this subject by stating that when apparent water velocities are low, DO is low; when they are high, DO is usually high.

All streams transport particulate and dissolved organic matter. The amount transported and the timing of transport varies with the productivity of the stream, the source and type of organic matter, and streamflow (Fisher and Likens 1973; Hobbie and Likens 1973; Liaw and MacCrimmon 1977; Naiman and Sibert 1978; Bilby and Likens 1979; Dance et al. 1979; Naiman and Sedell 1979). Organic matter that settles into redds can reduce the DO concentration as it decomposes; the extent of oxygen depletion depends on the amount and type of organic debris (Hargrave 1972) and the chemical, physical, and hydraulic characteristics (DO content, temperature, permeability, and reaeration capability) of the stream and its substrate. Excessive recruitment of organic material to a stream can result in reduced DO concentrations and intragravel water flow, leading to reduced survival of incubating embryos (Olssen and Persson 1986).

Although DO concentrations required for successful incubation depend on both species and developmental stage, we recommend that concentrations should be at or near saturation, and that temporary reductions should drop to no lower than 5.0 mg/L, for anadromous salmonids. Apparent velocities of water flowing through redds also must be maintained at acceptable rates because high DO alone does not guarantee optimum embryo development. In redds with similar DO concentrations, but different apparent velocities, embryonic development may be better in the redds with the higher rate of water exchange (Coble 1961). Mathematical models have been developed to estimate apparent velocity in redds (Bovee and Cochnauer 1977) and to assess transfer of DO between the stream and substrate (Chevalier and Carson 1985), concentrations of intragravel DO (Chevalier and Murphy 1985), salmonid egg respiration (Carson 1985), and fry emergence (Miller 1985).

Temperature

Water temperature during incubation affects the rate of embryo and alevin development and the capacity of water for dissolved oxygen, and (beyond certain limits) survival of the young fish. There are upper and lower temperature limits (thresholds) for successful incubation of salmonid eggs (Table 4.3). In general, the higher the temperature (within the acceptable range), the faster the rate of development and the shorter the incubation period and time to emergence. The amount of time required for embryos to hatch and for alevins to emerge from redds varies by species and perhaps by location. For example, time to 50% hatch for Pacific salmon species ranges from 115 to 150 d at 4°C and from 35 to 60 d at 12°C; coho salmon require the least time and sockeye salmon the most (Alderdice

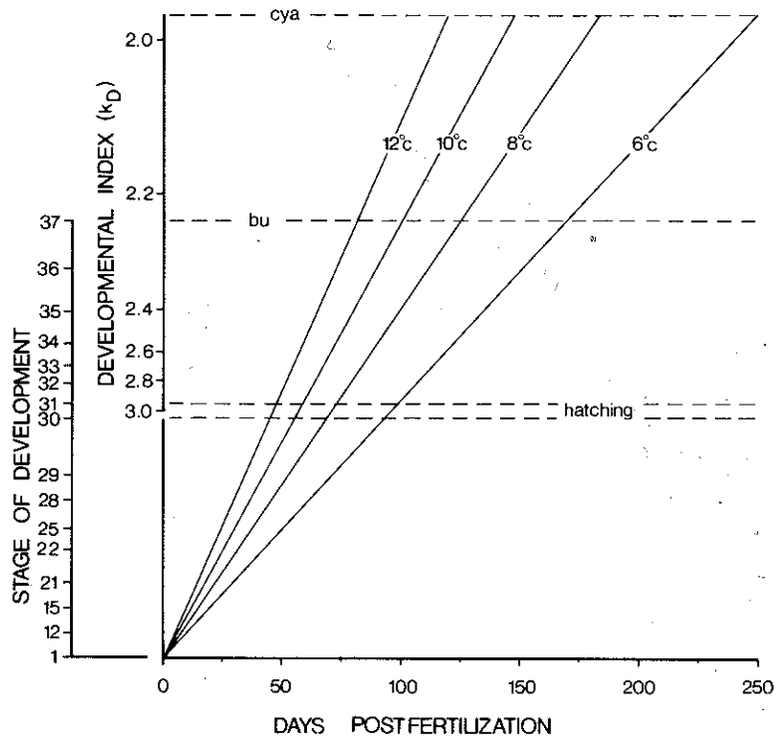

FIGURE 4.16.—Effect of temperature on the development of chinook salmon according to Vernier's (1969) stages of development and Bams's (1970) developmental index (k_D) in a graph from Heming (1982). In the graph, bu = button-up stage of development and cya = complete yolk absorption.

and Velsen 1978; Tang et al. 1987; Velsen 1987). Steelhead and rainbow trout require about 85 d at 4°C and 26 d at 12°C to reach 50% hatch. Heming (1982) graphed stage of development against time (Figure 4.16) for chinook salmon raised experimentally at several temperatures; from these graphs, he estimated emergence at 192 d at 6°C and 85 d at 12°C, about twice the time to 50% hatch. In field studies on the Columbia River, Chapman et al. (1982) found that Heming's curves were reasonable predictors of the time chinook salmon fry emerge. Time to hatch for lake trout is similar to that of chinook salmon, 80–90 d at 6°C (Dwyer 1987).

In many streams in which salmonids spawn, winter temperatures are lower than the 4.4°C minimum recommended for incubation in Table 4.3, but the eggs develop normally because spawning and initial embryo development occur when temperatures are within the suitable range. Combs and Burrows (1957) and Combs (1965) reported that pink and chinook salmon embryos could tolerate long periods of low temperature if the initial temperature was above 6.0°C and embryogenesis had proceeded to a critical developmental stage before the onset of lower water temperatures. Combs and Burrows (1957) believed that salmon produced from eggs deposited in water colder than 4.5°C would be less viable than fish produced from eggs spawned in warmer water. Wangaard and Burger (1983) reported 3.4°C as the temperature below which some newly spawned chum and pink salmon

embryos would be killed. Bailey and Evans (1971) defined the lower threshold temperature for pink salmon embryos as 4.5°C. In a summarization of available data, Velsen (1987) reported high mortalities for all Pacific salmon and steelhead when water temperatures were lower than 2–3°C after fertilization. Jungwirth and Winkler (1984) reported that embryos of fall-spawning fishes develop more slowly at any temperature, and have lower upper lethal incubation temperatures, than progeny of spring spawners. Incubation temperatures can also affect the size of newly hatched alevins. When Beacham and Murray (1985) incubated chum salmon eggs at temperatures of 4, 8, and 12°C, the newly hatched alevins incubated at 4°C were the longest, and those at 12°C were the heaviest, but there was no difference in size at emergence. Reiser and White (1981b) observed similar early differences among chinook salmon, which then reached equivalent sizes after 57 d of rearing.

Intragravel water temperatures are influenced by temperatures of the surface water, the thermal mass of the substrate, and the interchange rate of surface and intragravel water. Ringler and Hall (1975) observed that temperatures of intragravel water reached diurnal maxima 2–6 h after those of surface waters in an Oregon stream. Chapman et al. (1982) observed temperature lags of 2–8 h between surface and intragravel waters. There are seasonal as well as daily differences: intragravel water temperatures often are lower than surface water temperatures during summer, and higher during winter (Shepherd et al. 1986a). When salmonids spawn in areas close to groundwater inflows (Hansen 1975; Witzel and MacCrimmon 1983; Wilson 1984; Vining et al. 1985), embryos experience reduced extremes in water temperatures than they would otherwise.

Incubating embryos and alevins can be killed when frazil or anchor ice forms in streams and reduces water interchange between the stream and the redd. Anchor ice normally forms in shallow water typical of spawning areas and may completely blanket the substrate. Ice dams may impede flow or even dewater spawning areas. When such dams melt, the released water may, floodlike, displace the streambed and scour the redds. In an experiment by Reiser and Wesche (1977), eggs placed in plastic-mesh boxes 15 cm below the surface of the streambed completely froze even though the stream above was more than 13 cm deep. Anchor ice had formed at least twice during the incubation period. Neave (1953) and McNeil (1966b) also reported that embryo survival was poor at freezing temperatures.

Rearing in Fresh Water

The abundance of juvenile salmon, trout, and char in streams is a function of many factors, including abundance of newly emerged fry, quantity and quality of suitable habitat, abundance and composition of food, and interactions with other fish, birds, and mammals. Fausch et al. (1988) reviewed many of the models developed in recent years to predict the abundance of fish in streams from habitat variables. We next discuss variables of habitat quantity and quality, and where possible, list the preferences of juvenile salmonids.

The abundance of older fish generally increases as the abundance of juveniles increases until an upper limit (here termed carrying capacity) is reached. We believe that the relation between the seeding level—the number of young fish emplaced in a stream by adult fish or humans—and the abundance of older fish is

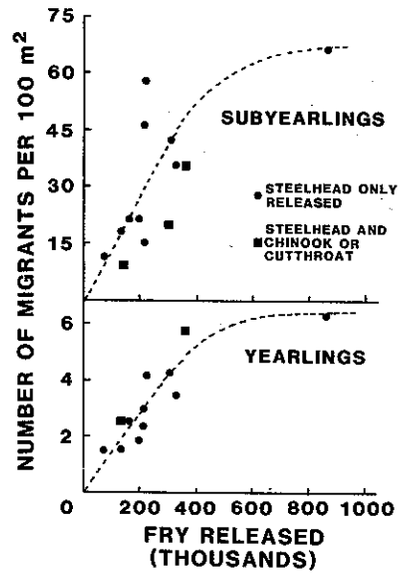

FIGURE 4.17.—Relation between the number of steelhead fry released in Big Springs Creek, Idaho, and the number of subyearling and yearling rainbow trout and steelhead per 100 m^2 that migrated from the stream. Each point represents one of the 1962–1974 year-classes (1962–1973 for yearlings); curves were fitted by inspection. (From Bjornn 1978.)

asymptotic for most salmonids that spend an extended period in streams. At relatively low seeding levels, environmental conditions that set the carrying capacity of a stream for a given age group of fish will place little constraint on the abundance of juveniles and older fish. As spawner abundance (or stocking) approaches that needed for full seeding, the biotic or physical factors that set the carrying capacity come into full play. Habitat variables we discuss here may set the carrying capacity of streams for salmonid fishes, but interactions among many of the relevant physical and biotic variables have not been well defined. In addition, variables that are important in one stream or season may be relatively unimportant in another.

Changes in spawner abundance and variation in the success of incubation and emergence affect the number of young fish entering a stream. Changes in the abundance of newly emerged fry can result in large or insignificant changes in abundance of older fish, depending on the shape of the reproduction curve and actual fry abundance. In two productive Idaho streams, the abundance of older steelhead was primarily a function of the number of newly emerged juveniles placed in the stream at seeding rates up to about 6 fish/m^2 (Bjornn 1978) (Figure 4.17). When steelhead were stocked at a rate of 12/m^2 in Big Springs Creek (right-most point in Figure 4.17), no more subyearlings or yearlings were produced than when 6/m^2 were stocked—evidence that the carrying capacity had been reached. In the Lemhi River, about the same number of steelhead smolts were produced (75,000–80,000) from releases of 2.5 and 4.6 million newly emerged juveniles—additional evidence that carrying capacity had been achieved. The carrying capacity for chinook salmon in the Lemhi River was not reached during 12 years of study in which natural egg-deposition rates ranged from 2 to 8/m^2 (Figure 4.18).

In less-productive Idaho streams, seeding rate (abundance of spawners) was the main factor regulating the abundance of juvenile steelhead (Figure 4.19) and chinook salmon when spawner abundance was relatively low. In Marsh Creek,

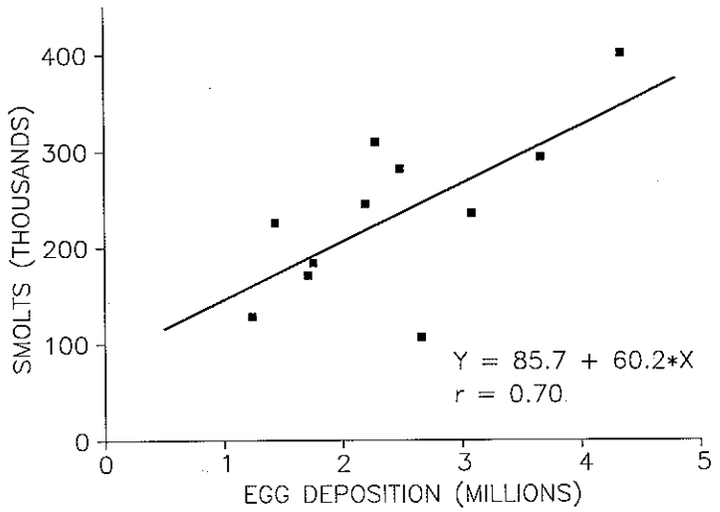

FIGURE 4.18.—Egg deposition *(X)* by adult chinook salmon in the upper Lemhi River, Idaho, and number of smolt-sized fish *(Y)* that later migrated past the Lemhi River weir during fall, winter, and spring, 1963–1973. (From Bjornn 1978.)

one of the relatively unproductive streams, the density of juvenile chinook salmon, monitored irregularly over 12 years, was related to spawner abundance over a nearly 20-fold range (Figure 4.20). Sekulich (1980) presented evidence that the summer carrying capacity for naturally produced salmon in the relatively unproductive streams was 2–3 g/m^2, lower than the carrying capacity of at least 13 g/m^2 in the relatively productive Lemhi River (Bjornn 1978). In Pacific coast streams, the biomass of coho salmon averaged 2–3 g/m^2 in several studies (Cederholm and Reid 1987).

The number of chinook salmon smolts produced in two Lake Michigan tributaries with alternating pool–riffle habitats was independent of the threefold difference in spawner densities that occurred in 2 years of study (Carl 1984). Even at their lower density, spawners apparently seeded the rearing area fully (about 80 spawners per hectare, 0.7–2.9 newly emerged fish per square meter).

For a given level of seeding, what factors in the stream environment regulate abundance or set the carrying capacity for juvenile salmonids? Density-independent environmental factors (amount of suitable habitat, quality of cover, productivity of the stream, and certain types of predation) set an upper limit on the abundance of juveniles, and the population is held to that level by interactions that function in a density-dependent fashion (competition and some types of predation). Carrying capacity, and hence fish production, may vary yearly if controlling habitat components, such as streamflow, vary widely from year to year at critical periods such as late summer (Smoker 1955). The carrying capacity of a stream may also vary with the season, differing, for example, between winter and summer (Bjornn 1978), and it may differ for the various life stages of fish.

Environmental factors can affect the distribution and abundance of juvenile salmonids throughout a stream or drainage or within specific segments of streams.

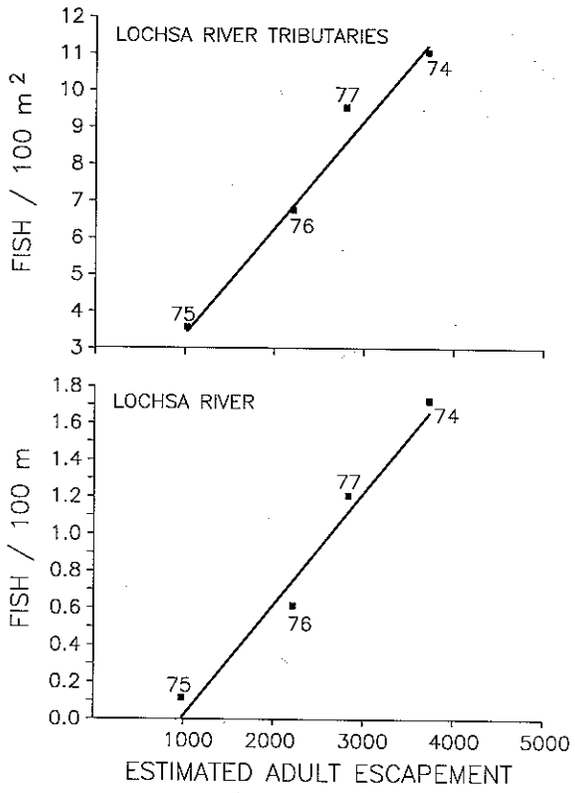

FIGURE 4.19.—Observed density of age-1 steelhead in relation to estimated number of adults returning to the Lochsa River and its tributaries, Idaho, 1974–1977. (Redrawn from Mabbott 1982.)

Temperature, productivity, suitable space, and water quality (turbidity, DO, etc.) are examples of variables that regulate the general distribution and abundance of fish within a stream or drainage. Factors to which fish respond at specific locations in a stream are velocity, depth, substrate, cover, predators, and competitors. Fish often spawn in limited parts of a drainage (sometimes in ephemeral streams), but

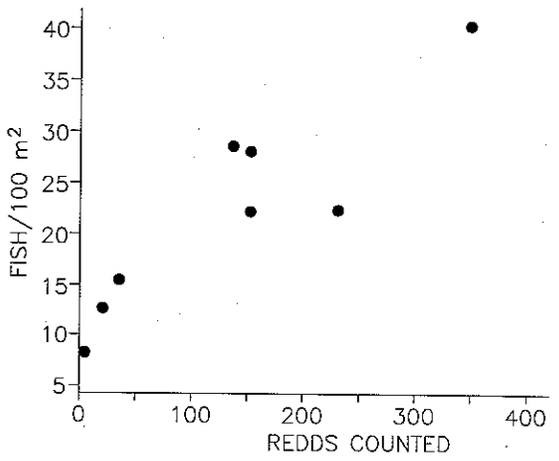

FIGURE 4.20.—Relation between chinook salmon redds counted and density of age-0 juveniles the following summer in an Idaho stream. (Authors' original data.)

the juveniles spread out and occupy most of the areas that are suitable and accessible (Everest 1973; Leider et al. 1986).

All of the general factors must be within suitable ranges for salmonids during the time they use a stream segment; otherwise, no fish will be present and there will be no concern about site-specific factors. Rarely, if ever, are most factors optimum for salmonid production. Often some factors may be near optimum while others are suboptimum but still in a suitable range.

Temperature

Salmonids are coldwater fish with definite temperature requirements during rearing. Water temperature influences the metabolism, behavior, and mortality of fish and the other organisms in their environment (Mihursky and Kennedy 1967). Although fish may survive at temperatures near the extremes of the suitable range, growth is reduced at low temperatures—because all metabolic processes are slowed—and at high temperatures—because most or all food must be used for maintenance. Many salmonids change behavior with increases or decreases in temperature.

Normal water temperatures in salmonid streams vary daily, seasonally, annually, and spatially. Humans have altered temperature patterns by changing riparian zone vegetation, diverting water, building reservoirs, and discharging hot water from power plants. Alterations of natural light and temperature patterns in streams can be beneficial or detrimental, depending on the situation, but the consequences of marked changes in the temperature regime of a stream are not fully understood. Small streams in dense forests of the Pacific Northwest, for example, might be too cold in summer for maximum growth of salmonids (Chapman and Knudsen 1980), but warming the stream by altering the riparian vegetation (Gray and Edington 1969; Narver 1972a; Moring 1975a; Moring and Lantz 1975; Murphy et al. 1981; Johnson et al. 1986; Murphy et al. 1986; Beschta et al. 1987) might not enhance growth unless food abundance can satisfy the increase in fish metabolism and other needs of the fish are met (Brett et al. 1969; Hughes and Davis 1986; Hartman et al. 1987; Holtby 1988a). Care must be taken to avoid unwanted warming of downstream waters and excessive loss of cover (both overhead bank and instream) that may be important in winter as well as in summer (Murphy et al. 1986). In many large streams, temperatures become too warm for salmonids in summer for a variety of reasons, including excessive exposure to the sun.

Temperatures that can be tolerated by fishes have been defined and determined in two ways (Brett 1952; Becker and Genoway 1979): slow heating of fish (to reveal the critical thermal maximum, CTM), and abrupt transfer of fish between waters of different temperature (to show the incipient lethal temperature, ILT). In general, upper lethal temperatures determined by the CTM procedure tend to be higher than those established with the ILT technique. The upper ILT for anadromous Pacific salmon, Atlantic salmon, trout, and char range from about 23 to 29°C, depending on species and acclimation temperature (selected examples are in Table 4.8). Half of the upper lethal values presented in Table 4.8 were taken from Brett (1952), who acclimated fish at 20°C and used 50% mortality at 1,000 min as the end point. Lee and Rinne (1980) reported CTM values of 29–30°C for hatchery stocks of rainbow, brown, and brook trout stocked in Arizona and two

TABLE 4.8.—Lower lethal, upper lethal, and preferred temperatures (°C) for selected species of salmon, trout, and char based on techniques to determine incipient lethal temperatures (ILT) and critical thermal maxima (CTM).

Species	Lethal temperature (°C)		Preferred temperature (°C)	Source	Technique
	Lower lethal[a]	Upper lethal[b]			
Chinook salmon	0.8	26.2	12–14	Brett (1952)	ILT

[a] Acclimation temperature was 10°C; no mortality occurred in 5,500 min.
[b] Acclimation temperature was 20°C unless noted otherwise; 50% mortality occurred in 1,000 min.
[c] Acclimation temperature was 15°C.

native trouts (Gila trout and Apache trout) when these fish were acclimated at 20°C and subjected to a temperature change rate of 1.2°C/h. Although some salmonids can survive at relatively high temperatures, most are placed in life-threatening conditions when temperatures exceed 23–25°C, and they usually try to avoid such temperatures by moving to other areas.

Lower lethal temperatures for salmonids depend somewhat on previous acclimation (Brett 1952) but they probably are no lower than −0.1°C (Brett and Alderdice 1958). Temperatures in the range of 1 to 4°C can be lethal if fish acclimated in warmer water are transferred abruptly into the cold water. Under natural conditions, fish are not subjected to cold water (<4°C) without prior acclimation in gradually decreasing temperatures, and thus lower lethal temperatures for most species are near 0°C.

Daily summer temperatures can fluctuate more than 15°C in small streams with flows less than 1 m^3/s and little or no shade (Meehan 1970; Bjornn 1978).

Temperatures can increase rapidly in a short distance under direct sunlight: 6°C in 1,000 m within a stream flowing at about 1.4 m^3/s in central Idaho, for example (Bjornn et al. 1968). As stream size and water mass increase, daily temperatures of streams fluctuate less and tend to reflect the local climate near the stream.

Many populations of native salmonids respond to natural temperature patterns in streams by moving upstream or downstream when water temperatures become unsuitable. Fish may use a section of stream during one season of the year, but move to other sections at other seasons because temperatures become unsuitable. Salmonids may not always avoid unsuitable temperatures, however, especially if the temperatures change rapidly and are not part of the normal pattern in which the fish evolved. Munson et al. (1980) found that rainbow trout accustomed to feeding in a certain location continued to enter the area after temperatures had been changed to a lethal level.

In small streams where daily maximum temperatures approach upper incipient lethal values, salmonids can thrive if the temperature is high for only a short time and then declines well into the optimum range. In an Idaho stream with daily maximum temperatures up to 24°C that lasted less than 1 h and minimums of 8–12°C, juvenile chinook salmon and steelhead maintained high densities and grew normally (Bjornn 1978). In larger Idaho streams where summer maximum temperatures were 24–26°C, but the minimums were relatively high (15–16°C), most young salmon and trout moved upstream or into tributaries where temperatures were lower (Mabbott 1982).

As water temperatures in temperate-zone streams decline in autumn, salmonids change behavior from mostly feeding and defending territory to hiding and schooling. The winter behavior patterns appear to us to be motivated by security. Fish that were curious and easily approached by divers in summer become wary and often dart from view in winter. Winter water temperatures in streams can range from freezing to relatively moderate, according to geographic and groundwater influences. Temperatures in coastal streams often are moderated by maritime climates. Inland, streams can become filled with flow ice, anchor ice, and ice jams during extreme cold spells. The temperature at which the change in behavior occurs apparently varies by species. Chapman and Bjornn (1969) reported that most of the steelhead and chinook salmon juveniles they tested in winter were visible above the substrate at 6°C but hid at 4°C (Figure 4.21). In a British Columbia stream, juvenile coho salmon and steelhead began shifting to winter positions at about 7°C (Bustard and Narver 1975a). Gibson (1978) found that Atlantic salmon began entering the interstitial spaces of rubble substrate in autumn when water temperatures dropped to 10°C, and most had disappeared at 9°C.

The response of salmonids to the lower temperatures that occur in autumn and winter in temperate streams can vary by species and size of fish. Small fish (<15–20 cm) tend to hide in interstitial spaces in the substrate of streams, or in other forms of cover if available, and may move to shallower water (Bustard and Narver 1975a; Gibson 1978), whereas larger fish may join together in schools and move long distances to find suitable winter habitat. In the Lemhi River drainage, Idaho, a large fraction of the young chinook salmon and steelhead moved downstream from rearing areas after their first summer (Bjornn 1971). The chinook salmon moved down into the Salmon River and even the Snake River

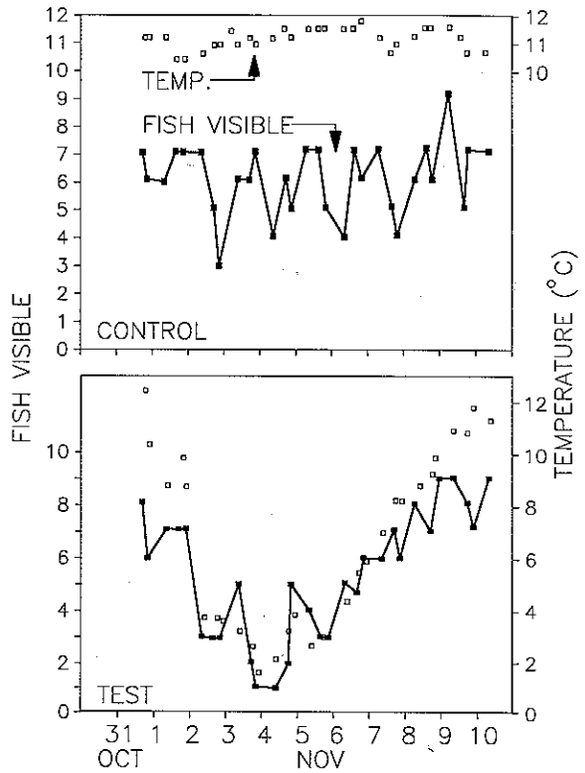

FIGURE 4.21.—Water temperature and number of age-0 steelhead visible above the substrate in test and control vats. (From Chapman and Bjornn 1969.)

(50–200 km) to spend the winter before continuing to the ocean as smolts the following spring. The steelhead moved downstream out of a tributary with a high summer carrying capacity (at least 12 g/m^2) but a lower winter carrying capacity, and spent the winter, the next summer, and the following winter in the larger stream before going to the ocean the following spring. Both the chinook salmon and steelhead moved downstream in response to low winter temperatures and a lack of winter cover. Fish migrating downstream in the fall ceased moving when placed in channels with large rock piles (which contained interstitial spaces used in winter) but continued moving downstream when placed in channels without the rock piles (Bjornn and Morrill 1972). In contrast, few juvenile cutthroat trout moved downstream in autumn in tributaries of other Idaho streams where densities were lower (2.1 g/m^2) and adequate amounts of suitable winter cover were apparently present (Mauser 1972). On sunny autumn days, the cutthroat trout could be seen in the stream in the afternoon when temperatures approached the daily high (8–10°C), but were not visible in the morning when temperatures were low (3–5°C).

Larger fish that may not be able to use voids in the substrate to hide in winter have been observed joining together in large schools (600 fish) and in some cases moving long distances in fall and spring. In the Coeur d'Alene River of Idaho, Lewynsky (1986) counted fish along transects throughout the summer, fall, and winter; in winter, larger (>20 cm) cutthroat trout moved from dispersed summer feeding stations throughout the river to a few large pools, where they became

much more wary and difficult to approach. The extent of seasonal movements of fish in response to temperature is illustrated by migrations of cutthroat and bull trout more than 100 km downstream in autumn and back upstream in spring and early summer in the Salmon River, Idaho (Bjornn and Mallet 1964). Winter temperatures and ice conditions apparently were unsuitable in the upper portions of the Middle Fork drainage and most of the fish larger than 15 cm moved. Temperatures in the main-stem rivers became marginal in summer for salmonids.

Temperature is one of the factors that contribute to quality of habitat for fish. If temperature is in a tolerable range for the fish, the question of optimum temperature becomes pertinent. Optimum temperature could be defined in relation to a variety of population or individual variables, including temperature preference, growth, efficiency of converting food to tissue, standing crops, and swimming performance. When Brett (1952) placed five species of Pacific salmon in a vertical temperature gradient, they all tended to congregate in the 12–14°C stratum.

Optimum temperatures, measured in terms of fish growth rate and food conversion efficiency, vary with the amount of food available. Brett et al. (1969) reported that growth of yearling sockeye salmon was highest at about 5°C when the daily ration (percent of body weight) available was 1.5%, but shifted to about 15°C when the ration was 6%. At highest temperatures, the growth rate declined regardless of food abundance. Food conversion efficiency peaked at 8–11°C (Brett et al. 1969)—lower than the 15°C associated with maximum growth, optimum metabolic scope for activity, greatest tolerance of oxygen debt, and maximum sustained swimming speed (Brett 1964). After tests with Atlantic salmon, Dwyer and Piper (1987) reported that maximum growth with unlimited food was attained at 16–19°C, but that growth efficiency was highest at 10–16°C.

Similar relations—with variations in the optimum temperature or temperature range—probably exist for other species. The optimum temperature for brook trout, for example, appears to be 14–16°C. Graham (1949), as reported in Mihursky and Kennedy (1967), listed 14–16°C as the temperature preferendum for brook trout, and Beamish (1964) gave 15°C as the temperature for maximum spontaneous activity. Dwyer et al. (1983) reported that brook trout grew most efficiently at 10 and 13°C. Jensen and Johnsen (1986) presented evidence that stocks of fish may be able to adapt to temperatures that might otherwise make their existence unlikely.

Brett et al. (1958) reported that the optimum temperature for sustained swimming was 15°C for sockeye and 20°C for coho salmon (Figure 4.22), and that maximum sustained swimming speeds at these temperatures were 35 and 30 cm/s, respectively. Sustained swimming performance was reduced to about 12 cm/s for sockeye salmon and to 6 cm/s for coho salmon at temperatures near 0°C. Davis et al. (1963) also found that the maximum sustained swimming speed of underyearling coho salmon was higher at 20°C than at 15 or 10°C. In a study of the critical swimming speeds of yearling rainbow trout as a measure of temperature preference, Schneider and Connors (1982) found no significant differences at 10, 15, or 20°C, but swimming performance was reduced at 25°C. The 25°C test temperature was 2°C less than the ILT measured for rainbow trout by Charlon et al. (1970).

The effect of water temperature on fish behavior and the regulation of densities in streams is not well understood, but there is some evidence that densities or

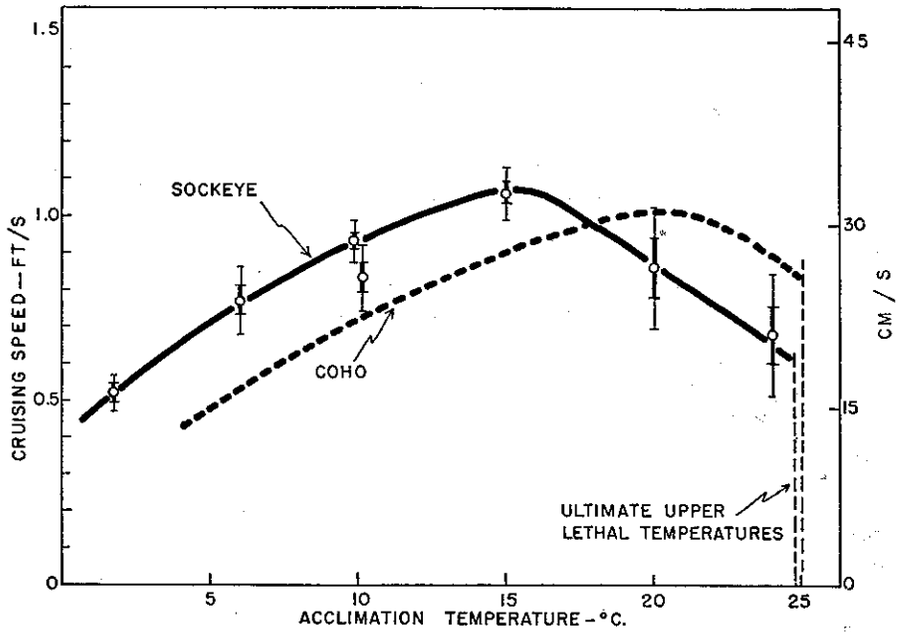

FIGURE 4.22.—Variation in cruising speed among temperature-acclimated underyearling sockeye and coho salmon, adjusted to common mean lengths of 6.9 cm and 5.4 cm, respectively. The fish were cultured under similar conditions and were 4 to 6 months of age. The sockeye salmon data are means (circles), standard errors (heavy vertical bars), and standard deviations. (From Brett et al. 1958.)

even production of fish may be less at high (but suitable) temperatures than at lower ones. In laboratory stream studies, Hahn (1977) found that twice as many steelhead fry remained in channels with daily temperature fluctuations of 8–19°C or a constant temperature of 13.5°C than in a channel held at a constant 18.5°C. At constant 8.5°C, the density of fish was twice that found in channels held at 13.5°C. Hughes and Davis (1986), who studied coho salmon and steelhead in laboratory streams, concluded that a moderate (4°C) increase in temperature could decrease the productivity of streams for those species when food is limiting. Glova (1986) found that habitat use by juvenile coho salmon and cutthroat trout in summer, when temperatures were 13°C, was different from that in winter, when temperatures were colder. When tested separately in summer, most fish of both species took up residence in pools, but, when tested together, most of the coho salmon stayed in pools and cutthroat trout remained in riffles. In winter at temperatures of 3°C, both species, whether together or separate, preferred pools and overhead cover.

Changes in water temperatures resulting from land and water use may affect fish indirectly as well as directly. In a small Vancouver Island stream, coho salmon emerged earlier when winter water temperatures became higher after logging, and detrimental downstream movement of the newly emerged fish occurred when freshets took place soon after emergence (Scrivener and Andersen 1984). Growth rate of coho salmon juveniles was inversely related to density in the stream, and the fish were larger in autumn after logging than before because of the earlier

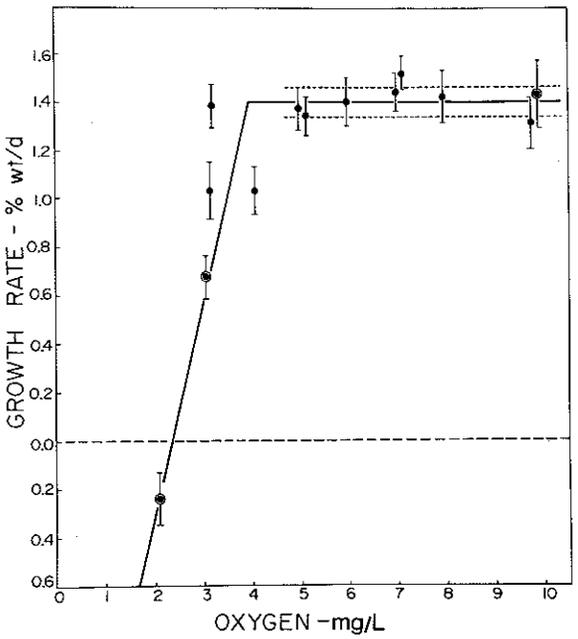

FIGURE 4.23.—Specific growth rate (percent of body weight per day ± SE) of fingerling coho salmon (5–10 g) in relation to oxygen concentration at 15°C. (From Brett and Blackburn 1981.) Dotted lines are 95% confidence limits for values with dissolved oxygen above 6 mg/L. Sloped line (fitted by eye) defines the zone of dependence of growth on dissolved oxygen.

emergence and longer period of growth. A dam on the Rogue River, Oregon, altered flows and temperatures in both summer and winter, and changed the timing of salmon and steelhead fry emergence, adult migration, fish distribution in the river, and adult mortality (Cramer et al. 1985).

Dissolved Oxygen

The waters of most natural salmonid streams have enough DO for juveniles, although concentrations in small streams may be reduced by large amounts of organic debris when temperatures are high and flows low (Hall and Lantz 1969). Streams downstream from deep, productive reservoirs may have marginally low DO concentrations at times if the discharge comes from the hypolimnion. The DO must be above a critical level for salmonids to exist in streams. Rainbow trout have survived laboratory tests at DO concentrations of less than 2 mg/L (Alabaster et al. 1957), and the survival threshold concentration for Atlantic salmon smolts is about 3.3 mg/L (Alabaster et al. 1979), but growth rate (Figure 4.23) and food conversion efficiency (Figure 4.24) are probably limited by concentrations less than 5 mg/L. Davis (1975), who reviewed information on incipient DO response thresholds and developed oxygen criteria related to concentration, water temperature, and percent saturation (Table 4.9), concluded that salmonids would not be impaired at concentrations near 8 mg/L (76–93% saturation), and that initial symptoms of DO deprivation would occur at about 6 mg/L (57–72% saturation). Davis et al. (1963) and Dahlberg et al. (1968) found the maximum sustained swimming performances of coho and chinook salmon decreased when DO concentrations were much below air-saturation levels (about 8–9 mg/L at 20°C).

In summary, salmonids may be able to survive when DO concentrations are relatively low (<5 mg/L), but growth, food conversion efficiency, and swimming

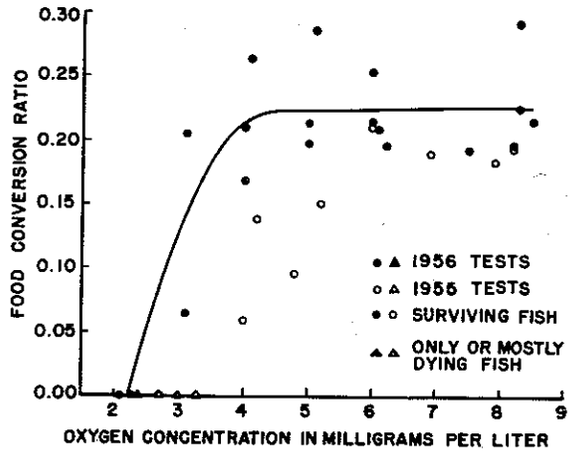

FIGURE 4.24.—Food conversion ratio (weight gained by fish/weight of food consumed) for frequently fed age-0 coho salmon in relation to dissolved oxygen concentration. A food conversion ratio of zero (not a negative ratio) has been assigned to each group of fish that lost weight. The curve has been fitted only to the 1956 data. (From Herrmann et al. 1962.)

performance will be adversely affected. High water temperature, which reduces oxygen solubility, can compound the stress on fish caused by marginal DO concentrations.

Most data on the oxygen requirements of salmonids come from laboratory studies. Brett and Blackburn (1981) appropriately urged caution when such data are extrapolated to fish in natural streams. Water qualities and the biological activities necessary for survival may differ between laboratory and field environments.

Turbidity

In most streams, there are periods when the water is relatively turbid and contains variable amounts of suspended sediments. Larger juvenile and adult salmon and trout appear to be little affected by ephemerally high concentrations of suspended sediments that occur during most storms and episodes of snowmelt (Cordone and Kelley 1961; Sorenson et al. 1977). Bisson and Bilby (1982) reported, however, that juvenile coho salmon avoided water with turbidities that exceeded 70 NTU (nephelometric turbidity units), which may occur in certain types of watersheds and with severe erosion. Berg and Northcote (1985) reported that feeding and territorial behavior of juvenile coho salmon were disrupted by short-term exposures (2.5–4.5 d) to turbid water (up to 60 NTU).

Newly emerged fry appear to be more susceptible to even moderate turbidities than are older fish. Turbidities in the 25–50-NTU range (equivalent to 125–275 mg/L of bentonite clay) reduced growth and caused more young coho salmon and steelhead to emigrate from laboratory streams than did clear water (Sigler et al.

TABLE 4.9.—Response of freshwater salmonid populations to three concentrations of dissolved oxygen. (Modified from Davis 1975.)

Response	Dissolved oxygen (mg/L)	Percent saturation at temperature (°C)					
		0	5	10	15	20	25
Function without impairment	7.75	76	76	76	76	85	93
Initial distress symptoms	6.00	57	57	57	59	65	72
Most fish affected by lack of oxygen	4.25	38	38	38	42	46	51

1984). Juvenile salmonids tend to avoid streams that are chronically turbid, such as glacial streams or those disturbed by human activities (Lloyd et al. 1987), except when the fish have to traverse them along migration routes.

Productivity of Streams

Streams vary in productivity due largely to the nutrients and energy available. The rates of primary and secondary production largely determine the amount of food available to fish. A detailed discussion of energy sources and processes is presented by Murphy and Meehan (1991, this volume).

The amount of food available to fish is one of the factors that set the salmonid carrying capacity of streams. In many infertile streams, summer fish production appears to be food-limited. A change in fish production, density, or growth when food availability increases or decreases is proof of food limitation. More coho salmon could be produced in a small Vancouver Island stream during summer when Mason (1976) increased the amount of food available. In another Vancouver Island stream, Slaney et al. (1986) added inorganic fertilizers (phosphorus and nitrogen) to a 29-km section and found large increases in primary production, no significant changes in invertebrate abundance and fish density, and significant increases in trout growth. The increased growth allowed steelhead to become smolts at a younger age; because this period of juvenile mortality was reduced, the stream produced more smolts.

Positive correlations between stream productivity and production, standing crops, and growth of brown trout were observed by McFadden and Cooper (1962). In Idaho streams that differed in conductivity by a factor of 10 (40 to 400 $\mu S/cm^3$), the production and standing crop of age-0 chinook salmon differed by a similar factor (T. C. Bjornn, unpublished data). Konopacky (1984) found juvenile chinook salmon and steelhead lost weight and eventually left laboratory streams when no food was supplied; he also found proportionate increases in production, but not in density, in response to two levels of daily ration. Wilzbach (1985) reported that most cutthroat trout left laboratory channels when they were given a daily ration of frozen brine shrimp equal to only 5% of their body weight, whether cover was provided or not, but they stayed when given a 15% ration.

Brett et al. (1969) defined the daily rations needed for maximum growth of sockeye salmon at various temperatures. If this relation is similar for other species of salmon and trout, a yearling salmonid in a stream with daily mean temperature of 10°C would need a daily food supply equivalent to 6–7% of its body weight to attain maximum growth. In streams that are food-limited, maximum growth rates may not be achieved by the fish because that may not be the most efficient use of resources. The social interactions that fish use to regulate densities and respond to food abundance may result in more fish growing at less-than-maximum rates, rather than fewer fish growing at maximum rates.

Juvenile salmonids can consume a large fraction of the invertebrates drifting during daylight in the streams they occupy (Allan 1982; Wilzbach et al. 1986), but fish do not appear to regulate the abundance of benthic or drifting invertebrates in streams except in very limited situations of time and space (Allan 1983). Production of aquatic invertebrates that juvenile salmonids eat depends on the amount of organic material available in streams. Bilby and Likens (1980) showed the importance of debris dams in small streams for the accumulation of coarse particulate organic matter. Nearly 75% of the organic matter deposited in first-order streams was associated with the dams, versus 58% in second-order streams and 20% in third-order streams. Fish also eat terrestrial invertebrates that are associated with vegetation surrounding streams.

Space

Space suitable for occupancy by salmonids in streams is a function of streamflow, channel morphometry, gradient, and (in many instances) various forms of instream or riparian cover. Suitable space for each salmonid life stage has water of sufficient depth and quality flowing at appropriate velocities. The addition of cover (extra depth, preferred substrates, woody debris, etc.) increases the complexity of the space and usually the carrying capacity. The addition of certain types of cover (overhead, for example) may make some areas in streams suitable for fish that would not otherwise be used.

The space an individual fish needs and uses—in some instances a territory—is a part of the total suitable space available. Food abundance (Chapman 1966), the competitors (Fausch and White 1981, 1986) and predators present, and the complexity of the habitat determine what part of the available suitable space an individual fish uses.

Fish densities in streams provide a measure of the spatial requirements of juvenile salmonids, but the wide variation in observed densities illustrates the diversity of habitat quantity and quality and other factors that regulate fish abundance. In a productive Idaho stream, end-of-summer densities of age-0 chinook salmon (9.6 g mean weight) have been as high as 1.35 fish/m^2 and 12.9 g/m^2 (Bjornn 1978). With the age-0 steelhead (4.5 g) also produced in the stream, the combined densities were 2.05 fish/m^2 and 16.1 g/m^2. These salmonids were not uniformly distributed throughout the length of the stream and densities in some sections were as high as 3.4 fish/m^2 (21.8 g/m^2). Total salmonid density, including the age-1 and older fish, has been as high as 3.5 fish/m^2 and 27.0 g/m^2. Spring-to-fall production (tissue elaborated) by age-0 chinook salmon and steelhead has been measured at rates as high as 20.3 g/m^2.

In less productive third- and fourth-order streams in Idaho, age-0 chinook salmon were less dense (usually <0.8 fish/m^2), the fish grew slower (end-of-summer weight, about 5 g), biomass standing crops were only 1–3 g/m^2, and few fish of other species were produced. Summer production was 1–2 g/m^2 (T. C. Bjornn, unpublished data). In coastal and inland British Columbia streams, Shepherd et al. (1986b) reported overall maximum densities of 0.14 age-0 chinook salmon/m^2 (five streams) and 0.41 age-0 and age-1 coho salmon/m^2 (nine streams).

Salmonids, especially the juveniles, also use the space available in side channels for rearing. Mundie and Traber (1983) found higher densities of steelhead (0.66 smolts/m^2 and 9.94 g/m^2) and coho salmon (0.85 smolts/m^2 and 12.8 g/m^2) in side-channel pools than are commonly found in the main channels of Pacific coastal streams. Peterson (1982a, 1982b) reported coho salmon moving into side-channel pools for the winter.

The amount of space needed by fish increases with age and size. Allen (1969) assembled data on densities for a variety of salmonids and found a positive relation between area per fish in streams and age (Figure 4.25) or length. For the streams he evaluated, 7–10-cm fish (which had completed the first year of life)

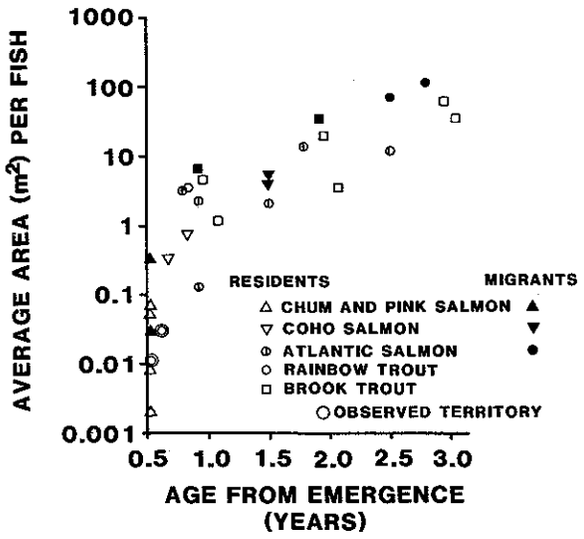

FIGURE 4.25.—Average area per fish (on a logarithmic scale) versus age for several salmonids in streams. (Redrawn from Allen 1969.)

were found at densities of 0.1 to 1.0 fish/m^2 (10-cm fish averaged 0.17 fish/m^2 and 1.7 g/m^2). Densities of larger and older fish were usually less than 0.1 fish/m^2.

Based on the foregoing, the summer space requirements of juvenile salmonids during their first year in streams probably range from 0.25 to 10 m^2 of stream per fish, depending on such things as the species and age composition of fish present, stream productivity, and quality of the space. The space required in winter has not been as well defined.

The presence of abundant space does not necessarily mean there will be large numbers of fish. The space must be in the right context with other needs of the fish. For example, the abundance of age-0 chinook salmon in some infertile Idaho nursery streams appeared to be asymptotically related to the size of pools (Figure 4.26). In pools up to about 200 m^2 in area (volume, 150 m^3), the number (or biomass) of fish observed was directly related to size of the pools. In larger pools, however, much of the space in the downstream portions was unused, despite the presence of suitable depths and velocities. Fish abundance was probably food-limited in these streams and thus the fish were concentrated in the upper portions of each pool, close to the incoming food supply.

The effect of reducing space available to fish in small pools of third-order streams was illustrated by Bjornn et al. (1977) in a stream sedimentation experiment. When sand was added to a natural pool, reducing pool volume by half and surface area of water deeper than 0.3 m by two-thirds, fish numbers declined by two-thirds.

Streamflow.—Streamflow, one of the basic determinants of the amount of space available for fish, varies seasonally in ways that depend on geography and climate. In coastal streams, flows are often high in winter because of heavy rain and snowfall. In inland areas, flows are most often high in spring as a result of snowmelt, but rain-on-snow events occasionally cause high flows in winter. In most unregulated salmonid streams of North America, flows are usually lowest in late summer, fall, or winter (Stalnaker and Arnette 1976a). Diversion of water

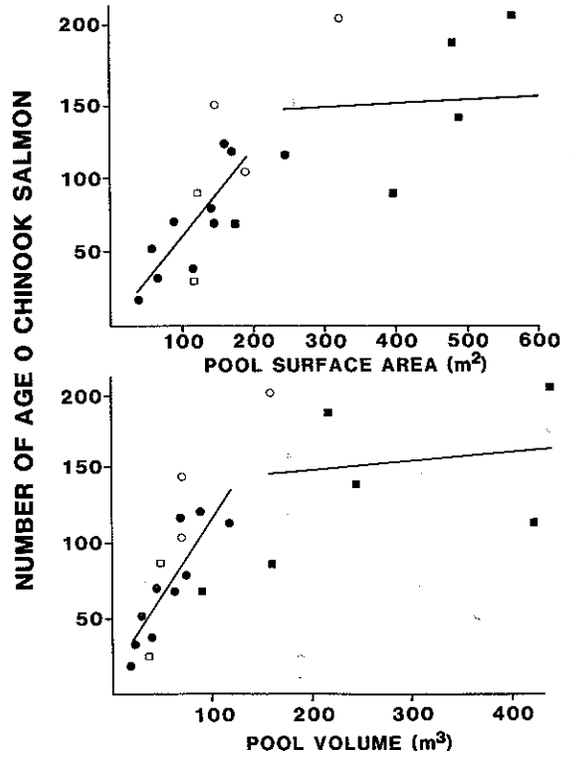

FIGURE 4.26.—Relation between pool surface area or volume in several Idaho streams (denoted by different symbols) and number of juvenile chinook salmon per pool. (Redrawn from Konopacky 1984.)

from streams and storage of water for municipal, agricultural, flood control, and hydropower uses usually lead to altered streamflows and potential changes in the carrying capacity of streams for salmonid fishes. The relation between streamflow and carrying capacity could vary with channel geometry and surrounding land forms; it probably differs, for example, between streams consisting mostly of riffles in a V-shaped canyon and streams with alternating pools and riffles in a broad valley. In general, the relation must start at the origin (no flow, no fish), increase (perhaps not uniformly) with increases in flow up to a point, and then level off or decline if flows become excessive. The relation between flow and carrying capacity is difficult to assess directly in natural streams, however, and there are few studies for reference. The roles of flow magnitude and seasonality in setting the carrying capacity of a stream have not been well defined.

Kraft (1972) diverted water from a 520-m section of natural stream channel in Montana for 3 months in summer and found that both physical stream characteristics and resident brook trout were more affected in runs than in pools. After a 90% reduction from normal summer flows (about 1.0 m^3/s), depth in runs decreased 38%, average water velocity decreased 73%, and cover decreased 50%; decreases were smaller in pools. The response of brook trout to the 90% flow reduction was variable, but many fish in the dewatered section moved from runs into pools; the number of fish decreased an average 62% in dewatered runs compared with 20% in runs that were not dewatered (Figure 4.27).

In an Oregon flume studied by White et al. (1981), water velocities, depths, wetted perimeters, and surface areas in runs declined with decreases in flow, as

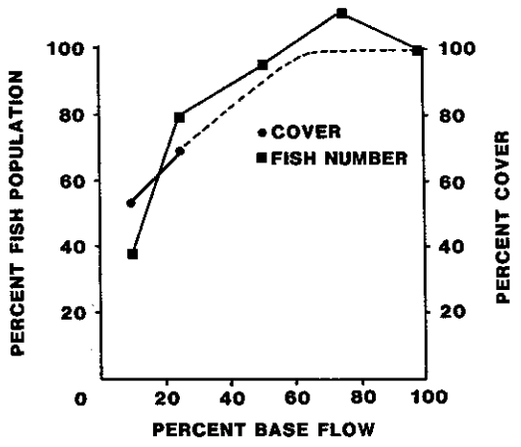

FIGURE 4.27.—Relations of fish number and cover to reductions in summer base flow in three runs in Blacktail Creek, Montana. (Data from Kraft 1968, as plotted by White 1976.)

did the abundance of wild steelhead juveniles, but the researchers were unable to determine the relative influences of the physical features on fish abundance. The authors also calculated an index (weighted usable area, WUA) of the amount of suitable habitat in the flumes for juvenile steelhead, based on IFIM. Their estimates of WUA from suitability curves for velocity and depth did not correspond closely with the number of fish remaining at each flow.

The IFIM, although controversial and incompletely validated, is a modeling procedure designed to help evaluate the importance of differing streamflows to the production of fish. The procedure generates a relation between WUA and flow. Typically, WUA increases asymptotically with flow (Figure 4.28), but the estimates can vary widely depending on the velocity and depth suitability indexes used. In an Idaho stream, WUA estimates for age-0 chinook salmon were highest at flows that occurred near the end of summer, and decreased when flows were higher or lower. The WUA values based on velocity and depth were highest for pools, followed by runs, and then riffles.

For IFIM models to be useful, there must be a definable relation between WUA index values and the standing crop or production of fish in a stream. Such relations can exist only if the physical variables included in the model (velocity, depth, substrate, cover, etc.) are the factors that regulate abundance. Stalnaker (1979) found that standing crop of brown trout was strongly correlated with WUA in 19 sections of 8 Wyoming streams. Orth and Maughan (1982) and Conder and Annear (1987) had less success in relating WUA index values to standing crops of fish or to another habitat quality index. Conder and Annear (1987) discussed the use of the IFIM to estimate changes in fish production in streams as related to streamflow. Nickelson et al. (1979) reported on studies of models that could be used to evaluate streamflow requirements of salmonids in Oregon streams. After several years of study, they recommended use of the IFIM with the addition of variables for pool volume and cover.

Smoker (1955) found a correlation between the commercial catch of coho salmon and annual runoff, summer flow, and lowest monthly flow in 21 western Washington drainages 2 years previously; the data covered the years 1935–1954. In the last two decades, hatchery production of coho salmon smolts has increased markedly and made such comparisons more difficult, but Mathews and Olson (1980) analyzed data

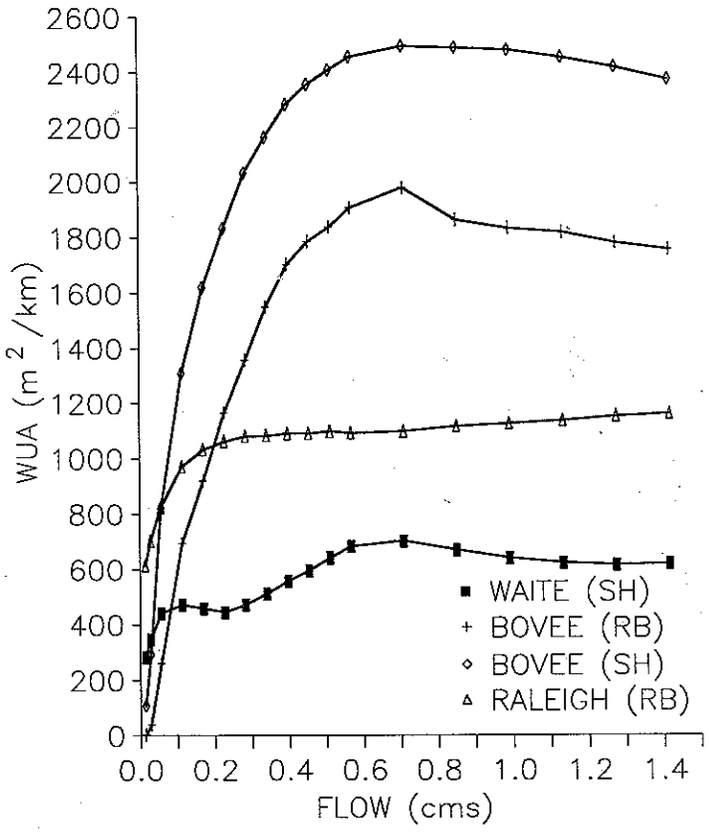

FIGURE 4.28.—Indices of suitable area (weighted usable area, WUA) versus flow (cubic meters per second) for juvenile steelhead (SH) and rainbow trout (RB) in a California stream based on different probability-of-use curves devised by Waite, Bovee, and Raleigh. (Ian Waite, unpublished data.)

from Washington for the years 1952–1977 and found that summer streamflow still had an important influence on total coho salmon production in Puget Sound area streams. Scarnecchia (1981) found that the coho salmon catch off the Oregon coast for the years 1942–1962 was correlated with total flow in five coastal rivers during the salmon's freshwater existence; however, the catch was poorly correlated with the 60-d period of lowest flow in these rivers. Nickelson (1986), in an analysis of coho salmon survival from smolt to adult off the Oregon–California coast, concluded that survival at sea was variable (related to upwelling), but density independent. The implication of the above studies is that the abundance of adult coho salmon is a function of the number of smolts produced, which is in turn related to streamflow and the other factors that regulate the production of smolts.

Velocity.—Given flow in a stream, velocity is probably the next most important factor in determining the amount of suitable space for rearing salmonids (Chapman 1966; deGraaf and Bain 1986); if the velocities are unsuitable, no fish will be present. Natural streams contain a diversity of velocities (Figure 4.29) and depths,

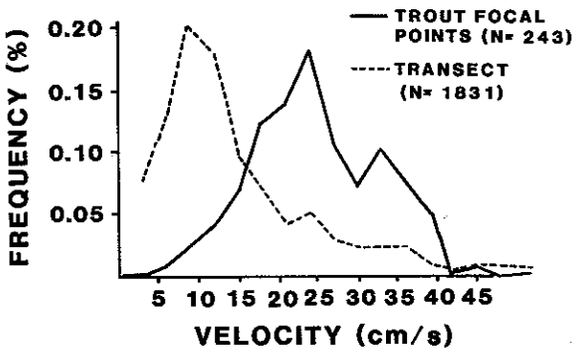

FIGURE 4.29.—Frequency of velocities at sites (focal points) occupied by trout in three sections of Uvas Creek, California, and frequency of velocities measured along transects in the stream. (From Smith and Li 1983.)

some of which are suitable for most salmonids. The velocities required and used by juvenile salmonids vary with size of fish, and sometimes with species. Some juvenile salmonids, as they grow, select sites in streams with increasingly faster velocities (Chapman and Bjornn 1969; Everest and Chapman 1972; Rimmer et al. 1984; Moyle and Baltz 1985), presumably to gain access to more abundant food (Chapman and Bjornn 1969; Fausch 1984). Sites used for feeding over long periods and the size of food items eaten may be selected largely to maximize net energy gain (Bachman 1984).

Water velocities required by fish of various sizes have been estimated from studies of the sites fish occupy in streams and of the swimming performance of fish in laboratories. Use of data from so-called field microhabitat studies to establish velocity and depth requirements has limitations because the sites selected by fish in natural streams are influenced by factors other than their velocity and depth preferences. Interactions with other fishes and the presence and location of cover alter sites selected by fish (Fausch and White 1981, 1986). Wild brown trout placed in a flume shifted position to stay within a suitable velocity range when flows were increased (Baldes and Vincent 1969). In a study by Shirvell and Dungey (1983), velocity was the most important factor determining the preferred sites of large brown trout (42 cm), but the fish often chose compromise positions to be close to food or cover.

Velocity and depth preferences may change seasonally. Chisholm et al. (1987) noted that brook trout selected areas of lower velocity (<15 cm/s) and deeper water (>30 cm) in winter than in summer, but showed no preference for substrate. Tschaplinski and Hartman (1983) noted similar shifts by coho salmon in winter to

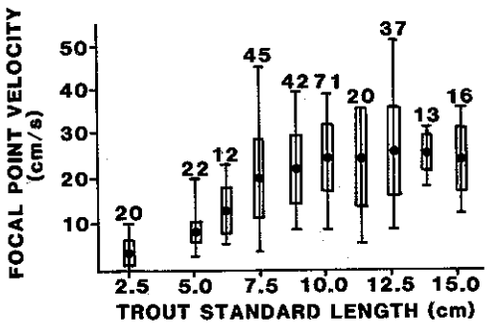

FIGURE 4.30.—Water velocities at focal points (means, ranges, and 95% confidence intervals) for trout of different standard lengths in a California stream. Numbers above data points are sample sizes. (From Smith and Li 1983.)

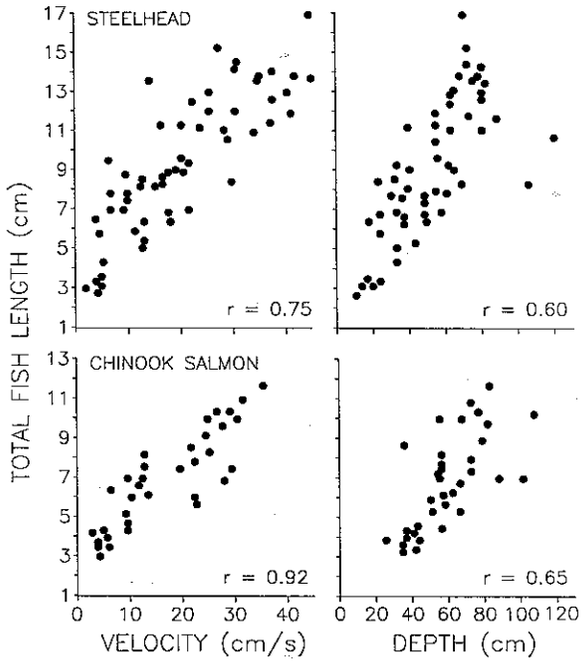

FIGURE 4.31.—Correlations between length of juvenile steelhead and chinook salmon and velocity and depth of water at sites (focal points) used by the fish in two Idaho streams. (Redrawn from Everest and Chapman 1972.)

sites (deep pools, undercuts, debris jams, side sloughs) with low velocity (<30 cm/s) but good cover.

Newly emerged fry (20–35 mm long) of salmon, trout, and char require velocities of less than 10 cm/s, based on studies of sites selected by the fish in streams (Chapman and Bjornn 1969; Everest and Chapman 1972; Griffith 1972; Hanson 1977; Smith and Li 1983; Konopacky 1984; Pratt 1984; Bugert 1985; Moyle and Baltz 1985; Sheppard and Johnson 1985). Larger fish (4–18 cm long) usually occupy sites with velocities up to about 40 cm/s (Figures 4.30, 4.31, 4.32; Table 4.10). Velocities at the sites occupied (focal points) by juvenile steelhead in a California stream were higher than the modal velocities in the stream (Figure 4.29), increased asymptotically with fish length (Figure 4.30), increased with temperature, and were less than the velocities at their usual feeding sites (Smith and Li 1983). Because invertebrate drift abundance increased with velocity across a stream section, there was a potential energetic benefit from feeding in the fastest water possible. In Idaho streams, young chinook salmon and steelhead occupied deeper and faster water as they increased in size (Figure 4.31), presumably to gain better access to food. By the end of summer, young chinook salmon (4–10 cm long) were found in the full range of available depths, but in velocities that were on the low end of those available (Figure 4.32).

Swimming performance as measured in the laboratory provides a measure of the ability of a fish to swim under specified conditions, but may not reveal velocities preferred by the fish. Brett et al. (1958) reported cruising speeds (speeds a fish could maintain for at least 1 h under stimulation) of juvenile coho salmon increased with fish size and temperature (Figure 4.33). At 10°C, cruising speeds

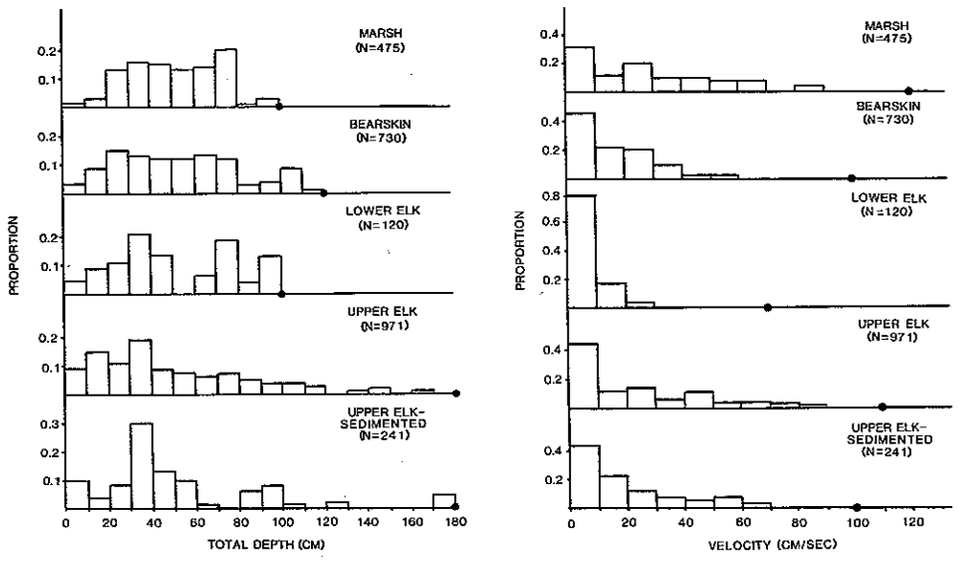

FIGURE 4.32.—Distribution of age-0 chinook salmon (77–89 mm mean total length) relative to water depth and velocity in pools of Idaho streams in August 1979. Dots indicate maximum water depth or velocity observed in the pools surveyed. (From Konopacky 1984.)

were 20–25 cm/s for 5-cm coho salmon and 35–40 cm/s for 9-cm fish; at 20°C, the speeds were 5–6 cm/s faster. Cruising speeds of fish are lower than speeds at which fish can swim for short bursts, but may be higher than water velocities observed at focal points selected by fish in streams. In a southeast Alaska stream, the mean velocity at focal points selected by age-0 (<7 cm long) and yearling (up to 12 cm long) coho salmon averaged 13–14 cm/s (T. C. Bjornn, unpublished data). Brett (1967) reported that juvenile sockeye salmon (136 mm mean length) could swim for 300 min in velocities up to about 37 cm/s (at 15°C) without becoming fatigued; at increasingly higher velocities, all fish eventually became fatigued (Figure 4.34). Velocities that did not produce fatigue in 300 min (<37 cm/s) were about half the cruising speed for fish of a given size.

Depth.—The depth of water juvenile salmonids use depends on what is available, the amounts and type of cover present, and the perceived threat from predators and competitors. Young trout and salmon have been seen in water barely deep enough to cover them and in water more than a meter deep. Densities (fish/m^2) of some salmonids are often higher in pools than in other habitat types (runs, riffles, pocket waters; Figure 4.35), but that may reflect the space available (there is more volume in pools per unit of surface) rather than a preference for deep water, especially for smaller fish (<15 cm long).

Fish usually are not uniformly distributed at all depths in a stream. Raleigh et al. (1986) presented index curves for chinook salmon in which suitabilities for newly emerged fry and juveniles were highest at depths of 25–60 cm. The curves were constructed from observations of fish distributions in streams. Everest and Chapman (1972) found significant correlations between size of fish and total water

TABLE 4.10.—Depths and velocities at sites used by salmonids in streams.

[a] Ages are in years or life stages, without units.

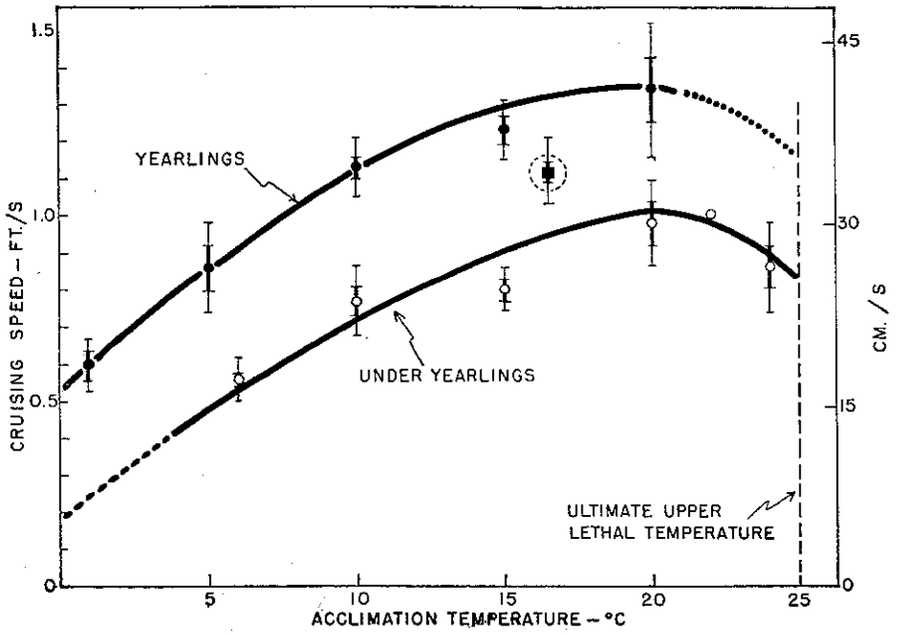

FIGURE 4.33.—Variation in cruising speed for temperature-acclimated underyearling and yearling coho salmon, adjusted in each age group to common mean lengths of 5.4 cm and 8.9 cm, respectively. The circled point between two curves is for exercised underyearling coho salmon acclimated to 16.5°C. Standard deviation (thin vertical bar) and standard error (heavy bar) are indicated for each sample. (From Brett et al. 1958.)

depth at sites (focal points) occupied by juvenile chinook salmon and steelhead (Figure 4.31). Correlations were poor between fish size and distance of focal point from the bottom; most fish, regardless of size, were near the bottom. In two Newfoundland Rivers, water depth was an unimportant factor in site selection by juvenile Atlantic salmon (deGraaf and Bain 1986).

If fish have a preferred depth of water, we believe it is readily subjugated to the needs for suitable velocities, access to food, and security from predators. Sites that fish select in streams must satisfy all the basic needs to enable the fish to survive. In laboratory streams, chinook salmon fry 30–40 mm long occupied a wide variety of

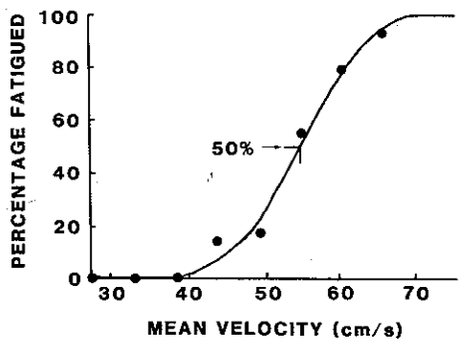

FIGURE 4.34.—Percentage of young sockeye salmon that became fatigued within 300 min at 15°C when forced to swim at the velocity indicated. The mean total length of the 104 fish in the sample was 13.6 cm. (Redrawn from Brett 1967.)

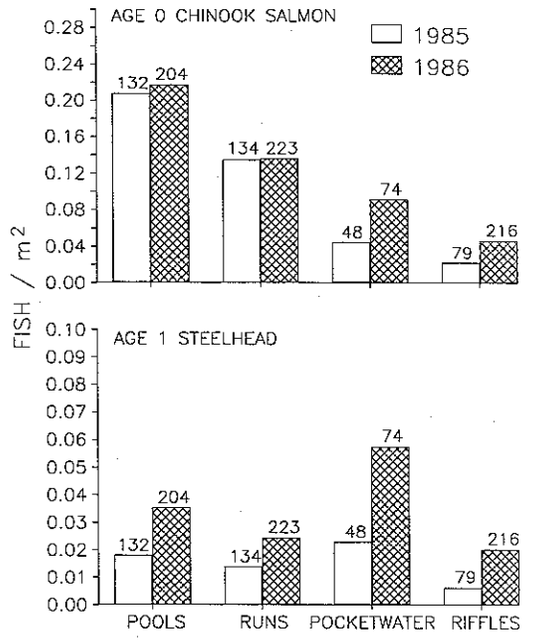

FIGURE 4.35.—Densities of age-0 chinook salmon and age-1 steelhead in various types of habitat in 22 Idaho streams. Numbers above bars represent the number of units of each type of habitat surveyed. (Authors' original data.)

sites (including the deepest water) when they were the only fish present, but only restricted areas when they shared the streams with yearling steelhead 70–120 mm long (T. C. Bjornn, unpublished data). The newly emerged fry were distributed throughout the water in both small pools (0.6 m wide, 1.2 m long, 0.32 m deep) and larger pools (1.5 m wide, 2.5 m long, 1.1 m deep) when no other fish were present and there was no threat of bird predation. The presence of only two yearling steelhead in a 4.8-m section of the smaller stream (two pools, two riffles, one run) changed the behavior of and site selection by the chinook salmon fry: some left the stream and those that remained stayed close to the bottom in the pools or moved into the interstitial spaces of the gravel substrate. When larger numbers of yearling steelhead were present, all chinook salmon fry left the stream or were eaten. In the larger stream, the fry moved to shallow water (<6 cm deep) above a sand bar, left the stream, moved into the substrate, or were eaten when yearling steelhead were present. A simulated kingfisher flight over the sand bar frightened the fry into the pool where they were vulnerable to predation by steelhead.

The relation between water depth in streams and fish numbers has not been empirically defined, but depends on the mixture of fish species and sizes, types and amounts of other cover present, and size of stream. In second- to fourth-order salmon streams, we suspect the relation is asymptotic, fish abundance increasing with increases in depth (more space) up to a point. We see no reason why fish that form schools in pools should become less abundant in extra deep water, but territorial fishes and those that select sites close to the substrate may not be as abundant in deep pools as in shallower types of habitat (runs and pocket water; Figure 4.35).

Substrate.—The substrates of salmonid streams are important habitats for incubating embryos and aquatic invertebrates that provide much of the food of

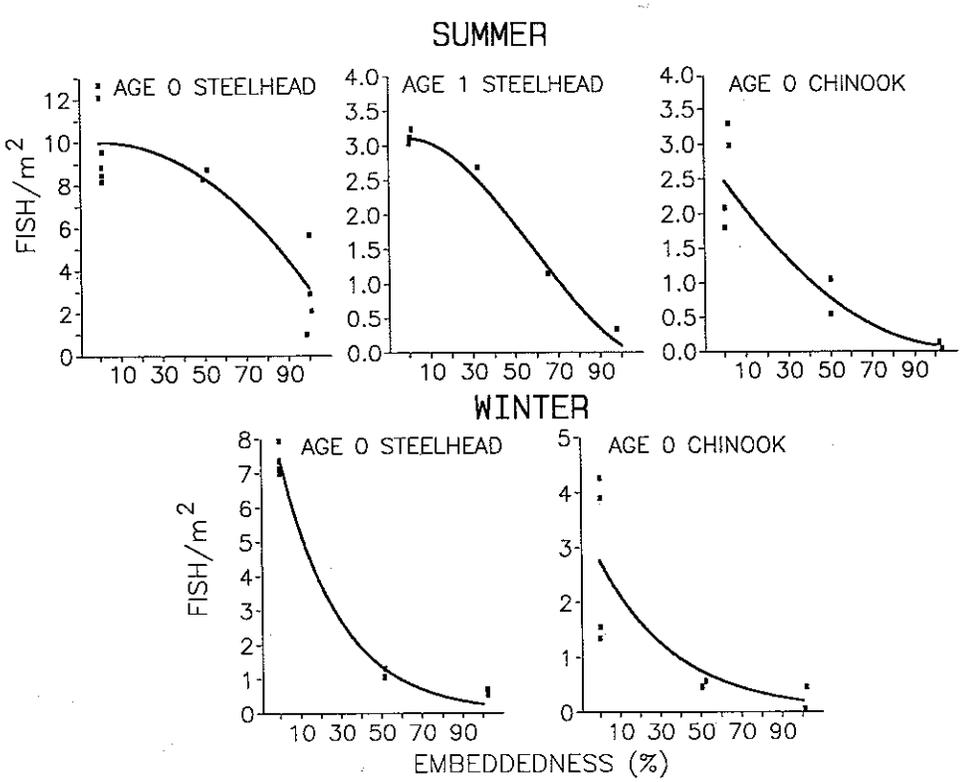

FIGURE 4.36.—Densities of chinook salmon and steelhead juveniles remaining in laboratory stream channels after 5 d during winter and summer tests to evaluate the effects of sedimentation. The channels had alternating pool–riffle configurations; fine sediments (<6 mm) were added to pools and riffles to embed the cobbles and boulders from 0 to 100%. (From Bjornn et al. 1977.)

salmonids, and they provide cover for fish in summer and winter. Silt and sand substrates have little or no value as cover for fish. Larger substrate materials (up to 40 cm in diameter) provide visual isolation and their interstitial spaces are often the primary cover, along with depth and water turbulence, in some streams.

Salmonids will hide in the interstitial spaces in stream substrates, particularly in winter, when the voids are accessible (Chapman and Bjornn 1969; Bjornn and Morrill 1972; Gibson 1978; Rimmer et al. 1984; Hillman et al. 1987). Newly emerged fry can occupy the voids of substrate made up of 2–5-cm diameter rocks, but larger fish need cobble and boulder-size (>7.5-cm diameter) substrates. The summer or winter carrying capacity of the stream for fish declines when fine sediments fill the interstitial spaces of the substrate (Figure 4.36). In a laboratory stream experiment, Crouse et al. (1981) found that production (tissue elaboration) of juvenile coho salmon was related to the amount of fine sediments in the substrate. When large substrate particles (>12 mm in diameter) were covered (embedded) with various amounts of fine sediments (<2 mm in diameter), fish production was reduced in direct proportion to the degree of embeddedness (expressed as a substrate score or geometric mean size of particles). In another laboratory stream study, Bjornn et al. (1977) found that the density of juvenile

steelhead and chinook salmon in summer and winter was reduced by more than half when enough sand was added to fully embed the large cobble substrate (Figure 4.36).

Much of the food eaten by salmonid fishes in streams is produced in the substrate. Particles that make up stream substrates, and thus the habitat of aquatic invertebrates, vary widely from silts and sands to boulders and barely fractured bedrock. Invertebrates differ in their ability to thrive in various types of substrates. Chironomids of various species do well in silts and sands, but the larger ephemeropterans, trichopterans, and plecopterans prefer a mixture of coarse sands and gravels. The addition of fine sediments to stream substrates as a result of watershed disturbances and erosion is worrisome because sedimentation may reduce the abundance of invertebrates. In streams where food is limiting for fish, a reduction in aquatic invertebrate abundance would lead to reduced fish production.

The influence of fine sediments on aquatic invertebrates and ultimately on fish has been investigated, but has not been clearly defined. Cordone and Kelley (1961) reported that fine sediments were detrimental to aquatic organisms. Brusven and Prather (1974) found that invertebrate abundance was reduced when larger streambed particles were fully embedded in fine sediments. Bjornn et al. (1977) found that many ephemeropterans, trichopterans, and simuliids were less abundant in riffles fully embedded with fine granitic sediments than in less-embedded riffle substrates. Hawkins et al. (1983) found decreasing numbers of invertebrates in shaded riffles as the percentage of fine sediments increased, but no such correlation existed in unshaded riffles. In seminatural laboratory streams, benthic and drifting invertebrates (mostly chironomids and ephemeropterans) were more abundant in sections with sand–pebble substrate than in sections with large gravel (Konopacky 1984).

Summer and winter carrying capacities of streams for salmonids may differ markedly because of the substrate present. For example, more than half the steelhead and chinook salmon that reared in two Idaho streams in summer left during fall and winter, but ceased migrating downstream when they encountered areas with larger substrate (Bjornn 1978). In laboratory experiments, fall and winter migrants stopped migrating downstream when placed in channels with large rocks, but continued migrating when put in channels with small gravel (Bjornn and Morrill 1972). After piles of large rock were added to provide cover in sections of a stream with small gravel, more juvenile steelhead stayed there in winter than previously (Chapman and Bjornn 1969). In summer, substrates contribute to a stream's carrying capacity by providing habitat for invertebrates that fish eat and, perhaps less importantly, by providing cover. In winter, the substrate is more important as a source of cover than as a source of food.

Cover

Cover is an important, but difficult to define, aspect of salmonid habitats in streams. Some of the features that may provide cover and increase the carrying capacity of streams for fish are water depth, water turbulence, large-particle substrates, overhanging or undercut banks, overhanging riparian vegetation, woody debris (brush, logs), and aquatic vegetation. Cover provides security from predation for fish and allows them to occupy portions of streams that they might

not use otherwise. The needs of fish for cover may vary diurnally, seasonally, by species, and by size of fish (Kalleberg 1958; Hartman 1963, 1965; Chapman 1966; Ruggles 1966; Butler and Hawthorne 1968; Edmundson et al. 1968; Allen 1969; Chapman and Bjornn 1969; Everest 1969; Lewis 1969; Wesche 1973; Hanson 1977; Cunjak and Power 1986). Cover is usually an important variable in models developed to estimate the standing crop of salmonids that could be expected in streams (Binns and Eiserman 1979; Conder and Annear 1987).

Fish abundance in streams has been correlated with the abundance and quality of cover. Standing crops of cutthroat trout in summer were correlated with the indices of cover (Figure 4.37) and surface area used by Wesche (1974). Juvenile steelhead and chinook salmon responded to various types (Figure 4.38) and amounts (Figure 4.39) of cover in winter by either staying in or leaving outdoor laboratory streams (T. C. Bjornn and C. R. Steward, unpublished data). More fish remained in channel pools with a combination of deep water, undercut bank, large rocks, and a bundle of brush than in pools with less cover. The number of chinook salmon remaining in pools increased with increasing amounts of cover (Figure 4.39).

The addition of structures or large boulders to streams to create pools and cover can increase the abundance of salmonids if the amount of suitable habitat is limiting the fish population. When gabions were added to an Oregon stream after logging, debris removal, and floods, the number, depth, and total volume of pools increased, as did the biomass of salmonids (House and Boehne 1985).

Large woody debris originating from riparian timber is a form of cover in many streams and its importance has become more widely known in recent years (Bisson et al. 1987; Holtby 1988a). For example, coho salmon production declined when woody debris was removed from second-order streams in southeast Alaska (Dolloff 1983). More large woody debris and juvenile coho salmon were found in

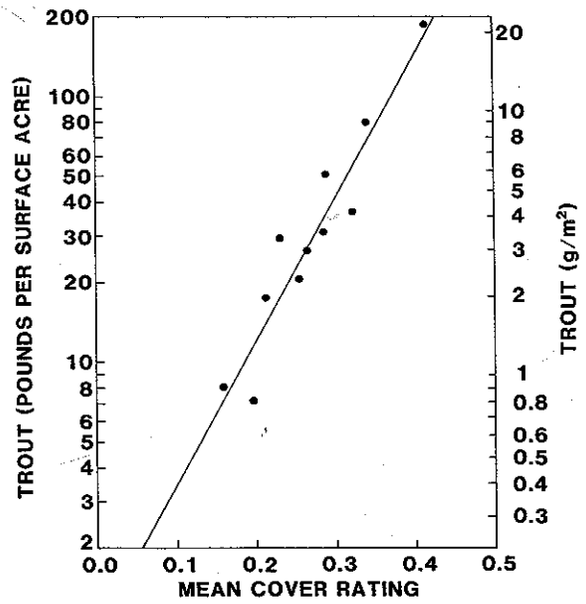

FIGURE 4.37.—Relation between mean trout cover rating and standing crop estimate of trout for 11 study areas. (From Wesche 1974.)

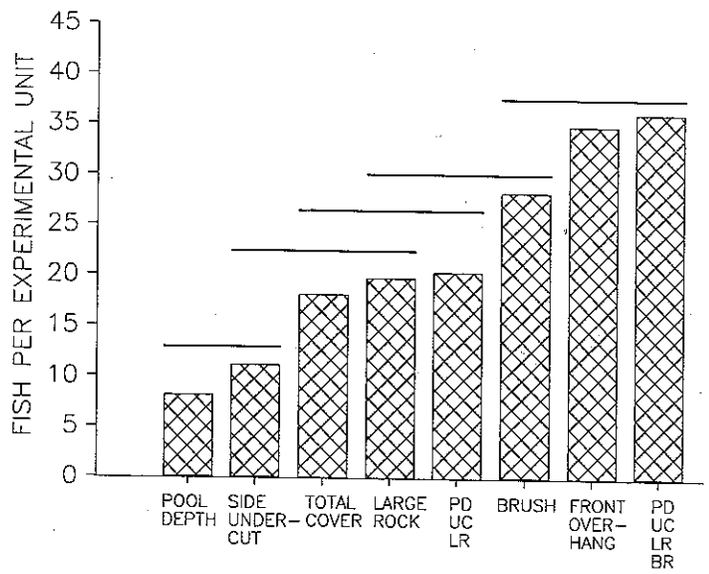

FIGURE 4.38.—Number of yearling steelhead that remained in sections of an outdoor laboratory stream in winter in pools that contained various types of cover. (T. C. Bjornn and C. R. Steward, unpublished data.) Bars not covered by the same horizontal lines were statistically different ($P < 0.05$).

streams surrounded by mature, mixed-conifer forest than in streams lined by red alder that had grown in a 20-year-old clear-cut (House and Boehne 1986). When wood debris was removed from a stream, the surface area, number, and size of pools decreased, water velocity increased, and the biomass of Dolly Varden decreased from 12.5 to 3.9 g/m^2 (Elliott 1986). In another stream, young steelhead were more abundant in clear-cut than in wooded areas in summer but moved to areas with pools and forest canopy in winter (Johnson et al. 1986). Bryant (1983, 1985)

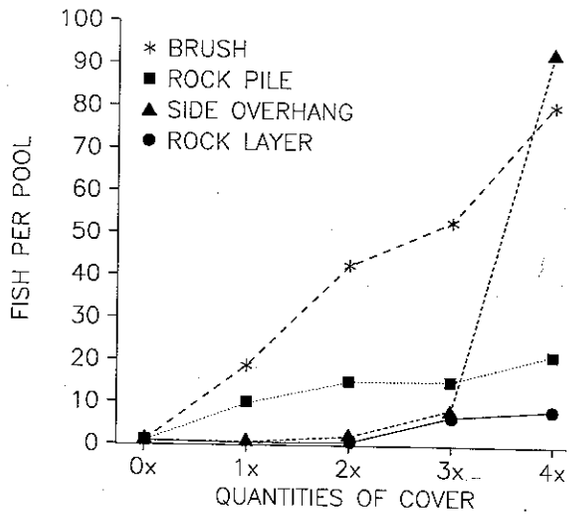

FIGURE 4.39.—Response (number remaining in pools) of yearling chinook salmon to various amounts of different types of cover in an outdoor laboratory stream during winter. (C. R. Steward and T. C. Bjornn, unpublished data.)

proposed guidelines for woody debris management in streams after he found a gradual loss of large debris from streams where riparian timber had been removed.

Overhead cover (including undercut banks, overhanging vegetation, logs, and debris jams) is often an important component of fish habitat in streams. Boussu (1954) reported increases in trout standing crop after the addition of overhanging brush as cover, and decreases when brush and overhanging banks were removed. Overhead bank cover, in association with water depths of at least 15 cm, was the single most important type of cover for brown trout in Wyoming streams (Wesche et al. 1985, 1987). In a small Lake Erie tributary, the distribution of subyearling rainbow trout, brown trout, and coho salmon was related to bank and instream cover (Gordon and MacCrimmon 1982). Brusven et al. (1986) found that 82% of age-0 chinook salmon preferred sections of a small stream channel with one-third overhead cover to sections without such cover. With the same stream channel, Meehan et al. (1987) showed that the fish preferred shade from artificial canopies to open areas, especially in the shallow reaches. Juvenile Atlantic salmon and brook trout were attracted to shaded areas of a shallow flume, but moved to deeper water when given the opportunity (Gibson 1978). Wilzbach et al. (1986), however, found that cutthroat trout foraged more effective on experimentally introduced invertebrate prey in pools within a recently logged area than in forested pools, presumably because light levels were higher in the logged area. Growth of trout was higher in pools of the logged section, but the investigators thought differences in foraging efficiency alone did not fully account for the slower growth in the forested pools.

Use of stream habitat and cover by juvenile salmonids may depend on the presence of other fish. Glova (1986) reported evidence of interactive segregation between juvenile coho salmon and cutthroat trout in summer. When tested separately, most fish of both species were found in pools, but when tested together, most coho salmon were in pools and cutthroat trout were in riffles. In winter, Glova (1986) found that both species, whether together or separate, preferred pools and overhead cover. Similar interactive segregation in summer has been demonstrated for coho salmon and steelhead: salmon used the pools and steelhead the riffles when the species were together in the same streams (Hartman 1965). In southeast Alaska streams, cover affected habitat use by coho salmon, steelhead, and Dolly Varden with respect to depth, position in the water column, and water velocity. Coho salmon and steelhead selected lower positions in the water column in pools without cover than in pools with overhead bank cover or instream cover (Bugert 1985). The presence or absence of Dolly Varden 10–20 cm long in pools caused shifts in habitat use by age-0 steelhead and coho salmon, even when some forms of cover were provided.

Seaward or Lakeward Migration

In some populations of salmonids, the fish spend their entire lives in a limited reach of stream (Miller 1954, 1957; Hunt 1974; Bachman 1984). In many other populations, however, juveniles may live in their natal streams for a few days to more than 3 years and then move to other areas to complete their maturation. Nonanadromous salmon, trout, and char may move downstream into lakes (upstream in some cases) or larger rivers. The anadromous salmonids eventually

migrate to the sea, but in some cases spend extended periods rearing or overwintering in streams (or lakes) other than their natal sites (Bjornn 1978; Leider et al. 1986). Regardless of the destination of the juvenile migrants, flows and water quality must be suitable for the migration to be successful.

The timing of most lakeward or seaward migrations of salmonids that rear for an extended period in steams appears to be regulated primarily by photoperiod, but streamflow, water temperatures, and growth may play a role in some areas. Chinook salmon and steelhead smolts migrated seaward from an Idaho stream at slightly different times, but the timing for each species was similar each year, and was modified only slightly by flow and moon phase (Bjornn 1971); water temperatures were similar each year. In a Norwegian river, water temperature (increase and general temperature in spring) accounted for most of the variation in timing of the seaward migrations of Atlantic salmon (Jonsson and Ruud-Hansen 1985); streamflow, cloudiness, and lunar cycle were not correlated with the migration.

Streamflows are usually adequate in unaltered streams because seaward migration commonly occurs in the spring. Seaward migration has been altered in streams and rivers from which large amounts of water are diverted or along which large reservoirs have been created. Streamflows that were sufficient before construction of dams become inadequate in large reservoirs. There is evidence that smolts depend on river currents during their downstream migration (Fried et al. 1978), and they have difficulty finding their way through large reservoirs with barely perceptible currents. The time required for a smolt to travel the 517 km from the Salmon River in Idaho to The Dalles Dam in the lower Columbia River increased by about 30 d during years with low flows after completion of six intervening dams. The poor success of smolts moving down through large reservoirs with low flows may be due in part to the suppression of some parr-to-smolt physiological processes; Adams et al. (1973) observed this condition when fish were held in relatively high water temperatures (15–20°C). The parr-to-smolt transition is often incomplete when fish begin to migrate and may fail to develop fully if the fish encounter high temperatures and reservoirs without perceptible currents.

Another hazard created at some dams is supersaturation of dissolved gases, particularly nitrogen, which can cause gas bubble disease in both upstream- and downstream-migrating salmonids (Ebel 1970; Ebel and Raymond 1976). Salmon may be more successful than steelhead in sensing and avoiding highly supersaturated waters (Stevens et al. 1980), but most salmonids migrating in the rivers are susceptible to gas bubble disease.

The magnitude of the effect dams and associated reservoirs can have on anadromous fishes is evident in data from the Columbia River drainage. Salmon and steelhead must pass up to nine dams in the Columbia and Snake rivers during their migrations to and from the sea. Smolt-to-adult survival rates declined from more than 4% before 1968 to less than 1.5% in the mid-1970s when all the dams were completed (Raymond 1988). In years with low flows (such as 1973 and 1977), smolt mortality averaged 45% at each dam and reservoir, compared to 15% in years with higher flows. In recent years, smolt-to-adult survival rates of steelhead and chinook salmon from the Snake River have increased to 2–5% with the help of spillway deflectors to reduce gas supersaturation, fish bypasses around

turbines, transportation around dams, and supplemental spills at dams without bypasses (Raymond 1988).

Summary

In the foregoing discussion of habitat variables, each factor was addressed separately, but the reader should keep in mind that fish usually respond to the combined effect of two or more of the physical, chemical, and biological variables in their environment. The fish may respond physiologically (altered growth and health) and behaviorally (site selection and interactions) to the array of environmental features they encounter. In streams where fish live and reproduce, all the important factors are in a suitable (but usually not optimum) range throughout the life of the fish. The mix of environmental factors in any stream sets the carrying capacity of that stream for fish, and the capacity can be changed if one or more of the factors are altered. The importance of specific factors in setting carrying capacity may change with life stage of the fish and season of the year.

Low streamflows, high water temperatures, and excessive turbidities impede adult salmon, trout, and char on their migration to spawning areas. These impediments occur even in pristine environments on occasion, but more often in drainages with irrigation, extensive agriculture, hydropower, surface mining, forest harvesting, and flood control projects. Once in the spawning areas, the amount and suitability of stream substrate and flows in the spawning areas are key factors. During incubation of the embryos and alevins, conditions within the redd dictate the number of young fish that will emerge into the stream. Adequate flows of well-oxygenated water and relatively small amounts of fine sediments (organic and inorganic) will allow a high percentage of the young fish to survive and emerge from the redd.

As soon as the young fish begin rearing in the stream, they become subject to predation by other fish, birds, and mammals, and they interact with the other fish present for choice feeding sites and cover. Given adequate numbers of young fish to use all the available habitat, the number and size of fish that can be produced in a stream is governed by the quantity and quality of space available, productivity of the stream, and the presence of competitors and predators. In summer, juvenile fish are primarily concerned with feeding and they select sites in streams that optimize the opportunity to obtain food, yet provide acceptable security from predation. In winter where water temperatures are low, the fish appear to be primarily concerned with security; they hide in cover or adopt behavior patterns that may have security benefits (such as gathering in large schools) and they are less interested in feeding. Because the requirements of salmonids and their use of habitat in winter are different from those in summer, the carrying capacity of streams or stream reaches may not be the same during both seasons. The changes in carrying capacity that result from alteration of stream features depend on the roles those features play in establishing the carrying capacity—roles that can change with time.

Temperate rainforests

ABSTRACT

Forests produce a myriad of ecosystem related benefits known as ecosystem services. Maximizing the provision of single goods may lead to the overexploitation of ecosystems that negatively affects biodiversity and causes ecosystem degradation. We analyzed the temperate rainforest region of the Pacific Northwest, which offers a multitude of ecosystem services and harbors unique biodiversity, to investigate linkages and trade-offs between ecosystem services and biodiversity. We mapped nine actual and potential ecosystem services, grouped into provision, supporting, regulating and cultural ecosystem service categories, as well as species richness of four taxonomic groups (mammals, birds, trees, and amphibians). We analyzed linkages and tradeoffs between ecosystem services, their overall diversity, and species richness as well as different levels of taxon diversity. We also tested if ecosystem service categories, in addition to climate and land cover parameters, could indicate species richness. We found significant positive linkages between ecosystem service diversity and species richness of all considered taxa. The provision of the majority of ecosystem services was higher in areas of high taxon diversity, indicating both positive relationships and slight trade-offs in maximizing single ecosystem services. In general, ecosystem service categories were a comparable indicator of species richness as climate. Our findings show that multifunctionality largely coincides with high levels of biodiversity within the study region. Hence, an integrative ecosystem management approach that incorporates ecosystem services and biodiversity concerns is needed to both provide diverse ecosystem benefits and conserve biological diversity.

1. Introduction

Ecosystem services and biodiversity conservation have become the two dominant, and potentially conflicting (Bullock et al., 2011; Marrs et al., 2007; McShane et al., 2011) management aims in conservation science during the last decades. Ecosystem services are the numerous benefits people directly or indirectly appropriate from the functioning of ecological systems and provide the foundations for human well-being (Daily, 1997; Nelson et al., 2009). The ecosystem services concept combines resource use, ecosystem management – including adaptation to impacts of driving forces such as land use and climate change – and the valuation of nature (Maskell et al., 2013), making it a key concept that bridges social and ecological systems (Carpenter et al., 2009). Biodiversity is vital for maintaining ecosystem processes and functioning (Duffy, 2009; Hector and Bagchi, 2007). Its loss has been shown to cause ecosystem degradation (Hooper et al., 2012). Hence, biodiversity is seen as essential requirement for the provisioning of ecosystem services (Diaz et al., 2006). Here it should be noted that as well as an instrumental value related to the provision of ecosystem services, the conservation of biodiversity is also a normative goal in its own right (Mace et al., 2012). Biodiversity conservation is therefore not solely contingent on the instrumental contribution to human well-being it may provide.

The increasing number of studies on the functional relationships between biodiversity and ecosystem services reveal mostly positive patterns (Gamfeldt et al., 2013; Hector and Bagchi, 2007; Maskell et al., 2013). However, many of these diversity-ecosystem services studies focus on a single facet of diversity such as one species group and a single ecosystem service, such as primary productivity (Costanza et al., 2007), pest control (Simon et al., 2010) or agricultural yields (Di Falco and Chavas, 2006). Managing an ecosystem for a single ecosystem service is potentially problematic as it may result in trade-offs in terms of associated biodiversity (Ingram et al., 2012; Ridder, 2008; Rodriguez et al., 2006) and thereby compromises conservation efforts. The interplay between the provision of multiple ecosystem services and biodiversity

represents an important knowledge gap (Geijzendorffer and Roche, 2013; Sircely and Naeem, 2012), potentially limiting our ability to effectively manage multifunctional landscapes for both ecosystem services provision and biodiversity conservation.

In this regard, it becomes vital to analyze ecosystems that are managed for diverse societal needs. Multifunctional ecosystems offer several services simultaneously to satisfy social, cultural, economic and environmental demands (O'Farrell et al., 2010). Hence, a diverse set of ecosystem services needs to be considered when assessing the relations between biodiversity conservation and ecosystem service provision in multifunctional ecosystems (Chan et al., 2006; Tallis and Polasky, 2009). This includes services that cannot be straightforwardly linked to specific ecosystem functions such as cultural services (Hernandez-Morcillo et al., 2013). Potential synergies between ecosystem services and biodiversity are expected, though they might vary across ecosystems and depend on the specific ecosystem services and aspects of biodiversity taken into consideration (Mace et al., 2012).

Forests are of immense global importance in delivering a myriad of benefits to humanity (Bonan, 2008; FAO, 2010; Schwenk et al., 2012). In particular, temperate rainforests represent an ecologically complex, unique ecosystem with high biodiversity importance, subjected to multiple human demands. We analyzed a region along the Pacific coastline of North America harboring the world's largest remaining extents of temperate rainforests (DellaSala, 2011). While currently offering a broad range of goods and services such as salmon (*Oncorhynchus* spp.), timber, water regulation and recreation, these rainforests are threatened by climate and land use changes (DellaSala, 2011; Fitzgerald et al., 2011).

We addressed three key questions to investigate linkages and trade-offs between ecosystem services and biodiversity across the temperate rainforest region of the Pacific Northwest: (1) How is ecosystem service diversity related to species richness across different taxonomic groups? (2) How are ecosystem services and their diversity linked to different diversity levels of the considered taxa? (3) In order to untangle the interrelations among the environment, ecosystem services and species richness we tested if the provision of ecosystem services, grouped by the millennium ecosystem service assessment (MA) categories, alongside environmental variables such as climate and land cover, indicate species richness. Here, we did not seek to explain the functional relations between biodiversity and ecosystem services categories. Rather, we described the patterns (Shmueli, 2010) between the types of ecosystem services provided, their diversity and biodiversity across the temperate rainforest region of the Pacific Northwest and discussed the implications of these patterns for multifunctional landscape management and conservation at a regional scale.

Recent studies focusing on the relationship between ecosystem services and biodiversity have taken a functional perspective and mostly considered limited ecosystem service categories such as provisioning or regulating services (e.g. Balvanera et al., 2006; Costanza et al., 2007; Schwenk et al., 2012) and single species groups such as plant species (e.g. Gamfeldt et al., 2013; Maskell et al., 2013; Tilman et al., 2012). By involving multiple taxa and multiple ecosystem services including supporting and cultural services, we aim to identify more comprehensive patterns relating ecosystem services to biodiversity.

Here we note that the direct quantification of ecosystem services is often problematic and that there might be considerable differences between the ecosystem services that potentially flow from a given ecosystem and the actual services that are appropriated at a given point in time. For example, timber harvest is an indicator for the appropriation of timber but provides limited information regarding the capacity of a given system to sustainably provide timber. Similarly it can be argued that benefits received (i.e. the direct quantification of services) from physically appropriated goods such as timber must be related to how those physical goods contribute to human well-being (Fischer et al., 2009). Given the importance of both the actual appropriation and the potential capacity to supply ecosystem services and the difficulty in directly and accurately quantifying multiple ecosystem services across large spatial and temporal extents, we focus on the mapping of proxy datasets that indicate nine important potential and actual ecosystem services within the temperate rainforest region of the Pacific Northwest. The following proxy data for ecosystem services were modeled: timber harvest, salmon abundance, deer hunting, net primary productivity, carbon storage in vegetation, organic matter in soil, forest importance for drinking water supply, landscape aesthetics, and park visitation. These proxies for ecosystem services were grouped into the MA categories of provision, supporting, regulating, and cultural ecosystem services (MA, 2005). Biodiversity was quantified in terms of spatially explicit species richness data for higher taxa, including mammals, birds, trees and amphibians. Diversity metrics were derived for ecosystem services and the higher taxa. Subsequently, we computed univariate models to reveal the patterns between ecosystem service diversity and species richness. Potential and actual ecosystem services and their diversity were linked to the higher taxon diversity. Multivariate direct gradient analyses were performed to assess if the MA ecosystem service categories are able to indicate species richness in interaction with and untangled from environmental variables such as climate and land cover.

2. Materials and methods

2.1. Study area

The study area was based on the original coastal temperate rainforest extent of the Pacific Northwest region (DellaSala, 2011) that shows an overall high proportion of forest coverage. All US counties that intersect the original coastal rainforest extent, including a buffer of 15 km, were incorporated into the study area of 325,614 km^2. This broad extent was chosen to ensure that climate and land cover gradients are well represented. Due to limited data availability, coastal rainforest regions located in British Columbia and Alaska were excluded from our analyses. All metrics related to species richness, ecosystem services and environmental data were mapped at a resolution of approximately 8 × 8 km – 3997 grid cells in total. It is important to note that the study extent, while dominated by forests, encompasses a spatially heterogeneous matrix of different land uses that in turn create spatially heterogeneous patterns of ecosystem service provision and biodiversity. The study extent comprised 55% forest, 33% scrub- and grassland, 7% cultivated areas and 5% developed/urban regions. Public lands in this region are managed under the Northwest Forest Plan that governs ecosystem management and biodiversity conservation (DellaSala and Williams, 2006). However, non-federal landowners frequently focus on timber management as the primary ecosystem service. ARCGIS 10.1 was used for all geo-processing work.

2.2. Ecosystem service data

The proxy data used refer either to the actual goods or services people appropriate from nature, known as 'ecosystem services', or to the capacity of the ecosystem to deliver those goods and services to society, conceptualized here as 'potential ecosystem services' (Vira and Adams, 2009). The data were based on physical occurrence of actual and potential ecosystem services, rather than the monetary or non-monetary values associated with those services.

All data were gathered from publically available datasets, further processed and linked to spatial data or were readily available in a spatially explicit format. We compiled GIS-layers indicating the nine potential and actual ecosystem services, which were also grouped into MA categories – i.e. provisioning, regulating, supporting, and cultural ecosystem services (MA, 2005). Detailed descriptions of the datasets and data sources can be found in the online appendix (Online appendix, Table A1).

2.2.1. Provisioning services

2.2.1.1. Timber harvest. Timber is one of the most prominent resources derived from forest ecosystems and has been intensively harvested from temperate rainforests in this region. This layer depicts the total volume of timber harvested in 2010 measured in thousands of board feet. Derived tabular data are based on the county level.

2.2.1.2. Salmon abundance. Salmon are an important economic and food resource for the entire coastal rainforest region in North America and they are the key for trophic dynamics and energy transfer (DellaSala, 2011). The salmon abundance data are based on observed (1998–2005) and modeled data at the watershed level (Pinsky et al., 2009). Watershed based data were normalized and then converted into gridded data.

2.2.1.3. Deer hunting. Hunting has been taking place for millennia across the coastal temperate rainforest region of North America (Schoonmaker et al., 1997). Hence, hunting can be considered as a traditional source of local food resources. This layer indicates overall deer hunting successes for 2010 measured in counted deer kills. Census data are obtained and mapped based on hunting management units defined by State Departments of Fish & Wildlife.

2.2.2. Supporting services

2.2.2.1. Net primary productivity. The Pacific coastal rainforests belong to the most productive ecosystems worldwide (DellaSala, 2011), and primary productivity is a key ecological function from which many other, directly used, ecosystem services flow. Gridded information on NPP is derived from NASA's MODIS satellite data in a 10 km^2 grid cell resolution based on monthly values averaged for 2010 in gC m^{-2} day^{-1}.

2.2.3. Regulating services

2.2.3.1. Carbon storage in vegetation. The storage of atmospheric carbon in biomass is essential to climate regulation and climate change mitigation. The coastal temperate rainforests in North America show high carbon densities compared to other forest ecosystems (DellaSala, 2011; Woodbury et al., 2007). Gridded data show total mean carbon content in vegetation for 1961–1990 and originate from outputs of the MC1 dynamic vegetation model (Bachelet et al., 2001a,b) in an 8.8 km^2 grid cell resolution.

2.2.3.2. Organic matter in soil. Organic matter strongly influences soil properties such as water retention, erodibility and fertility (Ontl and Schulte, 2012). Furthermore, soil represents a large carbon pool. The sequestration of atmospheric carbon in soil organic matter contributes to climate change mitigation (Lal, 2004). The data used indicates the total content of organic matter in soil expressed as percent by weight of the 2 mm soil fraction at the watershed level.

2.2.3.3. Forest importance for drinking water supply. Forests are known to serve as important regulators of drinking water, particularly in this region (DellaSala et al., 2011). This layer combines precipitation intensity, proportion of forests and population density per watershed and was derived from the USDA 'forests to faucets' dataset (Barnes et al., 2009). We used these data as proxy for water regulation (Todd and Weidner, 2010).

2.2.4. Cultural services

2.2.4.1. Landscape aesthetics. The possibility to experience landscapes that are largely undisturbed by human pressure is usually accepted as a great benefit that ecological systems may offer in terms of recreation (Gobster et al., 2007). The compiled dataset consists of several spatial layers related to infrastructure such as roads, railroads and settlements, and natural elements such as lakes, rivers and forests that are undisturbed by human influences. All layers were weighted according to their naturalness. Terrain roughness was incorporated as proxy for physical landscape heterogeneity. Each layer was weighted either positively or negatively except for terrain roughness that was weighted based on three states, low roughness as negative, medium roughness as neutral and high roughness as positive. The resulted 'landscape aesthetics' layer is considered as a potential ecosystem service since the quantification of the actual cultural values associated with the landscapes of the study region was beyond the scope of our analysis.

2.2.4.2. Park visitation. State and national parks represent essential recreation areas in the US (Daniel et al., 2012), facilitating environmental education and sustainable tourism. We mapped the tabular park visitation data for 2010 on state and national parks, derived from the PAD-US protected area database (v. 1.2). Subsequently spatial data were aggregated on county level since most of the state parks do not match the working resolution and hence would not have been visible for the analyses. We used this dataset as proxy for the provision of space for recreation and cultural experiences.

All data based on unequally sized areas were normalized based on area. Thus, every layer refers to equal area units. For further analyses all potential and actual ecosystem service layers were transformed to a standardized scale based on their maximum values (Raudsepp-Hearne et al., 2010). Hence, all ecosystem service values range between 0 and 1.

2.3. Species data

Spatially explicit species richness data for higher taxa, including mammals (between 1 and 85 species recorded), birds (88–223 species), trees (1–50 species) and amphibians (2–38 species) were obtained as gridded layer from several resources (Online appendix, Table A2). For tree species, we compiled a richness layer through aggregating range polygon data (Little, 1978). Selected species groups represent major parts of the overall species diversity that exists across the Pacific coastal temperate rainforests and contain numerous species of economic, cultural and conservation importance. Reptiles, as a further terrestrial vertebrate group, were not included into the analyses since they are not well represented, nor particularly abundant, across the Pacific coastal temperate rainforests compared to other regions of their occurrence (Böhm et al., 2013).

2.4. Applied statistical approaches

All statistical analyses were undertaken using R 2.15, including the packages 'raster' (v. 2.1.12) for handling spatial data, 'car' (v. 2.0.16) for building generalized linear models (GLMs), 'spdep' (v. 0.5.56) for correcting autocorrelation patterns, 'vegan' (v. 2.0.6) to obtain diversity indices and to perform principal component analyses (PCAs) as well as redundancy analyses (RDAs).

2.4.1. Simpson diversity metrics

Diversity metrics were derived by using the Simpson diversity index for potential and actual ecosystem services (Raudsepp-Hearne et al., 2010) and higher taxa ranging between 0 (low diversity) and 1 (high diversity). The Simpson index is illustrated by the following formula:

$$D = 1 - \sum_{i=1}^{R} p^2 i$$

R is the richness of taxa/ecosystem services and p_i is the proportion of abundances for the ith taxon/ecosystem service.

The Simpson diversity measure takes abundances into account and equals the probability that two entities taken at random from the dataset represent the same type (Simpson, 1949). The Simpson diversity of higher taxonomic groups was used as biodiversity metric that is comparable to the Simpson diversity of ecosystem services. A color map was compiled illustrating the degree of spatial correspondence between the diversity metrics across the study area.

2.4.2. Univariate linkage modeling: ecosystem service diversity – species richness

In order to model the relationship between ecosystem service diversity and species richness, we chose a univariate model approach using GLMs (Crawley, 2007). Due to the non-normalized distribution of model residuals, we opted for GLMs with Poisson error structure. Species richness data were selected as dependent variables and ecosystem service diversity as independent variable since Poisson-GLMs require real count data. Hence, we follow a descriptive approach rather than explaining the causal relationship between biodiversity and ecosystem services. GLMs also included quadratic terms and were reduced based on the Akaike information criterion (AIC), to avoid overfitting (Sakamoto et al., 1986). Since model residuals revealed patterns of spatial autocorrelation, we applied spatial eigenvector filtering to incorporate spatial autocorrelation structures (Dray et al., 2006; Griffith and Peres-Neto, 2006). Spatial eigenvectors are derived from a neighborhood matrix spanning a distance of 100 km, which was chosen due to highest spatial autocorrelation values within that distance. The number of incorporated spatial eigenvectors was based on Moran's I significance values for each GLM. Eigenvectors were included until they exceeded a significant Moran's I value ($p < 0.05$).

2.4.3. Ordination techniques: ecosystem service categories, land cover and climate – species richness

A multivariate direct gradient analysis was applied to investigate the proportion of species richness variances captured by potential as well as actual ecosystem services grouped into the MA categories and environmental variables. Initial analyses of data distribution and gradient lengths showed that linear models are a correct general assumption for our data. Hence we used a PCA to reduce multicollinearity inherent to the climatic parameters applied and a partially constrained RDA as overall multivariate model (Legendre and Legendre, 2012) to partition the explained variance of four different variable groups, such as potential and actual ecosystem services for each MA category, 'climate', 'land cover' and 'geography'. Species richness data from the considered taxonomic groups served as response variables and were subjected to Hellinger transformations as proposed for analyzing heterogeneous community datasets (Legendre and Gallagher, 2001). Climatic data were derived by performing a PCA, including 19 BIOCLIM variables that were obtained as downscaled spatial grids in a 2.5 arc-min resolution (Hijmans et al., 2005). The PCA scores from the first two principal components were extracted and subsequently used as 'climate' variable group for the RDAs (Hanspach et al., 2011). Land cover data were derived from the USGS land use survey 2006 comprising 16 land cover classes, including developed, forested, cultivated, wetland, herbaceous, scrubland and barren land cover types at a grid cell resolution of 30 meters. The original dataset was spatially downscaled to match the working resolution. To account for spatial autocorrelation effects, we defined latitude and longitude as a further variable group named 'geography'.

3. Results

3.1. Ecosystem service diversity and species richness

The compiled spatial layers of potential as well as actual ecosystem services, the derived Simpson diversity metrics of the considered taxa and ecosystem services varied across the study area (Fig. 1). The diversity of taxa and the diversity of ecosystem services were highly correlated, indicated by Spearman's rho = 0.719 ($p < 0.001$). Species richness maps for mammals, birds, trees and amphibians are shown in online appendix (Fig. A1).

Ecosystem service diversity showed significant positive interactions with the richness of mammal, bird, tree, and amphibian

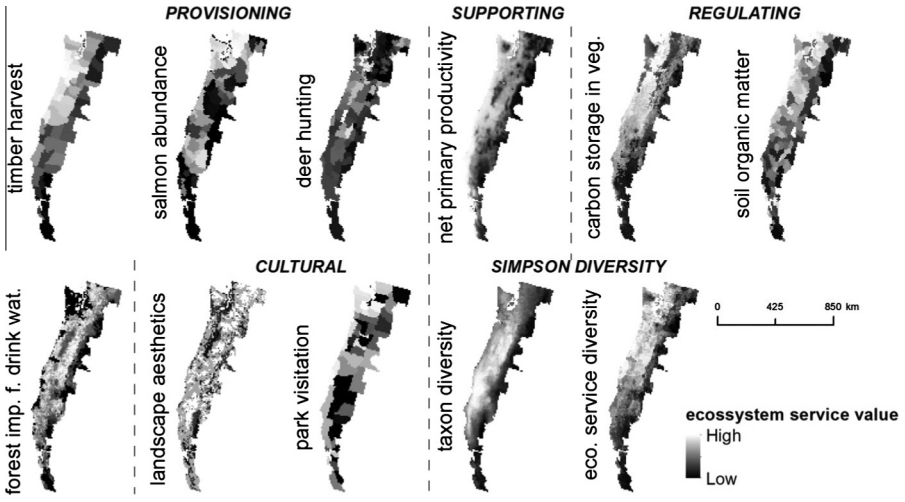

Fig. 1. Spatial distribution of nine potential and actual ecosystem services as well as the Simpson diversity of considered taxa and ecosystem services across the coastal temperate rainforest region of the Pacific Northwest, USA.

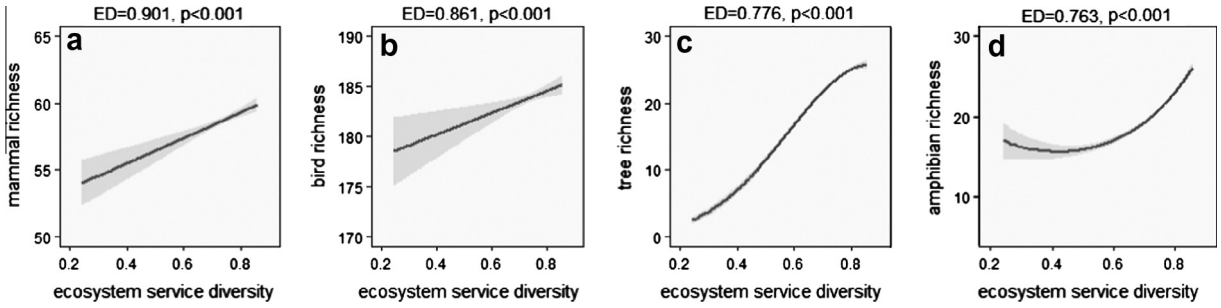

Fig. 2. GLM results for linkages between ecosystem service diversity and mammal, bird, tree, and amphibian richness. Incorporated spatial eigenvectors were kept at mean level. Light gray areas indicate the 95% confidence intervals of prediction errors (ED = explained deviance).

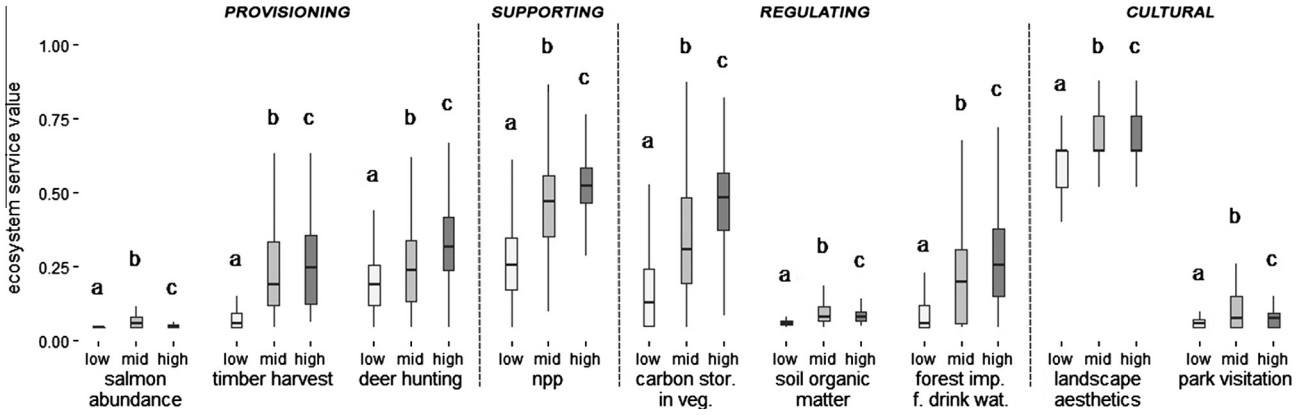

Fig. 3. Potential and actual ecosystem services for three levels of overall Simpson diversity of considered taxa (low = 0.335–0.514, mid = 0.514–0.573, high = 0.573–0.634). Grouping maintained equal sample sizes within each level. A Wilcoxon rank sum test was performed to assess the mean differences between Simpson diversity levels ($p < 0.001$). *P*-values were Bonferroni corrected to account for multiple testing.

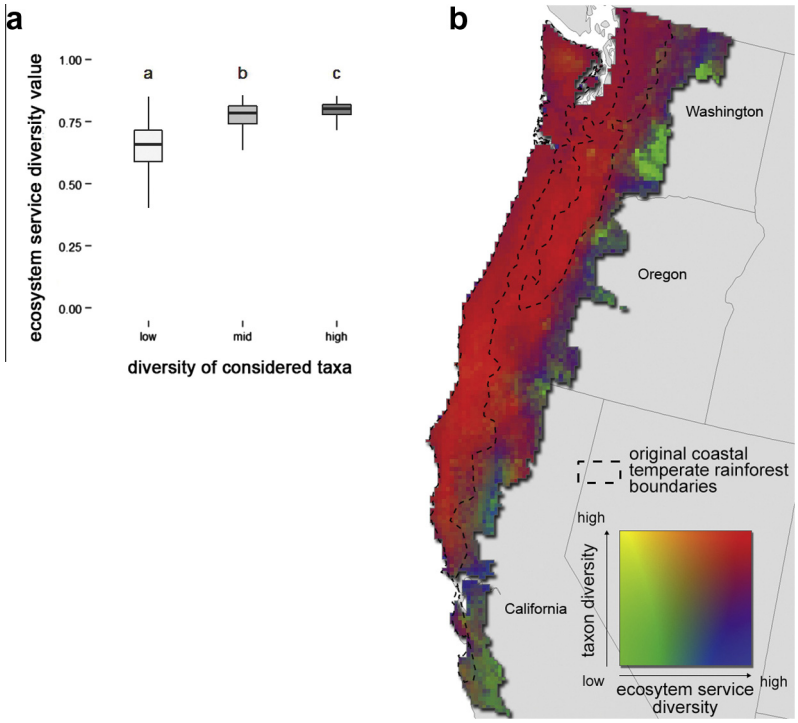

Fig. 4. (a) Ecosystem service diversity for three levels of overall Simpson diversity of the four considered taxonomic groups (low = 0.335–0.514, mid = 0.514–0.573, high = 0.573–0.634). Grouping maintained equal sample sizes within each level. A Wilcoxon rank sum test was performed to assess the mean differences between Simpson diversity levels ($p < 0.001$). *P*-values were Bonferroni corrected to account for multiple testing. (b) Spatial correspondence between ecosystem service diversity and diversity of considered taxa. Mapped pixel colors were assigned based on a RGB color space defined by ecosystem service diversity on the *x*-axis and diversity of four considered taxa on the *y*-axis.

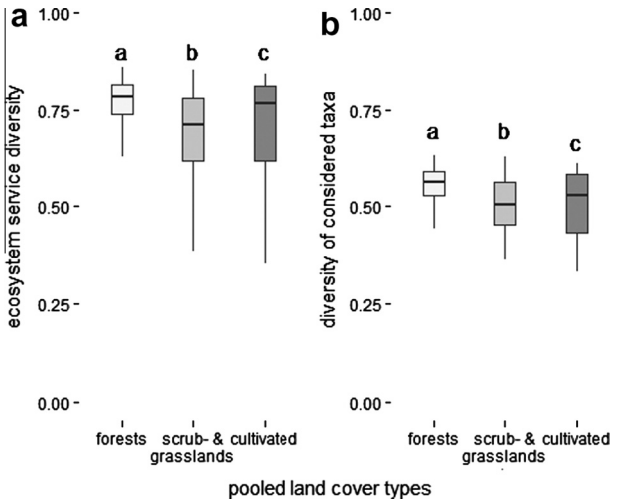

Fig. 5. Ecosystem service diversity (a) and diversity of considered taxa (b) for three pooled land cover types: forests, scrub- and grasslands, and cultivated areas. Developed land cover types were excluded due to minor relevance for the provisioning of analyzed ecosystem services.

species (Fig. 2, $p < 0.001$). Mammal and bird species richness increased linearly with higher ecosystem service diversity (Fig. 2a and b), tree richness showed a sigmoidal relationship indicating a saturation effect of tree species richness at the highest levels of ecosystem service diversity (Fig. 2c). Amphibian richness increased steeply with elevated ecosystem service diversity (Fig. 2d). The GLM on mammal richness had the highest model fit expressed as explained deviance (ED = 0.901), the model that considered amphibian richness the lowest (ED = 0.763).

3.2. Ecosystem services and taxon diversity

Higher values of ecosystem services were related to higher levels of the overall Simpson taxon diversity for most of the applied potential and actual ecosystem services across all MA categories (Fig. 3). However, salmon abundance, soil organic matter and park visitation differed from that pattern, indicating trade-offs between maxima of single ecosystem services and diversity of involved taxa. No pronounced ecosystem service gradient could be detected based on a PCA, including all modeled ecosystem services (not shown). The first two PCA axes together explained 46% of the overall variance.

Higher ecosystem service diversity was significantly linked to elevated taxon diversity (Fig. 4a, $p < 0.001$). However, less pronounced differences between medium and high levels of taxon diversity suggested a nonlinear relationship resulting in a saturation effect for ecosystem service diversity in areas of high taxon diversity. High spatial correspondence between ecosystem service diversity and the diversity of included taxa was shown within coastal temperate rainforest regions throughout most of the Pacific Northwest (Fig. 4b).

3.3. Ecosystem service categories as indicators for species richness

To assess both the distribution of ecosystem service diversity and the diversity of higher taxa for major land cover types, we pooled the detailed land cover types into three groups, namely, 'forests', 'scrub- and grasslands', and 'cultivated areas'. Highest diversity values for ecosystem services as well as considered taxa were significantly higher for forests (Fig. 5a and b, $p < 0.05$). Groups differed significantly as assessed through a one-way analysis of

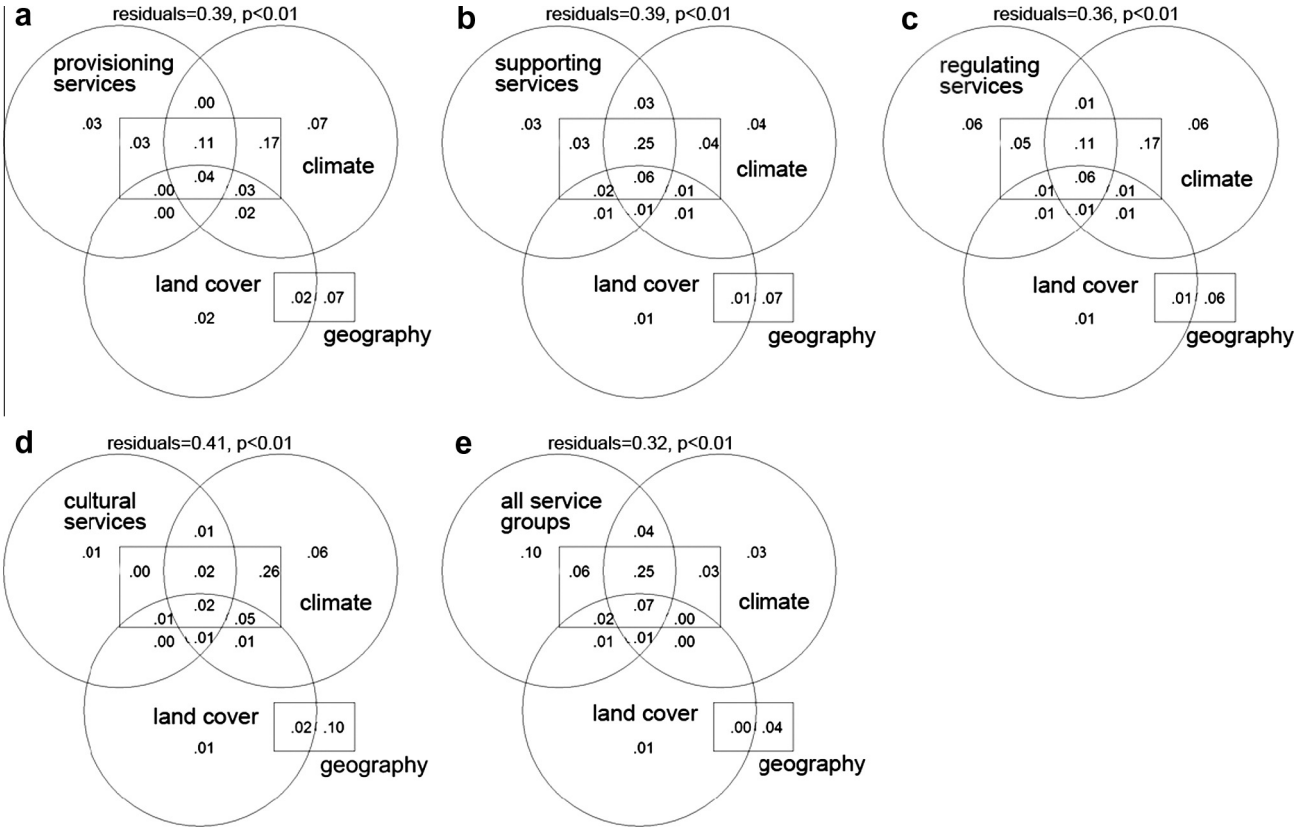

Fig. 6. RDA variance partitioning results for species richness including mammals, birds, trees and amphibians separately indicated by different ecosystem service categories: (a) provisioning, (b) supporting, (c) regulating, (d) cultural and (e) all potential and actual ecosystem services, climate, land cover (circles) and geography (rectangle). Displayed values show captured variances as adjusted R^2 for all single (non-overlapping parts of circles and the rectangle) and combined effects (overlapping parts of circles and the rectangle).

variance and a subsequent paired t-test ($p < 0.05$). P-values were Bonferroni corrected to account for multiple testing.

Constrained RDAs revealed that ecosystem service categories significantly indicated species richness in a comparable magnitude of land cover and climate (Fig. 6, $p < 0.001$). Among the RDAs that were fitted with single ecosystem service categories, the RDA with regulating services showed the lowest model error (Fig. 6c, residuals = 0.36) and the one that included cultural services the highest error (Fig. 6d, residuals = 0.41). The RDA incorporating the entire set of potential and actual ecosystem services as variable group showed the lowest model error among all RDAs (Fig. 6e, residuals = 0.32). However, for the majority of RDAs the climatic space was, after geography, the variable group that captured most of the species richness variances. This reflected both the prevailing climatic gradient that shapes diversity patterns across the temperate rainforests of the Pacific Northwest and an inherent autocorrelation pattern. Focusing on interactions between variable groups the climate-geography interactions showed the strongest effects followed by the ecosystem service category–climate interactions.

4. Discussion

4.1. Ecosystem service diversity and species richness

We found broad, positive relationships between ecosystem service diversity and species richness. Such a pattern confirms the findings of Egoh et al. (2009) who illustrated a spatial congruency between ecosystem services and biological diversity in South Africa. No trade-offs were observed in our study between ecosystem service diversity and species richness. Other studies reported both trade-offs and concordances between ecosystem service hotspots and biodiversity or its conservation (Chan et al., 2006; Turner et al., 2007). Our results clearly show that high levels of biodiversity are found in areas that provide diverse actual and potential ecosystem services across the coastal temperate rainforest region of the Pacific Northwest. This pattern was also apparent when all considered taxa were combined to one diversity index, particularly within the original coastal temperate rainforest boundaries. Though, some minor areas showed a contrasting pattern of low biodiversity but high ecosystem service diversity. These scattered areas were mostly distributed at the inland edges of our study region indicating transition zones to other ecosystems that might start to harbor different species inventories not included in our study.

Saturation effects were revealed for tree species and overall taxon diversity suggesting that further ecosystem service increases in regions of highly diverse ecosystem service provision coincide with marginally higher biodiversity levels. This might relate to redundancies of present species in terms of the necessary ecosystem functions that are required to maintain considered ecosystem services (Duffy, 2009; Hector and Bagchi, 2007). Notwithstanding, including more services and thus more ecosystem functions would probably incorporate more biodiversity needed to sustain these functions (Gamfeldt et al., 2008). Moreover, biodiversity reduces the vulnerability of ecosystems to disturbances, serving both as a backup for functional degradation and to ensure diverse and fast responses to perturbations hence improving overall ecosystem resilience (Mori et al., 2013).

4.2. Ecosystem services and their diversity for different levels of taxon diversity

The majority of our results indicate positive relationships between single ecosystem services included and the overall diversity of the considered taxa. Similar patterns are found in recent studies (Balvanera et al., 2006; Schneiders et al., 2012), in particular for productivity and biodiversity (Gamfeldt et al., 2013; Tilman et al., 2012) – though Costanza et al. (2007) found a temperature dependent relationship. The relation between timber harvest and taxon diversity was most surprising and probably, in part, resulted from a scale artifact inherent to the data used. It is important to note here that the established relationships do not imply causality. Yet, intense forest management is usually considered to have negative impacts on biodiversity (Bengtsson et al., 2000). The data used in our study did not include any information on how the forests are managed for timber harvest on a local scale. Hence, it is beyond the scope of our analyses to assess the effects of forest practices on biodiversity patterns.

Despite the largely positive patterns found, a few trade-offs were noticeable in our results. Salmon abundance, soil organic matter and park visitation were highest in areas with moderate levels of taxon diversity. Non-supporting patterns or trade-offs among ecosystem services are postulated (Bennett et al., 2009) and reported on a regional (Raudsepp-Hearne et al., 2010), continental (Haines-Young et al., 2012) and global scale (Naidoo et al., 2008). Though, in our case, no clear trade-offs among the studied ecosystem services could be detected.

4.3. Ecosystem service categories as indicators for species richness

Both, ecosystem service diversity and taxon diversity were highest in forested extents within the study region. Although the differences among land cover types were only marginal, it suggests that forests provide conditions most suited for supplying ecosystem services and biodiversity.

Using a multivariate approach, including the nine actual and potential ecosystem services grouped into MA categories as well as environmental variables showed that the different MA ecosystem service categories indicated species richness of the four different taxa in a comparable magnitude to climate and land cover. The capability of all ecosystem service categories, in interaction with climate, to indicate species richness illustrates that a management focusing on multiple ecosystem-based benefits and the current climatic conditions are synergistic for both ecosystem services and biodiversity. These findings support the idea that the ecosystem service approach could be used to monitor and manage biodiversity (Egoh et al., 2009). However, cultural services showed an overall weak link, probably due to the most indirect relationship to richness for instance compared to the considered regulating ecosystem services. Nevertheless, the management of ecosystems based on providing a diversity of ecosystem services might have co-benefits in terms of biodiversity conservation.

4.4. Ecosystem service approach and multifunctional ecosystems

Temperate rainforests of the Pacific Northwest simultaneously offer a multitude of ecosystem-based benefits. We were able to show that such a multifunctional ecosystem might serve as indicator of biodiversity and its conservation while delivering important goods and services to society. Our results are restricted to one region and spatial scale as well as one point in time. Thus, extrapolating these results to other regions featuring different ecosystem properties and species should be done with considerable caution. However, high biodiversity levels in multifunctional landscapes also have been shown before for areas with heterogeneous land use or agricultural regions (O'Farrell et al., 2010; Schneiders et al., 2012; Sircely and Naeem, 2012). Managing for multiple ecosystem services may also create conditions for higher levels of biodiversity. Given the co-occurrence of biodiversity and diverse ecosystem service provision, we suggest that biodiversity conservation should be integrated into the management of

multifunctional ecosystems and not only take place in areas explicitly designated for conservation.

4.5. Threats to ecosystem services and biodiversity: land use and climate change

North America's temperate rainforests are fragmented by logging, road building, and other human disturbances (DellaSala, 2011). Coinciding biodiversity loss and the degradation of ecosystem functions are expected due to habitat fragmentation and increasing land use intensity (Foley et al., 2005). However, sustainable trajectories of land use changes and restoration efforts have been positively linked to ecosystem service provision and biodiversity conservation (Nelson et al., 2009; Rey Benayas et al., 2009).

Ecosystem services in this region are threatened by a changing climate regime and projected vegetation shifts in Western North America (Wang et al., 2012). Dominant tree species and vegetation types in our study area are predicted to shift substantially until the end of the 21st century (Coops and Waring, 2011; Gonzalez et al., 2010; McKenney et al., 2007), probably detrimentally affecting both current ecosystem service and biodiversity patterns. Hence, an adaptive ecosystem management approach is needed to mitigate estimated impacts.

5. Conclusions

Our results confirm that multifunctional landscapes, here largely covered by temperate rainforests, co-occur with high levels of biodiversity. Thus, the management of ecosystem services should not substitute, but rather incorporate, biodiversity conservation since the two concepts are interdependently related through maintaining the functioning of ecosystems on the one hand and the management for goods and services on the other hand (Ingram et al., 2012; Mace et al., 2012). Based on our results, we derive the following management and research recommendations for the coastal temperate rainforest region across the Pacific Northwest.

1. The concepts of ecosystem services and biodiversity are not only linked, they act in concert. Based on our analysis, an integrative approach of ecosystem management that incorporates both ecosystem services and biodiversity is indeed beneficial in providing goods and services to society while maintaining biodiversity. We therefore support the perspective that multifunctional ecosystems should become a key for sustainable ecosystem management in this region, particularly in a way that optimizes land-use and strives for compatibility in management among different ecosystem services.
2. Our findings generally show that land managers who are interested in the provisioning of diverse ecosystem services are also able to maintain biodiversity. For instance, large landscape level management efforts inherent to the Northwest Forest Plan (DellaSala and Williams, 2006) represent approaches in which ecosystem management and biodiversity conservation on public lands are capable to produce multiple ecosystem benefits and, hence, help to maintain multifunctionality.
3. Research at finer spatial scales, incorporating time series data and information on how local forest management practices determine possible relationships between timber harvest, other ecosystem services and biodiversity would be useful for our study region. Standardized surveys and sampling protocols are required and data on socio-economical dynamics and ecosystem service valuations should be linked to assess the compatibility of (potentially competing) provisioning ecosystem services at the local and regional scale. Scenario driven analyses (Carpenter et al., 2006; Nelson et al., 2009) that consider climate and land-use changes are necessary since they may offer valuable insights about possible future trajectories of biodiversity and ecosystem service patterns in this region.

Acknowledgements

We thank the Leuphana University Lüneburg for providing the project fund. We are also very grateful to all governmental and non-governmental organizations that made available the data needed for our analyses. Finally we thank Pascal Fust for his contribution to the manuscript.

Abstract: *There is broad consensus that active management through thinning and fire is urgently needed in many forests of the western United States. This consensus stems from physically based models of fire behavior and substantial empirical evidence. But the types of thinning and fire and where they are applied are the subjects of much debate. We propose that low thinning is the most appropriate type of thinning practice. Treating surface fuels, reducing ladder fuels, and opening overstory canopies generally produce fire-safe forest conditions, but large, fire-resistant trees are also important components of fire-safe forests. The context of place is critical in assigning priority for the limited resources that will be available for restoration treatments. Historical low-severity fire regimes, because of their current high hazards and dominance by fire-resistant species, are the highest priority for treatment. Mixed-severity fire regimes are of intermediate priority, and high-severity fire regimes are of lowest priority. Classification systems based on potential vegetation will help identify these fire regimes at a local scale.*

Restauración de Bosques y Fuego—Principios en el Contexto del Sitio

Resumen: *Existe un amplio consenso de que en muchos bosques del oeste de EE.UU. se requiere con urgencia un manejo activo mediante tala y fuego. Este consenso se basa en modelos físicos de comportamiento de fuego, así como en importante evidencia empírica que aumenta cada año. Pero los tipos de tala y fuego y el lugar en que se aplican, son temas de mucho debate. Proponemos que la tala reducida es la más apropiada. El tratamiento de combustibles de superficie, la reducción de combustibles escalera y la apertura de doseles generalmente producen condiciones a salvo de fuego en los bosques, pero árboles grandes resistentes al fuego también son componentes importantes de bosques a salvo de fuego. El contexto del lugar es crítico en la asignación de prioridades a los limitados recursos disponibles para tratamientos de restauración. Los regímenes de fuego de baja intensidad, debido a sus altos riesgos actuales y la dominancia de especies resistentes al fuego, son la mayor prioridad para el tratamiento. Los regímenes de fuego de severidad mixta son de prioridad intermedia y los regímenes de fuego de alta severidad son de menor prioridad. Los sistemas de clasificación basados en la vegetación potencial ayudarán a identificar estos regímenes de fuego a escala local.*

Introduction

Transformation of the forested landscape in the western United States, especially dry, low-elevation forests dominated by ponderosa pine (*Pinus ponderosa* Dougl. ex Laws.), began in the second half of the nineteenth century with the introduction of livestock grazing. Beginning in the late nineteenth century and accelerating after World War II, selective logging of old, fire-resistant trees, extensive road building to facilitate logging, fire exclusion, and livestock grazing continued trends of forest and watershed degradation. Approaches to addressing these daunting problems are being developed and implemented, but a strategic approach will be required because restoration resources are limited. Strategically focused, integrated approaches are needed that will provide maximum benefits for a given cost while minimizing unintended adverse effects (Agee 1996; Rieman et al. 2000; Finney 2001). We summarize here the restoration potential of active management and principles related to fire resiliency that

Paper submitted November 14, 2003; revised manuscript accepted January 28, 2004.

should be applied when considering active management, and we emphasize a context of place in the planning process.

Restoration Concepts

There is broad agreement that restoration in some form and to some degree—of fire regimes, habitats, populations of fish and wildlife, productivity of soils, watershed integrity, and disturbance patterns—is appropriate (ICBEMP 2000; U.S. Department of Agriculture Forest Service 2000; Weatherspoon & Skinner 2002). However, there is more disagreement concerning restoration objectives and implementation strategies. Restoring landscapes to some semblance of pre-1850 conditions, or their "historic range of variability," is one common suggestion. Advocates presume that forest stands and landscapes restored to past conditions are more likely to support healthy populations of wildlife and fish. Habitats would be more like those to which species had adapted over thousands of years, and disturbance processes (fire, insects, disease, flooding, landsliding) could operate more sustainably in a more resilient landscape. However, although knowledge of historical conditions will be useful in guiding restoration efforts, attempts to precisely recreate past conditions will not be desirable or feasible (Christensen 1988; Swanson et al. 1994; Gregory 1997; Hessburg et al. 1999; Landres et al. 1999; Millar & Woolfenden 1999; Moore et al. 1999; Tiedemann et al. 2000; Allen et al. 2002).

Knowledge of historic conditions can help clarify the types, extent, and causes of ecosystem changes and can help identify management objectives and restoration priorities (Hessburg et al. 1999). Climates are now different than at any historic time, however, and will be different in the future (Millar & Woolfenden 1999). Species have been irrevocably added and subtracted, and the undesirable portion of the modern human imprint cannot be entirely eliminated. Historical reconstructions can provide good estimates of the large-tree component of past forests, but they are less reliable for small trees or other ecosystem elements such as herbaceous vegetation or wildlife (Fulé et al. 1997; Harrod et al. 1999). Although past fire regimes may be more accurately estimated than forest structure and composition (Stephenson 1999), "the natural fire regimes of the past are not the regimes of the present, nor will they be the regimes of the future" (Agee 1998). Conditions other than historic (or "natural") may need to be maintained to provide essential habitat for at-risk wildlife (ICBEMP 2000; Wisdom et al. 2000). Conditions that are "unnatural" yet sustainable and desirable may be quite appropriate for many state, private, and Native American lands.

Potential conflicts or trade-offs among reasonable objectives need to be recognized in setting restoration goals. Creating stands that are highly resistant to severe fire may unintentionally disturb soil, reduce canopy cover, and affect some fish and wildlife species (Rieman & Clayton 1997; Gresswell 1999). There are also fire-behavior trade-offs. Thinning of codominant trees will contribute to restoration of more open stand conditions in some areas and increase the growth of forbs and shrubs, which retain moisture until later in the season, reducing fire behavior (Agee et al. 2002). Yet opening the canopy can increase fire behavior by lowering the moisture content of dead surface fuels and increasing surface windspeed (van Wagtendonk 1996; Weatherspoon 1996; Agee et al. 2000).

Roads have many adverse ecological effects (Furniss et al. 1991; Noss & Cooperrider 1994; Rieman & Clayton 1997; Jones et al. 2000; Trombulak & Frissell 2000) but are paradoxical in terms of fire management. They open access so that human-caused ignitions increase but also decrease response time to wildfires, act as holding lines, and make prescribed fire easier to apply (Agee 2002). Most restoration effort can be focused on the substantially roaded portion of the landscape. In unroaded areas needing active management, prescribed fire with minimal necessary thinning and no road construction may be appropriate to maintain these important areas as reservoirs of biological diversity and ecological baselines (Noss 1999). The spatial focus of active management to alleviate road impacts and that to improve forest integrity will overlap considerably (Lee et al. 1997; Rieman et al. 2000).

Restoration Treatments

Ecological restoration efforts are often categorized as either active or passive. This can be a useful distinction, but the term *passive restoration* suffers from potential confusion with *passive management*, which some people consider equivalent (at least in some circumstances) to mere neglect or inattention to the needs of the land (Agee 2002). Passive restoration is the "cessation of . . . activities that are causing degradation or preventing recovery" (Kauffman et al. 1997) and can be considered the first step in restoration (National Research Council 1996).

The primary active restoration techniques we considered are thinning and prescribed fire. However, other active treatments focused on roads, weeds, livestock, and streams will also be needed. Thinning appropriate for restoration will focus on the cutting and removal of small trees and is variously known as understory thinning, thinning from below, or low thinning. Possible standards for placing boundaries on appropriate low thinning include diameter limits and percentile approaches. Diameter limits, such as restricting removal to trees <30 cm or <50 cm is one way to approach the problem, but the limit should vary by site. Trees that invaded some forests after fire

Table 1. Factors that increase fire resilience (adapted from Agee [2002] and Hessburg & Agee [2003]).

Principle	*Effect*	*Advantage*	*Concerns*
Reduce surface fuels	reduces potential flame length	control easier; less torching	surface disturbance less with fire than other techniques
Increase height to live crown	requires longer flame length to begin torching	less torching	opens understory; may allow surface wind to increase
Decrease crown density	makes tree-to-tree crown fire less probable	reduces potential for crown fire	surface wind may increase and surface fuels may be drier
Keep big trees of resistant species	less mortality for same fire intensity	generally restores historic structure	less economical; may keep trees at risk for insects

exclusion became effective can exceed 50–60 cm diameter, whereas on other sites trees that are 200 years old can be well below this size. Another approach is a percentile method, in which trees are ranked by size, and some size limit, such as the seventy-fifth percentile, is defined. This assures that the largest 25% of trees is left. Both approaches are likely to work best if applied in the context of place rather than being arbitrarily defined to fit all situations.

The majority of the trees removed in such thinnings are too small to have commercial value by conventional standards, but efforts are underway in the West to develop processing methods and markets for ever-smaller material. Before private investment emerges, assurances will be required that a supply of such material will be provided. Some trees thinned as a by-product of restoration activities will have commercial value (R. F. Noss. 2000. Society for Conservation Biology comment letter on U.S. Forest Service Roadless Areas Protection Initiative.). Restoration thinning may appropriately include the removal of dead trees, but traditional "salvage" logging will not provide restoration benefits. Removal of large, pre-1850 trees solely to pay for treatment will undermine the credibility of restoration efforts (Weatherspoon & Skinner 1995; Agee 1997*b*). Thinning is unlikely to meet all ecological objectives unless it is combined with prescribed fire (Weatherspoon 1996; National Research Council 1999; Lynch et al. 2000; Weatherspoon & Skinner 2002). Despite considerable anecdotal, modeling, and common-sense support for restoration thinning, scant empirical research has been done on the subject (van Wagtendonk 1996; Agee 1997*a*; Stephens 1998; Omi & Martinson 2002; Pollet & Omi 2002). Although additional scientific research is necessary, much can also be learned from routine monitoring, especially if it is structured to reflect a more consistent case-study approach (Shrader-Frechette & McCoy 1993).

Restoration objectives may be accomplished by prescribed fire alone in some forest types and conditions (Agee & Huff 1986; Biswell 1989; Weatherspoon 1996). It has been the primary restoration technique in drier forests of U.S. national parks. Yet prescribed fire applied too broadly could homogenize the landscape, create smoke problems, and damage wildlife habitat (Tiedemann et al. 2000). It can kill large trees that are intended to be saved by treatment (Agee 2003). The proportion of a landscape requiring treatment in order to have a significant effect on the spread and severity of wildfire is unknown. It is probable that areas less manipulated will be less effective per unit area, so that larger expanses of the landscape will have to be treated (Agee et al. 2000). Patterns of fuel treatment can affect fire intensity or rate of spread, and this topology has implications for designing landscape-level fuel-treatment patterns (Finney 2001).

Factors of Fire Resilience

A forest that is fire-resilient has characteristics that limit fire intensity and increase the resistance of the forest to mortality (Table 1). The first principle is to manage surface fuels to limit the flame length of a wildland fire that might enter the stand. This is generally done by removing fuel through prescribed fire, pile burning, or mechanical removal. This reduces the potential energy of a wildland fire and makes it more difficult for a fire to jump into the canopy (Scott & Reinhardt 2001). The second principle is to make it more difficult for canopy torching to occur by increasing the height to flammable crown fuels. This can be accomplished through pruning, prescribed fire that scorches the lower crown, or removal of small trees. The third principle is to decrease crown density by thinning overstory trees, making tree-to-tree crowning less probable. This will not be necessary on all sites and will be effective only if linked to the application of the first two principles (Perry et al. 2004 [this issue]). The fourth principle is to keep large trees of fire-resistant species (Hummel & Agee 2003). If fire behavior is successfully reduced but the fire is burning under fire-sensitive trees, high-severity fire will still occur as the trees may still all be killed. Active management can have positive or negative effects on fire-hazard potential (Table 2).

The influence of species composition and large trees on fire-resilient forests is illustrated by a simulation of fire effects (Fig. 1) based on the First Order Fire Effects Model (Reinhardt et al. 2002). A forest type with a historic low-severity fire regime—low-elevation

ponderosa pine/Douglas-fir (*Pseudotsuga menziesii* [Mirb.] Franco)—is contrasted with a historic high-severity fire regime—high-elevation subalpine fir (*Abies lasiocarpa* [Hook.] Nutt. and of lodgepole pine (*Pinus contorta* Dougl. ex Loud.) at various flame lengths. The ponderosa pine stand with historic structure suffers little mortality until flame lengths exceed 1.8 m. A similar species composition of smaller trees, similar to many second-growth pine-fir stands across the western United States, suffers higher mortality, but loss of basal area remains below 25% until flame lengths are 1.8 m or greater. If fuel treatments can reduce flame lengths under worst-case fire weather to 1.2 m or less, these forests will survive wildfire well. Restoration here will be ecologically effective at reducing wildfire damage.

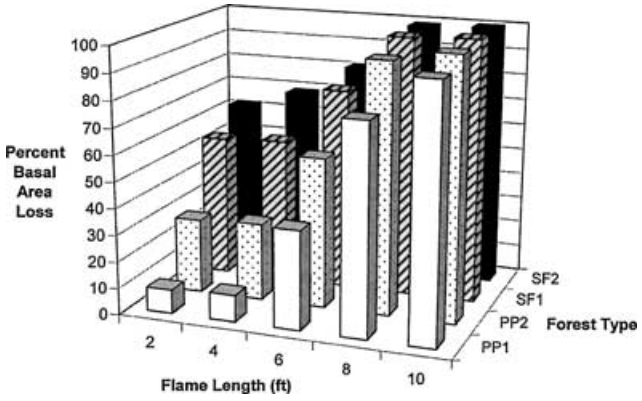

Figure 1. Percent loss of basal area by flame length for four classes of forest type or structure: PP1, historic mixed-conifer stand dominated by ponderosa pine with some Douglas-fir (density 15/ha, basal area 15 m^2/ha, trees 40–50 cm in diameter); PP2, same species composition and basal areas as PP1 but higher density (50/ha) and therefore smaller trees (15–25 cm in diameter); SF1, stand of subalpine fir and lodgepole pine with the exact structure characteristics of PP2, except these two species are substituted for ponderosa pine and Douglas-fir; SF2, stand of denser subalpine fir and lodgepole pine with 30 m^2/ha of basal area.

The high-elevation forest types have fewer fire-resistant species (Peterson & Ryan 1986), so the subalpine fir–lodgepole pine stand with the same structure as the second-growth ponderosa pine stand incurs about twice the loss of basal area, even at low flame lengths. Flame lengths of 1.8 m or higher create high-severity basal area losses of 70% or more. A typical natural stand structure in subalpine fir and lodgepole pine, with higher density and more small subalpine fir, incurs even greater losses. Investments in fire resistance by fuel treatment will be less effective in these higher-elevation stands.

Scale is an important parameter to consider in restoring fire-resistant forests. If fuel treatments are small and scattered, they may not be effective in fragmenting landscape fuel loads, and their efficacy at the stand level can be overwhelmed. On the 1994 Tyee fire in Washington, small treated areas of mixed-conifer forest underburned while adjacent untreated areas burned with crown fires. The heat created by the crown fires passed over the treated areas and scorched the tops of the trees that were later underburned. Many of these trees later died from the sandwiched scorch effect (J. K. Agee, personal observation). Empirical evidence from wildfires also supports the concept that areas treated with the goal of reducing fire hazard will burn with less severity than adjacent untreated areas (Omi & Martinson 2002). In the 2002 Hayman fire in Colorado, many areas where fuels had been treated before the fire experienced lower-severity effects than adjacent untreated areas (Finney et al. 2002*a*). Fuel treatment was not always successful in lowering severity, particularly during periods of incredibly severe fire weather (winds to 135 kph and fuel moistures of below 6% in all size classes). Under less severe conditions, fuel treatments appeared to alter severity, except where the treatments were carried out on a very small local scale or where they had been applied more than 10–15 years previously.

A Context of Place

Place is the most significant and most misunderstood element of the decision about where to carry out active restoration treatments. Some forest types are in critical need of active restoration, and others need no treatment at all. Recent national analyses suggest that the scale of needed restoration is immense, on the order of over 70 million acres (25 million ha), mostly in the West. Almost all of this area, designated condition class 3, occurs in low-severity fire regimes (Schmidt et al. 2002), and because of the coarse scale of the analysis, is generally not accurate or usable at the subregional scale. We suggest that more local classification such as the plant association (Daubenmire 1968) or plant association group, which is

an aggregation of closely allied plant associations within a forest series, has more utility at the fine scale.

Low-Severity Fire Regimes

Dry pine and mixed-conifer forest comprise most of the western low-severity fire regimes. Forests were typically shaped by what is sometimes referred to as a "stand-maintenance" fire regime of low-intensity, frequent fires that generally burned grasses, brush, small trees, and fallen needles and branches but had little effect on older trees with thick insulating bark. The death of lower branches from shading or the effects of fire raised the bottom of the canopy to the point where it was not adversely affected by typical fires. In extremely hot and dry weather, fires would tend to cover a larger area but still were unlikely to kill overstory trees (Agee 1997*b*). Although ponderosa pine is the most wide-spread forest species exhibiting these characteristics, similar dynamics pertained in areas where other fire-resistant species—Douglas-fir, Jeffrey pine (*Pinus jeffreyi* Grev. & Balf.), western larch (*Larix occidentalis* Nutt.), and many species of oak (*Quercus* spp.)—grow either in association with ponderosa pine or as dominants.

Although some areas still resemble historic conditions, it is these dry pine and mixed-conifer forests that typically have been changed the most by human activities in the last 150 years. Heavy livestock grazing depleted the fine fuels that carried the light, frequent fires and exposed mineral soil seedbeds for abundant young ponderosa pine that often became established before 1900 (Belsky & Blumenthal 1997; Miller & Rose 1999; Swetnam et al. 1999). Fire suppression beginning after 1910 allowed far more of these trees to persist, and logging concentrated on large, old trees (Biswell et al. 1973). These forests may have been deprived of 10 or more natural fire cycles. The result is forests that, as the result of continuing fire suppression, tend to burn less frequently, but when they do burn the fire is much more likely to reach the forest canopy and spread as a crown fire, killing many or all of the overstory trees. A historically low-severity fire regime has turned into a high-severity or mixed-severity fire regime over millions of hectares in the West (Morgan et al. 1996; Hann et al. 1997). These higher-severity fires are more apt to have detrimental effects on soils, watersheds, and wildlife habitat. And they can have serious consequences for humans who have settled in and around these forests.

Low-elevation pine and mixed-conifer forests offer the highest priorities for thinning—in conjunction with prescribed fire—to contribute to restoration of wildlife habitat while making forests more resistant to uncharacteristically severe fire (Miller & Urban 2000). Within these forests, priorities are to reduce surface and ladder fuels and raise the bottom of the live canopy (van Wagtendonk 1996; Agee et al. 2000). Thinning is most apt to be appropriate where understory trees are sufficiently large or dense that attempts to kill them with fire would run a high risk of also killing overstory trees (Christensen 1988; Arno et al. 1995; Fulé et al. 1997; Moore et al. 1999; Stephenson 1999). Using prescribed fire alone can be desirable in that it provides the full range of ecological effects of fire. Fire is an imprecise tool, however, whereas individual harvest can provide much more control over which trees are actually killed (Thomas & Agee 1986; Swezy & Agee 1991; Fiedler 1996; Sackett et al. 1996; Pollet & Omi 2002). The larger understory trees that are less likely to be safely thinned with fire are more apt to be large enough to have economic value if they are logged. This presents opportunities to defray expenses and provide employment and wood products, but it also creates economic pressure to cut larger trees. Even where understory trees can safely be thinned with fire, consideration needs to be given to potential smoke production and soil heating during subsequent burns that will be necessary to consume the dead understory trees once they fall to the ground (Agee 1997*a*; Sackett & Haase 1998).

Within the dry forest zone, high forest integrity will generally be associated with the presence of old-growth trees, especially ponderosa pine (Moir & Dieterich 1988; Wickman 1992; Covington & Moore 1994; Henjum et al. 1994; Brown et al. 1999; Kaufmann et al. 1999). Treatment of these areas could help secure the remnant intact stands from wildfire risks and extend more natural stand conditions across the landscape. Care should be taken, at the landscape scale, to retain some patches of young pine trees in an approximation of historic patterns (Allen et al. 2002).

Mid-seral ponderosa pine stands (roughly 60–100 years old) represent a secondary priority for restoration treatments. These stands are often developing old-growth characteristics but are usually too dense. Treatments to help maintain this trend can increase the probability that old-growth habitats are restored more quickly than they would be otherwise. Variable-density thinning mimics the clumped distribution and associated processes found in pre-1850 stands (Franklin et al. 1997; Harrod et al. 1999). Processes other than fire, particularly sources of mortality such as bark beetles, which are a key food source for woodpeckers and influence the subsequent decay of snags (Samman & Logan 2000; George & Zack 2001), should be provided for at the landscape level.

Reaching some desired future condition in one treatment, in contrast to a staged approach, is being debated (Covington 2000; Fulé et al. 2001, 2002; Allen et al. 2002). The debate is about the efficacy of treatment, how much of a landscape needs to be treated, and how to optimize fuel treatment in relation to other ecological objectives. One option is to rapidly emulate historic structure by retaining trees older than a particular year (1870 in the restoration of Fulé et al. 2001) and removing all others. Another is to combine that treatment with others using only minimal thinning or prescribed fire (Fulé et al. 2002).

Allen et al. (2002) argue that restoration should be aimed at resetting ecosystem trends toward an envelope of "natural variability." They caution that impatience, overreaction to risks of crown fire, extractive economics, or hubris could further damage ecosystems desperately in need of restoration.

Support for their call for caution is provided by data from the Grand Canyon provided by Fulé et al. (2002). They applied three treatments to ponderosa pine forest plus a control: a "full" restoration that removed all trees germinating after 1870 and applied fuel treatment, including prescribed burns; a "minimal" treatment that thinned small trees only around old-growth trees and applied the same fuel treatment as for the full treatment, and a "burn" treatment that used only prescribed fire. The most intrusive full treatment reduced crown-fire hazard the most. However, both the burn and control stands had crowning indices requiring windspeeds well above the 97th percentile wind recorded at the site over many years, and therefore crown fire was not a particularly severe threat. The scorch provided by the prescribed fire in the burn treatment reduced torching potential close to that achieved by the full treatment, so from a fire perspective alone a "full" restoration was not necessary at this site.

Mixed-Severity Fire Regimes

Mid-elevation moist forests of the western United States are more difficult to describe in general terms. Cooler, moister conditions allow less drought- and fire-tolerant species such as grand fir (*Abies grandis* [Dougl.] Lindl.), white fir (*Abies concolor* [Gord. & Glend.] Lindl.), Douglas-fir, western larch, and ponderosa pine to grow more densely in these areas. In some areas these sites support ponderosa pine–dominated stands that appear similar to the drier forests at lower elevations, although their fire histories may be more complex and variable over long time periods (Shinneman & Baker 1997; Brown et al. 1999; Veblen et al. 2000). Fire-return intervals of 40–80 years included areas burned from low to high severity, a "mixed-severity" fire regime. Fires of differing severity can occur in close proximity, creating a complex mosaic of forest structures in patches of varying size (Taylor & Skinner 1998). Fire suppression has generally been effective for one to four fire cycles and has allowed the development of denser, multistoried forests on more of the landscape. Although the fire regime can still be described as mixed, the relative proportion of fire types has shifted, and severe fires are more likely to occur on more of the landscape than they would have historically (Agee 1998; Agee 2002).

The mixed-severity fire regimes are less clearly candidates for thinning and/or fire restoration. Changes following decades of fire exclusion will often mean that reintroduction of prescribed fire without thinning will be problematic (Agee & Huff 1986). Past management practices may have led to development of old-growth stands with "unnatural" multiple canopy layers or accumulations of snags and logs, but these areas may provide key habitat that compensates for the loss and degradation of these habitat elements elsewhere (ICBEMP 2000; Wisdom et al. 2000). It may often be appropriate to attempt to secure such habitats from wildfire by treating adjacent areas (Agee 1996, 1998). Attention should be given to protecting large and old trees (Henjum et al. 1994; Allen et al. 2002). Large fir trees, especially those with heartwood decay, provide important habitat for many species (Bull et al. 1992, 1997; Bull & Hohman 1993), and efforts to "cleanse" the landscape of true firs should be avoided. Strategic location of fuel treatments may slow the spread of fire across the landscape (Agee 1999; Finney 2001; Finney et al. 2002*b*), but this concept has been explored only in computer models and needs refinement before being extensively applied. All in all, these complexities appear to recommend a cautious approach to restoration efforts in mixed-severity fire regimes.

High-Severity Fire Regimes

Wet and cold forests have historic fire-return intervals that typically exceed several centuries. In coastal areas, forests of Sitka spruce (*Picea sitchensis* [Bong.] Carr.) may show evidence of a single fire per millennium (Fahnestock & Agee 1983), whereas widespread western hemlock (*Tsuga heterophylla* [Raf.] Sarg.)–Douglas-fir forests had typical fire-return intervals exceeding 200 years (Agee 1993). At higher elevations, forests of subalpine fir, Engelmann spruce (*Picea englemannii* Parry ex Engelm.), mountain hemlock (*Tsuga mertensiana* [Bong.] Carr.), and lodgepole or whitebark pine (*Pinus albicaulis* Engelm.) predominate. These forests also have long fire-return intervals and contain a high proportion of fire-sensitive trees (Fig. 1). At periods averaging a few hundred years, extreme drought conditions would prime these forests for large, severe fires that would tend to set the forest back to an early successional stage, with a large carry-over of dead trees as a legacy of snags and logs in the regenerating forest. Young forests growing within a matrix of unsalvaged snags and logs may be the most depleted forest habitat type in regional landscapes, particularly at low elevations (Lindenmayer & Franklin 2002).

The fire regime for these forests can be described as "weather-dominated" in that high fuel loads are typical and the fire events that determine forest patterns occur under uncommon, extreme weather conditions that can result in stand-replacing fires over large areas (Agee 1997*b*). Although logging and road building have had some detrimental effects on these forests, natural ecological dynamics are largely preserved because fire suppression has been effective for less than one natural fire cycle. Thinning for restoration does not appear to be appropriate in these forests (Agee & Huff 1986). Efforts to

manipulate stand structures to reduce fire hazard will not only be of limited effectiveness (Fig. 1; Agee 1996, 1998) but may also move systems away from pre-1850 conditions to the detriment of wildlife and watersheds (Johnson et al. 1995; Weatherspoon 1996). Fuel levels may suggest a high fire "hazard" under conventional assessments, but wildfire risk is typically low in these settings.

Using Place to Set Priorities

Prioritizing restoration efforts is essential because resources are limited. An initial focus on areas most likely to provide benefits and that present a low risk of degradation of ecological values will build experience and credibility. Strategies for conserving both aquatic and terrestrial resources at multiple scales are based on similar principles: secure areas with high ecological integrity ("anchor habitats"), extend these areas, and connect them at the landscape level (Lee et al. 1997; Gresswell 1999). An approach that considers the condition of a watershed and its associated forests and the status of aquatic populations (Rieman et al. 2000) appears to offer the best prospects for balancing potentially competing objectives (Bisson et al. 2003). Restoration treatments should initially focus on uplands (Johnson et al. 1995; Gregory 1997; Lee et al. 1997). Carefully applied prescribed fire may be the most appropriate treatment in riparian areas that historically burned frequently (Kauffman et al. 1997; Agee 1999; Everett et al. 2003).

Although the principles of fire-safe forest can be applied to any forest, they will be most effective when applied to those that are at risk of uncharacteristically severe wildfire and those that are composed of species that develop fire resistance, primarily with thick bark. At least two scales of priority are likely to exist. At a coarse scale, historically low-severity fire regimes will receive highest priority, mixed-severity fire regimes will have moderate priority, and high-severity fire regimes will have low priority. High priority would be assigned, for example, to the ponderosa pine series, the Douglas-fir dry plant association group (PAG), and the grand fir dry PAG. Moderate priority would be assigned to Douglas-fir and grand fir wet PAGs and to the red fir (*Abies magnifica* Murr.) series. Low priority would be assigned to the Sitka spruce series, western hemlock series, Pacific silver fir (*Abies amabilis* [Dougl.] Forbes) series, mountain hemlock series, and subalpine fir series, unless unusual situations exist in which local treatment was needed. A second scale of priority can be defined within the low-severity fire regimes. Some of the more productive forests with a low-severity fire regime in the grand fir, Douglas-fir, and white fir series have experienced more substantial ecological change (Agee 2003) than drier sites in the ponderosa pine and Douglas-fir series. The accumulated biomass in these systems and their abnormally high tree density and wildfire potential argue for a higher priority for restoration within the low-severity fire regimes. Although treatment costs may be high, these sites also have high potential to offset costs through commercial use of thinned trees.

Conclusions

Action must be taken to reverse trends of ecosystem degradation due to past forest management. Thinning and fire will play a role in these restoration efforts, but both techniques will be controversial. Because thinning is a form of logging and prescribed fire can produce excessive smoke and can escape, these tools need to be strategically applied in ways and locations that will give them the highest prospects for success and the lowest likelihood of unintended consequences. Some areas need no treatment at all. Other areas needing treatment will have to be triaged because of limited resources. Based on current knowledge (adapted from Brown 2000; Allen et al. 2002), it appears that the most credible restoration efforts will

- place highest priority on historically low-severity fire regimes, with secondary priority on mixed-severity fire regimes, and lowest priority on high-severity fire regimes;
- be based on the ecology of the species and site, with presettlement conditions as a sustainable reference, recognizing different goals for a wide variety of landowners;
- be site-specific and consider the landscape context, including watershed conditions and fish and wildlife habitat;
- consider a range of restoration steps, rather than attempt complete restoration with a single treatment everywhere;
- maintain the most fire-resistant, large-tree component of the forest in active-management schemes;
- consider mechanical thinning and prescribed fire as acceptable tools, but in all cases apply fire-safe principles (Table 1);
- where thinning is used, apply minimal-impact harvesting techniques, and focus first on areas where road systems are largely complete; and
- make a commitment to long-term monitoring and adaptive management so that we learn by doing.

Abstract. Forest carbon sequestration via forest preservation can be a viable climate change mitigation strategy. Here, we identify forests in the western conterminous United States with high potential carbon sequestration and low vulnerability to future drought and fire, as simulated using the Community Land Model and two high carbon emission scenario (RCP 8.5) climate models. High-productivity, low-vulnerability forests have the potential to sequester up to 5,450 Tg CO_2 equivalent (1,485 Tg C) by 2099, which is up to 20% of the global mitigation potential previously identified for all temperate and boreal forests, or up to ~6 yr of current regional fossil fuel emissions. Additionally, these forests currently have high above- and belowground carbon density, high tree species richness, and a high proportion of critical habitat for endangered vertebrate species, indicating a strong potential to support biodiversity into the future and promote ecosystem resilience to climate change. We stress that some forest lands have low carbon sequestration potential but high biodiversity, underscoring the need to consider multiple criteria when designing a land preservation portfolio. Our work demonstrates how process models and ecological criteria can be used to prioritize landscape preservation for mitigating greenhouse gas emissions and preserving biodiversity in a rapidly changing climate.

Key words: biodiversity; carbon sequestration; climate change; Community Land Model (CLM); forest; mitigation; process modeling; western United States.

Introduction

Since the signing of the United Nations Framework Convention on Climate Change in Rio de Janeiro in 1992, the United Nations has recognized the need to formulate a global response to increasing greenhouse gas concentrations in our atmosphere. The subsequent adoptions of the Sustainable Development Goals (United Nations General Assembly 2015) and the Paris Agreement (United Nations Framework Convention on Climate Change (UNFCC) 2015) provided global targets for preserving biodiversity and limiting the negative effects of increasing greenhouse gas concentrations. Limiting global temperature to 1.5°C above the preindustrial average would limit negative climate impacts (IPCC 2018), including negative effects on biodiversity (Smith et al. 2018). Unfortunately, substantial enhancement or over-delivery of emissions goals in the Paris Agreement is necessary to limit warming to less than 2°C (Rogelj et al. 2016). Missing this target could destabilize Earth's climate, terrestrial, and aquatic systems (Steffen et al. 2018) with catastrophic consequences for biodiversity (Davis et al. 2018), ecosystem services, and humans (Barnosky et al. 2012). Already, ample observational evidence exists that changes in climate are inducing ecosystem transformations through tree mortality (Allen et al. 2010, Millar and Stephenson 2015) and changes in species composition (Allen and Breshears 1998, Millar and Stephenson 2015). Process-based (Settele et al. 2014, McDowell et al. 2016) and statistical (Rehfeldt et al. 2006, Williams et al. 2007, Pearson et al. 2013) models indicate a strong potential for continued ecological transformation, and paleological analyses indicate that, if we continue on our current emission trajectory, drastic changes in global ecosystem structure and function are likely by the end of this century (Nolan et al. 2018*a*).

Along with emissions, multiple biogeophysical processes, including carbon uptake by the land and oceans and ocean heat exchange (Solomon et al. 2009), influence atmospheric CO_2 (Canadell et al. 2007, Le Quere et al. 2018) and the integrated Earth system trajectory (Barnosky et al. 2012, Steffen et al. 2018). Recent measurements indicate the ocean heat uptake is at the high end of previous estimates (Resplandy et al. 2018), and decreasing land carbon uptake relative to carbon emissions (Canadell et al. 2007) is contributing to increasing atmospheric CO_2 and chances of climate destabilization (Barnosky et al. 2012, Steffen et al. 2018). Land preservation and timber harvest management (natural climate

solutions) are viable options for avoiding greenhouse gas emissions and increasing the magnitude of the land carbon sink (Griscom et al. 2017).

Forest management (e.g., land preservation, reduced harvest) can contribute to climate change mitigation and the preservation of biodiversity (MEA 2005). Globally, improvements to land management could provide an estimated 37% of the mitigation needed to stabilize warming below 2°C by 2039 (Griscom et al. 2017). Land management can also mitigate the negative effects that climate-induced ecosystem transformations have on biodiversity and watersheds, which influence ecosystem services that contribute to human well-being (Canadell and Raupach 2008, Griscom et al. 2017). The effects of land-use change vary globally (Bright et al. 2017), therefore regional analyses (Cameron et al. 2017, Law et al. 2018) are ideal for prioritizing lands for preservation and improving harvest management.

Here, we simulate potential forest carbon sequestration in the western United States, prioritize forest lands for preservation (i.e., no harvest) based on potential carbon sequestration and vulnerability to drought or fire, and compare this carbon priority ranking with measures of biodiversity to illustrate the spatial synergies and incongruities between these two preservation metrics. We use the Community Land Model 4.5 (CLM) to simulate future forest productivity and vulnerability to drought and fire. We prioritize land based on the spatial convergence of low future vulnerability to natural disturbance and three levels of potential productivity and determine the CO_2 mitigation potential that preserving medium- and high-priority forests could provide. We show the co-benefits and trade-offs to biodiversity preservation and ecosystem resilience by comparing current observations of aboveground carbon (Wilson et al. 2013), soil carbon (Weider et al. 2014), and species richness (Jenkins et al. 2015, USGS National Gap Analysis Program 2018) across the three forest carbon preservation priority categories. We use these combined analyses to underscore the need to consider multiple criteria when selecting forest lands for preservation.

Materials and Methods

Simulations of future forest vulnerability and potential carbon sequestration

We used the Community Land Model, version 4.5 (CLM; Oleson et al. 2013) to simulate the forest carbon cycle across the western United States (Appendix S1: Fig. S1) at a 4 × 4 km spatial resolution. The CLM is the land surface model within the Community Earth System Model (Hurrell et al. 2013). The CLM has prognostic carbon and nitrogen cycles and calculates multiple biogeochemical and biophysical process, such as photosynthesis, autotrophic and heterotrophic respiration, carbon allocation to plant tissues, decomposition, and surface energy balance. It also has a fire module that predicts area burned under future climate and biomass fuel conditions. Here, we used climate projections, described below, prescribed vegetation type (Appendix S1: Fig. S1), and prescribed soil type to drive the model. We employed several modifications that improved the CLM's simulation of aboveground carbon, net primary productivity, and ecosystem respiration across the western United States (Buotte et al. 2019b). In particular, these include specification of physiological parameters controlling photosynthesis for the dominant species in the major forest types (Appendix S1: Fig. S1) of the western United States (Berner and Law 2016, Law et al. 2018, Buotte et al. 2019b), enhanced drought sensitivity through species-specific stomatal response to soil moisture and leaf shedding during periods of drought stress (Buotte et al. 2019b), and improved fire simulation by incorporating regional ignition probabilities and fuel load constraints (Buotte et al. 2019b).

The CLM was started from bare ground and run with 1901–1920 climate data and prognostic fire turned off until soil carbon pools reached equilibrium. Improvements to the representation of drought stress and prognostic fire were implemented beginning in 1901. From 1901 to 1978, we forced CLM with CRUNCEP climate data (Mitchell and Jones 2005) statistically downscaled to 4 × 4 km and bias-corrected to our 1979–2014 climate data. Climate data from 1979 to 2014 were disaggregated from daily to 3-h intervals at 4 × 4 km resolution (Abatzoglou 2013). Downscaling and disaggregation details are provided in Buotte et al. (2019b). Furthermore, we used prescribed harvest to insure the model represented present-day stand ages (Pan et al. 2011).

It is crucial to assess model performance and thus we previously evaluated the modeled present-day carbon stocks, carbon fluxes, and burned area through comparisons with a suite of field and satellite observations (Buotte et al. 2019*a*,*b*). In particular, we compared modeled carbon stocks and fluxes with aboveground biomass interpolated from plot inventories (Wilson et al. 2013), carbon fluxes from five AmeriFlux sites, fluxes derived from plot inventories in Washington, Oregon, and California (Hudiburg et al. 2009, 2011), and net primary productivity estimated from the MODIS satellites (Berner et al. 2017*a*). We also compared modeled burned area with a burned area data set derived from the Landsat satellites (Eldenshenk et al. 2007). As detailed in Buotte et al. (2019b), simulated carbon fluxes agreed well with a variety of observations. Simulated net primary productivity was within the range of observed and satellite-derived net primary productivity at the state level. Across all forests in the western United States, simulated aboveground carbon was within one standard deviation of observation-based aboveground carbon (observed mean = 30.5 Mg C/ha, SD = 39.7 Mg C/ha, CLM mean = 59.1 Mg C/ha, SD = 45.5 Mg C/h, $R^2 = 0.80$). When grouped by forest type, simulated aboveground carbon was highly correlated with

19395582, 2020, 2, Downloaded from https://esajournals.onlinelibrary.wiley.com/doi/10.1002/eap.2039, Wiley Online Library on [01/12/2022]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

observations with a tendency toward higher simulated values ($R^2 = 0.84$, mean bias error = 4%). Over the forested domain, simulated area burned was highly correlated with observed area burned ($R^2 = 0.75$), with a 28.6% overestimate when compared with observations from the Monitoring Trends in Burn Severity (MTBS) database over 1984–2012 (Eldenshenk et al. 2007). However, Whittier and Gray (2016) determined that MTBS underestimates burn area by 20% when compared with inventory data, which implies CLM overestimates may be as low as 8%. These assessments illustrate that the model is accurately simulating important aspects of the current regional forest carbon cycle.

Our future CLM simulations were driven with two future climate projections. We used a Representative Concentration Pathway (RCP) 8.5 carbon dioxide emissions scenario for our future simulations because it best represents our current trajectory (Peters et al. 2013). We chose general circulation models (GCMs) based on data availability, representation of historical climate, and coverage of the range of projected future climate (Buotte et al. 2019b). We selected IPSL-CM5A-MR, which projects warm and dry future conditions, and MIROC5, which is close to the multi-model average for future temperature and precipitation across the western United States (Buotte et al. 2019b). Climate projections for 2015–2099 were downscaled, bias-corrected to the 1979–2014 climate observation data (Abatzoglou 2013), and disaggregated to a 3-h timescale. Downscaling and disaggregation details are provided in Buotte et al. (2019b).

The number of years with low annual allocation to stem growth and/or annual net primary productivity of 0 were used to determine forest vulnerability to drought stress (Buotte et al. 2019b). For each decade, we defined low vulnerability in grid cells with 0 yr of NPP = 0 and low allocation to growth, medium vulnerability in grid cells with 1 yr with NPP = 0 and/or 1–3 yr with low allocation to growth, and high vulnerability in grid cells with more than 1 yr with NPP = 0 and/or more than 3 yr with no allocation to growth (Buotte et al. 2019b). Grid cells were ranked with low, medium, or high vulnerability for both IPSL_CM5A-MR and MIROC5 forced simulations. For every grid cell, we calculated vulnerability to fire based on the increase in simulated area burned in the future compared with the past, weighted by the simulated area burned in the past (Buotte et al. 2019b). Final drought and fire vulnerability rankings included uncertainty due to climate projections by incorporating the drought and fire vulnerability ranking from simulations using each of the two climate projections, such that (1) uncertain, one GCM simulation ranked as low and one simulation ranked as high; (2) low, both GCMs low; (3) med-low, one low and one medium; (4) medium, both GCMs medium; (5) med-high, one medium and one high; (6) high, both GCMs high.

Further details on vulnerability calculation and assessment relative to observed mortality are provided in Buotte et al. (2019b).

We determined potential carbon sequestration (Keith et al. 2009*a*) by running CLM with no prescribed harvest beyond 2014 and summing net ecosystem productivity (NEP) from 2020 to 2099, thereby allowing forest type, soil properties, climate, and CO_2 concentrations to determine productivity. We pooled cumulative NEP across all grid cells and defined three categories of potential carbon sequestration based on the highest one-third ($>1.12 \times 10^5$ g /m^2), middle one-third, and lowest one- third ($<3.27 \times 10^4$ g C/m^2) of the distribution. We then ranked forested areas to identify low, medium, and high carbon preservation priority based on the spatial coincidence of low future vulnerability to drought and fire and potential carbon sequestration (Appendix S1: Fig. S2). Forests with low vulnerability to future drought and fire and the highest potential carbon sequestration were ranked as high priority for preservation as carbon preserves; low vulnerability and medium carbon sequestration potential were ranked as medium priority; all other combinations were ranked as low priority. Hereafter we refer to forest priority for preservation as carbon preserves as "carbon priority."

Tree mortality from bark beetles

Tree mortality from bark beetle attack is an important disturbance in western U.S. forests, but not currently incorporated into CLM. We therefore addressed the potential for future beetle mortality by assessing recent historical beetle mortality (Berner et al. 2017b) and existing future projections of climate suitability for beetle outbreaks (Bentz et al. 2010, Buotte et al. 2017) across our three forest carbon priority rankings.

Above- and belowground carbon stocks

We assessed observation-based estimates of carbon stocks (i.e., not our simulated carbon stocks) across forests in each carbon priority ranking. We used the Regridded Harmonized World Soil Database V1.2 (Weider et al. 2014) for belowground carbon stocks, and a gridded data set of aboveground carbon stocks based on field measurements and remote sensing (Wilson et al. 2013).

Species richness and critical habitat

We examined several aspects of biodiversity across forests with low, medium, and high carbon preservation priority. We acquired published tree species richness maps for the United States (Jenkins et al. 2015), species habitat maps for terrestrial vertebrates (amphibians, reptiles, birds, and mammals) from the U.S. Geological Survey Gap Analysis Program (USGS National Gap Analysis Program 2018), and species habitat maps identifying critical habitat by the U.S. Fish and Wildlife Service (U.S. Fish and Wildlife Service 2018). Each map was resampled to the 4×4 km CLM grid. We

19395582, 2020, 2, Downloaded from https://esajournals.onlinelibrary.wiley.com/doi/10.1002/eap.2039, Wiley Online Library on [01/12/2022]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

computed terrestrial vertebrate species richness by taxa and across taxa for each grid cell. We also identified whether a terrestrial vertebrate species was listed as threatened or endangered (T&E) by the U.S. Fish and Wildlife Service and then reassessed species richness for this subset of species. Last, we summarized these aspects of species richness and critical habitat by forest carbon priority rank.

Results

High-priority forest distribution and contribution to emissions mitigation

The high-carbon-priority forests are primarily along the Pacific coast and the Cascade Mountains, with scattered occurrences in the northern Rocky Mountains of Idaho and Montana (Fig. 1). Forests with medium carbon priority are more widely scattered throughout the western United States (Fig. 1).

High-carbon-priority forests cover 132,016 km^2 or 10.3% of the forested domain and have the potential to sequester 4,815–5,450 Tg CO_2 equivalent (Tg CO_2 e; 1,312–1,485 Tg C) in aboveground carbon between 2020 and 2099 (Fig. 1, Table 1, Appendix S1: Table S1). Medium-carbon-priority forests cover 9.5% of the forested domain and could sequester 1,842–2,136 Tg CO_2 e (502–582 Tg C). Low-carbon-priority forests cover 80.2% of the forested domain and could sequester 12,789–16,533 Tg CO_2 e (3,485–4,505 Tg C) by 2099. However, because the low-carbon-priority forests have higher future vulnerability, their carbon sequestration potential is less certain.

Co-benefits of preserving high-carbon-priority forests

The forests we identified with the greatest potential to sequester carbon during this century provide multiple ecological co-benefits. Recent tree mortality from bark beetle attack was the lowest in these high-carbon-priority forests (Appendix S1: Fig. S3). These forests have the highest average present-day soil carbon stocks (14% higher than medium and 65% higher than low carbon priority) and aboveground carbon stocks (41% higher than medium and 248% higher than low carbon priority; Fig. 2), and also currently support the highest tree species richness (Fig. 3). Furthermore, high-carbon-priority forests contain the highest proportional area of terrestrial vertebrate habitat for species listed as threatened or endangered by the U.S. Fish and Wildlife Service (Fig. 4), as well as the highest proportion of habitat designated as critical for threatened or endangered species survival (Fig. 4). There is less distinction in terrestrial vertebrate species richness by carbon priority rank, though high-carbon-priority forests tend to have higher amphibian and lower reptilian richness than forests with medium or low carbon priority ranks (Appendix S1: Fig. S4). It is important to highlight that the spatial

TABLE 1. Area, percentage of forested domain, and carbon sequestration potential during 2020–2099 (calculated as the sum of annual net ecosystem production, with business-as-usual harvest amounts) in each priority category.

Priority ranking	Area (km^2)	Forested domain (%)	Carbon sequestration potential during 2020–2099 (Tg CO_2e)†	Carbon sequestration potential during 2020–2099 (Tg C/km^2)
High	132,016	10.3	4,815–5,450 (1,312–1,485 Tg C)	0.036–0.041
Medium	120,800	9.5	1,842–2,136 (502–582 Tg C)	0.015–0.018
Low	1,023,872	80.2	12,789–16,533 (3,485–4,505 Tg C)	0.012–0.016

† Tg CO_2 equivalent. Values in parentheses are Tg CO_2.

distribution of species richness (Appendix S1: Fig. S5) indicates some areas of exceptionally high species richness (e.g., the Klamath region in southern Oregon and northern California) have a low carbon priority ranking due to medium to high future vulnerability, particularly to fire, or low forest productivity. Summaries of species richness and habitat area by state are provided in Appendix S1: Figs. S6 and S7.

Discussion

Hotter and drier conditions are expected to increase future tree mortality from drought (Allen et al. 2010, McDowell et al. 2016) and fire (Spracklen et al. 2009, Pechony and Shindell 2010) in parts of the western United States, thus preserving forests with the lowest vulnerability to future disturbance is one intuitive component of a land preservation strategy. Forest preservation offers a cost-effective strategy to avoid and mitigate CO_2 emissions by increasing the magnitude of the terrestrial carbon sink in trees and soil, preserve biodiversity, and sustain additional ecosystem services (Griscom et al. 2017). We show considerable potential for forests in the western United States to sequester additional carbon over the coming century and demonstrate that protecting high-carbon-priority areas could help preserve components of biodiversity. However, we also find high biodiversity in some areas with low future carbon sequestration potential due to slow growth or high vulnerability to fire. We therefore suggest that developing area-based retention targets (Maron et al. 2018) for both carbon and biodiversity metrics, along with the consideration of land ownership (Krankina et al. 2014), would allow the development of a portfolio of preserves to meet these criteria.

Preserving high-carbon-priority forests avoids future CO_2 emissions from harvesting and mitigates existing emissions through carbon sequestration. Regional fossil fuel emissions averaged ~260 Tg C/yr from 2003 to 2012 according to the U.S. Energy Information Administration (2015). Preserving the high-carbon-priority forests in the western United States would account for approximately 6 yr of regional fossil fuel emissions, or 18–20% of the global mitigation potential of natural forest management solutions Griscom et al. (2017) identified for the combination of temperate and boreal forests by 2099. This would increase to almost 8 yr of regional emissions, or 27–32% of temperate and boreal forest mitigation potential, if preservation was expanded to include medium-carbon-priority forests. Carbon dioxide emissions from soils in degraded forests account for roughly 11% of global net emissions (Houghton and Nassikas 2017). As the high-carbon-priority forests have the highest soil carbon, preserving these forests avoids

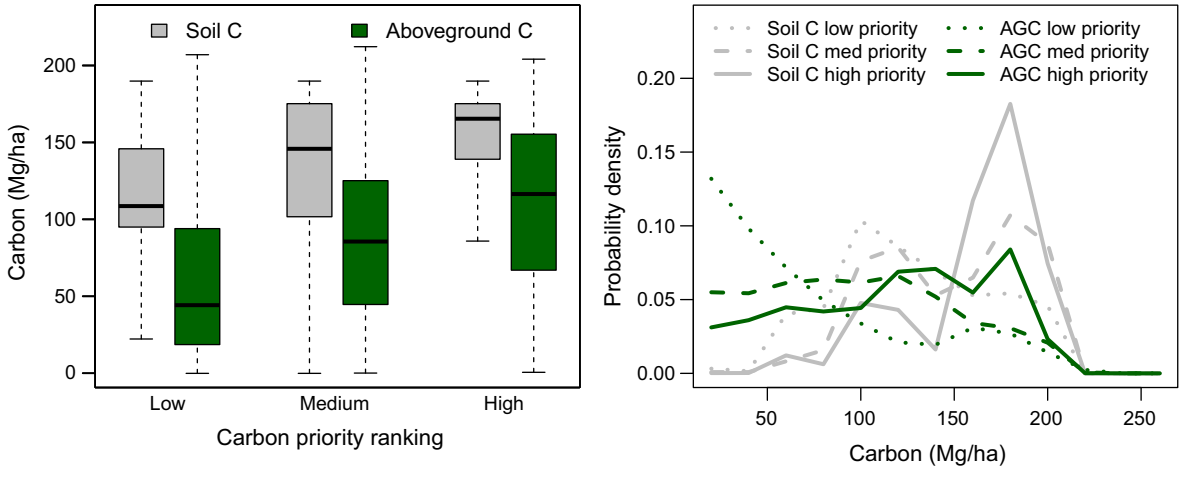

FIG. 2. Conterminous western U.S. forests ranked with the highest priority for preservation for carbon sequestration also have the highest current soil and aboveground carbon stocks. Carbon stocks from gridded measurements interpolated from observations (see *Materials and Methods*). Box plot components are mid line, median; box edges, first and third quartiles; and whiskers, max and min.

additional CO_2 emissions from the soil as surface litter and root material decay after harvest.

We found that high-carbon-priority forests in the western United States exhibit features of older, intact forests with high structural diversity (Keith et al. 2009b, Krankina et al. 2014), including carbon density and tree species richness. Forest resilience and adaptive capacity increase with increasing plant species richness (Morin et al. 2018, Watson et al. 2018), suggesting that preserving the high-carbon-priority forests would provide an added buffer against potential ecosystem transformation to future climate change.

Intact forests are particularly important for watershed protection by regulating soil permeability, overland flow, and erosion (DellaSala et al. 2011, Creed et al. 2016, Moomaw et al. 2019). Across the United States, National Forests are the largest source of drinking water (Furniss et al. 2010). In the Pacific Northwest, conversion of old-growth forests to plantations reduced summer stream flow by an average of 50% (Perry and Jones 2017). Preserving intact forests would provide the greatest benefit to watershed protection and clean water supply (DellaSala et al. 2011). Unfortunately, the area of forest interior (defined as forest area per land area) is declining faster than the total area of forest in the United States (Riitters and Wickham 2012). Remaining primary and intact forests need to be identified and incorporated in land management policies.

Recent studies have found positive relationships between carbon density and biodiversity across multiple biomes (Brandt et al. 2014, Lecina-Diaz et al. 2018), but also weak relationships at the stand scale (Sabatini et al.

19395582, 2020, 2, Downloaded from https://esajournals.onlinelibrary.wiley.com/doi/10.1002/eap.2039, Wiley Online Library on [01/12/2022]. 2019). We show that preserving forests in the western United States with high productivity and low vulnerability to future fire and drought can aid in the maintenance of vertebrate biodiversity, as these forests contain the highest proportion of critical habitat for threatened and endangered species. Because extinction rates are expected to increase with projected climate change (Segan et al. 2016), preserving critical habitat is an important consideration for maintaining biodiversity. Our analysis also shows that benefits to biodiversity depend in part on the biodiversity metric. For example, we found amphibian richness was the highest in forests we identified with high carbon priority, likely because these forests occur most often in the moist maritime climate suitable to amphibians. On the other hand, these wet, high-carbon-priority forests tend to have lower reptile diversity than low-carbon-priority forests, such as those in the Southwest where reptile diversity was highest. We show that spatial overlap in measures of biodiversity and potential carbon sequestration occurs such that land management policies can optimize both priorities. However, we also demonstrate that areas of high biodiversity are found in medium to low-carbon-priority forests. Therefore, sound land preservation strategies need to include multiple priority metrics (Brandt et al. 2014).

Indeed, preservation of carbon-dense primary (Mackey et al. 2015) and intact forests (Watson et al. 2018) is a critical but insufficient criterion for maintaining biodiversity. Secondary forests can support high biodiversity (Donato et al. 2009, Gilroy et al. 2014), as well as different species assemblages compared with primary forests (Ferreira et al. 2018). There are regions identified as globally significant centers of biodiversity (Olson et al. 2012; e.g., the Klamath-Siskiyou region in southwest Oregon) that we identified with medium to high future vulnerability due to fire. Therefore, when protecting biodiversity is a high conservation priority, disturbance-prone forests will need to be included in area-based targets (Maron et al. 2018). Regional assessments (Dass et al. 2018) that simulate vegetation transformation on multi-decadal timescales are needed to elucidate the effect of future disturbance regimes on plant community composition in order to assess potential future biodiversity and determine preservation priority rankings of disturbance-prone forests.

Because secondary forests also arise from a legacy of human intervention, conservation of managed landscapes will be an important component of policies to maintain biodiversity and enhance climate mitigation (Kremen and Merenlender 2018). Regional analyses have shown that lengthening harvest cycles can substantially improve carbon sequestration (Law et al. 2018) and biodiversity (Gilroy et al. 2014) and therefore provide pathways for additional climate mitigation (Griscom et al. 2017). Historical stand structure analysis indicates young trees may have played an important role in buffering against particular types of disturbance (Baker and Williams 2015). However, because young trees can be more vulnerable to drought stress than mature trees (Irvine et al. 2002), assessments of future climate vulnerability of young forests will be a critical factor when evaluating harvest strategies (Nolan et al. 2018b). Regional dynamic vegetation simulations with explicit treatment of forest regeneration are necessary to assess the effects of land management scenarios and develop strategies for managed lands.

Assessing the potential for future forest carbon sequestration has inherent uncertainties concerning realized future climate, forest growth, and sources of forest mortality. We address uncertainties in future climate by using two climate scenarios that span a wide range of variability in temperature and precipitation (Buotte et al. 2019b), though we acknowledge that future climate remains uncertain due to the trajectory of carbon emissions, climate sensitivity to these emissions, and climate feedbacks (Collins et al. 2014, Schuur et al. 2015). Furthermore, simulated forest growth depends on how the model was parameterized (White et al. 2000). Here, we used parameterizations developed specifically for forest types in the western United States (Hudiburg et al. 2013, Law et al. 2018, Buotte et al. 2019b), which improved model agreement with historical observations as compared with more general forest type parameterizations (Buotte et al. 2019b). In response to increasing CO_2 concentration, trees may increase their water use efficiency (Keenan et al. 2013, Schimel et al. 2015), however, this response may depend on nutrient availability (Oren et al. 2001, Norby et al. 2010). The CLM incorporates nitrogen limitation (Oleson et al. 2013), which allows the CLM to accurately simulate recent changes in NPP observed under increasing CO_2 concentrations (Smith et al. 2016).

Mountain pine beetles (*Dendroctonus ponderosae*) were responsible for the majority of tree mortality from beetles in the recent past (Meddens et al. 2012). Previous analysis (Buotte et al. 2019b) indicates our drought metric identifies forests vulnerable to beetle attack due to the presence of drought-stressed trees (Boone et al. 2011), increasing our confidence in our vulnerability metric's ability to capture this important disturbance agent. Importantly, future projections of beetle population dynamics (Bentz et al. 2010) do not indicate increasing beetle populations in areas we define with high carbon priority. Climate suitability for tree mortality from mountain pine beetles is projected to increase in some high-elevation whitebark pine forests (Buotte et al. 2017), which we ranked with low carbon priority due to lower carbon sequestration potential, or medium to high vulnerability to future drought or fire. Predictive models of beetle population dynamics for multiple beetle species, that include host tree status when appropriate, would increase our ability to incorporate specific spatial representation of future forest vulnerability to beetle attack. We simulated future fire, but the model does not capture the potential for anomalous mega-fires.

Therefore, our estimates of future carbon sequestration potential in the absence of large-scale mortality events are likely to be robust.

Preservation of high carbon density Pacific Northwest forests that are also economically valuable for timber production will have costs and benefits to consider, including socioenvironmental benefits, the feasibility of preservation, and opportunity costs harvest. There is tremendous potential for proforestation, growing existing forests intact to their ecological potential, which is an effective, immediate, and low-cost approach to removing carbon dioxide from the atmosphere (Moomaw et al. 2019). Proforestation serves the greatest public good by maximizing co-benefits such as biological carbon sequestration and unparalleled ecosystem services including biodiversity enhancement, water and air quality, flood and erosion control, and low impact recreation. The development of governance programs to promote forest preservation will be critical. Our study is a first step at identifying areas with the highest potential for natural co-benefits and proforestation.

Conclusions

If we are to avert our current trajectory toward massive global change, we need to make land stewardship a higher societal priority (Chan et al. 2016). Preserving temperate forests in the western United States that have medium to high potential carbon sequestration and low future climate vulnerability could account for approximately 8 yr of regional fossil fuel emissions, or 27–32% of the global mitigation potential previously identified for temperate and boreal forests, while also promoting ecosystem resilience and the maintenance of biodiversity. Biodiversity metrics also need to be included when selecting preserves to ensure species-rich habitats that result from frequent disturbance regimes are not overlooked. The future impacts of climate change, and related pressures as human population exponentially expands, make it essential to evaluate conservation and management options on multi-decadal timescales, with the shared goals of mitigating committed CO_2 emissions, reducing future emissions, and preserving plant and animal diversity to limit ecosystem transformation and permanent losses of species.

Acknowledgments

This research was supported by the Agriculture and Food Research Initiative of the U.S. Department of Agriculture National Institute of Food and Agriculture (Grants 2013-67003-20652, 2014-67003-22065, and 2014-35100-22066) for our North American Carbon Program studies, "Carbon cycle dynamics within Oregon's urban-suburban-forested-agricultural landscapes" and "Forest die-off, climate change, and human intervention in western North America," (and the U.S. Department of Energy (Grant DE-SC0012194). High-performance computing resources to run CLM on Cheyenne (https://doi.org/10.5065/d6rx99hx) were provided by NCAR's Computational and Information Systems Laboratory, sponsored by the National Science Foundation.

In My Opinion: Managing habitat for dispersing northern spotted owls—are the current management strategies adequate?

Joseph B. Buchanan

When the northern spotted owl (*Strix occidentalis caurina*) was listed under the Endangered Species Act (ESA) as threatened in 1990, a number of challenges immediately became apparent. One of the first to surface was the need to develop definitions of suitable habitat that could be used in the regulatory environment. Consequently, in the early years following ESA listing, much attention was directed at defining habitats that spotted owls used for nesting, roosting, or foraging. The emphasis of research on various aspects of the structure, quality, quantity, or landscape configuration of nesting habitats throughout the owl's distribution was considerable (e.g., Carey et al. 1990, Lehmkuhl and Raphael 1993, Buchanan et al. 1995, Meyer et al. 1998, LaHaye and Gutiérrez 1999) and overshadowed efforts to investigate the habitat conditions used by owls during dispersal (Miller et al. 1997).

After the Northwest Forest Plan was adopted to manage spotted owl populations on federal lands (Forest Ecosystem Management Assessment Team [FEMAT] 1993), regulations were implemented for the management of nonfederal lands in the region. In Washington, for example, the Northwest Forest Plan and state forest practices rules (in 1996) identified key landscape areas where the emphasis of spotted owl conservation would be the management of nesting, roosting, foraging, and dispersal habitats. On federal lands, spotted owl nesting habitat would be managed in late-successional reserves (LSRs). Federal lands between the LSRs would be managed largely for timber production (within the "matrix") or a combination of wildlife and human needs in "adaptive management areas" (FEMAT 1993). Areas between the LSRs would need to facilitate movement by juvenile and adult spotted owls among the LSRs. Nonfederal landscapes designated as Spotted Owl Special Emphasis Areas (SOSEAs) would provide demographic support, dispersal support, or a combination of these 2 functions under the state's forest practices rules (Washington Administrative Code 222-16-086). The SOSEAs are all adjacent to federal lands, and several are expressly designated as, or contain sub-units designated as, landscapes where spotted owl dispersal is of primary management importance.

In 1992 the United States Fish and Wildlife Service (USFWS) approved the first Habitat Conservation Plan (HCP) for spotted owls in the region (Simpson Timber Company 1992). This was followed by implementation of additional HCPs, many of which provided dispersal habitat as mitigation for incidental take permits that allowed harvest of forest used by territorial spotted owls for nesting, roosting, or foraging. These dispersal-based plans have been implemented on hundreds of thousands of hectares in the Pacific Northwest.

Despite this shift from retention of mature and older forests to management of younger forests as dispersal habitat, an interest in investigating the effectiveness of dispersal management plans has not emerged. This is surprising because dispersal long has been recognized as an essential component of spotted owl management (e.g., see Appendix P in Thomas et al. 1990). Moreover, dispersal has been an important ecological and management consideration for other listed species. Researchers and managers in the southeastern United States learned, for example, that poor landscape connectivity required the translocation of red-cockaded woodpeckers (*Picoides borealis*) to establish or maintain population clusters (DeFazio

et al. 1987). Consequently, the importance of developing credible landscape-level dispersal management plans is not a trivial concern. For this reason, I reviewed the available proposed and implemented dispersal management plans for northern spotted owls. The objectives of this paper are to 1) describe and explain the origins of the various definitions of dispersal habitat used in management, and 2) provide a preliminary evaluation of the suite of dispersal management strategies developed for spotted owls in the Pacific Northwest.

Dispersal and dispersal habitat

Dispersal is an important life-history stage for all wildlife species. It is a primary mechanism of gene flow among populations and by which individuals search out and acquire mates and colonize new territories. For this reason a considerable amount of effort has gone into studies of spotted owl dispersal behavior (Forsman et al. 1984, Miller et al. 1997, Ganey et al. 1998, LaHaye et al. 2001, Forsman et al. 2002). Much of this research has been used in ongoing spotted owl conservation efforts. Estimates of λ (lambda; the rate of population growth or decline), an analytical tool used to evaluate population performance, are sensitive to rates of emigration by juveniles (Forsman et al. 1996, Raphael et al. 1996). Dispersal was a key consideration in conservation strategies developed by the Interagency Spotted Owl Scientific Committee (Thomas et al. 1990; see Murphy and Noon 1992), the Spotted Owl Recovery Team (United States Department of the Interior [USDI] 1992), and for implementation of the Northwest Forest Plan (FEMAT 1993). The recovery strategy involved establishing a network of reserves across the landscape that would each support a cluster of breeding pairs. The amount of suitable habitat, size and spacing of reserves, and likelihood of successful dispersal were all important considerations in this reserve network design (Lamberson et al. 1992, 1994).

Dispersal can be defined in several ways. A variety of movements, such as might occur following a failed breeding attempt or efforts to prospect for new mates or territories, might be described as dispersal behavior because they involve an animal moving across a landscape, perhaps in unfamiliar terrain, searching for prey, habitat, or a mate (e.g., this would include "breeding dispersal" by spotted owls; see Forsman et al. 2002). For the purposes of this discussion, however, dispersal is defined as the collective movements of a juvenile during the period starting at departure from the natal area and ending at territory acquisition (Greenwood 1980, Miller et al. 1997). Miller et al. (1997) considered the dispersal process to consist of 2 distinct phases that they referred to as transience and colonization. The transient phase of dispersal included extensive or rapid movement through an area, whereas colonization indicated nonterritorial, short-term residence in an area. Juvenile spotted owls in the Pacific Northwest annually begin dispersing in September and October (Forsman et al. 1984, 2002) and typically move rapidly away from the natal area (transience), followed by varying periods of colonization and transience (Forsman et al. 2002).

Only one study has been conducted to examine the relationship between dispersing spotted owls and forest conditions across a landscape. This study, conducted in western Oregon, found a strong association between locations of dispersing spotted owls and old-growth forests (Miller et al. 1997). During the transience phase of dispersal, old-growth forest was used in proportion to its availability in the landscape (mean use = 35%; mean availability = 31%), whereas during colonization old-growth forest was used more than expected (mean use = 61%, mean availability = 33%; Miller et al. 1997). Closed sapling-pole-sawtimber stands (CSPS; stands of 2.5–53.3 cm dbh [diameter at breast height] trees with canopy closure of >60%) and "other" (reservoirs, rock outcrops, pastures, towns) landscape attributes were used in proportion to their availability during transience. Open sapling-pole stands (OSP; stands of 2.5–22.9 cm dbh trees and <60% canopy closure) and clearcuts (stands of <2.5 cm dbh trees and <40% canopy closure) were used proportionally less than would be expected based on availability during transience. During the colonization phase, the CSPS cover type was used slightly more than expected, and the OSP and "other" cover types were used proportionally less than expected (Miller et al. 1997).

The mortality rate of dispersing owls in western Oregon was associated with differing use of forest cover types (Miller et al. 1997). The mean mortality rate was lower for owls that used more OSP stands, compared to owls that did not use this cover type, and this may have been due to an abundance of an important food source, the dusky-footed woodrat (*Neotoma fuscipes*), in those stands (Miller et al. 1997). The primary sources of mortality among dis-

persing spotted owls were predation (68%) and starvation (26%) (Forsman et al. 2002). The degree to which starvation predisposed dispersing spotted owls to predation was unknown (Forsman et al. 2002). The study by Miller et al. (1997) did not evaluate the influences of landscape composition, in terms of stand age or successional stage, on mortality or the dispersal behavior of spotted owls. Their study landscapes contained stands of older forest and therefore likely differed from most of the landscapes where dispersal plans have been developed on nonfederal lands.

Management strategies for dispersal habitat

A number of different strategies have been developed for spotted owl dispersal management since 1990. These strategies included definitions of stand and landscape level features, some of which have become key elements of ongoing management efforts on federal and nonfederal lands. Many of the 18 proposed or implemented definitions (Table 1) were derived from a definition negotiated for the Murray Pacific Habitat Conservation Plan (Beak Consultants 1993). Some definitions were similar to or adopted the definition proposed by the Interagency Spotted Owl Scientific Committee (the "50-11-40" rule;Thomas et al. 1990).

Although the definitions differed in a number of ways, there were substantial similarities (Table 1). All of the definitions had a component for tree abundance, basal area, or canopy closure. Most definitions (72%) stated a proportion of the landscape that would be managed to a specific stand-level value. Two definitions included a description of the maximum allowable distance between patches of suitable dispersal habitat, and 4 definitions defined minimum patch size. Although several definitions called for snag retention, none of them *required* retention and many allowed snags to be removed and accounted for by "green recruitment trees." In most cases these trees could be small (e.g. 25–30 cm dbh). Nearly all stand-level definitions characterized dispersal habitat as very young forest lacking elements of structural diversity. Several elements of the Beak Consultants (1993) definition were based solely on aspects of forest growth patterns (Table 2). Most importantly, none of the definitions was explicitly linked to empirical data on spotted owls needed to support either the stand- or landscape-level components.

Are the management strategies adequate?

To date, there has been no attempt to empirically evaluate the adequacy of the proposed or implemented strategies for management of spotted owl dispersal habitat. Because of the lack of research to investigate or evaluate the dispersal strategies, a full evaluation of the strategies must await research on the topic. A preliminary evaluation, however, can be based in part on the hypotheses posited to explain the spotted owls' general preference for structurally complex older forests (Carey 1985). An evaluation of the factors identified by the original hypotheses may be useful in that the degree of consistency between the factors and the dispersal management strategies might provide an indication of the appropriateness of the strategies. The hypotheses summarized by Carey (1985) addressed habitat use relating to: nesting requirements, amelioration of heat stress, prey abundance, prey availability, predation risk, and ecological adaptation. The first hypothesis, that structurally complex forest is required for nesting, will not be discussed because nesting opportunities are not required by spotted owls during the dispersal phase. It is noteworthy, however, that successfully dispersing California spotted owls (*S. o. occidentalis*) often settled in previously used territories (LaHaye et al. 2001), indicating that juvenile spotted owls were able to use cues that revealed information about aspects of habitat quality when selecting an area in which to settle.

Amelioration of heat stress

Spotted owls are believed to have little tolerance of high temperatures (Weathers et al. 2001). Forests with multiple canopy layers generally provide greater thermoregulation opportunities for owls compared to conditions found in younger forest stands with simple canopy structure (Forsman 1976, Barrows and Barrows 1978, Barrows 1981, Forsman et al. 1984). Juvenile spotted owls in the Pacific Northwest begin dispersal in September and October (Forsman et al. 2002). Temperatures in the autumn are usually rather moderate compared to the summer months, so heat stress may not be an important factor at the beginning of the natal dispersal period. Conversely, because most first- and second-year owls do not breed, and may not hold territories, they, or other nonterritorial owls (i.e., those engaged in breeding dispersal), may disperse

Table 1. Elements of the 18 strategies developed (or proposed) to provide spotted owl dispersal habitat in Washington or Oregon between 1990 and 1999. The strategies are listed in approximately the sequence of their development; strategies described in Washington Forest Practices Board (2002) were developed in 1996.

Definition	Application area	Stand-level attributes	Landscape-level attributes
Interagency Spotted Owl Scientific Committee "50-11-40 rule" (Thomas et al. 1990)	Federal land in Washington, Oregon and California	Mean tree size of ≥28 cm dbh (diameter at breast height); canopy closure ≥40%.	At least 50% of the landscape outside Habitat Conservation Area (HCA) boundaries would meet stand-level conditions. Also, would have retained patches of ≥32 ha of suitable owl habitat at or near former spotted owl site centers, at an average of seven per township, in areas between HCAs.
Beak Consultants (1993)	Murray Pacific HCP; Western Cascade Mountains, Washington	Conifer forest with ≥70% canopy closure; ≥130 and ≤ 300 trees/0.4 ha that were ≥25 cm dbh (or larger trees of an equivalent basal area); where possible, retained ≥2 dominant or co-dominant trees and 3 snags ≥46 cm dbh per 0.4 ha of harvest; retained ≥2 30-cm diameter, 6.1 m logs per 0.4 ha at harvest.	Arranged forest patches such that stands of dispersal habitat were spaced no more than 0.4 km apart. About 43% of the ownership would meet the defined conditions by year 50, and would remain at this approximate amount between years 50 and 100.
Spotted Owl Science Advisory Group (Buchanan et al. 1994)	Unspecified nonfederal lands; Eastern Cascade Mountains, Washington	Supported "50-11-40" rule of the ISC (see above; Thomas et al. 1990) on an interim basis.	Supported "50-11-40" rule of the ISC (see above; Thomas et al. 1990) on an interim basis.
Spotted Owl Science Advisory Group (Buchanan et al. 1994)	Unspecified nonfederal lands; Western Washington	Supported Beak Consultants (1993) definition (see above) on an interim basis.	Supported Beak Consultants (1993) definition (see above) on an interim basis.
Northwest Forest Plan (USDA and USDI 1994)	Federal lands in Washington, Oregon and California	Not addressed.	In matrix areas (landscapes, between reserved areas, where timber harvest was emphasized) retained a) ≥15% of the green trees on each harvest unit, b) 40 ha of habitat around former owl site centers, and c) forest buffers along streams, ponds and wetlands. The remainder of the forest in matrix areas would be managed on a rotation age of ≥100 years.
Washington Forest Practices Rules (Washington Forest Practices Board 2002)	Nonfederal lands; Western Washington	Forest stands with ≥70% canopy closure; At least 70% composition of conifer trees ≥15 cm dbh; ≥130 and ≤300 trees/0.40 ha with a dbh of ≥25 cm or a basal area of 30 m of 25 cm or larger trees; ≥6.1 m of open space (relatively free of dead limbs) between the top of the understory vegetation and the bottom of the live canopy.	Forest stands ≥2 ha in size.
Washington Forest Practices Rules (Washington Forest Practices Board 2002)	Nonfederal lands; Eastern Cascade Mountains, Washington	Forest stands with ≥50% canopy closure; ≥50 and ≤200 conifer trees/0.4 ha with a dbh of ≥15 cm in even-aged stands, or ≥10 cm in uneven-aged stands (or a quadratic mean diameter of ≥23 cm and a relative density of ≥33); an average tree height of ≥20 m; ≥6.1 m of open space (relatively free of dead limbs) between the top of the understory vegetation and the bottom of the live canopy.	Forest stands ≥2 ha in size.

[a] HCP not implemented.

[b] Relative density is the basal area divided by $QMD^{0.5}$ (Curtis 1982).

[c] The quadratic mean is the square root of the arithmetic mean of squared values (Curtis and Marshall 2000).

Table 1 (*continued*). Elements of the 18 strategies developed (or proposed) to provide spotted owl dispersal habitat in Washington or Oregon between 1990 and 1999. The strategies are listed in approximately the sequence of their development; strategies described in Washington Forest Practices Board (2002) were developed in 1996.

Definition	Application area	Stand-level attributes	Landscape-level attributes
Longview Fibre Company (1995)[a]	Columbia Gorge, Washington	Conifer-dominated stands of an average height of ≥15 m with 321 – 741 trees/ha of >10 cm dbh.	Not addressed.
Rayonier Wildlife Plan (WFPB 1996)	Rayonier Wildlife Plan Area; Western Olympic Peninsula, Washington	Forest stands ≥30 years old; ≥70% conifer, <400 trees/0.4 ha, a quadratic mean diameter of 23 cm, and a basal area of 28 m^2/0.4 ha.	An estimated 40% of the plan area would meet or exceed the definition of dispersal habitat by 2020; the average amount of dispersal habitat at 5-year increments between 2025 and 2045 was predicted to be 43.8%. Also, a limit on clearcut size of 49 ha, a commitment that no less than 30% of the plan area would be commercially thinned during a rotation, that 3% of the area would remain in fixed reserves and 5% in floating reserves, and that 5% of the stands would be pruned during a rotation.
Weyerhaeuser Company (1995)	Millicoma Tree Farm; Western Oregon	Forest stands with ≥70% dominant or co-dominant conifers; ≥120 and ≤300 trees/0.4 ha with ≥25 cm dbh (or equivalent basal area constituted by fewer but larger trees); co-dominant tree height of ≥21 m; ≥6 m of clear sub-canopy space; ≥2 live trees or snags/0.4 ha, on average, of ≥9 m height and 28 cm dbh; ≥2 hard logs/0.4 ha ≥5 m long and ≥30 cm) in diameter. Possible future modification up to 400 trees/0.4 ha.	Forest stands ≥2 ha in size.
Plum Creek HCP (Hicks and Stabins 1995, Plum Creek Timber Company, Inc. 2000)	"I-90 Corridor", Western Cascade Mountains, Washington	Foraging and dispersal habitat based on Beak Consultants (1993), but including relative density[b] of 30–48 (equivalent to 175–280 trees/0.4 ha) in uplands,relative density of 48 in riparian areas; quadratic mean diameter (QMD)[c] of 25 cm in stands dominated by conifers.	Between 2006 and 2045, 6–10% of the plan area would meet definition of nesting roosting and foraging habitat; 7–34% would meet definition of foraging and dispersal habitat (combined totals would range between 17 and 42%). These goals will have been considered met if actual values are within 10–20% of the incremental or final targets.
Plum Creek HCP (Hicks and Stabins 1995, Plum Creek Timber Company, Inc. 2000)	"I-90 Corridor", Eastern Cascade Mountains, Washington	Foraging and dispersal habitat based on Beak Consultants (1993), but including forest stands dominated by Douglas-fir, ponderosa pine, and true fir, with a relative density of 33 and a QMD of 23 cm.	See above.
Weyerhaeuser Willamette (Weyerhaeuser Company 1996)[a]	Willamette Tree Farm; Central-western Oregon	At least 4 snags or green trees/0.4 ha of ≥30 cm dbh and ≥9 m height (snags and leave trees could be retained within riparian areas); would retain one live conifer ≥81 cm dbh (9 m tall), if possible, per 8 ha of harvested timber. Foraging habitat (used in landscape definition) defined as stands with ≥30% conifers, ≥70% canopy cover, 115 – 280 stems ≥10 cm dbh/0.4 ha, and dominant and co-dominant trees of ≥26 m (except in thinned stands, where trees could be shorter).	Would maintain ≥40% of the landscape, beyond 2025, in stands of ≥pole timber, including ≥20% foraging habitat (see stand-level attributes) in "zone 1" and ≥10% foraging habitat in "zone 2"; ≤20% of the landscape would be > 0.4 km from reserved areas or stands of ≥pole timber; would maintain approximately 243 ha of suitable habitat in connectivity patches, and temporarily maintain about 486 ha of habitat until equivalent new habitats developed on adjacent federal lands. A 28-ha core around known spotted owl site centers would be protected until the site became inactive, at which point the core could be harvested.

[a] HCP not implemented.

[b] Relative density is the basal area divided by $QMD^{0.5}$ (Curtis 1982).

[c] The quadratic mean is the square root of the arithmetic mean of squared values (Curtis and Marshall 2000).

Table 1 (*continued*). Elements of the 18 strategies developed (or proposed) to provide spotted owl dispersal habitat in Washington or Oregon between 1990 and 1999. The strategies are listed in approximately the sequence of their development; strategies described in Washington Forest Practices Board (2002) were developed in 1996.

Definition	Application area	Stand-level attributes	Landscape-level attributes
Crown Pacific (Biota Pacific Environmental Services 1999) [a]	Crown Pacific lands; Northwestern Cascade Mountains, Washington	Basic definition from Beak Consultants (1993) was adopted. In addition, ≥30% coniferous species, codominant trees ≥26 m tall, minimum tree diameter (counting trees ≥10 cm dbh) of 25 cm, tree density (of trees ≥10 cm dbh) of 115–280/0.4 ha, and ≥70 canopy closure. Would retain all safe snags >38 cm dbh along with ≥6 retention trees/0.4 ha (≥25 cm dbh and of which 3 are ≥38 cm dbh) of the harvest area.	Basic definition from Beak Consultants (1993) was adopted. In addition, stand-level definitions would apply to 50% of dispersal habitat on Class I-IV lands; minimum stand size of ≥8 ha and minimum stand width of ≥61 m. All snags or retention trees could be situated in riparian management zones and unstable slope areas.
Oregon Department of Forestry (1995)	Elliot State Forest; Oregon Coast Range	Essentially adopted the "50-11-40 rule" at the scale of quarter-township management areas. For other state lands defined dispersal habitat as forests with a QDBH of 28 to 45 cm.	Essentially adopted the "50-11-40 rule" at the scale of quarter-township management areas. For the North Coast Region, retained 70% of the landscape as dispersal habitat in areas outside breeding clusters; these landscapes would also contain 70% forests older than 50 years (including ≥10% with older forest structure) by year 50 of the plan.
Washington Department of Natural Resources (WDNR 1997)	DNR lands; Western Cascade Mountains, Washington	Forest stands with ≥70% canopy cover; ≥28 cm QDBH for the largest 100 trees/0.4 ha; the 40 tallest trees/0.4 ha ≥26 m tall; retention of ≥4 trees of the largest diameter class at harvest.	Dispersal landscapes would be managed such that 50% of the stands met the stand-level criteria.
Washington Department of Natural Resources (WDNR 1997)	DNR lands; Eastern Cascade Mountains, Washington	Forest stands with ≥50% canopy closure; ≥40 overstory trees/0.4 ha of ≥28 cm dbh; tree height of ≥18 m; retention of ≥4 trees of the largest diameter class at harvest.	Dispersal landscapes would be managed such that 50% of the stands met the stand-level criteria.
Weyerhaeuser-U.S. Forest Service land trade (Foster Wheeler Environmental Corporation 1996, U.S. Fish and Wildlife Service 1997)	Weyerhaeuser lands; Western central Cascade Mountains, Washington	From Washington Forest Practices Rules (Washington Forest Practices Board 2002). Foraging habitat defined as stands with ≥30% conifer stems, ≥70% canopy closure, 115 – 280 stems/0.4 ha of ≥10 cm dbh, and dominant/codominant trees of ≥26 m height, except for commercially-thinned stands where minimum tree height was 21 m. Snags would be retained where feasible and safe.	At least 40% of the plan area would meet the definition of dispersal habitat used in the land trade agreement. At least 37.5% of the dispersal habitat would be foraging habitat. Also, ≤20% of the area (roughly 5,261 ha) would be more than 0.4 km from patches ≥2 ha of dispersal habitat, with wildlife reserve trees (≥3/0.4 ha), if available, that were ≥3 m tall and ≥30 cm dbh, and green retention trees (2/0.4 ha; ≥25 cm dbh, ≥9 m tall, and at least 1/3 of height in live crown) would be retained in harvest units. The reserve and recruitment trees could be clumped in riparian or wetland management zones or across the landscape. In each 0.4 ha of forest harvested 2 downed logs (30 cm dia. at small end and ≥ 6.1 m in length, or an equivalent volume of larger logs) would be retained. A 28-ha core centered on any current spotted owl site center would be retained until site abandonment, at which time the core could be harvested.

[a] HCP not implemented.

[b] Relative density is the basal area divided by $QMD^{0.5}$ (Curtis 1982).

[c] The quadratic mean is the square root of the arithmetic mean of squared values (Curtis and Marshall 2000).

Table 2. Rationale for inclusion of specific required elements in the definition of spotted owl dispersal habitat developed for the Murray Pacific Habitat Conservation Plan (from Beak Consultants 1993). This plan, the first HCP in the Pacific Northwest, was developed for a 21,000+ ha tree farm in the western Cascade Mountains foothills in Washington. The rationale for snags and leave-trees was not provided because snags were not a required element of the plan. See Table 1 for the specific values of the elements included in the definition.

Element	Rationale
Tree species composition	Coniferous forests provide thermal cover and protection from precipitation, particularly during autumn and winter periods.
Tree size and density	25-cm trees provide perch opportunities in and below the canopy because such trees have branches of suitable size (3.8 cm at the base) for an owl to use. Stands grown at a density of ≥130 trees/0.4 ha would self-prune and provide open space for spotted owls flying through the understory. An upper limit of 300 trees/0.4 ha was identified as a compromise density at which tree mortality occurs due to competition.
Canopy "lift"	Spotted owls must be able to fly in the forest understory. An open area of 6.1 m between the ground and the canopy would occur on the plan area when trees were about 25 cm dbh and were able to self-prune if grown at a density of more than 130 trees/0.4 ha.
Canopy closure	This amount of canopy closure would occur at a density of 130 trees/0.4 ha.
Downed wood	The level of retention at harvest reflected current Forest Practices Rules.
Size of and spacing between patches	On average, a stand of 16 ha had an edge-to-interior ratio of 1:1; therefore, the average harvest size in the HCP would be 16 ha, and ranged from 2–49 ha. No rationale was given for using a 0.4-km spacing between patches, but it was inferred to reduce the number of crossings an owl would make over openings or areas of unsuitable habitat.
Percentage of landscape	It was inferred that a landscape with a high proportion of dispersal habitat would reduce the likelihood of predation by creating more cover and reducing the number of times owls would cross open areas where predation risk would be higher.

during subsequent summers (in either transience or colonization mode). These owls would benefit by the presence of structurally complex forest during those periods.

Prey abundance

The spotted owl's primary prey in much of the Pacific Northwest is the northern flying squirrel (*Glaucomys sabrinus*) (e.g., Forsman et al. 1984, 2001). Carey et al. (1999) found that capture rates of squirrels were higher in "niche diversification" (4.0±0.3 /100 trap nights) and old-growth (3.2± 0.1) stands compared to forests in the younger, competitive-exclusion phase of development (2.6± 0.2). They also found that capture rates of squirrels were positively associated with the amount of coarse woody debris in the stand. In fact, presence and amount of coarse woody debris explained 40% of variance in the carrying capacity of flying squirrels. Feen (1997) found that squirrel winter den sites were in areas with a greater basal area of dead conifer trees as compared to random sites. Carey et al. (1997) reported a strong positive association between abundance of large snags and population size of flying squirrels throughout the Pacific Northwest. Among the likely reasons for this relationship were 1) flying squirrels tended to den communally and therefore required larger-diameter snags (Carey et al. 1999), and 2) flying squirrels change dens often and therefore require a good number of snags or cavity trees within the home range (Carey et al. 1997). Also, Amaranthus et al. (1994) found that the abundance of truffles, an important food source for flying squirrels, was 20–30 times higher in 180-year-old forest than in 4–27-year-old forests with 11–14% cover of downed wood. It is unknown at what stage of forest development the abundance of truffles begins to approach levels noted in older forests.

Spotted owls also prey on a wide range of other small-mammal species (Forsman et al. 2001), and the collective abundance of these species may vary as a function of forest structure. Research conducted in the southern Cascade Mountains of Washington found that the combined total number of captures (per 100 trap-nights) of all small mammals was higher in old-growth stands than in fire-regenerated younger stands in both years of study. Capture rates (per 100 trap nights) in young stands were 5.07 and 5.88 in 1984 and 1985, respectively (West 1991). In contrast, capture rates of all small mammals in an intensively managed younger forest in southwestern Washington averaged 2.08/100 trap-nights (Stinson et al. 1997). Similarly, the total abundance of small

mammals was nearly 1.7 times higher in old growth than in managed second-growth forest on the Olympic Peninsula, Washington (Carey and Johnson 1995). In that study the variance in abundance of numerous small-mammal species in managed stands was positively related to the amount of coarse wood debris on the forest floor (Carey and Johnson 1995).

The relationship between prey availability in and owl use of particular cover types is obviously important. Owls that fail to consume an adequate amount of prey will starve to death (Miller et al. 1997), and those that struggle to secure adequate prey will experience nutritional stress, may become more susceptible to predation (Hirons et al. 1979), and may have lowered reproductive success (Newton 1779). The relationship between prey abundance and complex forest structure was consistent with the spotted owl's use of old-growth forest during transience and colonization phases of dispersal (Miller et al. 1997).

Prey availability

The spotted owl is a sit-and-wait predator, in that it scans its surroundings from a perch before locating and attacking prey. The relevance of this predatory behavior to the prey-availability hypothesis involves the availability of hunting perches (Forsman 1976, Forsman et al. 1984) and the susceptibility of prey present in the forest. Forests with complex structure provide perch locations at various locations in the canopy and subcanopy that likely provide more opportunities for owls to locate prey, and this likely equates to a greater availability of prey. In addition, the varied structure in the canopy, subcanopy, and forest floor in these forests likely provides a more diverse array of niches that serve as prey refugia interspersed with areas where the prey are vulnerable to predators (Carey 1985). Second-growth forests are in comparatively early stages of successional development and typically have less complex structure and provide less of this dispersion of within-stand patches, and fewer perch sites low in the sub-canopy (Oliver 1981). The ecological significance of these supposed differences in forest structure relative to prey availability to the spotted owl has not been evaluated, but the apparent relationship between structural complexity and a greater availability of prey is consistent with the preference for old-growth forests during dispersal (Miller et al. 1997).

Predation risk

The chief predators of the spotted owl are the northern goshawk (*Accipiter gentilis*), red-tailed hawk (*Buteo jamaicensis*), and great horned owl (*Bubo virginianus*) (Forsman et al. 1984, Miller and Meslow 1985, Carey et al. 1990). Northern goshawks are rather uncommon in substantial parts of the northern spotted owl's range (Watson et al. 1999), and appear to be rare in some designated spotted owl dispersal areas, probably due to the lack of suitable habitat in managed-forest landscapes (DeStephano and McCloskey 1997). In other areas they are more common, nest in the same cover types used by spotted owls, and build nests that may eventually be used by spotted owls (Forsman et al. 1984, Buchanan et al. 1993). Red-tailed hawks nest in forest and forage in clear-cuts and other open cover types. Anecdotal information suggests that goshawks and red-tailed hawks occasionally kill spotted owls, but their significance as predators of the owl is unknown (Gutiérrez et al. 1995, Forsman et al. 2002).

The great horned owl is a common and widespread species of forested landscapes within the range of the northern spotted owl (e.g., Irwin et al. 1991). In some areas, such as southwestern Washington and the Oregon Coast Range, it is much more numerous than the spotted owl (USDI 1992), and in some areas it may be the primary predator of spotted owls (Forsman et al. 1984, 2002; Gutiérrez et al. 1995). In the central Cascade Mountains in Oregon, 500-ha areas around great horned owl locations contained forests with a greater edge-to-old-forest area ratio, greater areas of shrub and forb vegetation, and lesser amounts of old and interior forest, compared to comparable areas around spotted owl locations (Johnson 1993). Compared to spotted owls, great horned owls were more often detected in landscape areas with only 10–20% old forest and were less commonly detected than spotted owls as the amount of old forest in the landscape increased beyond about 60% (Johnson 1993). Consequently, landscapes with high amounts of old forest will support fewer great horned owls, and landscapes with little old forest will support high densities of great horned owls. The landscapes being maintained or created for spotted owl dispersal were characterized by conditions that will support comparatively high densities of great horned owls (see Table 1), and this could result in higher mortality rates than in landscapes with fewer great horned owls.

Ecological adaptation

Prior to European settlement, the coniferous

forests of the Pacific Northwest were dominated by older forests and fire-regenerated younger-aged stands (Wimberly et al. 2000). At any given time, perhaps 30–45 percent of landscapes in western Washington and Oregon were generally unsuitable for spotted owls because of an incompatible vegetation association or the presence of forests lacking complex structure due to regeneration following wildfires (Eby and Snyder 1990, Wimberly et al. 2000). The remaining 55–70 percent of the region consisted of fire-regenerated young-, mature-, and old-forest cover types that would have been suitable for spotted owls. The owls likely dispersed through these forests and through a mosaic of remnant patches of old forest scattered throughout landscapes otherwise converted to the stand-regeneration phase (Oliver 1981) by stand-replacing fires. A preference for old-forest cover types (Gutiérrez et al. 1995) suggests that spotted owls adapted to disperse through landscapes dominated by structurally complex forest, although it is unclear whether juveniles seek old-forest cover types innately or as a learned response, perhaps to conditions at the natal site or foraging areas that support an abundance of prey (Carey 1985, E. Forsman personal communication). Given the reduction in both amount of old forest and abundance of snags on the landscape over the past century (e.g., Spies and Cline 1988, Thomas et al. 1990), the condition of forest landscapes currently available for spotted owls certainly is unprecedented.

Overview of the dispersal management strategies

Examination of the hypotheses associating spotted owls with various forest attributes and ecological conditions indicate inconsistencies between the function of forest attributes associated with dispersal management plans and the habitat attributes identified as important to spotted owls. Given the lack of understanding about dispersal habitat needs at the landscape level, this should be cause for concern. The greatest potential shortcoming in management strategies for dispersal habitat is the general lack of structurally complex forest conditions. For example, definitions of dispersal habitat generally have not required substantive retention of snags or downed wood following timber harvest. Although several of the management strategies recommended protection of snags at the time of harvest, these provisions essentially were voluntary and did not *require* retention of snags (i.e., snags generally could be removed for safety and operational reasons). Intensively managed forests are characterized by a dearth of snags (Spies and Cline 1988), and the requirement of snag retention is therefore unlikely to be achieved in most cases without dedicated management. Furthermore, with only one exception (and in a plan that was not implemented), strategies that retain green trees have not *required* that these trees become snags at any time during the life of the plan, typically a period of 50–100 years. Therefore, most of the implemented dispersal management strategies will result in landscapes dominated by younger, second-growth forests. These forests are managed on short rotations (e.g., 50 years) and typically lack the structural components (e.g., snags; Spies and Cline 1988, Wilhere 2003) of forests used by spotted owls.

Although Thomas et al. (1990) were unable to identify a threshold value of foraging habitat that would facilitate dispersal, they clearly recognized the importance of foraging requirements during dispersal. In addition, as a guiding principle Thomas et al. (1990) cited Wiens (1989:227), in stating "To establish reserves according to ecological insights requires both a consideration of broad-scale landscape configurations and knowledge of the ecological requirements of the species that are important in particular situations." Although many dispersal management plans required that 40–50% of the landscape meet a stand-level definition of dispersal habitat, it is unknown whether these targets are sufficient to support dispersing spotted owls, particularly given the lack of structural complexity in the vast majority of stands in dispersal landscapes. In Washington there are several regulatory definitions of suitable spotted owl habitat (WAC 222-16-085), including foraging habitat, and these or similar definitions do not appear in most of the 18 dispersal habitat plans. It is not evident that the majority of dispersal management plans have adhered to this guiding principle. Unfortunately, almost none of the plans contain an adaptive management element that would initiate different management practices to achieve a different target condition based on new knowledge. Therefore, in both the near term and the long term, the proposed and implemented strategies for management of spotted owl dispersal habitat may not produce conditions preferred by spotted owls and may result in dispersal-related mortality (due to starvation or predation) or other consequences that negatively influence juvenile recruitment.

Potential competition with barred owls

Although direct evidence demonstrating competition between the barred owl (*Strix varia*) and spotted owl is lacking, there is a growing concern that the barred owl, now sympatric with the northern spotted owl (Dark et al. 1998), is a superior competitor for resources (Kelly and Forsman 2003, Pearson and Livezey 2003). This potential competitive advantage is likely to occur in all seasons, including during dispersal.

Barred owls differ ecologically from spotted owls in a number of ways. Barred owls are habitat and prey generalists (in the Pacific Northwest), they appear to have greater reproductive output, and they disperse substantially longer distances (Mazur and James 2000) than is typical for spotted owls (Forsman et al. 2002). Consequently, if spotted owls compete with barred owls for resources during the nesting season, they may face an even greater challenge as they move across large dispersal landscapes dominated by younger forests of arguably lower-quality habitat. These dispersal forests provide nesting (e.g., in riparian hardwoods; J. Buchanan, personal observation) and foraging opportunities not exploited by spotted owls. Consequently, barred owls (local adults and their young as well as dispersing birds from adjacent areas) likely are present in dispersal landscapes when spotted owls begin dispersing. Given the generalist nature of prey selection by barred owls (Mazur and James 2000), these owls can persist in such landscapes and may well reduce populations of prey species that in many cases were probably marginal but otherwise available for spotted owls. Research will be required to understand the relationship between these 2 species during dispersal.

Recommendations

An empirical evaluation of the effectiveness of the current dispersal management strategies will be a complex task. A complete assessment of dispersal efficacy in intensively managed forest landscapes will require evaluation of both the suite of ecological conditions and relationships experienced by spotted owls and the influence of dispersal on the demographic health of the population (McPeek and Holt 1992). This is a daunting challenge because an investigation to identify stand- or landscape-level habitat conditions experienced by dispersing spotted owls that eventually influence population performance will be substantial and expensive. Addressing the relationship between dispersal and population demography likely would require that the demography and dispersal landscapes be contiguous, or approximately so.

Cost and logistical constraints are not the only barriers to a better understanding of the habitats used by spotted owls during dispersal. With the exception of a dispersal management strategy implemented by the Washington Department of Natural Resources (WDNR 1997), all other management strategies within HCPs are static and not subject to modification based on new information on spotted owl habitat requirements or the effectiveness of the original strategy. For this reason, the absence of adaptive management provisions seriously limits motivation to evaluate or modify the strategies. Evaluating and subsequently modifying dispersal management strategies, if necessary, may require using adaptive management principles in future Habitat Conservation Plans or other forest management planning efforts. In addition, it may be possible to employ tools such as conservation easements to offset costs that would otherwise be imposed on the United States Fish and Wildlife Service to modify existing HCPs on nonfederal lands.

Significant ecological factors that influence, or have the potential to influence, behavior and survival of spotted owls include the amount, quality, and distribution of suitable habitat, the availability and abundance of prey, and the presence of predators or competitors. It would be insightful to associate the ecological factors with assessments of survival, physiological condition (e.g., mass loss or rate of mass change; see Williams et al. 1999), and behavior (e.g., rate of movement, amount of colonization activity; Forsman et al. 2002). Radiotelemetry would be required to accurately link spotted owl area use with specific stand- and landscape-level attributes. In addition, measures of prey and predator abundance and the habitats they use could be obtained to evaluate the potential importance of these factors. A variety of modeling efforts could be applied (Mooij and DeAngelis 2003), and models could be generated that improve the management strategies currently in use (see Peterson et al. 2003).

There are certainly limitations in conducting the type of research described above. Every landscape or landscape segment is unique in some way, and this will influence predator and prey densities and

habitat functionality. These conditions will place certain limitations on the types of study designs and analytical procedures that can be applied. On the other hand, it should be possible to determine the ecological or environmental factors that influence the success of dispersing spotted owls. Research design should allow for credible investigation, and the information derived from research should be used to develop better dispersal management plans for spotted owls. We should learn from the example of the red-cockaded woodpecker and avoid relying on strategies that may not deliver.

Acknowledgments. I thank W. B. Ballard, M. A. Cronin, and E. D. Forsman for providing comments that improved the manuscript.

Joseph B. Buchanan, a wildlife biologist with the Washington Department of Fish and Wildlife since 1991, began studying spotted owls in 1988 while employed by the National Council for Air and Stream Improvement. His research on spotted owls has focused primarily on habitat use. For the last decade he has been the lead biologist with WDFW on a wide range of conservation and management issues involving spotted owls on state and private lands. He received a B.S. from Evergreen State College in 1981 and an M.S. in wildlife sciences from the College of Forest Resources, University of Washington, in 1991. He has broad interests in ornithology and avian conservation, and is particularly interested in the status, ecology, and behavior of shorebirds and their falcon predators.

Forest Service Large Fire Area Burned and Suppression Expenditure Trends, 1970–2002

David E. Calkin, Krista M. Gebert, J. Greg Jones, and Ronald P. Neilson

ABSTRACT

Extreme fire seasons in recent years and associated high suppression expenditures have brought about a chorus of calls for reform of federal firefighting structure and policy. Given the political nature of the topic, a critical review of past trends in area burned, size of fires, and suppression expenditures is warranted. We examined data relating to emergency wildland fire suppression expenditures, number of fires, and acres burned and developed statistical models to estimate area burned using drought indices for the USDA Forest Service from 1970–2002.

Keywords: wildland fire, Forest Service suppression expenditure trends, Palmer Drought Severity Index (PDSI)

Unprecedented expenditures on wildland firefighting over the past several years have brought federal wildland fire management to the forefront of political debate. Extreme fire seasons have occurred in 3 of the last 4 years (2000, 2002, and 2003), with federal expenditures on emergency fire suppression exceeding $1 billion in each of those 3 years. The fire season of 2002 was the most expensive on record. Federal firefighting expenditures totaled $1.6 billion, with the USDA Forest Service alone spending over $1.1 billion (National Interagency Fire Center 2003). In 2002, three western states experienced their largest single wildfire seasons on record: the Hayman fire in Colorado, the Rodeo-Chediski in Arizona, and the Biscuit in Oregon; an estimated 6.9 million acres burned nationwide. Our focus is on USDA Forest Service fire suppression expenditures, which account for nearly three-fourths of all federal suppression expenditures.

A variety of explanations have been offered for the high levels of emergency fire suppression expenditures, including excessive fuel loading caused by decades of successful fire suppression, increased development in the wildland-urban interface (WUI), lack of financial accountability of fire managers, and severe and prolonged drought (National Academy of Public Administration 2002). In fire-adapted ecosystems common throughout much of the West, there is strong evidence that past fire suppression has resulted in fuel loads well outside historic regimes and is largely responsible for the increased size and severity of some wildland fires (Arno and Brown 1991, Arno et al. 2000). Residential development in the WUI and the emphasis of federal firefighting organizations on protecting residential structures has also been mentioned as a potential factor increasing suppression expenditures (Snyder 1999). Additionally, there is much discussion about the lack of financial accountability of fire managers and an incentive system that makes fire managers more risk averse than socially optimal (USDA, USDI, NASF 2003). Risk aversion can cause both excessive use of firefighting resources and substitution of expensive (but less risky) capital resources for less expensive (but more risky) labor resources.

The influence of weather on fire season severity is well established. A number of recent studies have explored the relationship between drought and fire season severity (Westerling et al. 2003, Swetnam and Betancourt 1998, Balling et al. 1992). In a much-cited study of subalpine pine forest types, Bessie and Johnson (1995) state "forest fire behavior is determined primarily by weather variation among years rather than fuel variation associated with stand age." However, Agee (1997) and Betancourt et al. (2003) argue that, while weather is the dominant factor in determining fire severity and size in forest types that typically burn infrequently and at high intensity, fuel buildup cannot be discounted in the drier forest types that typically burn frequently but at low intensity.

Given the extreme fire seasons and associated suppression expenditures that have recently been experienced, it is important to examine the data to identify real trends and dispel any incorrect assumptions regarding USDA Forest Service emergency fire suppression expenditures. The following analysis is a first step in understanding emergency firefighting expenditures by critically exam-

ining macro-level data for the USDA Forest Service.

Methods

We examined data relating to emergency wildland fire suppression expenditures, number of fires, and acres burned for the USDA Forest Service from 1970 to 2002 for individual USDA Forest Service regions and aggregated for the continental United States. These data have been compiled from the USDA Forest Service's accounting system (Central Accounting Data Inquiry (CADI) for data prior to fiscal year 2000 and Foundation Financial Information System (FFIS) for fiscal year 2000 and beyond) and the National Interagency Fire Management Integrated Database (NIFMID), the USDA Forest Service's fire occurrence database. Financial data for the continental United States are from fiscal year 1971 to 2002, while regional acreage burned data are from calendar year 1970 to 2002. We compiled data on the total number of fires and all fires greater than or equal to 300 ac (class E, F, and G), which we call large fires, the cost per acre of suppressing the large fires, and total area burned by all fires and by large fires. Expenditure data are for emergency wildland fire suppression; initial attack funding is not included in this analysis. This focus was necessary due to changes in accounting structures within the initial attack budget. Historical data at the regional and national level were graphed, and, where appropriate, econometric models were developed to identify relevant trends.

A number of recent studies have used a common measure of drought, the Palmer Drought Severity Index (PDSI, Palmer 1965), to predict fire season severity including Balling et al. (1992), Swetnam and Betancourt (1998), and Westerling et al. (2003). The PDSI is a measure of the scope, severity, and frequency of prolonged periods of abnormally dry or wet weather and is useful as an indicator of general conditions and not local variations (National Oceanic and Atmospheric Administration, National Weather Service 2003). Swetnam and Betancourt (1998) identified a strong correlation between tree-ring-reconstructed regional fire-scar chronology and June-Aug. PDSI time series for the Southwest. Westerling et al. (2003) investigated associations between the PDSI and seasonal acres burned in western wildfires and identified positive correlations with PDSI 12–15 months prior to Aug. The authors conclude that this result appears to reflect a trade-off between fuel accumulation and flammability, with wet conditions in the previous year contributing to fuel accumulation and wet conditions in the current year suppressing fire activity by moistening the fuels, and, conversely, dry conditions in the previous year inhibiting fuel accumulation and dry conditions in the current year enhancing fire activity by drying the fuels.

There are indications of significant shifts in long-term weather regimes, influenced by interdecadal oceanic oscillations, over the period of analysis (Swetnam and Betancourt 1998). Weather in North America is affected by interdecadal oceanic circulation regimes in all three oceans that ring the continent, the Pacific, Arctic, and Atlantic Oceans (Hurrel 1995, Thompson and Wallace 1998, Mantua and Hare 2002). Among the most prominent were ocean-climate regime shifts in the early 1940s, mid-1970s, around 1987–89, and most recently around 1997 (Hare and Mantua 2000). The regime shifts in the 1940s and 1970s are associated with a three-decade cooling trend in the middle of an otherwise continuous warming trend over the 20th century (Folland et al. 2001). With the regime shift in the mid-1970s, the western United States has undergone two extreme wet-dry cycles unlike anything since the onset of the 20th century. The extreme El Niños in 1983 and 1998 punctuate the wet episodes, while the 1987–89 regime shift and the most recent years (ca. 2000–2002) were among the driest in historic times. The 1987–89 regime shift produced prominent signals in all three oceans, but persisted in the Arctic and North Atlantic to the present. These wet and dry periods may have increased the severity of fire seasons, especially since 1987. Vegetation fuels increased during the extended wet periods, while fires were more limited, and then the fuels were dried and easily combusted during the extended dry periods.

Table 1. Fire season months by region (provided by Tom Wordell, Wildland Fire Analyst, National Interagency Coordination Center).

Region	Fire season months
Pacific Northwest	June, July, Aug.
Northern California	July, Aug., Sept., Oct.
Southern California[a]	July, Aug.
Western Great Basin	June, July, Aug., Sept.
Eastern Great Basin	June, July, Aug., Sept.
Northern Rockies	June, July, Aug.
Rocky Mountain	June, July, Aug., Sept.
Southwest	May, June, July
South	Mar., Apr., May, June
East	Mar., Apr., May

[a] Additionally, we evaluated a fire season for Southern California including July, Aug., Sept., Oct., and Nov. to represent the effects of Santa Ana winds in the fall months. Results for both models are presented in Table 2.

We developed statistical models to predict area burned for individual Geographic Area Coordination Center (GACC) regions using Palmer drought indices as explanatory variables. We used the following base model:

$$\text{area burned}_t = \text{fn}\ (\text{PDSI(fire)}_t,\ \text{PDSI}_{t-1},\ \text{annual dummy})$$

Area burned is total area burned by all USDA Forest Service fires in the specified region. PDSI(fire)_t is the average PDSI over the fire season, and PDSI_{t-1} is the previous year's average annual PDSI for that region. Palmer drought indices used in this analysis were provided by Neilson and aggregated at the GACC regions. PDSI(fire) was averaged for the individual regions based on the primary fire season months shown in Table 1. For the Southern California region, we examined two alternative fire season definitions. The first, including only July and Aug., was identified by Tom Wordell of the National Interagency Coordination Center (NICC). The second included the months of July and Aug. as well as Sept., Oct., and Nov. to represent the potential effects of Santa Ana winds on fire season severity. The annual dummy variable was included to test for variation in area burned related to weather regime shifts over the study period.

Results

Emergency firefighting expenditures are spent to suppress escaped fires, wildland fires 300 ac or larger (classes E, F, and G). Most fire starts are contained before the fire meets the definition of escaped wildfire. Over the period of analysis, between 97.2 and 99.7% of all fires were contained in the smaller fire classes A through D. However, a

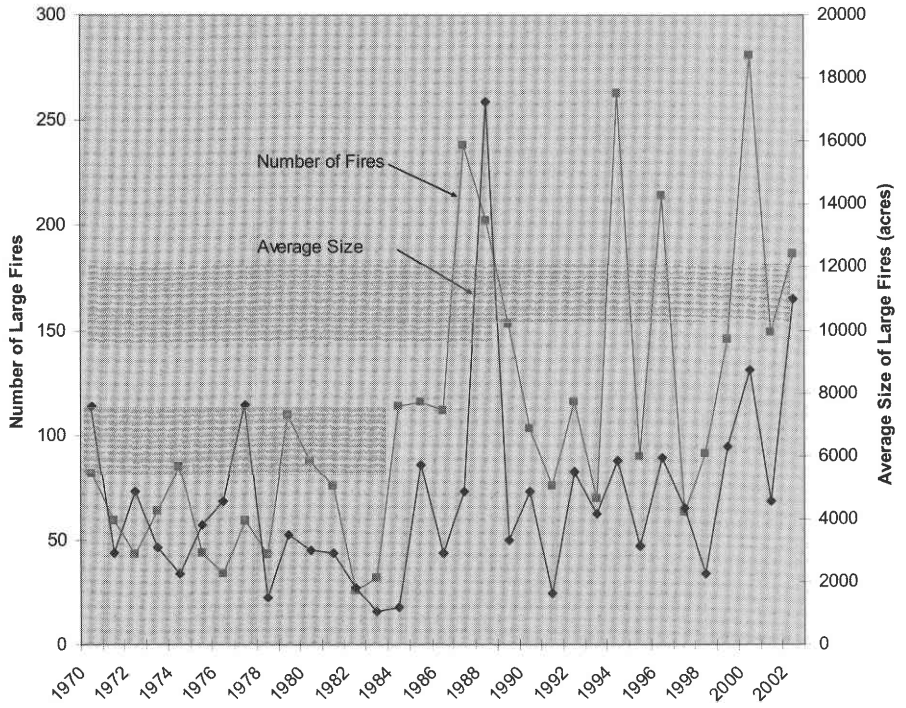

Figure 1. Number and average size of USDA Forest Service large fires (class E, F, and G).

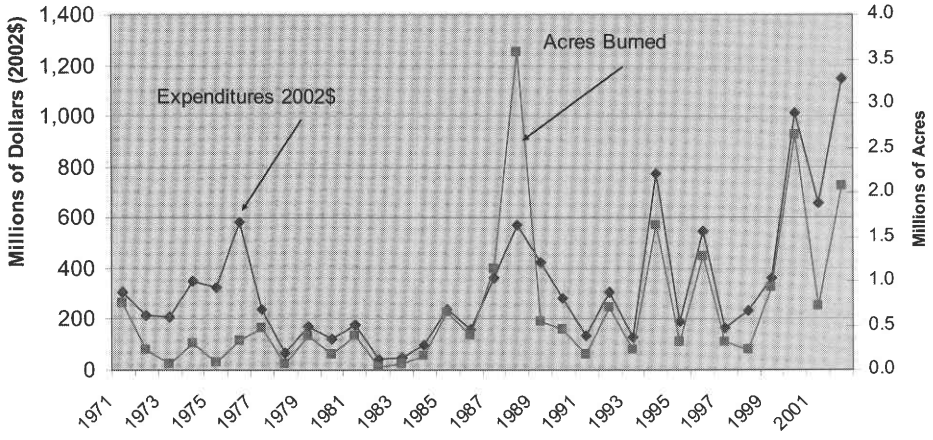

Figure 2. USDA Forest Service suppression expenditures (2002$) and area burned.

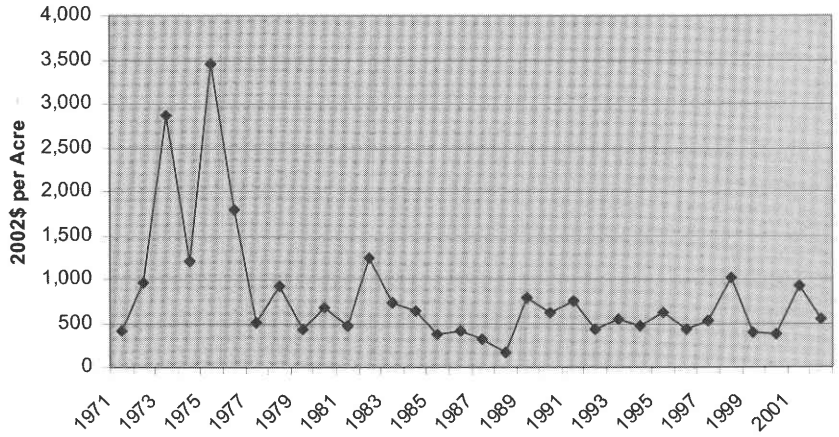

Figure 3. USDA Forest Service suppression expenditures per acre (2002$).

majority of all acres burned occurred in the larger fire classes. Averaged over the length of the study period, large fires accounted for only 1.1% of all fires but accounted for 97.5% of the area burned. Furthermore, there appears to be a trend of an increasing number of large fires and average size of these large fires over time (Figure 1).

Total annual emergency firefighting expenditures are extremely volatile, but an increasing trend is obvious in the data with nine of the 10 most expensive fire seasons (adjusted to 2002 dollars) occurring since 1987 (see Figure 2). Moreover annual suppression expenditures exceeded $1 billion in both 2000 and 2002.

Total expenditures can be broken down into two parts, total acres burned on large fires and the cost per acre of fighting these fires. Figure 3 displays that emergency suppression expenditures per acre burned have, in fact, exhibited a downward trend that starts to flatten out in the late 1980s. However, total area burned shows a different trend, increasing and becoming far more volatile around 1987 (Figure 2). If you simply take the average of area burned from 1970–1986 and 1987–2002, you see that the average has increased from approximately 285,000 to over 1,000,000 ac per year. Simply put, suppression expenditures increased and became erratic when acres burned increased and became erratic. Graphing emergency fire expenditures against total area burned (Figure 2) shows the close correlation between total expenditures and area burned (Pearson's correlation coefficient equaled 0.76 while the correlation between expenditures and cost per acre was an insignificant −0.019).

Results of modeling area burned as a function of PDSI were regional specific, but common patterns were evident. From the generic model described in Equation 1, the following model was developed:

$$\text{Ln (area burned}_t) = B_0 + B_1\text{*PDSI(fire)}_t + B_2\text{*PDSI}_{t-1} + B_3\text{*D1987}_t$$

Coefficient values, levels of significance, and model fit for the individual regional models are presented in Table 2. We transformed area burned using the natural logarithm to improve model fit based on results from Box-Cox tests (Green 1993). Not surprisingly, PDSI fire season was negative and significant in all regions; area burned increases when the fire season is drier. The previous year's PDSI was positive and significant (at

Table 2. Econometric model results for individual GACC regions (all results significant at the 0.05 level unless italicized with significance level in parenthesis).

Region	Constant	$PDSI(fire)_t$	$PDSI_{t-1}$	$D1987_t$	R^2
Pacific Northwest	9.453	–0.578	*0.185 (0.202)*	1.357	0.56
Northern California	9.717	–0.405	*0.204 (0.101)*	0.885	0.38
Southern California (July, Aug.)	10.776	–0.175	0.466	*0.503 (0.124)*	0.43
Southern California (July—Nov.)[a]	10.802	–0.193	0.454	*0.447 (0.176)*	0.43
Western Great Basin	7.652	–0.351	0.505	1.908	0.56
Eastern Great Basin	9.934	–0.600	0.699	1.847	0.67
Northern Rockies	9.211	–1.086	0.509	1.462	0.74

Southwest	10.212	–0.220	*0.268 (0.073)*	0.942	0.37
South	10.135	–0.361	0.271	0.627	0.56
East	9.028	–0.429	0.375	*0.087 (0.691)*	0.29

[a] Two fire season definitions were examined for Southern California. The first includes only July and Aug., while the second includes July and Aug. as well as Sept., Oct., and Nov. to represent the effects of Santa Ana winds on fire season severity.

the 0.05 level) in all regions except the Pacific Northwest and Northern California (significant at the 0.202 and 0.101 levels, respectively). These results are consistent with Westerling et al. (2003); moist growing seasons in the previous year increase fuel loading and thus area burned in the following fire season. Residual analysis of a model using only the two PDSI variables, as well as recursive residuals and Chow tests (Green 1993), confirmed that a structural shift in the model occurred around 1987 consistent with a significant shift in weather regimes. The annual dummy variable (D1987) was defined as 0 for years 1970–1986 and 1 for 1987 forward. The coefficient for D1987 was positive and significant in eight of the 10 models, indicating that after accounting for variations in PDSI, total area burned increased significantly starting in 1987. The coefficient for the dummy was positive but insignificant for the Southern California and Eastern regions (significant at the 0.124 and 0.691 level, respectively). The two alternative fire season definitions for Southern California performed equally well in predicting area burned with only modest changes in model parameters.

We calculated estimated area burned using a "smearing" estimate (Duan 1983) from the individual regional models and aggregated these results to determine estimated total area burned in the continental United States. Figure 4 presents the results of graphing estimated area burned against actual area burned for the United States over the length of the data series. The estimated acres burned tracks the actual acres burned very closely ($R^2 = 0.90$).

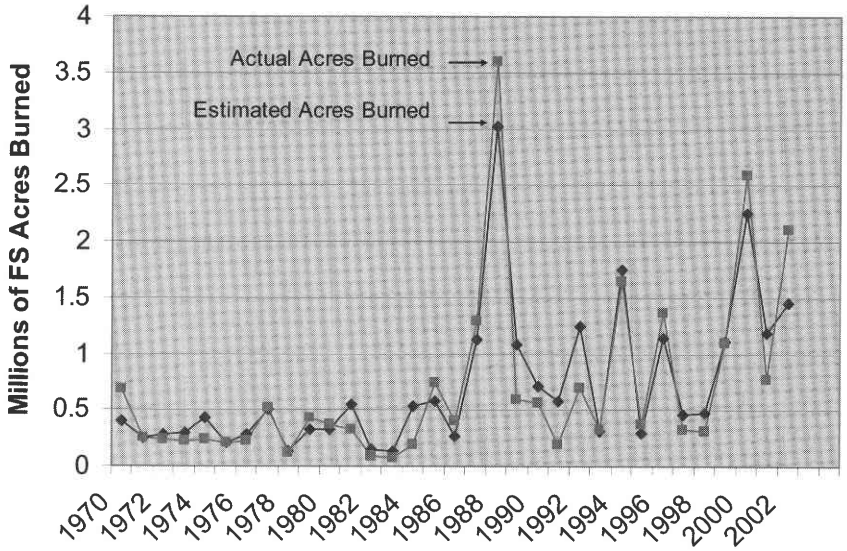

Figure 4. Estimated versus actual USDA Forest Service area burned.

Discussion

Total USDA Forest Service emergency fire suppression expenditures have been increasing over time with expenditures exceeding $1 billion in 3 of the last 4 years (including FY 2003). This increase in suppression expenditures appears to be related to the increase in acres burned (which also increased substantially over the same period) and not a per acre increase in suppression expenditures (trend for average per acre expenditures did not increase). Large fires represent a small number of the total fires, but constitute the bulk of total area burned; 1.1% of all fires burned 97.5% of total area. Both the number of large fires and average size of large fires appear to have increased over time.

Total area burned tracks suppression expenditures very well. Area burned can be modeled successfully using current and past regional drought indices, yet a significant dummy variable improves model fit, implying that total area burned significantly increased after 1987. The common rationales for increasing fire expenditures do not account for this structural shift. Increasing development within the wildland-urban interface has been increasing over the study period, but does not account for any distinct shifts. Firefighting agencies are likely focusing more resources on structural protection, reflecting the development trends in the WUI, but those shifts are also continuous and do not explain a major change occurring in 1987. Excessive fuel loading has certainly been responsible for the increased size and severity of some wildland fires, but fuel loading has been building for decades. The key factor that we believe is driving the system and interacting with the excessive fuel loads is the weather. Over the past 15 years, a long-term weather regime shift, caused by oceanic interdecadal oscillations, has increased the length and intensity of the wet and dry periods. During wet periods, fine fuel growth increases fuel loading where fuel loads are often already well above historic

conditions due to past fire exclusion. During prolonged, intense dry periods, these fuels dry out, and then if a fire starts, it is more likely to be large and of high intensity.

Currently, cost containment strategies are being put forward as the means to control the unprecedented suppression expenditures seen in the last several years. In the fall of 2003, a blue ribbon panel is being convened by the USDI and USDA to address cost containment. The Large Fire Cost Reduction Action Plan (USDA, USDI, NASF 2003) highlighted this issue, stating that "we must elevate cost containment commensurate with other objectives." Along these lines, there have been recommendations to reduce utilization of high cost resources such as aircraft. We do not deny that inefficiencies in fire suppression efforts likely exist and that these actions should be identified and addressed. However, making assumptions that reducing the use of high-cost resources will improve cost containment is premature. The production functions for fire suppression resources are largely unknown, as is the effect in certain instances of not applying suppression resources. Without this additional information, high cost, highly effective resources may be replaced with lower cost, but less effective resources. The results of our analysis suggest that the current level of suppression expenditures is largely a function of acres burned, and acres burned are largely a function of weather-related variables. Current weather patterns are exacerbating a difficult firefighting environment due to fuels accumulation and WUI development. Strategies to contain costs based on anecdotal information without carefully thought out analysis may in fact increase fire damages and overall costs.

PNAS OPINION

Wildland-urban fire disasters aren't actually a wildfire problem

David E. Calkin[a,1], Kimiko Barrett[b], Jack D. Cohen[c,2], Mark A. Finney[d], Stephen J. Pyne[e,2], and Stephen L. Quarles[f]

Major fires like this one, a damaging wind-fueled fire near Superior, Colorado, in December 2021, are typically defined as an issue of *wildfires* that involved houses. In reality, they are *urban fires* initiated by wildfires. That's an important distinction. Image credit: iStock/milehightraveler.

Consider several of the most devastating fire disasters of the last century. In August 2023, the wildfire-initiated urban conflagration of Lahaina, Hawaii, damaged or destroyed more than 2,200 structures and killed 98 people. In December 2021, the Marshall Fire sparked conflagrations in Superior and Louisville, Colorado, destroying 1,084 structures and killing two. In September 2020, the Almeda Drive Fire in the communities of Talent and Phoenix, Oregon, destroyed 2,600 homes and killed three. In November 2018, the Camp Fire initiated ignitions in Paradise, California, destroyed 18,804 buildings, and killed 85. In November 2016, fires spread through Gatlinburg and Pigeon Forge, Tennessee, destroying 2,460 structures and killing 14.*

These fire disasters burned in vastly different environments. But all had human causes (power lines contributed to at least three), were near communities, occurred during extreme wind events, then inflicted their damage as urban conflagrations. Almost all destruction occurred within the first 12 hours after ignition. These fires immediately overwhelmed wildland and structural firefighting efforts, which were largely ineffective during the initial and extreme phase of the fire. Further, all these fires occurred since 2016. It's clear that structures and whole communities were vulnerable to ignition and burning—irrespective of what initiated the fires.

Society largely regards the wildfire problem as the destruction of human communities. Collectively, disaster fires, such as those mentioned here, have been

*Although the Chimney Tops 2 Fire on the Great Smoky Mountains National Park ignited on November 23, 2016, may have contributed to the burning of Gatlinburg and Pigeon Forge, multiple power line ignitions during the extreme weather event of November 28 preclude the ability to identify a single or dominant ignition source that resulted in the community destruction.

lumped into a category of wildland–urban interface fires. These problem fires were defined as an issue of *wildfires* that involved houses. In reality, they are *urban fires* initiated by wildfires. That's an important distinction—and one that has big repercussions for how we prepare for future fires. To date, these repercussions have not received enough attention.

The Right Framing

Community fire destruction has become a national crisis, a systemic problem that will only worsen without aggressive, appropriate intervention—and this intervention will have to look far different than the current dominant paradigm. Climate change is blurring the boundaries that had defined where, when, and how fires burn (1). The needed changes will challenge ideas, institutions, and policies. The first step: reframing, from a focus on the wildlands to one centered on the structure and its immediate surroundings.

To effectively address this urban conflagration crisis requires that we fundamentally redefine the WU fire problem. Calkin et al. (2) developed a community wildfire risk framework that starts with a focus at the individual home level and identifies realistic objectives, effective mitigations, and responsible parties to reduce WU fire risk. The framework highlights the critical role of individual homeowners and local government, while recognizing that the traditional federal and state land-management agencies with responsibilities for wildland fuels management and suppression response have limited impact on community destruction. However, many of the recent investments to address wildfire risk to communities, such as the Bipartisan Infrastructure Investment and Jobs Act of 2021 and the Inflation Reduction Act of 2022, are primarily directed toward fuel treatments in natural areas governed by public land-management agencies.

The practice of modifying the built environment to growing wildfire risk requires multidisciplinary understanding of wildfire behavior, structural ignition vulnerabilities, urban resilience, and landscaping vegetation.

The wildfire management system's default response is to suppress wildfire wherever and whenever possible, with few exceptions (3). It extends an urban fire service model into the wildlands. With fire exclusion as the primary solution to both community and wildland protection, risk reduction translates to fire suppression and landscape fuel reduction. As wildfire losses increase, the assumption that community protection should be a primary focus of federal wildfire management efforts has become entrenched within both agency culture and federal legislation.

But even as wildfire suppression costs and use of technology have skyrocketed, we are experiencing more damaging urban fires. Clearly, the answer to community adaptation resides in the communities themselves (2, 4), and until the WU fire problem statement is redefined to recognize the key role of structure ignition and focus on creating ignition-resistant communities, risk-reduction strategies will continue to be ineffective and insufficient.

The Right Response

In 2022, the US Forest Service released the *Wildfire Crisis Strategy*, outlining an ambitious goal of treating an additional 20 million acres of US Forest Service land and 30 million acres of other federal, tribal, state, and privately owned land "to address wildfire risks to critical infrastructure, protect communities, and make forests more resilient" (ref. 5; see also ref. 6). While federal land-management agencies—primarily the US Forest Service and Department of Interior—have been tasked with wildfire risk reduction, most wildfire ignitions are caused by humans and occur on private lands (7), including those that destroy a majority of structures in the western United States (8). Furthermore, what has often been considered a western United States issue has now come to the fore in locations with limited wildfire experience, such as Gatlinburg, Tennessee, and Lahaina, Hawaii, thus creating additional challenges. As a result, actions on private land are essential to achieving fire-adapted communities across the country.

The community disaster sequence occurs when more homes are ignited than responders can protect (Fig. 1). Once structures are burning in a community, they become sources of lofted embers, radiant heat, and flame contact. Thus, community fire growth can accelerate quickly, resulting in urban conflagration that's exacerbated in higher-density development due to structure-to-structure fire spread. Reducing the likelihood that a home will ignite interrupts the disaster sequence by enabling effective structure protection. New construction siting, design, construction materials, and landscaping requirements should take wildfire potential into account. This will improve community resilience and ensure that new development does not increase community risk. The best way to make existing wildfire-vulnerable developments ignition resistant is to work within the limited area of the "home ignition zone"—a home and its surroundings within 100 feet (which may include neighboring homes). There are ways to reduce home ignition risk. Homeowners should install nonignitable roofing materials and flame- and ember-resistant vents; clean gutters of flammable debris; ensure that wooden steps, fences, and decks do not directly contact a home's flammable materials; and remove flammable materials immediately surrounding buildings and under attached decks (9–11).

Initiating substantial changes to the built environment requires that all levels of society address deeply rooted cultural expectations and develop a fundamentally new paradigm for community and homeowner responsibility. Such changes will take time. Communities need robust evacuation planning, including resilient early warning systems, identification and enhancement of egress routes, and consideration of support for individuals with mobility difficulties that all recognize the complexity of individual decision-making during emergency events (12). The community disaster sequence typically occurs during extreme wind events; thus, ignition-prevention programs should address infrastructure resilience and human behavior under these conditions.

Unfortunately, many communities and local governments often lack the resources, budget, staff, and experience to implement and maintain parcel- and neighborhood-level risk-reduction measures. The practice of modifying the built

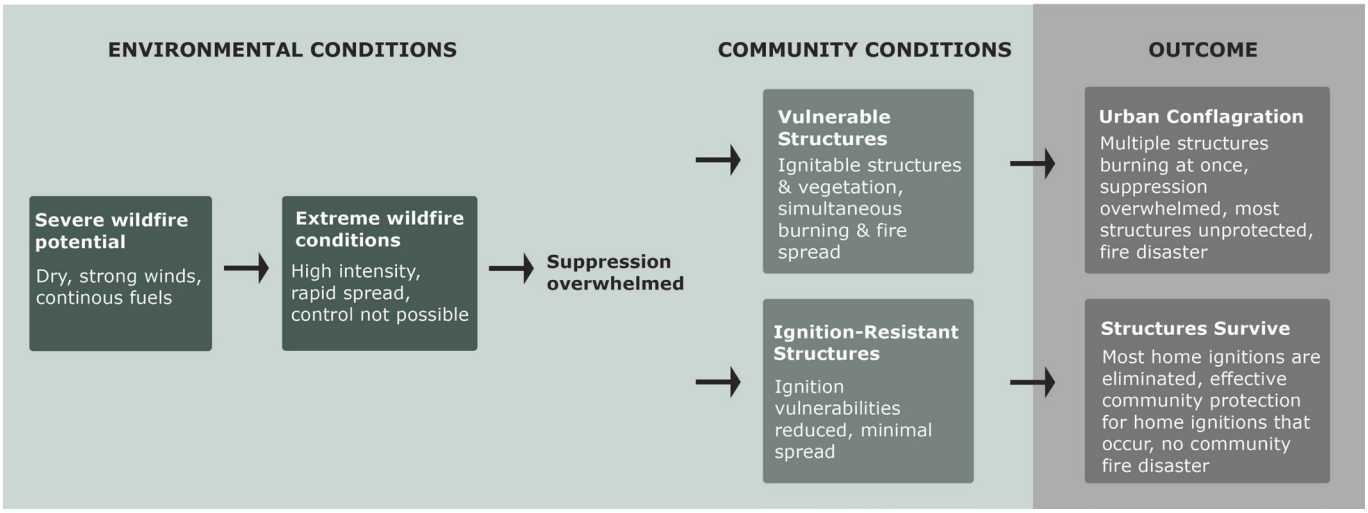

Fig. 1. The community fire disaster sequence. Enabling wildfire conditions set the stage for disaster, but the condition of the community defines the outcome.

environment to growing wildfire risk requires multidisciplinary understanding of wildfire behavior, structural ignition vulnerabilities, urban resilience, and landscaping vegetation. Such know-how is not intrinsic institutional knowledge for public land-management agencies. As such, an appropriate response may resemble public health measures, where protecting the host from infection (home ignition prevention) is emphasized over trying to eliminate the infectious agent (wildfire).

Community leaders and locally elected officials are central to implementing effective wildfire mitigation strategies. And these leaders require significant technical assistance and financial support from federal and state levels. They need administrative mechanisms to direct funding and technical assistance to communities; this will require enhanced interagency coordination among federal and state-level departments, which can administer resources to local jurisdictions. Initial efforts in California, Colorado, and Oregon are structuring home ignition mitigation programs on this model, with the underlying objective of delivering funding, support, and expertise to communities and individual residents (13–15).

A New Perspective

All such projects and reforms must recognize an important truth: The current wildfire management approach has inverted the wildfire problem. wildland fires do not, per se, encroach on communities. Rather, it's communities that have impinged on wildlands, where fires play an important ecological role. Predominant strategies continue to apply limited, risk-averse reactions that emphasize community protection at the expense of both resilient landscapes and safe, effective wildfire responses. Forward-looking ecological and practical thinking would help move communities away from continually degrading fire-adapted ecosystems and underinvesting in community resilience. Instead, this change in thinking will move toward a sustainable approach that consistently promotes ecological and human ecosystem benefits.

Communities and governments need to accept living with wildland fire. They must recognize that fire in the wildlands is ecologically appropriate and inevitable—and it does not significantly influence community fire destruction (16). To do this, we must communicate differently on the nature of the WU fire problem and the ecological necessity of wildland fire. We must empower our public land managers and tribal partners to utilize fire appropriately to sustain resilient ecosystems and adapt our communities to this natural reality.

Inasmuch as people and communities are implicated in the wildfire problem, so, too, are they part of the solution. Federal land-management agencies cannot resolve this crisis alone; we all have a role to play in reducing wildfire risk in the places we live. Stronger collaboration in public and private partnerships, such as those that increase alignment between insurance providers, residents, and local and state governments, could further encourage and incentivize risk-reduction measures at the individual parcel and neighborhood scale.

The Wildfire Partners Program in Boulder County, Colorado, offers a model for an integrated approach to wildfire mitigation. It supports homeowners in reducing risk on their property by local government providing technical and financial support, including individual home assessments, vulnerability reports, and grants to subsidize necessary work, while offering a platform where insurance providers actively engage with homeowners to retain coverage on mitigated homes (17). This interdisciplinary approach builds wildfire resiliency from the bottom up and helps temper the expectation that the federal government is exclusively responsible for community protection.

Wildfire risk is complex, and local context matters. The ability to adapt reflects the realities, resources, and diverse needs of any one community. Effective solutions must account for localized nuance (18). Federal and state administrations can help direct funding, assistance, and technical expertise for wildfire mitigation. Communities with high social vulnerability will likely need additional support.

The recent addendum to the "National Cohesive wildland Fire Management Strategy" (19) specifies an important goal: "Human populations and infrastructure are as prepared as possible to receive, respond to, and recover from wildland fire." Achieving this vision means confronting the failed approach of trying to remove fire from our landscapes. We

Downloaded from https://www.pnas.org by 199.68.205.95 on January 9, 2024 from IP address 199.68.205.95.

must recognize that our communities were developed in a climate and environment that no longer exist. We have the tools and knowledge to reduce community wildfire risks. But we must address the profound and deeply rooted misalignment of political and social expectations regarding what it means to live with wildfire. Now is the time to invest in long-term, economically efficient solutions, rather than short-term, risk-averse tactics.

We have to live with wildland fire. We don't have to live with fire in our communities.

Preventing DISASTER

Home Ignitability in the Wildland–Urban Interface

Wildland-urban interface (W-UI) fires are a significant concern for federal, state, and local land management and fire agencies. Research using modeling, experiments, and W-UI case studies indicates that home ignitability during wildland fires depends on the characteristics of the home and its immediate surroundings. These findings have implications for hazard assessment and risk mapping, effective mitigations, and identification of appropriate responsibility for reducing the potential far home lass caused by W-UI fires,

By Jack D. Cohen

Once largely considered a California problem, residential fire losses associated with wildland fires gained national attention in 1985 when 1,400 homes were destroyed nationwide (Laughlin and Page 1987). The wildland fire threat to homes is increasing and is commonly referred to as the wildland—urban interface (W-UI) fire problem. Since 1990, W-UI fires have threatened and destroyed homes in Alaska, Arizona, California, Colorado, Florida, Michigan, New Mexico, New York, and Washington. Extensive or severe fires in Yellowstone in 1988, Oakland in 1991, and Florida in 1998 attracted much media coverage and focused national attention on wildland fire threats to people and property

Federal, state, and local land management and fire agencies must directly and indirectly protect homes from wildfire within and adjacent to wildlands. Davis (1990) indicated that since the mid-1940s, a major population increase has occurred in or adjacent to forests and woodland areas. Increasing residential presence near fire-prone wildlands has prompted agencies to take actions to reduce W-UI fire losses.

When an apparently all-encompassing, seemingly unstoppable W-UI fire occurs, the rapid involvement of many homes over a wide area produces a surreal impression; some homes survive amid the complete destruction of surrounding residences. After the 1993 Laguna Hills fire, some termed this seemingly inexplicable juxtaposition a "miracle.' Miracles aside, the characteristics of the surviving home and its immediate surroundings greatly influenced its survival.

Wildland fire and home ignition research indicates that a home's exterior and site characteristics significantly influence its ignitability and thus its chances for survival. Considering home and site characteristics when designing, building, siting, and maintaining a home can reduce W-UI fire losses.

W-UI Fire Loss Characteristics

W-UI residential fire losses differ from typical residential fire losses. Whereas residential fires usually involve one structure with a partial loss, W-UI fires can result in hundreds of totally destroyed homes. Particularly during severe W-UI fires, numerous

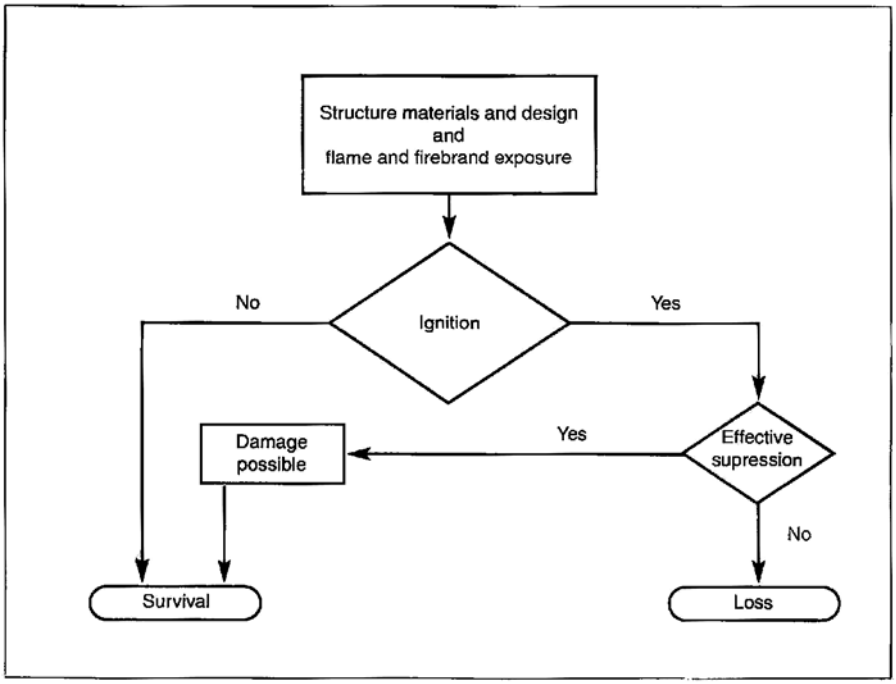

***Figure 1*. The structure survival process**

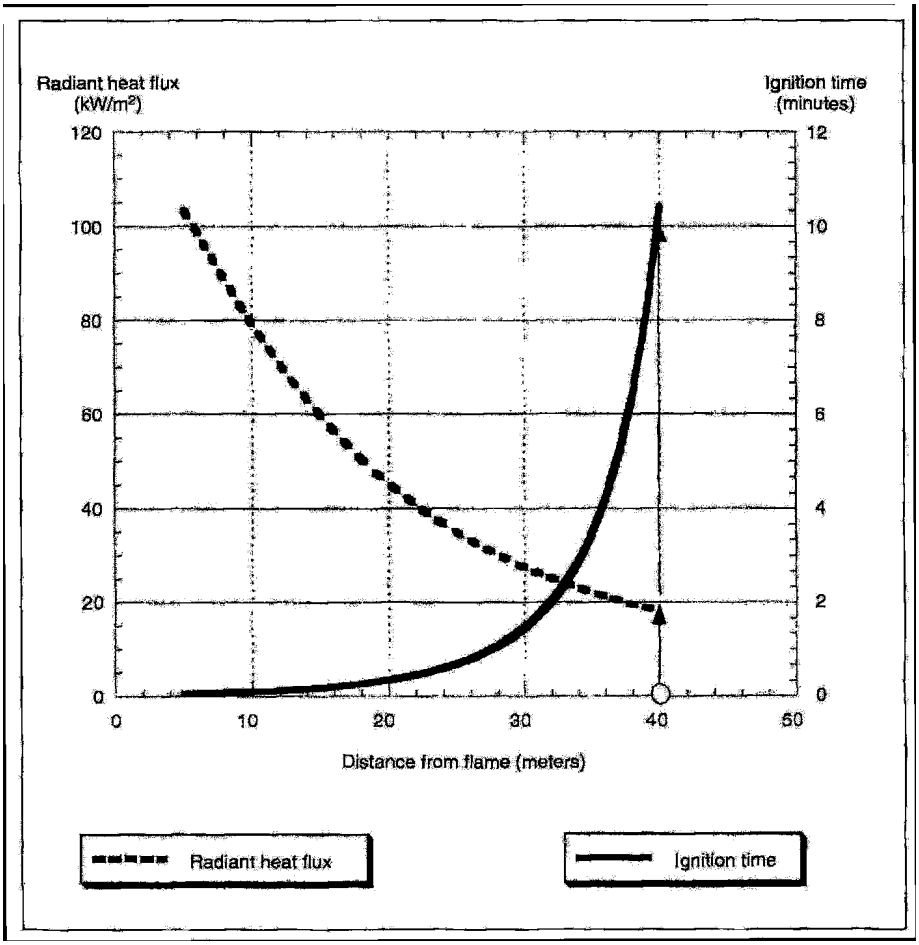

***Figure* 2.The incident radiant heat flux is shown as a function of a wall's distance from a flame 20 meters high by 50 meters wide, uniform, constant, 1,200 K, black-body. The minimum time required for a piloted wood ignition is shown given the corresponding heat flux at that distance.**

homes can ignite in a very short time. The usual result is that a home either survives or is totally destroyed; only a few structures incur partial damage (Foote 1994).

The W-UI Fire commonly originates in wildland fuels. During dry, windy conditions in areas with continuous fine fuels, a wildland fire can spread rapidly, outpacing the initial attack of firefighters. If residences arc nearby, a wildland fire can expose numerous homes to flames and lofted burning embers, or firebrands.

A rapidly spreading wildland fire coupled with highly ignitable homes can cause many homes to burn simultaneously. This multistructure involvement can overwhelm fire protection Capabilities and, in effect, result in unprotected residences. Severe W-UI fires can destroy whole neighborhoods in a few hours—much faster than the response time and suppression capabilities of even the best—equipped and staffed firefighting agencies. For example, 479 homes were destroyed during the 1990 Painted Cave fire in Santa Barbara, most of them within two hours of the initial fire report. The 1993 Laguna Hills fire in southern California ignited and burned nearly all of the 366 homes destroyed in less than five hours.

Whether a home survives depends initially on whether it ignites; if ignitions with continued burning occur, survival then depends on effective fire suppression. *Figure 1* shows that home survival begins with attention to the factors that influence ignition. These factors determine home ignitability and include the structure's exterior materials and design combined with its exposure to flames and firebrands. The lower the home ignitability the lower the chance of incurring an effective ignition.

Ignition: A local Process

Ignition and spread of fire, whether on structures or in wildland vegetation, is a combustion process. Fire spreads as a continuing ignition process whether from the propagation of flames or from the spot ignitions of firebrands. Unlike a flash flood or an avalanche, in which a mass engulfs objects in its path, fire spreads because the requirements for

combustion are satisfied at locations along the path. The basic requirements for combustion—the fire triangle—are fuel, heat, and oxygen. An insufficiency of any one of the three components, which can occur over a relatively short distance, will prevent a specific location from burning. "Green islands" that remain after the passage of a severe, stand-replacement fire demonstrate this phenomenon. Commonly one can find a green, living tree canopy very close to a completely consumed canopy.

The requirements for combustion equally apply to the W-UI fire situation. In the wildland fire context, fire managers commonly refer to vegetation as fuel. However, for the specific context of W-UI residential fire losses, a house becomes the fuel. Heat is supplied by the flames of adjacent burning materials that could include firewood piles, dead and live vegetation, and neighboring structures. Firebrands from upwind fires also supply heat when they collect on a house and adjacent flammable materials. The atmosphere amply supplies the third necessary component, oxygen.

A wildland fire cannot spread to homes unless the homes and their adjacent surroundings meet those combustion requirements. The home ignitability determines whether these requirements are met, regardless of how intensely or fast—spreading distant fires are burning. To use an extreme example, a concrete bunker would not ignite during any wildland fire situation. At the other extreme, some highly ignitable homes have ignited without flames having spread to them. These homes directly ignited from firebrands.

Firebrands are a significant ignition source during W-UI fires, particularly when flammable roofs are involved. Foote (1994) found a significant difference in home survival solely based on roof f1ammability. Homes with nonflammable roofs had a 70 percent survival rate compared with 19 percent for homes with flammable roofs. Davis (1990) reported similar results related to roof flammability.

Reducing W-UI fire losses in the context of home ignitability involves mitigating the fuel and heat components sufficiently to prevent ignitions. However, the question of sufficiency (or efficiency) remains: How much, or perhaps more appropriately, how little fuel and heat reduction must be done to effectively reduce home ignitions? To answer this question, we must first quantify the heat source in terms of the fuel's ignition requirements; specifically, how close can flames be to a home's wood exterior before an ignition occurs?

Research Insights

Diverse research approaches are providing clues for assessing the fuel and heat requirements for residential ignitions. Structure ignition modeling, fire experiments, and W-UI fire case studies indicate that the fuel and heat required for home ignitions only involve the structure and its immediate surroundings—the home ignitability context.

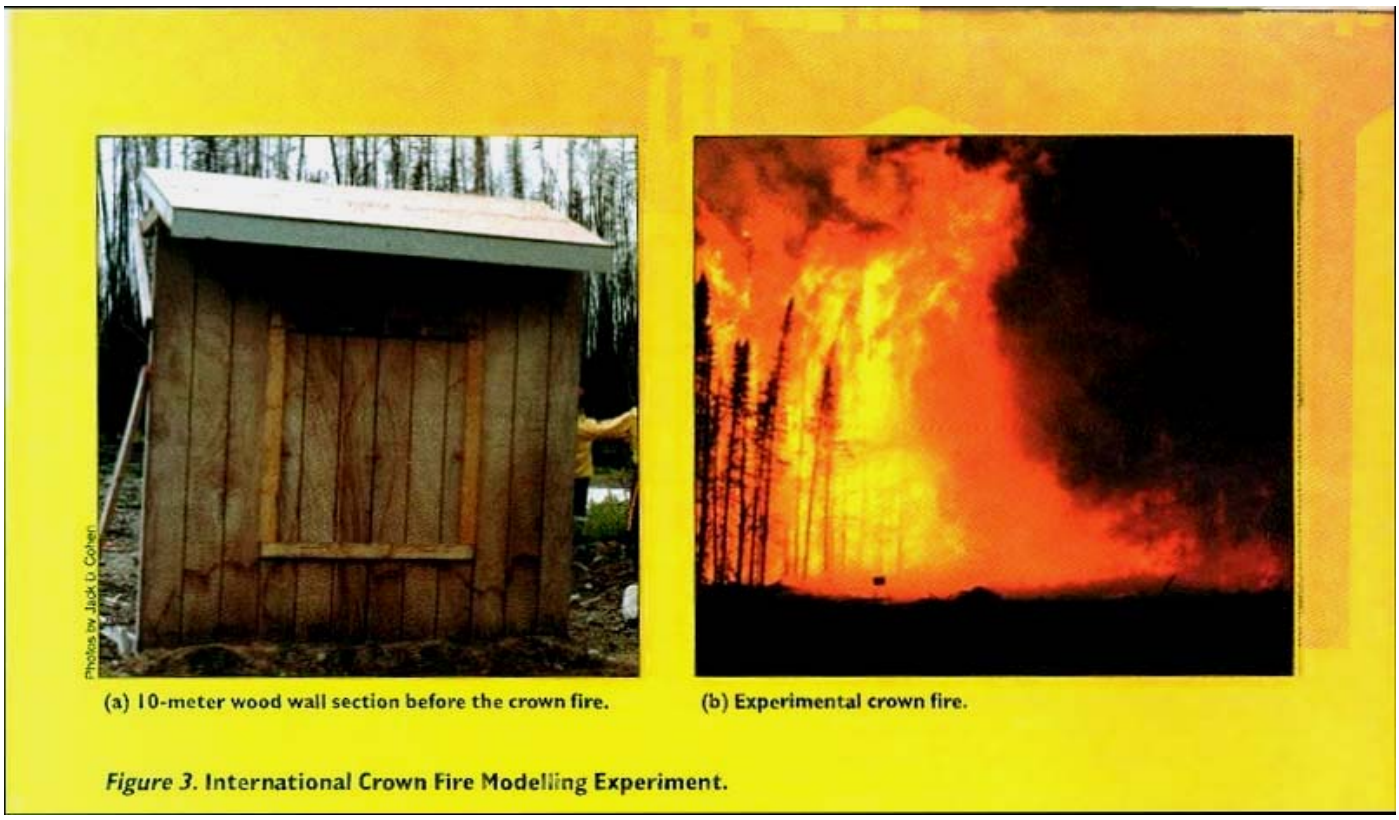
Modeling. The Structure Ignition Assessment Model (SIAM) (Cohen 1995) is currently being developed to asses the potential for structure ignitions from flame exposure and firebrands during W-UI fires. One function of SIAM is to calculate the total heat transferred, both radiation and convection, to a structure for varying flame sizes and from varying distances. From the calculated heat transfer, SIAM calculates the amount of heat over time that common exterior wood products can sustain before the occurrence of a piloted ignition (Tran et al. 1992).

Piloted ignition When wood is sufficiently heated, it decomposes to release combustible volatiles. At a sufficient volatile—air mixture, a small flame or hot spark can ignite it to produce flaming; thus, a piloted ignition.

Based on severe-case assumptions of flame radiation and exposure time, SIAM calculations indicate that wildland flame fronts comparable to crowning and torching trees (flames 20 meters high and 50 meters wide) will not ignite wood surfaces at distances greater than 40 meters (Cohen and Butler, in press). *Figure 2* shows the radiant heat a wall would receive from flames depending on its distance from the fire. The incident radiant heat flux, defined as the rate of radiant energy per unit area received at an exposed surface, decreases as the distance increases.

Figure 2 also shows that the time required for ignition depends on the distance to a flame of a given size. At 40 meters the radiant heat transfer is less than 20 kilowatts per square meter

1 kW/m^2	Maximum for indefinite skin exposure.
10.4 kW/m^2	Pain after three seconds of skin exposure.
16.0 kW/m^2	Second-degree burn after five seconds of skin exposure.



Source: Drysdale 1985.

(kW/m^2), which translates to a minimum piloted ignition time of more than 10 minutes.

Ten minutes, however, is significantly longer than the burning time of wildland flame fronts at a location. Large flames of wildland fires typically depend on fine dead and live vegetation, which limits the intense burning duration at a specific location to less than a few minutes. Recent crown fire experiments have demonstrated a location-specific burning duration of 50 to 70 seconds.

Experiments. Field studies conducted during the International Crown Fire Modelling Experiment (Alexander et al. 1998) provide data for comparisons with SIAM model estimates. Total heat transfer (radiation and convection) and ignition data were obtained from heat flux sensors placed in wooden wall sections.

The instrumented walls were located on flat, cleared terrain at 10, 20, and 30 meters downwind from the edge of the forested plots. The wall section at 10 meters was 2.44 meters wide and 2.44 meters high with a 1.22-meter eave and roof section (*fig. 3a)*. Exterior plywood (T-1-11) covered the wall with oriented-strand board covering the roof section and the eave soffit. Trim boards were solid wood with wood fiber composition board on the cave fascia. None of the materials were treated with fire retardant.

(a) 10-meter wood wall section before the crown fire. (b) Experimental crown fire.

Figure 3. International Crown Fire Modelling Experiment.

The forest was variably composed of an overstory of jack pine *(Pinus banksiana)* about 14 meters high with an understory of black spruce *(Picea mariana).* The spreading crown fire produced flames approximately 20 meters high. *Figures 3b and 3c* show examples of the experimental crown fire.

Five burns were conducted where wall sections were exposed to a spreading crown fire. As the crown fires reached the downwind edge of the plot, turbulent flames extended into the clearing beyond the forest edge. In two of the five burns, flames extended beyond 10 meters to make contact with the 10-meter wall section. When flame contact occurred, the 10-meter walls ignited; however, without flame contact, only scorch occurred, as shown in *figure 3d.* The wooden panels at 20 meters experienced light scorch when flames extended beyond 10 meters from the experimental plot, and no scorch from the other burns. The 30-meter wall section had no scorch from any of the crown fires.

Figure 4 displays the average total incident heat flux (radiation and convection combined) corresponding to the wall at 10 meters *(fig. 3d)* and the crown fire shown in figures *3b and 3c.* The average total incident heat flux is calculated from two sensors placed 1 meter apart in the wall. The amount of heat received by the wall increased as the flame front approached and decreased as the fine vegetation was consumed. The initial heat flux "spike" was caused by a nonuniform crowning flame front.

The flux-time integral shown in *figure 4* indicates whether sufficient heating has occurred to pilot-ignite wood (Tran et al. 992). SIAM uses the flux-time integral for calculating ignition potential, a correlation of the incident heat flux and the time required for piloted wood ignition.

The flux-time correlation identifies two principal ignition criteria: (1) A minimum heat flux of 13 kW/m^2 must occur before a piloted ignition can occur for any exposure time, and (2) piloted ignition depends on attaining a critical heating dosage level (heat transfer and its duration). These criteria are graphed in *figure 4.* The flux-time integral only increases for incident heat fluxes greater than the minimum of 13 kW/m^2, and the flux-time integral threshold value of 11,500 is shown as the ignition threshold. As seen in the figure, the flux-time integral does not reach the ignition threshold, indicating an exposure insufficient for ignition and corresponding to no actual occurrence of a wall ignition. Therefore, a home at some distance from a large flame front, such as a crown fire, may not receive sufficient energy to meet the minimum for ignition over any time period. In addition, a home closer to a large flame front can receive a high heat flux (for example, 46 kW/m^2 as shown in *figure 4*), but without the necessary duration to meet the threshold for ignition.

The flux-time integral plot indicates the duration of the heat transfer relevant to ignition. The heat transfer duration relevant to ignition combines the heat transfer from the approaching crown fire plus the burning time of the fire after it has reached the end of the plot. The observed time required for the flux-time integral to increase from zero to its maximum value corresponds to the heat transfer duration significant for ignition. *Figure 4* indicates a duration of 65 seconds (flux-time plot from 75 seconds to 140 seconds).

Case studies. Case studies of actual W-UI fires provide an independent comparison with SIAM and the crown

(c) Experimental crown fire.

(d) After crown fire exposure the wall scorched but did not ignite. Note the lack of wall scorch under the eave because of the radiation "shading" from the eave.

fire experiments. The actual fires incorporate a wide range of fire exposures. The case studies chosen examine significant factors related to home survival for two fires that destroyed hundreds of structures. The Bel Air fire resulted in 484 homes destroyed (Howard et al. 1973) and the Painted Cave fire destroyed 479 homes (Foote 1994).

Analyses of both fires indicate that home ignitions depend on the characteristics of a structure and its immediate surroundings. Howard et al. (1973) observed 86 percent survival for homes with nonflammable roofs and a clearance of 10 meters or more.

Dicussion

A comparison of the SIAM model calculations in *figure 2* with the observed heat flux from the experimental crown fire in *figure 4* indicated that the model overestimates the heat flux. The model calculation at 10 meters reveals a radiant heat flux of 70 kW/m^2, which exceeds the highest total heat flux of 46 kW/m^2 observed

At the 10-meter wall section in *figure 4*. SIAM calculations

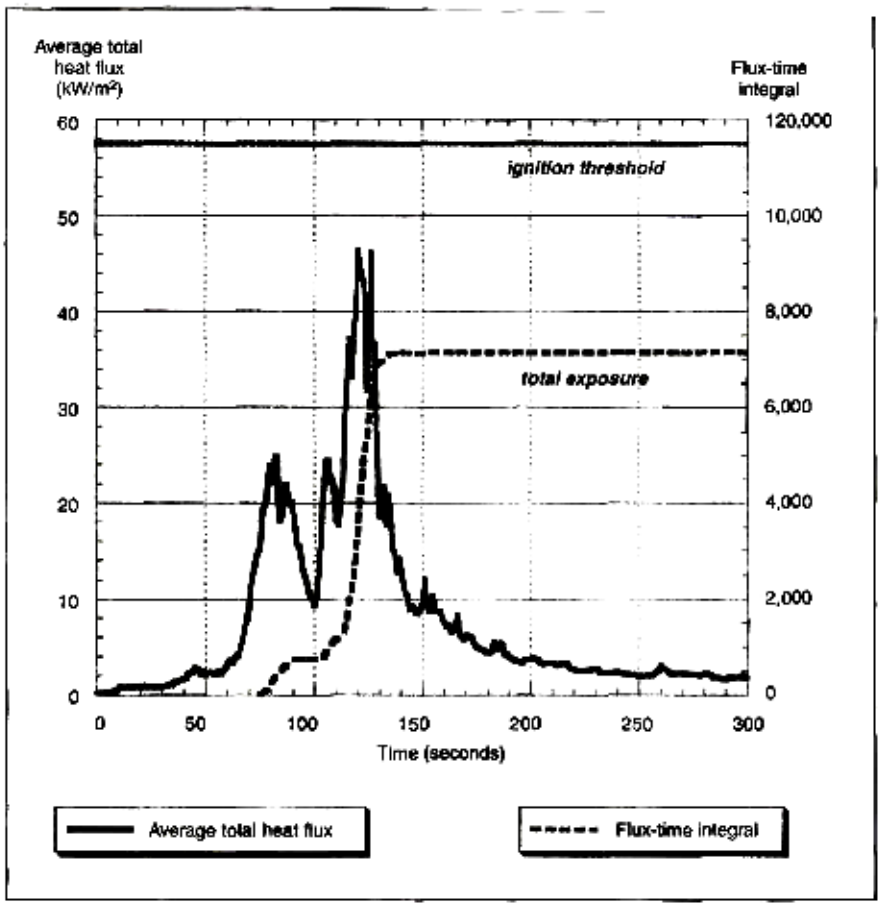


Figure 4. Actual average total incident heat flux and flux-time integral for the crown fire and 10-meter wall section shown in figure 3.

overestimate the heat transfer because the severe-case assumptions designate a homogeneous, black-body radiating flame front. Real flame fronts do not meet these assumptions and produce a significantly smaller radiant heat flux by comparison. For a given flame front, the SIAM calculations represent an extreme-case estimate of radiant heat transfer, and thus an extreme-case estimate of ignition potential.

Given the duration of the experimental heat flux (65 seconds), we can calculate the heat flux and corresponding distance required for ignition. At 65 seconds, the ignition time graph (*fig. 2)* indicates ignition at a flame distance of less than 30 meters. If the heat flux duration is extended by a factor of five to 325 seconds, the flame distance for ignition is less than 40 meters. By comparison, the 10-meter wall sections in the crown fire experiment did not ignite without flame contact and all burns produced little or no scorch to wall sections at 20 and 30 meters. The W-UI fire case studies indicated approximately 90 percent survival with a vegetation clearance on the order of 10 to 20 meters for homes with nonflammable roofs. Thus, the case studies support the general flame-to-structure distance range of 10 to 40 meters as found through modeling and experiments.

However, firebrands can also cause homes to ignite during wildland fires. Although firebrands capable of ignition can originate from a fire several kilometers away, homes can only be threatened if the firebrands ignite the home directly or ignite adjacent flammable materials that then ignite the home.

Analyses of potential home ignitions using modeling, experiments, and case studies did not explicitly address firebrand ignitions. However, firebrand ignitions were implicitly considered because of the firebrand exposures that occurred during the crown fire experiments and the case studies. The experimental crown fires provided a firebrand exposure that resulted in spot ignitions in the dead wood and duff around the wall sections hut not directly on the walls. In the case studies, firebrand ignitions occurred throughout the areas affected by the Bel Air and Painted Cave fires. The high survival rate for homes with nonflammable roofs and 10- to 20-meter vegetation clearances included fire-brands as an ignition factor, thus indicating that firebrand ignitions also depend on the ignition characteristics of the home and the adjacent flammable materials.

Conclusions

The key to reducing W-UI home fire losses is to reduce home ignitability. SIAM modeling, crown fire experiments, and case studies indicate that a home's structural characteristics and its immediate surroundings determine a home's ignition potential in a W-UI fire. Using the model results as guidance with the concurrence of experiments and case studies, we can conclude that home ignitions are nor likely unless flames and firebrand ignitions occur within 40 meters of the structure. This finding indicates that the spatial scale determining home ignitions corresponds more to specific home and community sites than to the landscape scales of wildland fire management. Thus, the W-UI fire loss problem primarily depends on the home and its immediate site.

Consequently if the community or borne site is not considered in reducing W-UI fire losses, extensive wildland fuel reduction will be required. For highly ignitable homes, effective wildland fire actions must riot only prevent fires from burning to home sites, but also eliminate firebrands that would ignite the home and adjacent flammable materials. To eliminate firebrands, wildland fuel reductions would have to prevent firebrand production from wildland fires for a distance of several kilometers away from homes.

Management Implications

Because home ignitability is limited to a home and its immediate surroundings, fire managers can separate the W-UI structure fire loss problem from other landscape-scale fire management issues. The home and its surrounding 40 meters determine home ignitability, home ignitions depend on home ignitability, and fire losses depend on home ignitions. Thus, the W-UI fire loss problem can be defined as a home ignitability issue largely independent of wildland fuel management issues. This conclusion has significant implications for the actions and responsibilities of homeowners and fire agencies, such as defining and locating potential W-UI fire problems (for example, hazard assessment and mapping), identifying appropriate mitigating actions, and determining who must take responsibility for home ignitability

W-UI fire loss potential. Because home ignitions depend on home ignitability, the behavior of wildland fires beyond the home or community site does not necessarily correspond to W-UI home fire loss potential. Homes with low ignitability can survive high-intensity wildland fires, whereas highly ignitable homes can be destroyed during lower-intensity fires.

This conclusion has implications for identifying and mapping W-UI fire problem areas. Applying the term wildland-urban interface to fire losses might suggest that residential fire threat occurs according to a geographic location. In fact, the wildland fire threat to homes is not a function of *where* it happens related to wildlands, but rather to *how* it happens in terms of home ignitability. Therefore, to reliably map the potential for home losses during wildland fires, home ignitability must be the principal mapping characteristic. The home threat information must correspond to the home ignitability spatial scale, that is, those characteristics of a home and its adjacent she within 40 meters.

Home fire loss mitigation. W-UI home losses can be reduced by focusing efforts on homes and their immediate surroundings. At higher densities where neighboring homes may occupy the immediate surroundings, loss reductions may necessarily involve a community. If homes have a sufficiently low home ignitability, a community exposed to a severe wildfire can survive without major fire destruction. Thus, there is a need to examine the reduction of wildland fuel hazard for the specific objective of home protection. There are various land management reasons for conducting wildland vegetation management. However, when considering the use of wildland fuel

hazard reduction specifically for protecting homes, an analysis specific to home ignitability should determine the treatment effectiveness.

Responsibility for home ignitability. If no wildfires or prescribed fires occurred, the wildland fire threat to residential development would not exist. However, our understanding of the fire ecology for most of North America indicates that fire exclusion is neither possible nor desirable. Therefore, homeowners who live in and adjacent to the wildland fire environment most take primary responsibility for ensuring that their homes have sufficiently low home ignitability. Homes should not be considered simply as potential victims of wildland fire, but also as potential participants in the continuation of the fire at their location.

A change needs to take place in the relationship between homeowners and the fire services. Instead of home-related presuppression and fire protection responsibilities residing solely with fire agencies, homeowners must take the principal responsibility for ensuring adequately low home ignitability.

The fire services should become a community partner providing homeowners with technical assistance as well as fire response in a strategy of assisted and managed community self-sufficiency (Cohen and Saveland 1997). For this approach to succeed, it must be shared and implemented equally by homeowners and the fire services.

Abstract: *Efforts to suppress wildfires have become increasingly problematic in recent years as costs have risen, threats to firefighter safety have escalated, and detrimental impacts to ecosystems have multiplied. Wildfires that escape initial suppression often expand into large, high-intensity summer blazes. Lost is the legacy of smaller fires that likely burned outside extreme weather and fuel conditions and resulted in less severe impacts. Despite the recognized need for modifications to existing policies and practices, resource agencies have been slow to respond. The spread of exotic species, climate change, and increasing human development in wildlands further complicates the issue. New policies are needed that integrate social and ecological needs across administrative boundaries and broad landscapes. These policies should promote a continuum of treatments with active management and reduction of fuel hazard in wildland-urban interface zones and reintroduction of fire in wildlands. Management goals should focus on restoration of the long-term ecological health of the land. Projects that reduce fuel loads but compromise the integrity of soil, water supplies, or watersheds will do more harm than good in the long run. Despite significant ecological concerns, learning to live with fire remains primarily a social issue that will require greater political leadership, agency innovation, public involvement, and community responsibility.*

Key Words: forest management, U.S. Forest Service, policy, public lands, wildfire

Políticas para Fuegos No Controlados y Tierras Públicas: Integrando el Conocimiento Científico con los Intereses Sociales en Paisajes

Resumen: *En años recientes, los esfuerzos para suprimir los fuegos no controlados se han vuelto cada vez más problemáticos por el incremento de costos, el aumento de las amenazas a la seguridad de bomberos y se la multiplicioń de los impactos perjudiciales a los ecosistemas. Los incendios que escapan la supresión inicial a menudo se expanden a grandes conflagraciones estivales de alta intensidad. Se ha perdido el legado de fuegos menores que probablemente se llevaban a cabo en condiciones climáticas y de combustible extremas que tenían impactos menos severos. A pesar del reconocimiento de la necesidad de modificaciones a las políticas y prácticas actuales, las agencias han respondido lentamente. La expansión de especies exóticas, el cambio climático y el incremento del desarrollo humano en áreas silvestres complican el problema aún más. Se requieren políticas nuevas que integren necesidades sociales y ecológicas más allá de límites administrativos y en paisajes amplios. Estas políticas deben promover un continuo de tratamientos con gestión activa y reducción de riesgo de combustión en la interfase área silvestre-urbana y la reintroducción de fuego en áreas silvestres. Las metas de la gestión deben enfocar en la restauración de la salud ecológica a largo plazo. Los proyectos que reducen la carga de combustible pero que comprometen la integridad del suelo, las reservas de agua o cuencas hidrológicas no serán de mucha utilidad en el largo plazo. A pesar de preocupaciones ecológicas*

Paper submitted October 28, 2003; revised manuscript accepted December 16, 2003.

significativas, aprender a vivir con fuego seguirá siendo un aspecto social que requerirá de mayor liderazgo político, innovación de agencias, participación del público y responsabilidad comunitaria.

Palabras Clave: administración de bosques, fuego no controlado, política, Servicio Forestal Estados Unidos, tierras públicas

How Wildfire Defines Policy: Historical Review

The history of wildfire in the United States and our attempts to control it contain many lessons to guide future policies for management of public and private lands. Destructive fires that ravaged the West and Midwest in the late 1800s and early 1900s led to federal policy declaring that all wildfire is bad. Wildfire was viewed as a destructive force that must be contained. Following World War II, this goal of suppressing all wildfires nearly became a reality with the availability of scores of firefighters, heavy construction equipment, smoke jumpers, and aerial tankers. Agencies seemed to be winning the war against wildfire, contributing to the illusion that all wildfire could be excluded from the land. The Yellowstone Fires of 1988, however, served to remind us of the unpredictability and occasional futility of our fire-control policies. Seemingly catastrophic wildfire seasons in recent years have reinforced the contention that a new approach to wildfire is needed.

Much of our western landscape evolved with wildfire and depends on this natural process to recycle nutrients, improve soil productivity, start plant succession processes, and contribute to overall watershed health. Our zealous efforts to suppress wildfire have diminished these ecological functions and altered fire regimes across much of the West (Agee 1993, 1997). Agencies and the scientific community have made progress in recognizing what ails our forests and grasslands, but our legacy of treating fire as a dangerous and destructive force has made agencies slow to translate improved scientific understanding into on-the-ground management changes. As a result, half the year is spent in widespread talk about the need to reintroduce fire into fire-adapted ecosystems, but the other half of the year is spent suppressing all wildfire at substantial economic cost. The federal fire bureaucracy spends hundreds of millions of dollars annually on wildfire suppression, more than a billion dollars in a "bad" fire year, with little oversight or accountability (General Accounting Office [GAO] 1999, 2001).

The years from 1871 to 1910 reshaped public opinion on wildfire. At that time, fire was used to clear land for agriculture or to drive wildlife, or was inadvertently started along railroads. By the late 1800s, the combination of drought and slash left behind by logging began producing large and uncontrollable wildfires. The 1871 Peshtigo Fire in northeastern Wisconsin, in which some 1500 people died and more than 486,000 ha burned, remains the single most tragic wildfire in our history (Pyne 1982). Fires in Michigan, again the legacy of timber cutting, burned another 1.0 million ha that same year (Pyne 1982). Forest cover was destroyed and topsoil turned to ashes or washed away once the forests were burned. The land lost its ability to dampen floods or temper drought. Watershed function—the basic ability to catch, store, and release water over time—was lost across broad landscapes. By 1900, 32 million ha of charred and decimated stump lands lay east of the Mississippi.

The West was not far behind. The year 1910, the year of the Great Fires, created the foundation for how federal agencies would relate to wildfire (Pyne 2001). The U.S. Department of Agriculture Forest Service (USFS), founded only 5 years earlier, was a fledgling agency with few resources. A combination of slash-and-burn forestry, expanding railroads, drought, and wind caused more than 2.0 million ha to burn that year across the West, mostly in Idaho and Montana. Seventy-eight firefighters died, numerous civilians perished, and several towns burned to the ground. Ultimately, the U.S. Army was called in to fight fires throughout the West. The destructive fires of 1910 led the federal government to declare war on wildfires. The USFS responded with military-like zeal and declared fire suppression its primary charge. Leaders in the agency believed that the only solution to fires was "the full-scale development of the forests with roads, trails, telephone lines, lookout towers, and a resident staff sufficient to patrol and attack fires while they were small" (Pyne 2001). By 1935 the "all fires out by 10 AM" policy was formally adopted (Pyne 1982). By the 1940s, the USFS had developed the most effective wildfire-fighting capability in the world. As a result of this early and widespread intervention in wildfire, we lost the legacy of many smaller fires that were likely to have burned at lesser intensities.

Smokey Bear and his slogan—"Remember, only you can prevent forest fires."—was perhaps the most successful public awareness campaign ever. In 1968 a national advertising company noted that Smokey was the most popular symbol in the United States, better known than the president (Pyne 1982). The perception that all wildfire is bad became universal. The National Interagency Fire Center was established in Boise, Idaho, in the 1960s as the wildfire-fighting command center and soon became a model of government interagency cooperation.

In 2000 wildfires were front-page news from May to September, starting with the loss of over 200 homes in the Cerro Grande Fire in Los Alamos, New Mexico, and

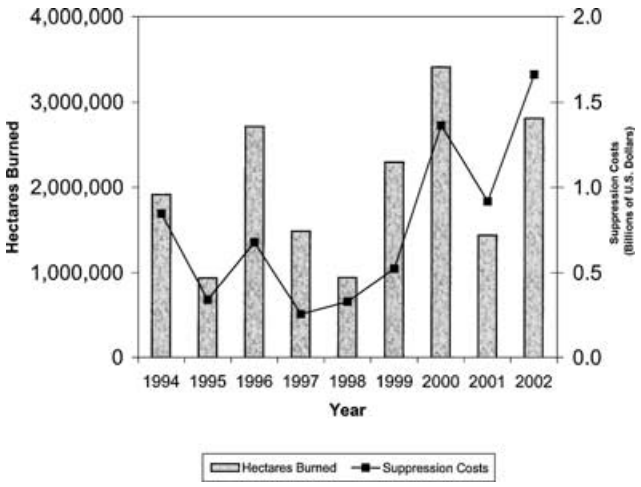

Figure 1. Hectares burned in the United States and wildfire suppression costs for federal agencies, 1994–2002. Data from National Interagency Fire Center (2003).

continuing with multiple large fires in Montana and Idaho. The years 1988, 1994, 2000, and 2002 were clarion calls that society's century-long attempt to control fire in the fire-adapted ecosystems of the West was not working. With advanced technology and an army of firefighters, 98% of wildfires are typically snuffed out in the initial attack. In spite of this extraordinary "success," the total amount of the landscape burned each year has increased in recent decades compared with the mid-1900s (Agee 1997), and more than 2.5 million ha burned each year in 1963, 1969, 1988, 1996, 2000, and 2002 (an average of 1.6 million ha has burned each year between 1960 and 2002) (National Interagency Fire Center 2003). The costs of wildfire suppression have risen in recent years as more land has burned (Fig. 1). More than $1 billion was spent in 2000 and 2002 by federal agencies (National Park Service, Fish and Wildlife Service, Bureau of Indian Affairs, Bureau of Land Management, and Forest Service) fighting fires on public lands. Clearly this is an economic burden that cannot continue indefinitely, especially for federal land-management agencies that are otherwise underfunded for basic resource inventory, monitoring, and management.

For nearly a century, the widespread suppression of fire and other factors, such as livestock grazing, past timber harvest practices, and other human activities, have resulted in altered ecosystems and more broad-scale wildfires during dry years. In many cases, it is our interruption of natural processes that reduces the ability of the land to heal itself, resulting in even more serious problems. Scientific assessments indicate that in the Interior Columbia River Basin, prior to European settlement, about 2.4 million ha burned per year (Hann et al. 1997). With recent intense fire suppression, less than 203,000 ha has burned each year (Hann et al. 1997). In spite of a century of fire suppression, we have learned that the question is not if forests will burn but when, where, and with what intensity.

Challenges of Natural Complexity, Exotic Species, and Suburban Sprawl

For agency policies concerning wildfire to be effective in the long term, they must be specific to local forest conditions and adaptable to new information about the natural environment and to changing social concerns. The spread of exotic species is a good example of the need for policies to adapt to changing situations. The Department of the Interior estimates that noxious weeds spread at a rate of 688,500 ha annually (Bureau of Land Management 1996). Exotic grasses, noxious weeds, and other alien species are among the greatest threats now facing the integrity of public lands (Dombeck et al. 2003).

If their seeds or spores are present, exotic species will thrive and spread, complicating fire-suppression activity. Fire engines, bulldozers, or other vehicles may spread exotic species as well (Backer et al. 2004). Federal agency wildfire policies, management actions, and research on wildfire must respond to such threats from exotic species. For example, burn-area emergency rehabilitation efforts should recognize that grass seeding for erosion control often degrades native species recovery and that long-term damage to ecosystems often overshadows short-term gain in soil stabilization (Beyers 2004 [this issue]). Even the use of "certified weed-free hay" for erosion control may be suspect when the amount free of weeds is only 95% or even 99%. The use of weed-free hay on post-fire recovery efforts in the Klamath National Forest resulted in the introduction and spread of exotic yellow starthistle (*Centaurea solstitialis* L.) on forest lands (J. Perkins, personal communication). During the massive Biscuit Fire in 2002, the USFS required that equipment be power-washed or rinsed with chlorine-treated water to prevent Port-Orford Cedar root disease, which is spread by water or mud contaminated with exotic *Phytophthora* spores. This is a good example of how federal agencies can and should apply ecologically sound management even during emergency wildfire situations.

Wildfire suppression, introduction of exotic species, livestock grazing, timber harvest practices, and replanting cutover lands with dense conifer plantations have changed fuel loads and fire regimes in many western forests and grasslands. A recent broad-scale assessment of national forest lands and land administered by the Bureau of Land Management (BLM) in the Interior Columbia River Basin documented a 25% increase in young trees in dry forest types such as ponderosa pine (*Pinus ponderosa* Dougl. ex Laws.) and dry grand fir (*Abies grandis* [Dougl.] Lindl.)–white fir (*A. concolor* Gord. & Glend.)

associations in Idaho and western Montana (Hann et al. 1997). The assessment also found that ponderosa pine has been replaced by grand fir and white fir in 19% of its range and by Douglas-fir (*Pseudotsuga menziesii* Mirb.) in another 20%. Open, park-like stands of ponderosa pine were estimated to be at 25% of their historic range, whereas Douglas-fir and true firs had more than tripled their range (Hann et al. 1997). Overall, the assessment concluded that 46% of National Forest and BLM forestlands in Idaho, western Montana, eastern Washington, and eastern Oregon were at a low rating for overall ecological integrity. Most private lands in the region are in even worse condition. Of the lands classified in the report as low in ecological integrity, 61% occur outside of federal management (Quigley & Arbelbide 1997).

By the 1990s, the complexity and patchiness of many fire-adapted forest ecosystems were greatly diminished. Young Douglas-fir, grand fir, and other species formerly controlled by small fires were growing in large numbers. The meadows were disappearing, and the remaining large pines were surrounded by smaller trees that competed for water during droughts and provided "ladder fuels" that allowed fire to reach upper branches to torch and kill trees. The GAO (1999) reviewed the status of western forests and concluded that the over-accumulation of trees presented a severe wildfire risk to approximately 16 million ha in the Intermountain West.

Some forests have naturally high fuel loads and a history of stand-replacing wildfires that burn at high intensity (Agee 1993). Lodgepole pine (*Pinus contorta* Dougl. ex Loud.) forests in the West, for example, require high-intensity fires to reseed and restore themselves. Other forests, occurring for example in the Klamath-Siskiyou region of northwest California and southwest Oregon, are characterized by fires that burn at mixed intensities (Odion et al. 2004 [this issue]). Forests characterized by high- or mixed-intensity fires present special concerns that cannot be addressed simply by policies that seek to reduce tree densities or fuel loads.

Wildfires that burned in Oregon's Siskiyou National Forest during 2001 and 2002 illustrate this complex dilemma. In September 2001, lightning started the Craggie fire in the Kalmiopsis Wilderness. The fire was in extremely rugged terrain and posed no threat to structures. The 39,000-ha Silver fire had burned the same area in 1987, and other large fires were known from the same area in 1938 and the summers of 1917 and 1918 (T. Atzet, personal communication). Rather than being allowed to burn, the Craggie fire was immediately attacked by aerial tankers and helicopters. By the time it was controlled, 111 ha had burned with a suppression cost of $2.2 million. Forest Service policy dictated that the fire be attacked and controlled because of dry conditions and high fuel loads despite the shorter days of mid-September and the onset of cooler and moister weather. To some, allowing the Craggie fire to burn might have seemed risky. But the alternative is a fire in some future year that occurs in the middle of summer with even more fuel present.

This is precisely what happened in 2002. In July of that year, during a hot, dry summer, lightning started a series of fires in Oregon, including several in and around the Kalmiopsis Wilderness. Because of the large number of fires burning at that time, no firefighters were available to fight the Kalmiopsis fires for the first 4 days. In the dry, rugged terrain and hot weather, the wildfires grew rapidly. In August, several fires around the Kalmiopsis combined to form the Biscuit fire and spread to 116,000 ha with more than 2000 firefighters on the lines. By the time the Biscuit fire was contained in September, fire had swept across nearly 203,000 ha despite thousands of firefighters, dozens of bulldozers, and many air tankers. Firefighting costs reached $150 million, making this the most expensive fire fought in the nearly 100-year history of the USFS, even more expensive than the previous record, the Yellowstone fires of 1988, which cost $120 million to suppress. The costs of such massive firefighting efforts are not just high in terms of dollars, but also in terms of firefighter safety, damage caused by bulldozers to fragile soils and sensitive botanical areas, and the potential for spread of exotic organisms by firefighting equipment.

In spite of the impression created by media reports that the Biscuit fire destroyed the forest, the fire burned in a classic mosaic pattern across the landscape. This benefits many ecosystem functions and restores habitat diversity. According to burn-area emergency rehabilitation surveys by the USFS, approximately 16% of the area burned at high severity, 23% at moderate severity, and 41% at low severity, and 20% was unburned or burned at very low severity (Siskiyou & Six Rivers National Forests 2002). According to the report, 70% of the area that burned at high severity contained enough surface rock to protect soil against accelerated erosion. In the long run, restoration of fire will occur in one form or another. How fire returns to these fire-adapted ecosystems is the question.

An expanding human population, especially in western states, is the single greatest factor confounding federal fire-management policies. Nearly all western states are growing faster than the national average. According to the U.S. Census Bureau, population increased 13.2% nationally from 1990 to 2000 but increased 28.5% in Idaho, 29.6% in Utah, 30.6% in Colorado, 40.0% in Arizona, and 66.3% in Nevada during this same period. Much of this growth occurred as urban areas sprawled into surrounding wildlands. Only two western states, Montana (12.9% increase) and Wyoming (8.9%), fell below that national average.

With an increase in home construction along wildland boundaries and private inholdings within national forests and BLM public lands, federal agencies are focusing more of their firefighting efforts on protecting human lives and property. But in the debates that followed the intense fire seasons of 2000 and 2002, too little discussion focused

on the central issue of homeowners assuming more responsibility for reducing the vulnerability of their homes to wildfire by building with fire-resistant materials and storing flammable materials away from structures. In the western United States, few communities or local governments have enacted zoning requirements to guide the growth of homes along the wildland-urban interface or building requirements to reduce the flammability of structures. And insurance companies do not require "fire-wise" practices as a condition of insurability.

Toward Policies that Reflect Ecological and Social Needs

The magnitude of the fires in 2000 and a 1999 GAO report on the need for a cohesive strategy for wildfires resulted in development of the National Fire Plan and associated fire-management policies by the USFS, National Park Service, U.S. Fish and Wildlife Service, BLM, Bureau of Indian Affairs, and National Association of State Foresters. The National Fire Plan, developed in 2000, spelled out a $10-billion effort over a 10-year period to protect communities and restore healthy forests in fire-adapted ecosystems (USFS 2000). In 2002 President Bush's Healthy Forests Initiative called for modifications to the National Fire Plan that would expedite fuel-reduction projects by reducing environmental impact analysis, public involvement, and appeals and litigation associated with the National Environmental Policy Act (Office of the President 2002).

Most ecologists and agency administrators agree that reducing the levels of hazardous fuels on forests and rangelands is essential to protect adjacent human communities and to restore healthy watersheds. The agreement ends here, as some in the timber industry call for aggressive logging to restore forests and the environmental community decries such a rationale as simply another way to increase timber cutting. The public land manager walks a fine line. Even the most well-reasoned decisions often result in criticism.

The priority for fuels management should be places where forests and communities intersect, such as wildland-urban interface zones and watersheds that supply municipal drinking water. If such areas contain uncharacteristically high fuel loads, projects that thin small trees and remove brush followed by the careful use of prescribed fire should be welcomed by a broad cross-section of interests. On the other hand, building roads and cutting trees in remote roadless areas far from human communities makes neither ecologic nor economic sense (DellaSala & Frost 2001).

Local communities need to shoulder greater responsibility for regulating sprawl and for encouraging proactive efforts by homeowners to reduce the risk of home ignition during wildfire. In remote or inaccessible wildlands, wildfires should be closely monitored but allowed to burn if outside of extreme summer weather and not threatening to human communities. In roaded and previously logged areas that are not part of the wildland-urban interface, management should focus on utilizing fire processes at a low risk—under acceptable weather conditions and fuel loads—and thinning small-diameter materials as prescribed by the local management context and to restore the health and integrity of the land. Meanwhile, fire programs of federal agencies should focus the overwhelming majority of their hazardous-fuels reduction and suppression efforts on protecting lives and property in the areas where forests and communities meet, including efforts to help landowners reduce fire risk in the immediate vicinity of their homes. Such an approach would help restore natural fire cycles in remote places, save tens of millions of dollars, and, above all, minimize risks to firefighters.

This is not to say that a let-it-burn philosophy should prevail in all areas. The challenge is to put fire back on the land in a way that minimizes the risk to people and communities while mimicking natural fire regimes to the extent possible. We should allow what would have historically been the smaller wildfires to burn, including those that naturally start early or late in the fire season when weather can moderate fire intensity. Many forests evolved with fire and indeed need fire for healthy development. The complicating factor is increasing human population. The sprawl of housing developments in rural areas, foothills, and even on mountainsides is occurring all over the country, especially in fire-prone areas such as California and the Intermountain West. Making matters worse, many homeowners fail to take steps to protect their homes and lives such as avoiding flammable wood roofs and cedar siding, keeping woodpiles away from the home, clearing vegetation adjacent to the house, and other common-sense precautions (Cohen 2000). The most important factors determining whether a building will burn during a wildfire are the degree of flammability of construction materials and fuels within 40 m of buildings (Cohen 1999, 2000). People who build homes in fire-adapted landscapes must assume responsibility for reducing fuels and the ignitability of buildings and the immediate space around their homes. Local government zoning ordinances should take into account fire-prone areas as they already do for flood-prone areas.

Traditional organizational structures and appropriations make increased interagency coordination of wildfire management difficult (GAO 2001). Nonetheless, reducing wildfire risk while restoring healthy watersheds will require a new level of coordination among federal agencies, state governments, and the public. Substantial interagency cooperation has been achieved in fire suppression through the National Interagency Fire Center in Boise, Idaho. It is time that similar levels of cooperation be developed for wildfire reintroduction through careful monitoring of wildfires in roadless and wilderness areas and expanded but judicious use of prescribed fire. Public

Table 1. Recommended principles and rationales for developing wildfire policies that meet ecological and social needs.

Principle	*Rationale*
Integrate policies across both private and public lands.	Wildfires know no boundaries.
Strengthen coordination across agencies and communities for wildfire introduction.	Interagency coordination has improved wildfire suppression, and the same coordination is needed to reintroduce wildfire successfully.
Develop a continuum of priorities and actions between urban and wildland environments.	Meeting social concerns through more active management is appropriate in urban areas, whereas meeting ecological needs is more important in wildland areas
Strengthen homeowner education to reduce ignitability of their homes.	Home characteristics and vegetation within 40 m of structures principally determine potential for home ignition during extreme wildfires.
Value forest diversity and variability in historic fire regimes.	The substantial variation in plant communities, fuel loading, and fire regimes must be recognized to maintain and restore diversity.
Wildland policies should emphasize ecosystem resilience rather than fire control.	Wildfire is critical to maintaining the diversity and productivity of many natural communities.
Encourage reintroduction of ecologically appropriate fire where possible.	Historic fire regimes should be reestablished except where development densities dictate alternate approaches.
Ensure monitoring, evaluation, and public involvement in fire management policy.	Adaptive management is needed to address natural complexity and change; increased public involvement is needed to foster understanding and public trust

participation in the process should be strengthened, not weakened, in order to build trust and integrate the concerns of communities. New relationships must be forged across disciplines and administrative boundaries to successfully implement policies and plans. Some preliminary principles for developing ecologically and socially responsible wildfire policies are presented in Table 1.

It is important that wildfire policies be well founded in ecological principles. It will do little good in the long run if projects that reduce fuel loads compromise the basic integrity of soils, water supplies, or watersheds. Fuel management should be part of a broader strategy of restoring watershed health rather than designed solely on the basis of fuels. As important as ecological principles are, however, living with fire largely remains a social issue that will require greater agency leadership and community responsibility.

Although government agencies and land managers tend to be adverse to risk, leadership must support innovation and adaptive management to achieve success. To avoid risk in wildfire management today is to advocate even larger uncontrolled wildfires with greater threat to human life, property, and ecosystems in the future. Neither thinning nor extensive logging will fire-proof our forests. Planning in fire-adapted ecosystems requires an understanding of local forest type, fire history, potential fire behavior, past management actions, land-use changes, watershed needs, species viability, and relative risk to human communities (USFS 2000). Uncertainty associated with these factors can best be addressed through adaptive management—the process of monitoring, evaluating, and making changes to management based on monitoring results. Acceptance of risk taking or the need to change management direction is a difficult pill to swallow in many agencies. Changing these agency cultures and public attitudes will be among the greatest hurdles to effective wildfire policy.

Response to Comments on "Post-Wildfire Logging Hinders Regeneration and Increases Fire Risk"

D. C. Donato,[1]* J. B. Fontaine,[2] J. L. Campbell,[1] W. D. Robinson,[2] J. B. Kauffman,[3] B. E. Law[1]

We reported that postfire logging 2 to 3 years after the 2002 Biscuit Fire was associated with significant mortality in natural conifer regeneration and elevated potential fire behavior in the short term as a result of increased surface fuel loads. We underscore the strength of our study design and statistical conclusions, provide additional details of the research setting and scope, and address comments pertinent to forest development and fire ecology.

Although Newton *et al*. (*1*) and Baird (*2*) provide no compelling evidence to refute our findings, we are pleased with the opportunity for dialogue and to expand on our article (*3*). We respond by underscoring the strength of our study design, providing additional details of the research setting and scope, and addressing comments pertinent to forest development and fire ecology.

Study background. We reported that postfire logging (salvage) 2 to 3 years after the 2002 Biscuit Fire was associated with significant mortality in natural conifer regeneration and elevated potential fire behavior in the short term due to increased surface fuel loads (*3*). Our study design has robust inferential power (*4*), and the data strongly support these straightforward conclusions, as verified by independent statistical evaluations (*5*, *6*).

Our scope of inference (*3*) is the salvage of the Biscuit Fire [see (*4*) for study details]. Areas sampled were typical of portions of the Biscuit Fire designated for salvage (*4*). Responses to postfire logging may vary between and within fires, forest types, and technique/timing of logging. Similar patterns of seedling damage/reduction resulting from postfire logging operations have been documented across a range of conditions (*7*–*11*), which may be because postfire logging is often conducted under the presumption of negligible natural regeneration and is therefore not designed to protect it. The logging techniques on which we reported (handfelling with helicopter yarding >2 years postfire) occur on public lands throughout the western United States.

The hypothesis that prompt postfire logging could have different effects merits study. Currently, there are no data comparing effects of early versus delayed logging operations (*12*) and, to date, the few relevant studies of prompt postfire logging have also reported reductions in seedling densities (*7*, *8*). More field data are needed to elucidate the range of potential effects under different conditions and prescriptions.

Short-term data from well-designed studies, such as (*3*), are important in providing benchmarks for long-term studies and isolating the mechanisms through which management affects forest processes. To date, the few longer term studies of postfire logging (*13*) have been confounded by multiple postfire treatments (e.g., logging, fuel treatment, replanting). A review of postfire management studies (*12*) states, "when treatments involve logging as well as other site preparation measures, it is impossible to distinguish the specific causative factor behind any observed vegetation change." We maintain that research on postdisturbance management effects will be most valuable when each treatment is studied as a distinct variable [e.g., (*3*, *14*)].

Early regeneration. Although various reforestation practices after live tree harvest in southwest Oregon have been well studied (*1*, *15*), natural post-wildfire regeneration remains far less studied in the region. Postfire conditions differ substantially from conditions following live tree harvest in several important ways [e.g., (*16*, *17*)], including seedbed qualities, legacy structure, and stress seed crops. Thus, we caution against extrapolating knowledge from postharvest studies to natural post-wildfire regeneration.

Early regeneration data provide insight into important processes, including seed production, dispersal, germination, and early survival. The relation between short-term effects of postfire logging on these processes (*3*) and long-term recruitment patterns (*1*, *18*, *19*) is key to understanding the legacy of logging effects on stand development. Conifer regeneration following wildfires can be limited during two phases: (i) initial establishment due to seed source deficiency in large burned areas, and (ii) subsequent competition, survival, and release. We reported on the former, not the latter. This is important in light of uncertainties regarding the degree to which this first phase would occur in high-severity portions of the Biscuit Fire (*20*, *21*). We did not draw further conclusions about long-term effects of postfire logging (*3*). Relevant long-term data from replicated experiments do not exist (*12*).

Postfire succession in mixed-evergreen forests of the Klamath-Siskiyou region (which covers much of southwest Oregon and northwest California), is characterized by a period during which broadleaf vegetation forms a substantial overstory component (*19*). Several authors have suggested that, in the presence of shrub competition, early conifer establishment is especially important in attaining eventual conifer dominance (*15*, *20*, *22*). Alternatively, current studies indicate a variable, protracted conifer regeneration period in this region, with peak establishment generally within 5 years of fire and persistence in the presence of broadleaf species (*18*). Under either scenario, establishment of seedlings 2 to 3 years after fire represents an important period of succession in the Klamath-Siskiyou region. Subsequent competition from broadleaf vegetation has been shown to occur with or without postfire logging (*13*) and is therefore a related but separate issue from the results of our study (*3*).

With respect to regional stocking standards (*23*), we followed federal definition M, which states that a suitable tree (capable of meeting forest management objectives) "may qualify as a component of the stand by having survived at least one growing season in the field." The vast majority of seedlings we reported had been present for at least two growing seasons by 2005 (*24*). Regional stocking standards include prescriptions for density and distribution (*1*, *23*). We reported data pertinent to density standards, quantified at the hectare scale using an effective method (*4*) and assessed for variability at the treatment scale (across logging units) rather than within each logging unit. Traditional stocking surveys (*1*) were not our intent. We indicated that the median density we quantified exceeded that found in adequately stocked sites per the Biscuit management plan [since sites must be stocked at a minimum density (*23*)]. This was a benchmark for comparison and not a conclusion regarding stocking per se, which is quantified differently. Because much of the Biscuit salvage was planned in land use allocations for which very low densities and variable spacing were prescribed (*25*), we suggest that stand level density is an important parameter relative to other stocking standards.

Fuel dynamics. Although fuel composition, arrangement, and continuity are all important variables contributing to potential fire behavior, a predominant factor affecting behavior of the flame front is the mass of fine downed wood (*26*, *27*). We reported an increase by a factor of about 5 in fine downed wood as a result of postfire logging (*3*), which suggests that

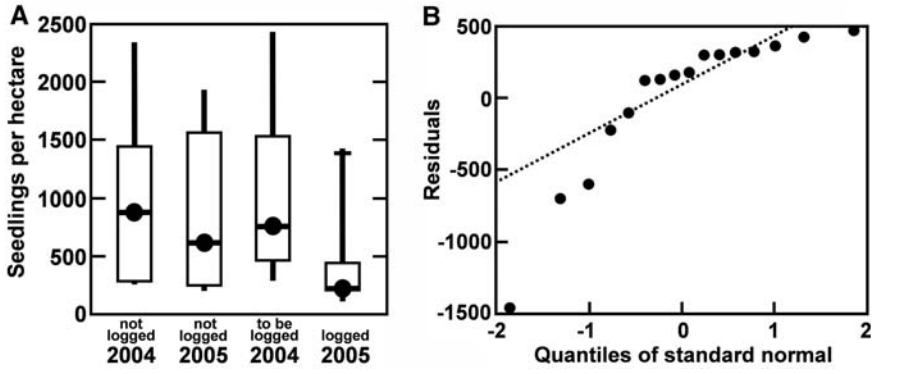

Fig. 1. (**A**) Box-and-whisker plots of Biscuit Fire seedling data (seedlings per hectare) from (*3*) and (**B**) residuals from parametric test [analysis of variance (ANOVA)] on interannual changes in untransformed seedling data, as in (*2*). (A) shows tendency toward positive skewness (typical for ecological count data) for all groups and unequal variance, as well as marked difference between the 2005-logged sample compared with other samples. Dot within box is the median; box edges are the 25th and 75th percentiles; whiskers represent the data range; points beyond 1.5 times the interquartile range from the quartiles are drawn as horizontal lines across the whisker. Shapiro-Wilk normality test (*32*) indicates lack of normality: W = 0.7173, $P = 0.0023$ for 2005-logged plots. (B) shows that parametric ANOVA tests on untransformed data, as in (*2*), are prone to spurious results for the seedling data due to substantial departure from normality (Shapiro-Wilk normality test: W = 0.7226, $P = 0.0026$ for annual change in density between years in logged plots). Analyses after data transformations or nonparametric analyses are highly preferred (*31*).

salvaged environments are predisposed to fires of greater intensity than unsalvaged sites in the near term. Fire behavior modeling of different salvage/fuel-treatment scenarios, parameterized with field data, will best characterize potential fire behavior in postfire settings. However, standard fire behavior models [e.g., (*26*)] do not include fuel continuity as an independent variable and therefore assume similar connections between fuel loads and fire behavior.

One of the primary purposes of the Biscuit management plan was to reduce the "risk" of high intensity and/or stand replacement fire (*21*); thus, we presented our results relative to this objective (*28*). Prescriptions also called for broad ranges of downed wood levels for soil function and habitat (*21*). Our observation was that downed wood levels following logging were variable relative to prescriptions, often as much a function of inherent, localized felling and handling practices as they were reflective of any specific prescription. Regardless, our research quantified higher postsalvage fuel loads, which are associated with higher potential fire behavior, thus adding empirical field data to what has only been modeled thus far (*29*).

Given the observed pulse of surface fuels after logging and its potential effects on surface fire behavior, our suggestion that leaving woody material (dead trees) standing could result in lower fire hazard is a reasonable hypothesis. Surface fuel loads derived from fire-killed trees are determined by the dynamic balance between inputs (from the canopy) and outputs (decomposition). As such, no scenario produces a larger pool of fine (up to 7.62 cm) and 1000-hour [7.62 to 20.32 cm (*19*)] fuels than a single one-time input from clearfelling shortly after a fire.

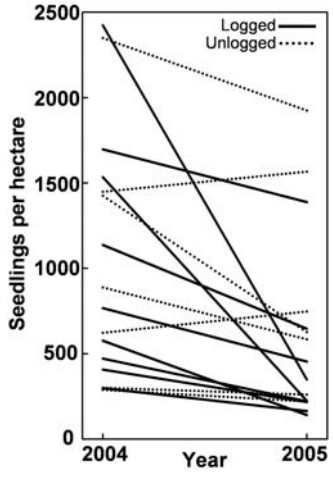

Fig. 2. Changes in seedling densities between 2004 and 2005 for logged and unlogged plots, with logging occurring between measurement periods. Equivocal variation between years can be seen in the unlogged plots (no consistent trend), whereas logged plots all show marked declines.

Long-term interactions between these inputs and live fuel succession are poorly understood, especially for the largest fuel size classes. As we stated in (*3*), hypotheses regarding long-term fire potentials merit study [see (*30*)].

Statistical analysis. All appropriate, conservative methods for analyzing our data yield robust, biologically and statistically significant effects (*3*, *5*, *6*). These methods employ either nonparametric analyses that do not require normality or equal variance, or a common transformation ($\log_e$) to more closely meet assumptions of parametric tests [Fig. 1 and (*31*)]. Parametric tests on untransformed data, as in (*2*), are prone to spurious results due to substantial departure from normality and unequal variance (Fig. 1).

Table 1. Seedling densities for each of the 16 burn plots before and after logging treatment. The following are test statistics and one-tailed *P* values from multiple analytical methods of testing the hypothesis that the reduction in seedling density in logged plots exceeded interannual variation in unlogged plots. Rank sum test on percentage change in each plot: W = 53, $P = 0.006$; rank sum test on untransformed (raw) changes: W = 60, $P = 0.045$; two-sample *t* test on percentage change in each plot: $t_{14} = 3.15$, $P = 0.004$; two-sample *t* test on changes in $\log_e$-transformed densities: $t_{14} = 2.70$, $P = 0.009$; two-sample *t* test on untransformed (raw) changes: $t_{14} = 1.52$, $P = 0.075$ [to our understanding this is equivalent to the analysis of Baird (*2*); see also Fig. 1B]. One-tailed tests are logically appropriate because, given the time frame of study as well as the timing of logging relative to the interannual and seasonal timing of regeneration, the immediate effect of logging on seedling densities (if different from zero) would be a reduction (*7*–*10*).

Plot	Seedlings per hectare 2004	Treatment	Seedlings per hectare 2005
1	298	logged	164
2	471	logged	221
3	767	logged	454
4	576	logged	141
5	407	logged	217
6	1534	logged	224
7	2423	logged	349
8	1697	logged	1388
9	1137	logged	646
10	288	unlogged	220
11	622	unlogged	747
12	300	unlogged	260
13	888	unlogged	584
14	1448	unlogged	1566
15	1425	unlogged	626
16	2349	unlogged	1924

Baird's (*2*) description of our analysis is misleading. Repeated measures are irrelevant because we did not assume independence of 2004 and 2005 measurements within each plot (Table 1). We intended to quantify annual change within plots. In addition, our descriptive estimate of the sample-wide change in logged plots between years was a 71% decline in the sample median, which does not arise from analysis of any particular plot. Rather, the median is a conservative measure of central tendency for the entire sample before and after logging, providing descriptive information at the broader, treatment-wide level.

Because the sample of unlogged plots showed no consistent or statistically significant pattern in changes in seedling density over time (Fig. 2 and Table 1) (*3*, *6*), and new in-seeding as well as mortality was occurring [see (*18*)], the statistically significant change in logged plots was attributed to logging. Analyses that include the

variation observed in the unlogged sample also yield findings of significant logging effects that differ only in the point estimate of effect magnitude (Table 1) (*5*, *6*).

Independent statistical evaluations of our data support the conclusions of significant effects of postfire logging on seedling regeneration and fuels (*5*, *6*). As stated in one such review, "Although there can be differences of opinion on methods of analysis, all reasonable methods will lead to congruent conclusions" (*5*).

The study design, results, and conclusions presented in (*3*) are strong, relevant, and straightforward. Newton *et al*. (*1*) and Baird (*2*) present different perspectives, but provide no data or evidence from other studies to contradict our findings and conclusions. A short-format paper such as ours is not intended to review or explore every angle but to present key data that will stimulate discussion and further research. We hope our research findings and comments provide direction for future studies and management.

24. Such seedlings count toward meeting standards for density/distribution, even before a stand is "accepted" as beyond the juvenile stage [see definition P in (*23*)].
25. The management plan for Late Successional Reserves prescribes initial densities of 250 to 375 trees per hectare (eventual objective is 150 to 200 trees per hectare "free-to-grow") with variable, microsite-based spacing of 4.5 to 12 m (*21*). Low stocking rates would be possible even when stands are within this spacing prescription, which increases the relevance of stand level densities measured at broader scales.

Abstract. Following severe wildfires, managing fire hazard by removing dead trees (post-fire logging) is an important issue globally. Data informing these management actions are relatively scarce, particularly how fuel loads differ by post-fire logging intensity within different environmental settings. In mixed-evergreen forests of Oregon, USA, we quantified fuel profiles 3–4 years after stand-replacement fire – assessing three post-fire logging intensities (0, 25–75, or >75% basal area cut) across two climatic settings (mesic coastal, drier interior). Stand-replacement fire consumed ~17% of aboveground biomass. Post-fire logging significantly reduced standing dead biomass, with high-intensity treatment leaving a greater proportion (28%) of felled biomass on site compared with moderate-intensity treatment (14%) because of less selective tree felling. A significant relationship between logging intensity and resulting surface fuels (per-hectare increase of 0.4–1.2 Mg per square metre of basal area cut) indicated a broadly applicable predictive tool for management. Down wood cover increased by 3–5 times and became more spatially homogeneous after logging. Post-fire logging altered the fuel profile of early-seral stands (standing material removed or transferred, short-term increase in surface fuels, likely reduction in future large fuel accumulation), with moderate-intensity and unlogged treatments yielding surface fuel loads consistent with commonly prescribed levels, and high-intensity treatment resulting in greater potential need for follow-up fuel treatments.

Introduction

Stand-replacing fires affect many forest ecosystems globally (Bond and Keeley 2005) and are key drivers of woody biomass dynamics (Spies *et al.* 1988; Everett *et al.* 1999; Pedlar *et al.* 2002; Hall *et al.* 2006). Following wildfires, managing fuels (biomass) is often a key concern, as the eventual fall of fire-killed trees may function as a positive feedback mechanism by providing fuel for subsequent fires, or 're-burns' (Brown *et al.* 2003). The widespread practice of post-fire logging (i.e. salvage) often carries an objective of reducing woody fuel loads and thus fire behaviour and effects in the event of a re-burn (e.g. McIver and Starr 2001; McGinnis *et al.* 2010). However, little empirical information exists to inform these management actions – in particular how post-fire fuel loads are affected by different post-fire logging intensities across different forest settings (McIver and Starr 2001; Peterson *et al.* 2009).

Although post-fire logging often aims to reduce future fire severity, the few empirical studies of actual fires occurring after post-disturbance logging have shown equivocal results, including reduced severity (Buma and Wessman 2011), increased severity (Hansen 1983; Thompson *et al.* 2007) and unchanged or mixed results (Kulakowski and Veblen 2007; Fraver *et al.* 2011). Mechanisms behind these varying observations remain unclear. Timber harvest in general is known to increase surface woody fuel loads by transferring non-merchantable branches and tree tops ('slash') to the surface, where most fires propagate (Snell and Brown 1980; Pyne *et al.* 1996; Stephens *et al.* 2009). Exactly how this premise extends to logging of dead trees has

Journal compilation © IAWF 2013

not been well quantified for most forest types. Recent studies indicate that surface fine fuel loads (<7.6-cm diameter) are indeed elevated following post-fire logging (Donato *et al.* 2006*a*; McIver and Ottmar 2007; Keyser *et al.* 2009; McGinnis *et al.* 2010) and empirical data and models suggest these elevated loads may persist for ~20 years in some settings (McIver and Ottmar 2007; McGinnis *et al.* 2010). Yet coarse woody fuels (>7.6-cm diameter) may accumulate less on the surface over the intermediate term (~10–50 years) if stems are removed, which could reduce potential fire effects such as soil heating (McIver and Ottmar 2007; Keyser *et al.* 2009; Monsanto and Agee 2008). Post-fire management can also influence live vegetation (Stuart *et al.* 1993), and this may further affect subsequent fire behaviour. To better identify relationships between post-fire fuels, management treatments and observed fire effects, data are needed on specific effects of individual activities such as logging, slash burning and vegetation management (McIver and Starr 2001; Donato *et al.* 2006*b*).

The quantity and distribution of fuels remaining after post-fire logging may vary widely by harvest method and biophysical setting. Treating slash fuels after felling of live trees is well known to be important for reducing total fuel loads and fire potentials (e.g. Weatherspoon and Skinner 1995; Graham *et al.* 2004; Agee and Skinner 2005). For fire-killed trees, however, the relative need for such follow-up treatments after differing levels of logging intensity has scarcely been reported, and no information exists on how this varies across forest types or settings. Such information is essential to informed post-fire decisions and meeting fuel management objectives (Peterson *et al.* 2009).

In this study, we investigated fuel dynamics in stand-replacement (high-severity) portions of the 2002 Biscuit Fire, a large wildfire in south-west Oregon, USA. Our objectives were to: (1) quantify aboveground biomass, composition and vertical distribution following stand-replacement fire relative to intact mature-to-old growth forest, including all material (fine and coarse, live and dead) in both the aerial and surface fuel strata and (2) quantify immediate changes in these profiles resulting from post-fire logging, as influenced by harvest intensity and biophysical setting (mesic coastal forest type *v.* drier inland forest type). We focussed on empirically measured fuel profiles rather than modelled fire behaviour because available models have not been calibrated or tested for post-fire environments, especially for the necessary custom fuel models (Passovoy and Fulé 2006; Cruz and Alexander 2010).

Methods

Study area

The study was conducted in the Klamath–Siskiyou Mountains, a coastal range in the state of Oregon, USA (Fig. 1), within the mixed-evergreen and *Abies concolor* zones (Franklin and Dyrness 1973). The region experiences a moist Mediterranean climate with warm, dry summers (mean maximum July temperature: 27°C) and cool, wet winters (mean minimum January temperature: 2°C) (Fontaine *et al.* 2010). Mean annual precipitation ranges from 140–500 cm over the burn area, with <15% falling from May–September (Daly *et al.* 2002; prismclimate.org). Forests are dominated by conifers, Douglas-fir (*Pseudotsuga menziesii*), white fir (*A. concolor*) and sugar pine (*Pinus lambertiana*); evergreen hardwoods, tanoak (*Lithocarpus densiflorus*), Pacific madrone (*Arbutus menziesii*) and canyon live oak (*Quercus chrysolepis*); and shrubs, greenleaf manzanita (*Arctostaphylos patula*) and snowbrush (*Ceanothus velutinus*). Fire regimes are complex, described as low- to mixed-severity with median return intervals ranging from 5–35 years in drier plant associations to 50–>100 years in higher elevation and wetter associations (Agee 1991; Agee 1993; Wills and Stuart 1994; Taylor and Skinner 1998; Stuart and Salazar 2000; USDA 2004). Stand-replacement fire effects (≥90% overstorey mortality) typically occur in variably sized patches as part of a burn mosaic (Donato *et al.* 2009*a*; Halofsky *et al.* 2011).

All sample areas were mature-to-old-growth (M/OG) Douglas-fir-dominated forests currently or before stand-replacement fire (see Thornburgh 1982; Agee 1993 for developmental and structural descriptions). Study areas were on steep slopes (generally >20°) between ~600 and 1300-m elevation, at mid-slope positions on a full range of aspects. Soils were derived from metasedimentary, metavolcanic and coarse-grained igneous parent materials (USDA 2004). We excluded conditions generally irrelevant to post-fire logging: extremely steep rocky areas, riparian zones, ultramafic soils (see Whittaker 1960), areas burnt with low or moderate severity (USDA 2004) and pre-existing plantations and shrub fields.

The Klamath–Siskiyou region is renowned for floristic diversity due in part to sharp topoedaphic and climatic gradients (Whittaker 1960); among the most important gradients are west-to-east trends in moisture and productivity. Western portions of the area (Fig. 1) receive greater maritime influence, experience less severe summer moisture deficits and have longer fire return intervals than do inland sites to the east (Daly *et al.* 2002; USDA 2004). As such, mesic western areas tend to support higher basal area and aboveground biomass than do drier eastern areas.

Study fire

The Biscuit Fire of 2002 burnt with mixed severity over 200 000 ha of the Klamath–Siskiyou Mountains. Relative proportions of low, mixed and high severity (as assessed by vegetation change) were respectively ~30, 27 and 43% (USDA 2004). The fire perimeter encompassed a broad range of biophysical conditions and spanned both western and eastern plant associations (Fig. 1). Following the fire, the Rogue River-Siskiyou National Forest implemented post-fire logging in limited areas of the burn. In addition to recouping economic value, stated objectives included reducing fire hazards associated with residual wood (USDA 2004).

Post-fire logging occurred mostly during the fall–spring of 2004–2005 (2–3 years post fire) with some additional logging during the winter–summer of 2005–2006 (3–4 years post fire). Logging occurred in stand-replacement patches ranging from ~4 to >1000 ha. Harvest units (spatially distinct logging parcels within timber sales) ranged from 1–70 ha in size (mean 8 ha). Trees were hand felled and de-limbed on site, generating slash in place. Logs were removed by cable or helicopter yarding. Prescriptions for down wood retention in severely burnt sites varied from 24 to 106 Mg ha^{-1} depending on plant association (USDA 2004). Slash treatment (prescribed burning of slash accumulations) occurred in <30% of sampled stands. All

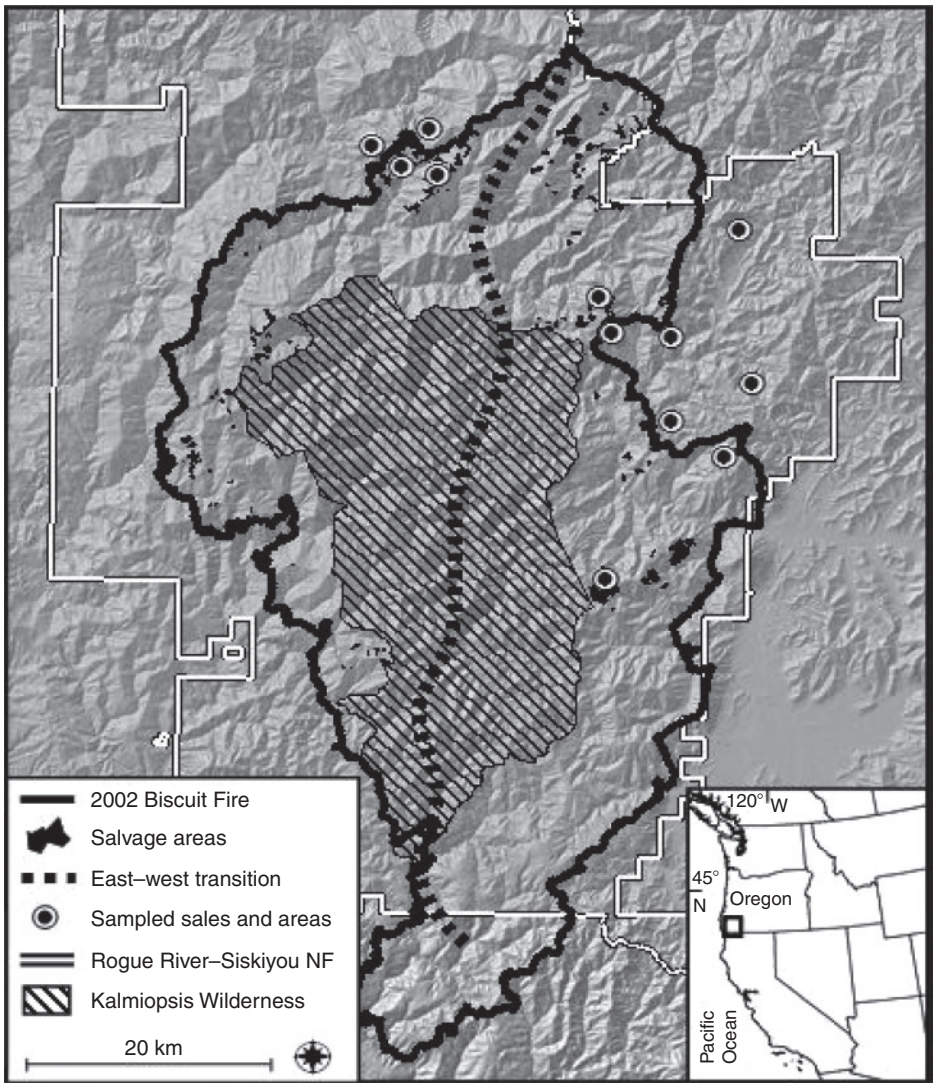

Fig. 1. Study area and sampling locations for quantification of fire and post-fire logging effects. Dots correspond to post-fire timber sales and adjacent unburnt areas in which sample stands were located (total $n = 38$ stands: 30 in the Biscuit Fire and 8 unburnt mature/old-growth stands). We sampled all large Biscuit Fire timber sales completed by late 2005, with one exception in the extreme west of the fire. Dashed line approximating transition zone between mesic westerly plant associations and drier easterly plant associations adapted from USDA (2004). Spatial data courtesy of Rogue River–Siskiyou National Forest.

post-logging data presented here from the Biscuit Fire reflect effects of tree harvest only (which was the only dead wood treatment in >70% of the stands), and not any subsequent treatments. Harvest prescriptions called for retention of 3–29 large (>41 cm) snags per hectare and variable retention of smaller (<41 cm) snags depending on merchantability (USDA 2004).

We categorised stands into three levels of treatment intensity: unlogged (U), logged at moderate intensity (M) and logged at high intensity (H). Moderate-intensity harvest units were helicopter yarded with 25–75% basal area cut at the hectare scale (mean 46% ± 5.5 s.e.); high-intensity harvest included a mix of cable and helicopter yarding with >75% basal area cut at the hectare scale (mean 89% ± 3.5 s.e.).

Data collection

We sampled all large Biscuit Fire timber sales completed by late 2005, with one exception in the extreme west of the fire due to access logistics. We sampled 26 stands in the eastern portion of the fire and 12 in the western portion (68% east, 32% west), corresponding to the distribution of Biscuit post-fire logging (67% east, 33% west by area). Study areas were identified *a priori* from Forest Service spatial data layers on proposed sale boundaries, burn severity and pre-fire forest cover and type. We interspersed treatment and control stands by sampling unlogged burn areas in and around each sampled sale. Unburnt M/OG stands were also sampled over a broad area corresponding to the distribution of sampled burn stands (Fig. 1). Study plots

(no more than one per harvest unit) were located randomly within harvest units and adjacent unlogged areas. Pre-treatment measurements occurred in the summer of 2004; post-treatment measurements (including re-measurement of control stands) occurred in the summers of 2005 and 2006, within 3–9 months of logging. The 26 eastern stands consisted of eight U stands, seven M stands, six H stands and five unburnt M/OG stands. The 12 western stands included three each of the four treatments.

We sampled each stand with a 1-hectare plot with a layout based on regional forest inventory protocols (USDA 2003*b*). All aboveground biomass pools were measured, partitioned by fuel stratum (*sensu* Pyne *et al.* 1996). Aerial biomass was defined as standing over- and mid-storey components (live and dead trees >10-cm diameter at breast height, DBH). Surface biomass was defined as standing understorey components (live and dead small trees, shrubs, forbs, grasses), down woody detritus, stumps and forest floor (litter and duff). Aerial and standing surface biomass were each measured in four regularly spaced circular subplots ranging from 2-m radius for the surface stratum to 17-m radius for the aerial stratum (surface and aerial subplots were concentric) (see USDA 2003*b*). For each tree we recorded species, DBH, total height, decay class (per Cline *et al.* 1980) and percentage of stem surface with bark and wood charring. For understorey hardwoods, shrubs, forbs and grasses we recorded percentage cover by species. Hardwoods and woody shrubs were further measured on an individual basis for live crown dimensions (length, width, height), basal diameter of live stems, and height and count of dead stems by 2-cm-basal diameter class. Forest floor mass was quantified by collecting eight systematically located 5.6-cm-diameter cores down to the mineral surface in each subplot (32 samples per plot), then separating litter and duff components, and drying at 70°C to constant mass.

We sampled down woody detritus by size class (see Agee 1993) along four 75-m planar intercept transects (Brown 1974; Harmon and Sexton 1996) radiating from plot centre in subcardinal directions. Coarse woody detritus (CWD; 7.63–20.32-cm and >20.32-cm classes) was surveyed along all 75 m of each transect and recorded for diameter, species, decay class and charring (Donato *et al.* 2009*b*). Fine woody detritus (FWD) was tallied by size class and char presence; survey lengths were, beginning from the distal end of transects: <0.62-cm class, 5 m; 0.63–2.54-cm class, 15 m; 2.55–7.62-cm class, 25 m.

Biomass computations

We computed stem mass for all trees using species- and region-specific allometric diameter-volume equations and wood densities (Walters *et al.* 1985; Means *et al.* 1994; Van Tuyl *et al.* 2005). Masses of tree foliage, bark, branch and unmerchantable tops were estimated directly from species-specific allometric equations (Means *et al.* 1994). Merchantable mass was defined as sound conifer stemwood >20-cm diameter (USDA 2004). All biomass components were adjusted for individual-specific metrics of bark and wood charring, top breakage and decay class status (Harmon and Sexton 1996; Appendix 1); as well as plot-specific ocular estimates of foliage and branch consumption (*sensu* USDA 2003*a*). Due to confounding of fire effects with definitions of decay class 1–2 characteristics (e.g. fine branch loss; Cline *et al.* 1980), recently fire-killed trees were assigned mean decay class 1–2 inputs. We computed biomass of surface-layer hardwoods and shrubs by empirically derived allometric equations (Donato *et al.* 2009*c*). Mass of forbs and low shrubs was estimated from regional equations relating cover to mass per area (Means *et al.* 1994). We computed mass of down woody detritus from line intercept data using standard geometric scaling and species- and decay-specific wood density values (Brown 1974; Harmon and Sexton 1996). Down wood was corrected on an individual piece basis for mass loss due to charring (Donato *et al.* 2009*b*).

Statistical analysis

Fire effects

To quantify apparent fire effects on aboveground biomass pools, we compared M/OG stands to three-year post-fire stands (unlogged). For this comparison we present means and 95% confidence intervals (CIs) by biomass category to evaluate magnitude of differences rather than obtain test statistics. Data for fire effects assessment were pooled across western and eastern stands because exploratory two-way analysis of variance (ANOVA; Ramsey and Schafer 2002) showed that fire effects did not differ strongly by forest type ($P > 0.05$ for all burn × forest type interaction terms).

Post-fire logging effects

To assess how post-fire logging effects varied by logging intensity and biophysical setting, we analysed fuel loads as a function of the three treatment levels (U, M, H); two forest types (mesic, drier); and a treatment × forest type interaction term in a two-way ANOVA. The forest type term allowed biomass levels in each treatment to vary between mesic *v.* drier stands, whereas the interaction term tested whether treatment effects varied by forest type. We analysed live and dead total biomass by stratum as well as fine and coarse down woody fuels. To provide management-relevant information on the implemented prescriptions, we also present trends in basal area and snag density among treatments.

Analysis of forest type and treatment differences was focussed on post-treatment comparisons ($n = 30$ burn stands (U = 11, M = 10, H = 9)). Because treatments were not implemented randomly (per the agency management plan), we also present results of a two-way ANOVA for the subset of stands for which we were able to collect before–after data ($n = 19$ (U = 8, M = 7, H = 4)) to assess whether strong differences among treatments existed before logging and whether the pre–post change was greater in treated stands than in controls. We could use only this subset for before–after analyses because 'reconstructing' stand density in logged stands for which we did not have pre-treatment data was precluded by the incidental felling, fragmentation and burial of an unquantifiable amount of small- and medium-sized stems. For all analyses, models were evaluated by residual-*v.*-fit plots using standard diagnostics (Ramsey and Schafer 2002). We $\log_e$-transformed basal area and snag density data to reduce heteroscedasticity. Biomass data were not transformed because the data were symmetrically distributed and showed no consistent pattern in residual spread. Specific treatment comparisons were performed by computing 95% CIs for each treatment within each forest type; lack of

overlap of CIs with means of other groups was interpreted as evidence for differences (Ramsey and Schafer 2002).

Results

Fire effects

Most aboveground biomass persisted through stand-replacement fire. Mean residual dead mass after fire was 515 Mg ha^{-1}, 83% of the 616 Mg ha^{-1} in M/OG stands (Table 1). Aside from converting live biomass to dead (mean post-fire live : dead ratio = 1 : 99), the primary effect of fire was to consume the forest floor and fine fuels in the surface layer (Table 1). Mean forest floor mass after fire (1.1 Mg ha^{-1}) was 96% lower than in M/OG stands (27.2 Mg ha^{-1}) (Table 1). Mean surface wood mass was also lower in post-fire stands by 47–73% for all size classes except the >20.32-cm class, which was similar (Table 1). Live surface biomass (regenerating vegetation) 3 years post fire was already similar to that in M/OG stands (Table 1, Fig. 2).

Consumption of aerial biomass was minimal (Table 1, Fig. 3). Foliage consumption approached 100% but most aerial wood consumption was of twigs (needle-bearing and adjacent branchlets), which compose a small fraction of total mass.

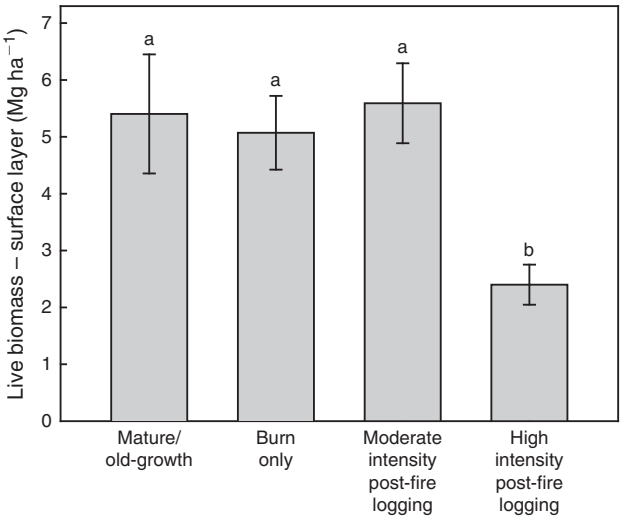

Fig. 2. Mean (±s.e.) live biomass in the surface layer (mid- and over-storey trees excluded). See Table 3 for statistical comparisons. Data are aggregated across the drier to mesic forest types because treatments effects were similar in both types (Table 3). Lower-case letters above bars denote significant differences based on the ANOVA at $\alpha = 0.05$; see Table 3 for full statistical outputs. Regenerating vegetation had already achieved similar biomass 3–4 years post fire as in mature/old-growth stands, and was lower after high-intensity logging.

Consumption of larger branches and stems was negligible (Table 1, Fig. 3, Donato 2008).

Following fire, mesic stands had higher residual biomass (mean 709 Mg ha^{-1}, 95% CI: 555–864) than did drier stands (mean 435 Mg ha^{-1}, 95% CI: 340–530). Tree biomass drove this difference, associated with larger mean snag diameter (44.9 *v.* 36.5 cm) and dead basal area (94.3 *v.* 68.1 m^2 ha^{-1}). Post-fire dead basal area averaged 83% Douglas-fir, 3% incense cedar and 3% white fir in mesic stands; and 65% Douglas-fir, 21% sugar pine and 6% white fir in drier stands. Hardwoods constituted a mean of 11% of total basal area in mesic stands (mainly tanoak) and 4% in drier stands (mainly Pacific madrone).

Post-fire logging effects

Pre-treatment comparisons

We detected no significant pre-existing differences among treatments in terms of basal area, stem densities, fine and coarse woody fuels or live and dead biomass (Table 2). Change magnitudes (post-treatment value minus pre-treatment value) were significantly greater in logged *v.* unlogged stands for all variables except live biomass and density of small snags (Appendix 2).

Post-treatment comparisons

Aerial dead biomass decreased monotonically with increasing harvest intensity in both forest types (Fig. 3, Tables 3, 4). Conversely, surface dead biomass increased monotonically with harvest intensity in both forest types, with treatment effects greater in mesic stands (Fig. 3, Table 3). Post-fire logging reduced standing dead basal area and large snag densities to a greater degree in mesic stands than in drier stands (Table 3).

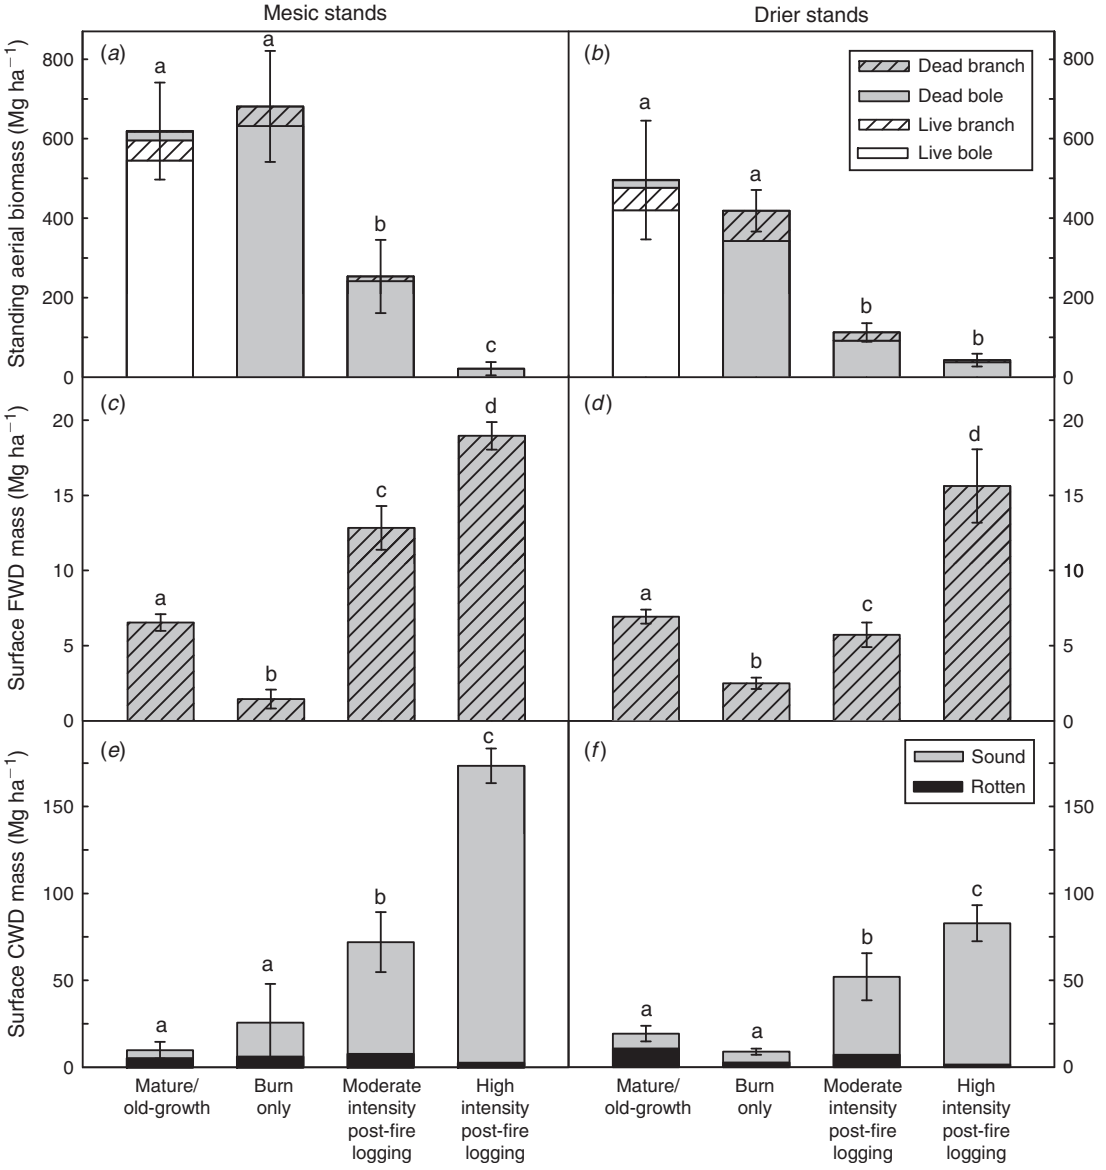

Fig. 3. Mean (±s.e.) aerial (*a–b*) and surface (*c–f*) wood biomass in mature/old-growth stands, and following stand-replacement fire and post-fire logging. Lower-case letters above bars denote significant differences based on the ANOVA at $\alpha = 0.05$; see Table 3 for full statistical outputs.

Live surface-layer biomass remained similar to unlogged stands after moderate-intensity logging, but was lower after high-intensity logging (Fig. 2).

In mesic sites, total biomass removal was estimated at 50 and 66% of post-fire biomass in M and H stands (Table 3). In drier sites, estimated total removal was 58 and 63% in M and H stands (Table 3). Total dead biomass remaining after logging did not differ strongly between moderate- and high-intensity logged stands in either forest type, with broadly overlapping confidence intervals (Table 3). Thus, with high-intensity harvest, more biomass was felled but not removed.

Surface woody fuel loads of all size classes increased following moderate- and high-intensity logging (Fig. 3, Tables 3, 4). Relative to drier stands, logging in mesic stands resulted in greater increases in both fine and coarse surface fuels (Fig. 3, Table 3). When harvest intensity was assessed as a continuous variable, post-logging surface fuel loads were significantly positively related to basal area cut (Fig. 4). As a reference, both moderate- and high-intensity logging resulted in surface fuel loads exceeding those in M/OG stands, except for in the smallest size class (Tables 1, 4).

Surface woody fuel loads became more spatially homogeneous following logging, whereas spatial patterns of live biomass remained similar. Mean surface cover of woody detritus was 6.3, 20.4 and 34.1% in U, M and H stands, compared with 14.5% in M/OG (Fig. 5*a*). Hectare-scale heterogeneity in CWD mass (coefficient of variation (CV%) among transects within a stand; Fraterrigo and Rusak 2008) decreased with logging

Table 2. Assessment of pre-treatment similarity for the subset of stands with before–after data ($n = 19$), by two-way ANOVA
Comparisons are results of Fisher's *F*-protected least significant difference comparisons with α set at 0.05 to aid interpretation (Ramsey and Schafer 2002). U, burnt, unlogged; M, burnt, moderate-intensity logged; H, burnt, high-intensity logged. *F* statistics and *P* values are shown for treatment effect only; for variables with significant mesic–dry differences, mesic stands had higher absolute amounts. See Appendix 2 for side and interaction terms, means and 95% CIs by treatment, and analysis of pre-post change values

Stand characteristic	Pre-treatment

intensity, with a CV% respectively of 110.9, 56.7 and 40.3 in U, M and H stands, compared with 72.0 in M/OG stands (Fig. 5*d*). These effects were similar in each forest type.

Discussion

The effect of post-fire logging on fuel profiles and stand structures varied significantly with harvest intensity and among forest types. Our findings yield several inferences regarding post-disturbance biomass dynamics and for developing post-fire management prescriptions.

Fire effects

Our estimate of total biomass consumption by stand-replacement fire (17%) agrees well with literature estimates for Douglas-fir and mixed-conifer forests (16–24%) (Fahnestock and Agee 1983; Campbell *et al.* 2007; Meigs *et al.* 2009). Even active crown fires that kill nearly all trees tend to consume little aerial biomass – primarily leaves and small branches (Call and Albini 1997) – with most actual consumption occurring in the surface stratum.

Post-fire logging effects

Treatment effects by biophysical setting and intensity

As expected, post-fire logging removed some aerial biomass and transferred some to the surface, but these effects varied by biophysical setting and logging intensity. Surface fuel loads increased more with logging in mesic *v.* drier stands; mesic stands had more basal area standing, more basal area cut and thus larger increases in surface fuels. This was reflected in the positive relationship between the amount of basal area cut and resulting surface fuels (Fig. 4). This relationship likely has applicability across forest types, as the structural metric of basal area is generally a strong predictor of bole and branch biomass even as stand composition varies. For example, whereas post-fire logging in comparatively low-basal-area *P. ponderosa* forests resulted in much lower surface fuel loads than we report (McIver and Ottmar 2007; Keyser *et al.* 2009), the relationships between basal area cut and surface fuel accumulation in those studies correspond well to the association shown in Fig. 4. This predictive relationship could be used as a tool for post-fire management to anticipate ranges of surface fuel loads given different harvest intensities.

An important factor in post-disturbance stands is fuel continuity (Fraterrigo and Rusak 2008; Donato *et al.*, in press). In the case of fire, consumption of ground and surface fuels generally results in highly patchy residual fuel and low horizontal continuity. Re-burns are thus unlikely to carry through young stands initially. Post-fire logging decreased this spatial heterogeneity, resulting in more spatially continuous woody surface fuels (Fig. 5). In high-intensity logged stands, percentage cover of wood was higher, and stand-scale variation in CWD mass lower, than in burn-only or M/OG stands. The areal cover of live vegetation was little affected, however. Increased continuity of woody fuels may become important if it helps close the window of low fire spread capacity sooner, or if, in combination with other fuel components, post-harvest fuels contribute to meeting a threshold for fire propagation. In highly productive fire-prone regions such as the Klamath–Siskiyou, the low fire spread window may close relatively quickly as regenerating vegetation and new litter inputs accumulate on the surface, likely within 5–10 years (Table 1, Fig. 2; Hobbs *et al.* 1992; Stuart *et al.* 1993; Fontaine *et al.* 2009). Assessing the effects of changes in fuel continuity is difficult because common fire models do not adequately address stand-scale spatial heterogeneity (e.g. Stephens and Moghaddas 2005).

Relevance to follow-up treatments

These data indicate that with moderate-intensity logging, a mean of ~86% of felled tree biomass was actually removed from the site whereas ~14% remained on the ground as slash (6.1 : 1 ratio), compared with high-intensity logged

Table 3. Post-treatment stand characteristics (point estimate, 95% CI) and statistical comparisons of unlogged (U), moderate-intensity logged (M) and high-intensity logged (H) burn stands
$n = 8$, 7, 6 for U, M, H in drier stands; and 3 each for U, M, H in mesic stands. See Table 4 for standard errors and individual biomass pools. 95% CIs were derived from two-way ANOVA outputs. Trt, treatment (U, M, H), Ftype, forest type (mesic, drier)

stands in which the ratio averaged ~72 : 28% (2.6 : 1). In general, moderate-intensity logging on the Biscuit Fire occurred when only fire-killed trees deemed merchantable were felled, whereas high-intensity logging occurred when nearly all fire-killed trees were felled and only merchantable logs then yarded. This greater selectivity of moderate-intensity treatment suggests a more deliberate approach to post-fire wood management that is more likely to result in prescribed down wood levels, *v.* high-intensity treatment in which resulting levels become more dependent on timber decay status and merchantability, regardless of prescription (see Rickards 1989).

From a management perspective, optimum ranges of down wood in fire-prone forests aim to balance the ecological functions of dead wood with its contribution to fire potentials (Brown *et al.* 2003). Though not derived specifically for the Klamath–Siskiyou region, the range given for cooler forests (23–68 $Mg ha^{-1}$ of CWD) provides context for the post-logging fuel loads we measured. After moderate-intensity logging or no treatment, surface CWD loads were within or near this range (Fig. 2). High-intensity logging generated surface fuel loads well above these levels. This suggests that moderate-intensity logging or no treatment may result in acceptable (or even prescribed) fuel loads in the short term, whereas high-intensity logging may require additional treatments to mitigate short-term fire potentials.

Data following timber harvest alone provide insight as to when slash treatments may be warranted, and are relevant to operations in which slash is left on site (e.g. McIver and Ottmar 2007; and much of the Biscuit Fire). Studies in both young and mature unburnt stands have reported increased fire severity associated with untreated slash from logging and fuel-reduction treatments (e.g. Weatherspoon and Skinner 1995; Stephens 1998; Raymond and Peterson 2005; Stephens and Moghaddas 2005). Our empirical data suggest a potential need for follow-up slash treatments after dead tree (snag) removal as well, primarily after high-intensity logging, consistent with a modelling study conducted in the Sierra Nevada mountains of California, USA (Stephens 1998). Relatively few of our sampled stands from the Biscuit Fire received secondary treatments, precluding sufficient sample size or timing to assess their effects.

Influence of harvest timing

The time period between fire and logging may play a role in the amount of surface fuels generated (longer time → greater snag decay → lower merchantability → more material left on ground after felling). Our data suggest this was not a major driver in the case of the Biscuit fire because (1) no fine fuels have timber merchantability in any case and (2) nearly all coarse fuel increases could be accounted for by non-merchantable species and parts, pre-fire decay, and standard timber defect and breakage rates (Snell and Brown 1980). Based on our biomass data and allometries for merchantable boles (Means *et al.* 1994), we estimate that at least ~40% of post-fire biomass is not merchantable, even immediately post fire. This again highlights the importance of considering the non-merchantable component of post-fire wood (fine and fragmented or rotted coarse fuels) where management of early-seral fire potentials is an objective.

Table 4. Mean (s.e.) aboveground biomass pools (Mg ha^{-1}), separated by category, 3–4 years after stand-replacement wildfire and subject to three post-fire treatments: unlogged (U), moderate-intensity logged (M) and high-intensity logged (H)
$n = 8, 7, 6$ for U, M, H in drier stands; and 3 each for U, M, H in mesic stands

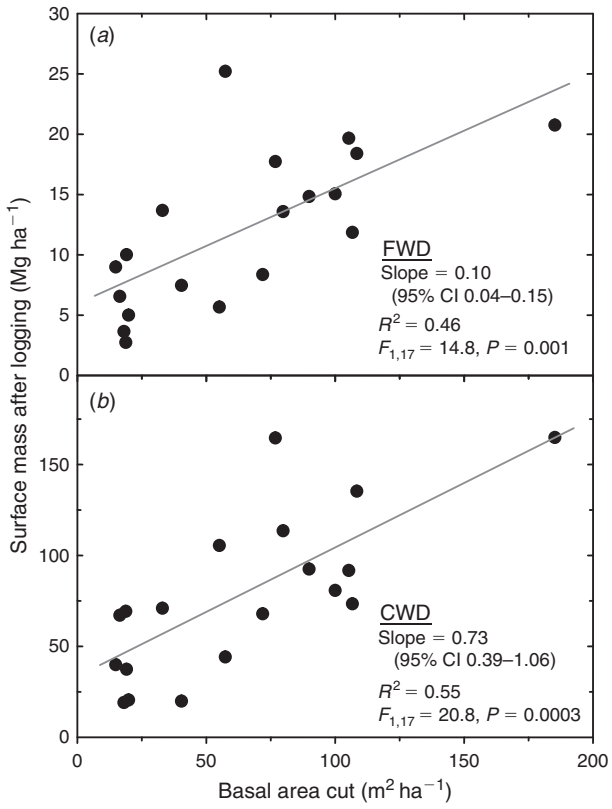

Fig. 4. Surface mass of fine (*a*) and coarse (*b*) woody detritus after post-fire logging as a function of total basal area cut.

Longer term considerations

These data provide information on immediate changes in fuel profiles with post-fire logging and are short term in nature. Over time, slash fuels left in place will decay and snags left in place will fragment and fall to the surface. Studies from dry continental-interior forest types (e.g. *P. ponderosa* or *P. contorta*) indicate that unlogged stands eventually accumulate greater surface fuel loads (Monsanto and Agee 2008; Keyser *et al.* 2009). McIver and Ottmar (2007), also working in interior dry forests, used models to project post-fire surface fuel loads and suggested that fine fuel loads remained greater in logged stands for ~20 years, but coarse fuel loads would be lower in logged stands from ~20–50 years post fire. Passovoy and Fulé (2006) concluded that, in the absence of management, CWD loads up to 27 years post fire in a ponderosa pine system remained within acceptable ranges outlined by Brown *et al.* (2003), and suggested that post-fire logging for fuel reduction appeared unnecessary. The need for and outcomes of management treatments may depend largely on forest type as well as yarding method and slash treatment, but the latter have not always been clear for studies of older fires and considerable uncertainties remain.

Initial studies in the Klamath–Siskiyou region suggest that unlogged stands may not have higher fuel loads until at least two to three decades after fire (Donato 2008). Longer-term snag dynamics are poorly understood for mixed-evergreen forests of the western USA, but forest inventory data suggest relatively rapid wood decay in this region (Hudiburg *et al.* 2009), which may lessen the surface accumulation of snag biomass. Consistent with this pattern is evidence of greatly diminished woody

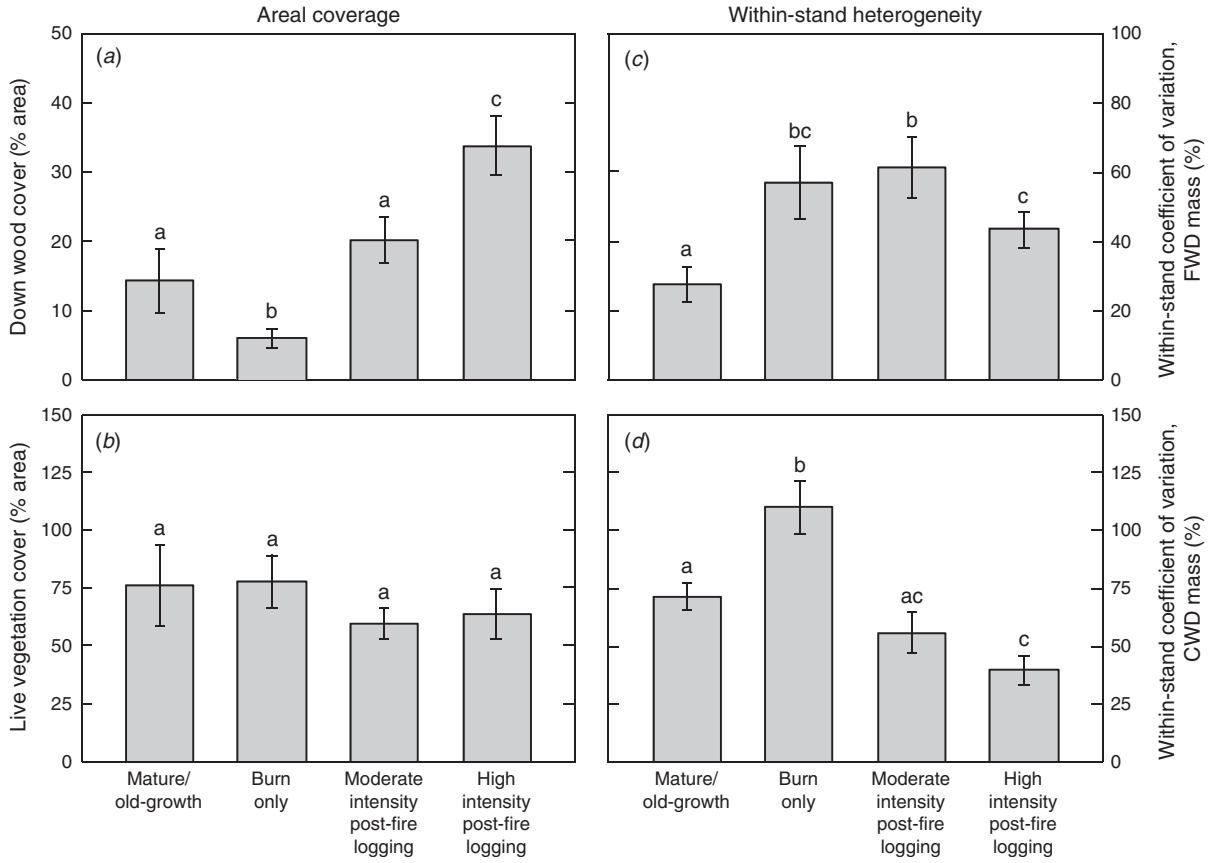

Fig. 5. Mean (±s.e.) cover and spatial variation in surface fuels. Lower-case letters above bars denote significant differences at $\alpha = 0.05$ based on the one-way ANOVA across all stands. Areal coverages are percentage of ground area of down wood (*a*) and live vegetation (*b*). Within-stand spatial heterogeneity is estimated by computing the coefficient of variation among transects within each sample stand, for fine down wood (*c*) and coarse down wood (*d*).

biomass in 18-year-old fires in this region and little to no difference in surface fuel loads between managed and unmanaged stands at that post-fire age (Donato 2008). Evidence also suggested rapid decay of snag and down wood biomass, with single-exponential decay constants (Harmon *et al.* 1986) of ~0.030 to 0.040 for all standing and down material combined; a value comparable with other studies in Douglas-fir forests (Sollins 1982; Agee and Huff 1987; Spies *et al.* 1988). Those findings agree well with observations 10 years after another fire in the region (56.5 *v.* 56.8 Mg ha^{-1} in logged *v.* unmanaged stands; Bureau of Land Management, Medford, OR, unpubl. data, 2003), as well as a recent study from the Sierra Nevada that reported higher dead fuel loads in post-fire logged stands up to 21 years after fire (McGinnis *et al.* 2010). In highly productive fire-prone systems, fast decay may reduce the contribution of residual post-fire wood to early-seral fire potentials, whereas the live component of regenerating vegetation, which accumulates biomass and continuity quickly (Hobbs *et al.* 1992), may be a much more important driver of fire potentials in young stands (Donato 2008).

Uncertainties and future research

An important research objective is better quantifying regional differences in snag decay rates, standing biomass and productivity within the context of post-fire fuel profile development. Remarkably few studies have quantified the overall decay rate of post-disturbance snags – integrating fragmentation, falling and mineralisation during both the standing and down phases (see Donato *et al.*, in press). We hypothesise that discrepancies in fuel loads between post-fire logged and unmanaged stands are greater for drier, continental interior forest types, and less so for mesic and coastal forest types, owing to higher rates of vegetation growth and wood decay in the latter systems.

Another seldom addressed issue for post-fire logging is that of fire regime context. Management of post-fire residual wood is often concerned with avoiding surface fuel loads deemed to be excessive with respect to fire potentials (Brown *et al.* 2003); however, pulses of dead wood are a characteristic feature of mixed- and high-severity fire regimes (e.g. Spies *et al.* 1988). Within the context of historic variation, therefore, the ecological basis for reducing post-fire fuels may be most pertinent in low-severity fire regimes where large pulses of fire-killed trees are considered outside the historic range of variation (see Monsanto and Agee 2008).

Although the applicability of common fire models to post-fire settings is not well established (Passovoy and Fulé 2006), known relationships between fuel loads and surface fire behaviour (Rothermel 1983) suggest that post-fire logging may

elevate fire potentials in the short term, other factors being equal. Exploratory analysis using the model BehavePlus 3.0 (Andrews *et al.* 2005) supported this inference, with predicted fire behaviour (e.g. rate of spread, surface flame length, soil heat flux) simply scaling upward with increased fine and coarse fuel loads in treated stands (Donato 2008). Slash from logging or fuel-reduction treatments has been associated with increased fire severity in both young and mature stands in various settings (e.g. Weatherspoon and Skinner 1995; Raymond and Peterson 2005; Stephens and Moghaddas 2005). Nevertheless, local fire behaviour depends on many factors such as fuel continuity, weather, etc., in addition to fuel load. Although we observed greater homogeneity in surface fuels after treatments, fuel continuity is poorly addressed in fire models (Stephens and Moghaddas 2005). Predicted effects could be lessened if fire cannot spread in very young stands due to low continuity, or amplified if post-logging fuels meet a threshold for fire propagation. Other uncertainties include the role of localised pockets of snag-fall (or slash) accumulation, and how the landscape context of post-fire logging units affects larger-scale fire spread.

Snags may contribute to fire behaviour by 'candling' and providing ember sources that can lead to spot fires. Oregon's 1933 Tillamook Burn, which re-burnt three times at 6-year intervals, is a commonly cited example of the fire contribution of snags since fires ceased to occur following extensive snag removal (Kemp 1967). However, the Tillamook Burn narrative is complicated by the fact that all three re-burns were started by post-fire logging operations and burnt through a mix of both logged and unlogged areas (Kemp 1967; Peterson *et al.* 2009). Surface or ground fuels are the primary carrier of wildfire and contribute most to soil heating and regeneration mortality (Pyne *et al.* 1996). The role of snags in fire behaviour has been the subject of little quantitative study, is not captured by available fire modelling frameworks and warrants future research.

Conclusions and management implications

Post-fire logging in this high-biomass, fire-prone system reduced standing fuel mass as expected, but the amount of material transferred to the surface varied by both environmental setting and treatment. Post-logging fuel loads were greater in higher basal-area mesic forests and with higher-intensity harvest. These findings suggest that reports of either increased or decreased fire severity following post-disturbance logging (Hansen 1983; Kulakowski and Veblen 2007; Thompson *et al.* 2007; Buma and Wessman 2011; Fraver *et al.* 2011) may stem in part from variation among studies in terms of harvest intensity and pre-disturbance forest structure. We also found that the efficiency of biomass removal (the proportion of biomass felled and removed versus felled and left on site) and the spatial heterogeneity of surface fuels both decreased with increasing harvest intensity. The general relationship we identified between harvest intensity (basal area cut) and resulting surface fuels likely has applicability across diverse forest types and could provide a useful predictive tool for developing post-fire management prescriptions.

Post-fire timber harvest is generally an economic rather than restorative undertaking (Peterson *et al.* 2009). From a fire management perspective, studies from several regions have reported inherently high fire potentials in early-seral stands, with limited efficacy of stand-level fuel treatments in reducing these potentials (Roloff *et al.* 2005; Stephens and Moghaddas 2005; McIver and Ottmar 2007; Thompson *et al.* 2007; McGinnis *et al.* 2010; but see Weatherspoon and Skinner 1995). As such, alternative or additional treatments may be necessary where objectives include reducing fire potentials, such as landscape fuel breaks (Agee *et al.* 2000) and managing for diverse vegetation structure (Donato *et al.* 2012). Where post-fire logging is conducted, our results suggest that moderate-intensity treatment results in surface fuel loads most consistent with prescribed levels when compared with high-intensity treatment, and may reduce the potential need for follow-up fuel treatments (e.g. slash piling, burning). Because moderate-intensity treatment leaves a greater proportion of snags standing, it may also be most compatible with objectives pertaining to the many other ecological roles of snags (e.g. wildlife habitat; Fontaine *et al.* 2009). Longer-term effects of post-fire logging on snag-fall inputs and coarse fuel loads remain an important research question. Finally, given the paucity of data on post-fire management effects, designing management projects with replication, pre-treatment data and controls as in this study will best clarify the tradeoffs of various post-fire interventions.

Appendix 1. Adjustments to tree mass computations for decay and fragmentation

Adjustments to tree mass components for decay status (e.g. wood density) were largely obtained from Harmon and Sexton (1996). For broken-topped trees, stem volume was computed using an equation for a tapered cylinder, $0.8\ \pi r^2 h$, and branch and bark masses were reduced proportional to amount of crown lost to breakage. Additional adjustments for branches and bark were adapted from several sources as shown in Table A1.

Table A1. Decay class adjustments to tree branch and bark computations
Estimates adapted from Cline *et al.* (1980), Harmon and Sexton (1996), Van Tuyl *et al.* (2005)

Characteristic	Decay class				
	1	2	3	4	5
Ratio of branch volume to original volume	1.00	0.80	0.40	0.00	0.00
Ratio of branch density to original density	1.00	0.78	0.67	0.38	0.37
Ratio of bark mass to original mass	1.00	1.00	0.20	0.00	0.00

CONSERVATION OF AQUATIC AND FISHERY RESOURCES IN THE PACIFIC NORTHWEST:

Implications of New Science for the Aquatic Conservation Strategy of the Northwest Forest Plan

ABSTRACT

Twenty years have elapsed since a major science synthesis and planning effort led to adoption of the Aquatic Conservation Strategy (ACS) of the Northwest Forest Plan (NFP) in 1994. Their purpose was to protect and restore riparian and aquatic ecosystems on Pacific Northwest federal forest lands and to ensure that forest management plans achieved legally required and socially desired multiple use objectives, including water quality, aquatic and wildlife resources. In this paper, we review relevant science emerging since 1993 to assess whether proposed changes to the ACS, including reduced riparian reserve protections and a substantially lowered burden of proof for watershed-disturbing activities, are scientifically justified. Observed and anticipated effects of climate change, and of cumulative anthropogenic stressors operating in the nonfederal lands surrounding NFP lands strongly indicate the need to strengthen, not weaken key ACS protections. Roads and ground disturbance associated with mechanical thinning and fuels reduction activities, especially within Riparian Reserves, cause adverse environmental impacts that generally offset or exceed presumed restorative benefits. Headwater streams warrant wider riparian forest buffers than current ACS provisions to ensure effective retention of sediment and nutrients derived from upslope logging, fire, and landslides. Widespread and sustained ecological harm caused by roads is now widely recognized, and ACS measures should be strengthened to more effectively arrest and reduce road impacts in all catchments. Grazing, mining, post-disturbance logging (e.g., fire salvage), water withdrawal, and aerial application of toxic chemicals can cause both acute and chronic harm to aquatic ecosystems. Existing ACS standards and guidelines would need to be strengthened to more effectively control these impacts. A more thorough and current scientific review and synthesis by federal agencies to inform a future ACS is long overdue. Unfortunately, no such review has occurred, while recent agency and legislative proposals would substantially reduce protective provisions of the ACS and NFP by increasing the extent of logging and other mechanized forest management, such as fuels treatments.

Introduction: Origins of the Aquatic Conservation Strategy

In 1994, region-wide social protest over logging old-growth forests, court injunctions on federal forest timber sales, and a rare presidential "roundtable" summit, led to sweeping changes the management of federal forest lands in the U.S. Pacific Northwest. The federal agencies with primary land management responsibilities, the U.S. Department of Agriculture's Forest Service (USFS) and U.S. Department of Interior's Bureau of Land Management (BLM), jointly adopted a new, regional conservation and management framework now known as the Northwest Forest Plan (hereinafter referred to as the NFP, or the "Plan"). The NFP was designed to meet President Clinton's call for an approach that would (1) satisfy federal courts and lift the injunctions, (2) protect the environment, and (3) help stabilize the regional economy (GAO 1999). The Plan's Record of Decision (USDA and USDI 1994) offered a "scientifically sound, ecologically credible, and legally responsible" long-term management strategy for federal lands within the range of the northern spotted owl (*Strix occidentalis cauria*). The NWP region encompasses over 99,000 square km (24.5 million acres) within the highly productive forest zones of western Washington and Oregon and northern California. In addition to spotted owls and other wildlife species dependent on late seral forests, these federal lands also harbor sensitive, declining, and federally listed salmon species (FEMAT 1993; USDA and USDI 1994). Declines in once-abundant salmon and other fish assemblages, amphibians and invertebrates (e.g., river mussels) indicate substantial and persistent loss of aquatic ecosystem integrity (Hughes et al. 2004; Kaufmann and Hughes 2006).

To ensure that the new plan had the sound scientific basis necessary to withstand legal scrutiny, the federal agencies convened an interagency and interdisciplinary panel of scientists (Forest Ecosystem Management Assessment Team, FEMAT 1993) to develop the rationale and options for conservation provisions of the Plan. Recognizing that terrestrial and freshwater species fundamentally share the same landscape, FEMAT scientists developed a system of terrestrial reserves and conservation provisions and a separate but overlapping Aquatic Conservation Strategy ("ACS").

Since the NFP was adopted, social and political pressure have mounted to significantly recast or eliminate the Plan (e.g., Johnson and Franklin 2012), including key elements of its ACS. In late 2013, two bills were introduced in Congress (S.1784 and H.R.1526) that would substantially reshape management on approximately 8000 square km (roughly 2 million acres) managed by the BLM in western Oregon. Separately, the BLM has initiated an administrative planning process intended to result in a decision to replace the NFP policies. These efforts appear principally motivated by the goal of increasing commercial timber production (Blumm and Wigington 2013, DellaSala et al. 2014). Meanwhile, the Forest Service has adopted guidance that would permit substantial alteration of key elements of the ACS in future revisions of its National Forest Management Plans in the Pacific Northwest.

Both agency and congressional proponents of significant alterations of the NFP and its ACS have referred generally to "new science" as a basis for many proposed changes. However, we find that post-1993 scientific findings relevant to the ACS have not been synthesized and addressed in a systematic manner. In this paper we review the key ACS elements, briefly discuss several proposed modifications, and identify concerns about the likely consequences of proposed modifications. Finally we identify needed improvements in the protective measures in the ACS as indicated by new and emerging scientific knowledge, and suggest the form future revisions of ACS provisions might take if they are to be responsive and robust to recent scientific advances.

Core Design Elements of the Aquatic Conservation Strategy

FEMAT (1993) articulated the ACS with two spatial and two programmatic components for managing watersheds and riparian areas: (1) *Key Watersheds,* a land allocation comprising hydrologically discrete areas that putatively contain much of the remaining higher-quality aquatic habitat and offer the greatest potential protection for recovering at-risk fish species. These watersheds are priorities for active restoration, ARE subject to a "no net increase" mandate for road density and watershed analysis mandate for major land use activites.

TABLE 1.
The nine narrative ACS Objectives describing watershed functions and processes and which apply landscape-wide (USDA and USDI. 1994. Record of Decision, p.B-11).

Forest Service and BLM-administered lands within the range of the northern spotted owl will be managed to:

1. *Maintain and restore the distribution, diversity, and complexity of watershed and landscape-scale features to ensure protection of the aquatic systems to which species, populations and communities are uniquely adapted.*
2. *Maintain and restore spatial and temporal connectivity within and between watersheds. Lateral, longitudinal, and drainage network connections include floodplains, wetlands, upslope areas, headwater tributaries, and intact refugia. These network connections must provide chemically and physically unobstructed routes to areas critical for fulfilling life history requirements of aquatic and riparian-dependent species.*
3. *Maintain and restore the physical integrity of the aquatic system, including shorelines, banks, and bottom configurations.*
4. *Maintain and restore water quality necessary to support healthy riparian, aquatic, and wetland ecosystems. Water quality must remain within the range that maintains the biological, physical, and chemical integrity of the system and benefits survival, growth, reproduction, and migration of individuals composing aquatic and riparian communities.*
5. *Maintain and restore the sediment regime under which aquatic ecosystems evolved. Elements of the sediment regime include the timing, volume, rate, and character of sediment input, storage, and transport.*
6. *Maintain and restore in-stream flows sufficient to create and sustain riparian, aquatic, and wetland habitats and to retain patterns of sediment, nutrient, and wood routing. The timing, magnitude, duration, and spatial distribution of peak, high, and low flows must be protected.*
7. *Maintain and restore the timing, variability, and duration of floodplain inundation and water table elevation in meadows and wetlands.*
8. *Maintain and restore the species composition and structural diversity of plant communities in riparian areas and wetlands to provide adequate summer and winter thermal regulation, nutrient filtering, appropriate rates of surface erosion, bank erosion, and channel migration and to supply amounts and distributions of coarse woody debris sufficient to sustain physical complexity and stability.*
9. *Maintain and restore habitat to support well-distributed populations of native plant, invertebrate, and vertebrate riparian-dependent species.*

(2) Riparian Reserves, a land allocation of varying widths along streams and lakes where aquatic and riparian objectives receive primary emphasis and where management is constrained according to activity-specific standards and guidelines. (3) *Watershed Analysis* is an assessment procedure designed to recommend how to tailor management priorities and actions to the biophysical limitations and perceived restoration needs of individual watersheds. (4) *Watershed Restoration*, a long-term program of somewhat unspecified scope and content, but which may include such wide-ranging provisions as road decommissioning, instream habitat alterations, and other measures (ROD 1994).

Late Successional [forest] Reserves, Congressionally designated reserves, and administratively withdrawn areas are land allocations outside of the specific components of the ACS, but they provide additional protection for portions of watersheds, riparian and aquatic ecosystems, particularly in terms of how they regulate landscape-wide management disturbances. In turn, aspects of the ACS also help provide habitat and connectivity for terrestrial wildlife species (ROD 1994, p.7). Many birds, mammals, amphibians, and invertebrates benefit from roadless areas (Trombulak and Frissell 2000); require large trees or wood debris for nesting or other uses; or rely on riparian forests for refuge, foraging, or dispersal (Pollock and Beechie 2014).

Beyond land allocations, the ACS imposes constraints on habitat-degrading management activities in two other ways: 1) It provides binding *standards and guidelines* that explicitly constrain numerous potential management activities within riparian reserves and key watersheds. 2) It requires all management activities on surrounding federal forestlands to be consistent with maintaining and restoring watershed functions and processes that are described in nine narrative ACS objectives (Table 1). The activity-specific standards and guidelines were intended to "prohibit and regulate activities in Riparian Reserves that retard or prevent attainment of the [ACS] objectives" (USDA and USDI 1994). The precaution that management activities may not retard recovery is a potent requirement. In order to ensure an action does not retard or prevent attainment of recovery, managers must ascertain the net effects of any proposed action on natural recovery processes at site-specific areas and larger spatial scales. This requirement addresses the observation (FEMAT, 1993) that past ecological degradation caused by numerous incremental harms often is not recognized. Cumulative effects across the landscape commonly offset gains from those passive or active management measures claimed to benefit ecological conditions and aquatic resource values.

Although it is beyond the scope of this paper to enumerate the many activity-specific standards and guidelines that comprise the ACS, some specific examples will be discussed because they are conspicuously affected by new or emerging scientific knowledge. The nine over arching ACS objectives also have binding force and constitute forest-wide standards and guidelines themselves (ROD 1994). This approach was explicitly intended to constrain activities in geomorphically, hydrologically, and ecologically sensitive areas and to limit the cumulative impacts of activities throughout a watershed (FEMAT 1993, V-29). The identified goal was to maintain conditions within a broadly conceived "range of variability" across multiple spatial and temporal scales, by evaluating, avoiding, or reversing ecologically harmful management at watershed and site-specific scales. The science of ecological restoration broadly recognizes that avoidance of adverse impacts is far more effective than post-hoc remediation of impacts (Kauffman et al. 1997, Karr et al. 2004, Roni et al. 2008), and this principle is codified in the Plan's Standards and Guidelines for watershed restoration (guideline WR-3 clearly states: "*Do*

not use mitigation or planned restoration as a substitute for preventing habitat degradation.") During the mid-1990s, some federal agencies argued that site-specific failure to meet ACS objectives was broadly acceptable if unacceptable outcomes were not expected to be observed at larger scales. However, courts have validated that the conservation burdens delineated in the ACS apply to both site- or project-specific as well as larger scales, such as a watershed, planning area, or national forest.[1] The guiding language in the nine narrative objectives directs managers to "maintain and restore" specifically identified ecological conditions and functions. Hence management activities that will affect aquatic ecosystems may be pursued only under a reasonable assurance that they are restorative or protective in nature. It is not sufficient that management activities produce acceptably small adverse impacts, or cause harms that might potentially be mitigated by other measures.

Courts have ruled that FEMAT (1994) embodies the best available scientific information pertaining to the impacts of forestry activities on salmon and their habitat in the Pacific Northwest federal forests and that the Plan adequately integrates FEMAT's scientific representations[2]. Several scientific reviews (e.g., Spence et al. 1996, DellaSala and Williams 2006, Reeves et al. 2006a, Everest and Reeves 2006) have broadly concluded that while a great deal of new information has been published, the fundamentals and rationale of FEMAT and the ACS remain consistent with available scientific information. However, no interagency scientific panel comparable to the scope of FEMAT has been reconvened to formally address the broad question of how new scientific information may affect the validity of the ACS and how that might in turn affect Endangered Species Act (ESA) consultations, Clean Water Act (CWA) compliance, or NEPA, NFMA, and other relevant project level planning processes.

Because the ACS is incorporated into agency land use management plans, it is directly enforceable by third parties pursuant to the over arching resource planning statutes of the USFS and BLM. While the majority of distribution of salmon species in the Pacific Northwest lies downstream of federal forest watersheds, the federal lands provide important high-quality refugia for many populations (Burnett et al. 2006), and federal forests confer regional hydrologic benefit to water quality and ecosystem integrity downstream. Implementation of the ACS on federal forests has become a foundational baseline component for attainment of salmonid recovery under the Endangered Species Act and of water quality standards under the Clean Water Act. For example, federal ESA salmon recovery plans in Oregon and California rely heavily on Plan implementation (e.g., NMFS 2007, pp. 402-403, NMFS 2012, pp. 3-48, 49). Furthermore, because of the extent to which ACS implementation is widely assumed to represent the federal contribution to aquatic ecosystem conservation, changes have regulatory implications for nonfederal lands. For example, the underlying analyses of Habitat Conservation Plans granted to nonfederal landowners in the Pacific Northwest under the ESA, with assurances extending 40-50 years, explicitly rest on full ACS implementation on surrounding federal lands. (See e.g. WA DNR 2005). Similar expectations

1 See e.g. Pac. Fed'n of Fishermen's Ass'ns et. al. v. Nat'l Marine Fisheries Serv., 71 F. Supp. 2d 1063 (W.D. Wash. 1999) ("PCFFA II")(finding that the Plan requires a determination of consistency with the ACS objectives at the project scale); Pac. Fed'n of Fishermen's Ass'ns et. al. v. Nat'l Marine Fisheries Serv. 265 F.3d 1028 (9th Cir. 2001) ("PCFFA III") (finding NMFS' biological opinions on 23 timber sales affecting then-listed Umpqua cutthroat trout and Oregon Coast coho salmon failed to assess site-level impacts).

2 See e.g. Seattle Audubon Soc'y v. Lyons, 871 F. Supp 1291, 1303 (W.D. Wash. 1994), aff'd sub nom., Seattle Audubon Soc'y v. Moseley, 80 F.3d 1401 9th Cir. 1996) (finding adequate scientific support in the plan's decision record and "unprecedented thoroughness" of the agencies' effort to meet "the legal and scientific needs of forest management").

undergird the state of Oregon's restoration plan for salmon and water quality.[3] In basins where water quality standards are not being met, state and federal regulators routinely consider the ACS to be an adequate implementation plan for BLM and Forest Service managers. Substantive alteration and weakening of the ACS threatens to upset a complicated web of region-wide conservation planning that is explicitly and implicitly dependent on the future habitat quality and recovery rate that the ACS is designed to achieve.

Changes to the ACS Proposed by Administrative and Legislative Efforts

ACS Riparian Reserves. Based on the nested set of ecological rationales considered in FEMAT (1993), the ACS specified a set of "default" widths of the Riparian Reserve land allocation to be a) at least two site-potential tree heights (*ca*. 100 m or 330ft) on either side of fish-bearing streams, and b) at least one tree height (*ca*. 50 m or 160 feet) on non-fish bearing streams. Within these reserves, the conservation of aquatic and riparian-dependent terrestrial resources receives primary emphasis. Beyond these default delineations, Riparian Reserves must be drawn to protect areas susceptible to channel erosion and mass wasting. The Riparian Reserve widths were based on ecosystem process considerations (FEMAT 1993, Olson et al. 2007) and broadly specified population viability and habitat considerations for seven groups of salmonids and many terrestrial and avian species. Various sources (e.g., Johnson et al. 2012) have estimated that based on the high stream densities prevailing over much of the region, roughly 40% of total acres within the Plan area are located within the "default" Riparian Reserve system. However, only about 11% of the Plan area lies in Riparian Reserves associated with those areas (often referred to as "Matrix lands") where commercial logging is expected to be concentrated, and where the Riparian Reserve allocation most directly restricts potential logging activity and other management-related disturbances. Very few of the many completed watershed analyses offered a scientific rationale for reducing default Riparian Reserve areas in any location; a larger number identified site-specific reasons to expand Riparian Reserves beyond the specified default widths (Pacific Rivers Council 2008).

Proposed Changes to the ACS and Riparian Reserves. The BLM's 2008 Western Oregon Plan Revisions (WOPR) proposed a new regime of management for the "Oregon and California (O&C) Lands, distributed widely across western Oregon (Blumm and Wigington 2013). The WOPR proposed greatly reducing default Riparian Reserve widths, primarily arguing that ACS default delineations include some upland or "non-riparian" vegetation and that summer stream shade and large wood recruitment to fish-bearing streams could be maintained with narrower reserve widths. Narrative objectives and standards and guidelines were also reduced or eliminated, allowing commercial timber harvest in Riparian Reserves for pervasive "safety and operational" reasons. The analyses and rationale underlying the WOPR were withdrawn by BLM in 2009 in significant part because they were deemed unlikely to survive consultations with ESA enforcement agencies (the National Marine Fisheries Service and US Fish and Wildlife Service). In a recent regional planning document, BLM (2013) argued again that "Riparian Reserve boundaries extend out beyond the water influence zone and are wider than necessary for water quality protection" but provided few or no specific scientific citations to support these claims. BLM has provided little scientific rationale or empiri-

cal validation for their decision to selectively focus on hydrophilic vegetation, proximate stream shade, and large wood recruitment as the only ecological considerations dictating riparian reserve delineation—in contrast to the much more comprehensive set of biophysical functions considered in FEMAT and the NFP ACS. (Note, as detailed later in this text, we also disagree with BLM's specific simplifying assumptions about effect of Riparian Reserve width on maintenance of shade and wood recruitment, and further conclude that other functions, such as nutrient retention, implicate much wider and less-disturbed reserves.)

A similar extremely constricted perspective on riparian ecological functions appears to underlie two Congressional bills for BLM lands in western Oregon (the "O&C" Lands), one of which (H.R. 1526, http://defazio.house.gov/issues/bipartisan-oc-forests-plan) would reallocate some 675,000 ha (1,667,000 acres) to an "O&C Trust"," the primary purpose of which is timber management (Blumm and Wigington 2013). Areas equivalent to Riparian reserves in the Trust would be designated at about half the width of the current ACS default requirement for steams (with extremely limited buffers for springs, seeps, wetlands, and unstable landscapes). A U.S. Senate bill introduced in 2013 (S.1786) would allocate about 50% of O&C lands to so-called "forestry emphasis areas," cut default Riparian Reserve areas by half across all stream types, with further narrowing if watershed analysis deems them "not ecologically important." The bill would provide for potentially extensive commercial logging in the rubric of thinning riparian areas where stands are younger than 80 years of age; only stands older than 120 years would be protected from logging. These older stands remain in scattered small patches across O&C lands but are important ecologically given high levels of timber cutting on surrounding nonfederal lands (DellaSala et al. 2013). Environmental review at the project level would also be curtailed from current requirements, including but not limited to eliminating the requirement for project-level determinations of consistency with ACS objectives.

Meanwhile the USFS—which manages the majority of federal forestlands in the three state NWP area, has focused on incrementally replacing the ACS with new provisions in upcoming revisions of individual National Forest Plans. In 2008 the Forest Service adopted new regional planning guidance (USDA 2008) that generally mirrors the NFP default riparian area widths and key watersheds allocations, but altered the narrative ACS Objectives, Watershed Analysis, and other NFP direction for management within reserve areas. This guidance stakes a claim for expanded agency discretion to undertake a broader range of vegetation and ground-disturbing management activities within riparian reserves, including but not limited to thinning and other commercial logging and livestock grazing. The 2008 Forest Service regional guidance, if implemented in future revised Forest Plans, would allow actions that alter riparian reserve resources and goals, as long as managers can present a general argument that impacts would be offset by other, beneficial actions or naturally-occurring improvements dispersed or averaged across time or space. The apparent intent of these changes is to reduce the burden for analysis of environmental impacts associated with such projects, which would, for example, streamline approval of more aggressive implementation of mechanized and commercial thinning and other vegetation- and ground-disturbing actions within Riparian Reserves. We are concerned that the 2008 USFS planning guidance has not been subject to rigorous external or scientific review, and if implemented could have harmful consequences for riparian and aquatic resources that have not been adequately evaluated or disclosed.

Weakening of the Northwest Forest Plan ACS will impact numerous listed fish, wildlife and plant species by changing the range of acceptable on-the-ground outcomes from management actions. Across the Pacific Northwest,

reduced protections for listed species and water quality via changes in the ACS would likely necessitate reconsideration of many existing agency programs and initiatives that have been premised on implementation of the 1994 ACS measures.

ACS Watershed Restoration. The ACS intended watershed restoration to be strategically identified and prioritized through *Watershed Analysis*, with particular emphasis on improving ecological conditions in *Key Watersheds*. Protection through passive restoration (Kauffman et al. 1997) of existing high-quality habitat is explicitly prioritized over active instream rehabilitation. To be effective, instream habitat-improvement projects rely on concurrent long-term riparian and catchment-scale protection and rehabilitation measures, and these must be programmatically tiered to management plans affecting each watershed. Hence site-specific active measure, such as instream habitat structures or riparian tree planting, should not be claimed to mitigate for ongoing or future harmful and degrading management actions (Frissell and Nawa 1992, Frissell and Bayles 1996, Roni et al. 2008).

Proposed Changes in Watershed Restoration Policy. In contrast, the current Senate Bill would simply allocate $1 million annually for instream wood placement and $5 million for road removal or "improvement" across the BLM's O&C land area, and apparently exclude such activities from environmental analysis under NEPA. In doing so this bill would decouple active restoration measures from land management decisions. The bill would also alter the programmatic approach to watershed restoration, as discussed in the next section.

Proposed changes to ACS Key Watershed allocations. The Senate and the House bills and the BLM (2013) call for revising Key Watershed allocations in place for the past 20 years under the NFP and ACS. Many current Key Watersheds would apparently be dropped from the allocation under the House bill, with the consequences for conservation planning and species at risk unevaluated; the Senate Bill calls for a revised watershed classification to accommodate new land allocations.

Certain revised Key Watershed delineations might in theory benefit particular populations of species such as ESA-listed coho salmon. However, the concept of prioritizing conservation efforts in Key Watersheds is undermined when watershed-scale priorities are upended and reshuffled on a time frame that is decades shorter than the amount of time expected for significant watershed restoration to occur. Effective watershed restoration requires a sustained commitment to aquatic resource protection and restoration, coupled with appropriately conditioned and scaled land management and effectiveness monitoring extending for decades to centuries (FEMAT 1993). Critical components of the ROD for the ACS include requirements for no road construction within inventoried roadless areas within Key Watersheds, and no net increase in road density within each Key Watershed. These protections for Key Watersheds would apparently be lost under the Congressional proposals, at least for those Key Watersheds that would be de-designated. Although the 2013 Senate bill would retain a process it refers to as "Watershed Analysis" its purpose appears to be inverted: it would not focus on watershed restoration, but on identifying ecological changes due to increase commercial logging over that which might occur under the default prescriptions specified in the bill.

CHANGES IN TERRESTRIAL LAND ALLOCATIONS ALSO AFFECT WATERSHED INTEGRITY

Land allocations within the NFP and other authorities, but outside of the ACS, including Late Successional Reserves, Wilderness, other congressionally designated or "administratively withdrawn" lands, and inventoried roadless areas, can confer additional protection to watersheds. These land allocations can prevent or retard road network expansion, and other disturbances, allowing natural ecosystem maintenance and natural recovery processes to proceed. They limit the spatial extent of disturbances across watershed and stream networks, and reduce the incidence or likelihood of adverse cumulative impacts. Many Key Watersheds are closely associated with such specially designated lands, though unfortunately few are largely or entirely nested such within such conservation delineations (Frissell and Bayles 1996). As a consequence, when new proposals strip away the protection conferred by Late Successional Reserves, roadless areas, or other administrative designations, watersheds are placed at greater risk of impact from forestry activities. Land disturbance from roads, logging, grazing, or other actions can undermine the benefits of restoration and land protection elsewhere in the same watershed (Espinosa et al. 1997), depending on the geography of the watershed in question. The trade-offs of cumulative risk and potential harm to watersheds and sensitive or listed aquatic species from changes in land allocation have not been rigorously assessed in the Congressional and administrative proposals. Such trade-offs amount to a wholesale re-casting of NFP land allocations for the region that includes and surrounds the O&C lands. Each of the 2013 Congressional bills proposes to substantially re-allocate protection of older forests, generally by focusing protection on older stands rather than the more expansive Late Successional Reserves of the present NFP. Moreover the Congressional bills make special provision for thinning under nearly all land allocations, with guidelines allowing for agency-determined findings of need and some minimal requirements for tree retention. Although the NFP did not prohibit thinning or salvage logging in these areas, the legislative bills favor more extensive and intense logging and increasing fragmentation by logging roads than have previously occurred in areas now classified as Late Successional Reserves.

NEW SCIENCE THAT INFORMS AQUATIC CONSERVATION STRATEGY AND PRACTICES

In the following section we discuss some relevant new science published since the convening of FEMAT (1993). We provide selected citations and briefly summarize our view of major implications for the purpose of developing and improving an effective aquatic conservation framework. While our interpretations and recommendations focus on the ACS, many of the citation sources and their implications are derived from studies of other regions and ecosystem types out of necessity because of limited research done in the Pacific Northwest. Just as in FEMAT (1993), relevant scientific information that is critical to define and frame topics of crucial conservation concern sometimes originates from other similar regions, and often spans a variety of disciplines.

In this paper we were not able to comprehensively address all areas of scientific advancement concerning forest management, water quality and aquatic conservation. Some topics await further elaboration. For example, we do

not comprehensively discuss the literature on impacts of logging and roads on streamflow patterns (e.g., Moore and Wondzell 2005), and subsequent effects on stream geomorphology, habitat, and biota. However, we do consider known effects of forest management and climate change on streamflows as a contributing concern under several topic headings. Most importantly, we also do not assess new science pertinent to non-aquatic and amphibian wildlife species in this report. This important work remains to be done.

Management after Wildfire, Disease, and Other Disturbances. Salvage logging of dead or dying trees after fires, insect outbreaks, and other disturbances in Pacific Northwest forests continues to be undertaken in the region, and its effects are a recurring ecological concern (see review by Lindenmayer and Noss 2006). Soon after the NFP was adopted in 1994, the scientific community began to weigh in on the inadvisability of post-disturbance logging. Scientists have catalogued the critical importance of large standing live trees, snags, and downed wood from fallen trees in the post-disturbance recovery of natural forests, including stand successional pathways, watershed processes, and wildlife and fish habitat (e.g., Gresswell 1999, Minshall 2003). Numerous scientific syntheses provided precautionary advice against post-fire logging on a wide range of causal grounds (e.g., Beschta et al. 2004, Karr et al. 2004, Lindenmayer et al. 2004, Lindenmayer and Noss 2006, Donato et al. 2006, Noss et al. 2006). More recent work has identified the potential importance of pulses in trophic energy following high-severity wildfire (Malison and Baxter 2010) for persistence and recovery of aquatic and riparian species. This new information builds on a more longstanding recognition that wildfire, that among its many other effects, plays an important long-term role in the generation of complex wood debris structures in streams (Minshall 2003). Other reviews focused on plant and landscape ecology broadly call into question the effectiveness of salvage logging insect-infested trees to control insect outbreaks (e.g., Black et al. 2013, Six et al. 2014). Similar concerns about the consequences of salvage logging curtailing natural ecosystem recovery processes pertain to salvaging of stands affected by any natural mortality agent, such as windthrow or volcanism.

However, post-disturbance logging was not expressly ruled out in the NFP and ACS, and the political demand for salvage logging remains high, so large post-fire salvage logging projects have been pursued by the USFS and BLM in many areas, including on occasion within Key Watersheds, Riparian Reserves, Late Successional Forest Reserves, and designated critical habitat of listed species (see DellaSala et al. 2014). Scientific consensus on the inadvisability of post-disturbance logging largely emerged in the years just after FEMAT, hence the ACS should be strengthened to reflect such sources as the recommendations in Beschta et al. (2004), Karr et al. (2004), and Black et al. (2013).

We conclude that for maintenance of forest ecosystem integrity*, post-disturbance logging should be prohibited in Riparian Reserves, Key Watersheds, Late Successional Reserves, and other areas where conservation is a dominant emphasis. Post-disturbance actions should prioritize road decommissioning or systemic road drainage improvements, and suspension of livestock grazing to reduce harm under the increased hydrological stresses expected in post-fire forests and their aquatic and riparian habitats and biota.*

Forest Thinning Intended to Reduce Tree Density or Wildfire Fuels. Current ACS language allows the agencies to "apply silvicultural practices for Riparian Reserves to control stocking, reestablish and manage stands, and acquire desired vegetation characteristics needed to attain…objectives." The agencies carry a project-specific burden to establish

the need for thinning and that outcomes are ecologically restorative. Recently the USFS and BLM have pressed to increase in the average size of thinning projects apparently to reduce the number and cost of site-specific environmental analyses by broadening their scope. Agency initiatives presume extensive use of mechanical harvesting methods in conjunction with commercial timber sales to thin trees in Riparian Reserves and other areas where conservation values are given highest priority. In wetter forest types, the primary claim that thinning is restorative rests on the assumption that the growth rate and vigor of those trees left alive after thinning will likely improve, thereby hastening the future development of larger-sized trees in the stand. In drier forests, the primary rationale is that thinning is needed to promote a generalized reduction in fuel loads, thereby presumably reducing the risk, or severity, or rate of spread, of wildfire and that thinning can increase fire resistance of selected individual trees.

Regardless of silvicultural intent, mechanized treatments in Riparian Reserves can disturb vegetation and soils in close proximity to surface waters, where the risk of sediment delivery and other impacts is demonstrably high (Rashin et al. 2006, Dwire et al. 2010). Logging activity that disturbs soils within riparian buffers can also reduce the buffer's effectiveness to retain sediment and nutrients delivered from upslope sources. Thinning or other disturbance of coniferous or deciduous trees and shrubs within riparian and wetland areas can cause decades of diminished summer low flows (after an initial few years during which low flows may increase), as a consequence of increased water demand by rapidly re-growing vegetation (Hicks et al. 1991, Moore and Wondzell 2005). In addition, thinning and yarding of logs from near-stream areas requires or encourages the construction of roads in close vicinity to streams, where the likelihood of sediment delivery and other impact from roads is increased (Luce et al. 2001). Bryce et al. (2010) found that for sediment-sensitive aquatic vertebrates and macroinvertebrates, minimum-effect levels for percentage fines were 5% and 3%, respectively, meaning that even small increases in fines can adversely affect salmonids and their prey.

Mechanized thinning and fuels operations usually require higher-density road access to be feasibly implemented. Mechanical treatments for fuels reduction are particularly problematic because recurring entries at roughly 10-year intervals are necessary to sustain the desired conditions (Martinson and Omi 2013); such a forest management regime strongly favors, if not requires, a permanent, high-density road network. Many thinning projects involve road and landing construction and reconstruction, as well as elevated haul and other use of existing roads, all of which significantly contribute to watershed and aquatic degradation. Even if constructed roads and landings are deemed "temporary," their consequent impacts to watersheds and water bodies are long lasting or permanent. The hydrological and ecological disruptions of road systems and their use (Jones et al. 2000, Trombulak and Frissell 2000, Gucinski et al. 2001, Black et al. 2013), exacerbated by other effects of vehicle traffic, will likely outweigh any presumed restorative benefit to streams and wetlands accruing from thinning and fuels reduction. In recent years, the prospect of future thinning or fuels reduction projects often has become the basis for the USFS or BLM to avoid or delay decommissioning environmentally harmful roads, even when fiscal resources were available for the work. Prescribed fire without extensive mechanical treatment is of much less concern, as it is more feasible to apply in sparsely-roaded wildlands, entails far less soil disturbance, and if conducted in proper times and places it can more adequately mimic the ecological effects of natural wildfire.

Substantial questions remain about the putative ecological benefits of thinning and

fuels reduction. This is critical because agency proponents commonly argue that the desired ecological benefits outweigh the adverse environmental effects of logging and fuels treatments. Dispute among federal agencies about claimed ecological benefits of thinning in moister, Douglas-fir-dominated forest types (widespread in the Pacific Northwest) led to an interagency scientific review in 2012-2013 (Spies et al. 2013). That panel concluded that increased tree growth might be better obtained from thinning very young, high-density stands--which very seldom produces commercially saleable logs. They further concluded that thinning produces unusually low-stem-density forests and causes long–term depletion of snag and wood recruitment that is likely detrimental in most Riparian Reserves (Spies et al. 2013, and see Pollock et al. 2012, Pollock and Beechie 2013). Further depletion of wood recruitment in headwater streams can adversely affect the behavior of debris flows in Pacific Northwest watersheds in ways that further reduce residual wood debris and its important functions over extensive portions of streams and rivers (May and Gresswell 2002), where present-day wood abundance is decimated compared to historical conditions (Sedell et al. 1988, Pollock and Beechie 2014). Finally, recent reviews also raise compelling, unanswered questions about the effectiveness of thinning forests for attempted control of insect outbreaks (Black et al. 2013, Six et al. 2014).

The effect of thinning on fire behavior and effects within riparian areas has been little studied. For western North American forests in uplands the literature is replete with ambiguous and conflicting results regarding the effects of thinning and other mechanical fuels treatments on fire severity, rate of spread, and recurrence. Moreover, the probability of a fire burning through a treated stand within the limited time window of potential effectiveness of a fuels treatment has been shown to be very small (Lydersen et al. 2014, Rhodes and Baker 2008). Any presumed benefit is even less persistent in Riparian Reserve areas where woody vegetation regrows rapidly after treatment, and where in moister forest types fire tends to recur with lower frequency. Equally important, we question whether managers should be striving to reduce fire severity in riparian areas as a rule, considering that high-severity fire plays a natural and historical role in shaping riparian and stream ecosystems (Gresswell 1999, Minshall 2003, Benda et al. 2003, Malison and Baxter 2010). Other natural forest disturbances, including windthrow, insect outbreaks, and landslides on forested slopes, appear to play a similarly important role in generating pulses of wood debris recruitment to streams, establishing a long-lasting source of ecological and habitat complexity.

Considering the difficult-to-justify costs and recognized inherent risks of adverse impact associated with such operations in sensitive areas, balanced against the uncertainty in intended benefits, we conclude the following: *Thinning and fuels reduction by means of mechanized equipment or for commercial log removal purposes should be generally prohibited in Riparian Reserves and Key Watersheds. Any thinning or fuels treatment that does occur as a restorative treatment in Riparian Reserves (e.g., to remove non-native tree species from a site) should retain all downed wood debris on the ground. Thinning projects that involve road and landing (including those deemed "temporary") construction and/or reconstruction of road segments that have undergone significant recovery through non-use should also be prohibited, due to their long term impacts on critical watershed elements and processes.*

Road Networks and Their Management. Roads are ecologically problematic in any environment because they affect biota, water quality, and a suite of biophysical processes through many physical, chemical, and biological pathways (Trombulak and Frissell 2000, Jones et al. 2000, Al-Chokhachy et al. 2010).

The magnitude of existing road impacts on watersheds and streams in the Plan may equal or exceed the effect of all other activities combined. Firman et al. (2012) reported that density of spawning coho salmon across coastal Oregon streams was negatively associated with road density. Kaufmann and Hughes (2006) found that road density in Coast Range streams was associated negatively with 25-50% of the variability in condition of aquatic vertebrate assemblages. More recently, Meredith et al. (2014) showed that the abundance of habitat-forming wood in Columbia Basin streams declined with proximity to roads, and the effect was roughly the same magnitude as that of natural climate and vegetation differences or long-term livestock grazing.

Roads are necessary to support logging, mining, grazing, and motorized recreation, but the existing federal forest road system far outstrips the extent of those demands. The number and poor condition of USFS and BLM roads, the agencies' inability to prevent current roads from deteriorating and harming streams, and the pervasive effects of roads on the physical and biological environments were recognized in FEMAT (1993). In addition, forest roads have been the subject of high-profile national dialogue and policy reviews since the development of the Plan (Gucinski et al. 2001, Pacific Rivers Council 2008). The ACS's primary means of protecting streams from roads and encouraging effective restoration are twofold: First, ASC objectives discouraged locating roads within Riparian Reserves, and second, roadless areas were to be maintained and overall road density reduced in Key Watersheds. For a small number of Key Watersheds where road network reduction has been pursued, agency monitoring efforts have reported improvements of certain instream habitat conditions, a response not detected elsewhere (Gallo et al. 2005, Reeves et al. 2006a). Often overlooked is that proposals to reduce the size of Riparian Reserves could provide more free rein for the construction of roads and landings in closer proximity to streams, markedly increasing the likelihood of sediment delivery and alteration of near-stream hydrology.

How to substantially reduce road density in critical watersheds and improve road drainage, stream crossings, and other factors that affect streams and aquatic biota, while maintaining sufficient roads for other forest uses, remain central challenges to forest planning and management. The ACS and other operative policies have lacked sufficient means and impetus to accomplish this in the past 20 years. We therefore suggest five policy changes to achieve needed road reductions: 1) *Prohibit the construction of new permanent and "temporary" roads*, except in limited instances were construction of a short segment of new road is coupled with and necessary for the decommissioning of longer and more damaging segments of existing road. 2) *Allow no net increase in road density in any watershed*. New "temporary" roads and landings should be considered to be roads and counted towards road density levels for at least several decades after decommissioning. 3) *Strengthen road density restrictions for Key Watersheds and establish unambiguous standards and metrics for net road density reduction, which include adequate accounting for landings and the impacts of so-called "temporary" and decommissioned roads and landings*. 4) *Improve the system of classification (e.g., road type, use) and inventory (e.g., whether a road is active or decommissioned), and mapping (i.e., update maps to reflect current conditions)* to ensure that agency bookkeeping of road miles corresponds with actual field conditions. This provision is necessary because at present many roads "disappear" when dropped from the inventory, but they in fact remain on the landscape causing watershed impacts. Also, lax road mapping programs and narrow definitions of what constitutes a road can significantly under represent the actual road densities. 5) *Require each proposed forestry and other development project to meet a target of incremental reduction of the road system* in

all watersheds affected by the project. Road density redution should be required until road density in the affected watershed is lower than the target established on the basis of biological response.[4] Finally, 6) *roads for which there are not adequate funds for maintenance and upkeep should be decommissioned*.

Riparian Reserves for Protecting Stream Temperature. Conservation (including restoration) of natural thermal regimes of streams and rivers was but one of many factors considered when ACS default riparian reserve widths were determined in the initial design of the ACS. In recent years the land management agencies and others have commonly assumed shade from riparian vegetation is the predominant proximate control on stream temperature, and some research has suggested that trees within 30 m or so of the stream margin contribute over 90 percent of the effective shade (e.g., Reeves et al. 2013). Furthermore, it has been suggested that headwater streams that do not carry water in summer should presumably not need shade to conserve summer thermal maxima in downstream waters. These two premises have become a primary rationale for proposals by BLM and in congressional bills to reduce default Riparian Reserve widths for some stream types, with the intent of increasing the area of Matrix land or equivalent that is subject to commercial logging. From the perspective of temperature protection, we have four concerns with this rationale for shrinking Riparian Reserves.

First, *redundancy*: most current analyses rest on a static view of riparian stand structure and function—that is, shade is modeled as a nearest single layer function of the existing standing trees only. The tree nearest to the stream margin is attributed as the contributor to shade, even though one or more trees standing behind it, slightly farther from the stream, may contribute shade as well. But when trees fall or die in the so-called "inner zone," then the "outer zone" trees become a replacement source of shade. Obviously, if the outer zone trees have been logged, that functional redundancy is lost and any riparian disturbance, man-made or natural, may lead to incrementally reduced stream surface shade—and an increase in stream temperatures.

Second, *density*: whereas we measure canopy shade with fixed-resolution instruments, little is known about how measurements of shade translate to actual solar penetration. In the coarsest sense, a canopy densiometer is used to visually estimate canopy cover with only 17 sample points that are irrespective of solar path. Even more quantitative instruments, such as the Solar Pathfinder or SunEye have the tendency to overlook the value of small canopy gaps or multiple canopy thickness in reducing light intensity reaching the stream, as does the densiometer. "Redundant" tree canopies create a shade structure that is dense compared to that of a single tree, and this may substantially affect the actual solar energy reaching the water surface in ways that we that we seldom adequately measure.

Third, *groundwater*: thermal response is affected in numerous ways by near-surface groundwater, which affects both surface streamflow rate and the temperature of water at the point of delivery. After initial increases in base flow following logging, summer base flow can decline for many years as a consequence of rapidly re-growing second-growth vegetation and its evapotranspiration demand (Hicks et al. 1991, Moore and Wondzell 2005). Logging in the outer areas of Riparian Reserves or forest-

4 E.g., 1 mile per square mile (0.62 km per square km) for watersheds with Pacific salmon, steelhead and cutthroat trout (Lee et al. 1997, Thompson and Lee 2000, Carnefix and Frissell 2009), and 0.5 miles per square mile for watersheds supporting bull trout (USFWS 1999; Baxter et al. 2000, see Fig 5 and Appendix, showing that population growth remained negligible in streams with higher road densities; and Ripley et al. 2005, Fig. 5 showing that probability of bull trout occurrence in Alberta tributary streams dropped by half where road densities exceeded about 0.6 miles per square mile).

ed wetlands can contribute to or conceivably magnify this effect. Accordingly, in some Pacific Northwest watersheds, stream temperature is more strongly associated with catchment-wide logging than with streamside vegetation cover (Pollock et al. 2009). Stream warming in such watersheds (often containing gently sloping or hilly terrain and numerous forested wetlands) could be influenced by reduced canopy shade over large areas of near-surface groundwater. Warming also could be influenced by changes in shallow groundwater flux rates and the level of the water table (Poole et al 2008). Hence, stream temperatures in some circumstances can become warmer at their point of origin (in spring, summer and fall) following watershed logging. Other research has established the importance of the hyporheic flow exchange in determining surface water thermal regime (Poole and Berman 2001, Baxter and Hauer 2001, Poole et al. 2008). The hyporheic zone may include extensive areas of shallow subsurface flow within montane alluvial valleys. In summer this subsurface pool may be dominated by spring snowmelt or cool rain runoff that cools surface streams when it discharges in midsummer (Poole and Berman 2001, Wondzell 2011). The extent of hyporheic storage and exchange bears a somewhat uncertain relationship to surface landforms, and until the decades after FEMAT, land management agencies lacked both the methods and incentive to accurately map these critically important areas (Torgersen et al. 1999, Baxter and Hauer 2001, Ebersole et al. 2003, Poole et al. 2004, Poole et al. 2008, Torgersen et al. 2012). Sediment accumulation in streambeds, or loss of step pools and other structures contributing to channel complexity—often formed by stable large wood—is thought to reduce entrainment of surface flows into, hence flow exchange with, the hyporheic zone (Moore and Wondzell 2005, Poole et al. 2008).

Given these uncertainties, and the increased importance of such groundwater source areas under future climate changes, any management change that increases the areal extent of logging in watersheds poses a risk of contributing to undesired stream warming. Notably, winter and spring stream temperatures can be of comparable importance to summer temperatures in meeting the habitat needs of species. In particular, temperatures of seasonably intermittent streams (even though they may be non-fish-bearing in summer or support salmonids only in early summer) can be important for salmon and other species in winter and spring (Wigington et al. 2006), and are directly and indirectly influenced by riparian canopy shade, thermal insulation, and other forest conditions that mediate water temperature fluctuations.

Fourth, *channel migration*: over time, stream channels migrate and even small streams have secondary channels that may flow only during the rainy season. However, existing side channels and backwaters provide important rearing and refuge habitat for salmonids, and they are commonly unmapped or mapped poorly. In addition, if riparian buffers are narrowed, some of these channels may migrate outside the narrowed buffer and be exposed to direct sunlight and substantially warmed. For instance, the sources of LWD are impaired during channel migration where outer zones have been harvested. Washington state and private forest practices rules have included criteria designed to identify and protect channel migration zones for many years (Brummer et al. 2006); in the ACS, explicit rules for their delineation are left to watershed analysis.

Considering the multiple ecological factors and processes that affect stream temperature and considering that temperature conservation is but one of many significant functional factors influenced by streamside forests, we *find no sufficient scientific support for reducing current ACS Riparian Reserve default widths for any stream type. In many watersheds and stream segments, larger areas of forest protection are warranted to prevent warming of*

shallow groundwater, particularly given likely trends future climate change, and the expectation of increased influence of wildfire and other "unmanaged" forest disturbances (Westerling et al. 2006).

Riparian Reserves and Nutrient Retention. The role of forested riparian buffers in retaining nutrients mobilized by upslope disturbance, or delivered to watersheds in precipitation and fertilization, is globally recognized. Forested buffer zones are commonly prescribed to reduce nutrient delivery to streams in agricultural landscapes (Sweeney and Newbold 2014). Logging and fuels management treatments that disturb green vegetation generate increased nitrogen leaching from forest soils that enters streams and wetlands by both surface and subsurface flow paths (Wenger 1999, Gomi et al. 2002, Kubin et al. 2006). Any ground-disturbing activity or condition (such as a road network) tends to mobilize phosphorus in association with soil erosion. Logging disturbs vegetation and soils over large areas, and scaled over large landscapes or river basins, initial disturbance of forested lands tends to generate larger net increases in nutrient loading than repeat disturbances of already-altered agricultural or urban lands (Wickham et al. 2008; note this observation is from a large population of monitoring sites and remains true even though agricultural lands are commonly more heavily fertilized than forest lands). Over time, nutrient loading to headwater streams transfers downstream, where nutrients accumulate in rivers, lakes, estuaries, and nearshore marine ecosystems (Freeman et al. 2007). For all of these reasons, forestry operations have been identified as a major contributor to nutrient loading, eutrophication, and associated impairment of water quality in Pacific Northwest lakes (Blair 1994, Dagget et al. 1996, Oregon DEQ 2007), rivers and estuaries (Oregon DEQ 2007).

Cumulative nutrient impairment of downstream receiving waters can occur without violation of nutrient standards in headwater streams, simply as a consequence of sustained increases in loading from storm water runoff from forest roads and periodic logging. In effect, logging alters the entire regime of nutrient and sediment export, and nutrient losses to surface waters are endemic and widespread consequences of logging and other disturbance of forested watersheds.

The question of what role Riparian Reserves play in nutrient retention has received insufficient consideration in the Pacific Northwest. Research on the nutrient retention efficiency of various forested buffer widths from the Upper Midwest and other regions (Nieber et al. 2011, Sweeney and Newbold 2014) suggests that average phosphorus and nitrogen retention is around 80% for undisturbed buffer zones of 30 m (100 feet) wide. Extrapolation suggests that buffers of 45 m (150 feet) or greater might be necessary to attain 90-99 percent retention of nutrients mobilized by upslope disturbance. These distances are likely too small for Pacific Northwest forests, where slopes are steeper, soils tend to be more porous, and macropores or channeled flow from uplands are more common than in the Midwest (all factors identified in Nieber et al. [2011] as reducing retention efficiency).

By virtue of their high density of surface channels across most mountainous landscapes, headwater streams with seasonal flow receive a large portion of the nutrients mobilized by up-slope disturbance (Gomi et al. 2002, Freeman et al. 2007). Therefore, full protection of wide Riparian Reserves along even the smallest stream channels (and surface-connected wetlands) is likely necessary for effective nutrient retention when surrounding uplands are disturbed. Channel network expansion from gully erosion (Reid et al. 2010) or roads (Wemple and Jones 2002) and channel simplification through loss of woody debris or sediment increases also reduces retention efficiency of nutrients, sediment, and organ-

ic matter in headwater systems. Moreover, thinning or other disturbance of vegetation or soils within the Riparian Reserve could short-circuit the benefit of riparian forest buffers, by creating a near-stream source of nutrients that is not fully mediated by the retention capacity of the default-width riparian zone.

Although more research is needed in the Pacific Northwest on nutrient retention, current scientific knowledge is sufficient to justify three recommendations. 1) *Continuous, no-cut Riparian Reserves exceeding 50 m (160 feet) along all streams and wetlands are generally needed to mitigate the effects of up-slope logging on nutrient loading to both freshwater ecosystems and downstream marine environments.* 2) *Cessation of livestock grazing in Riparian Reserves, road network reduction, and reconfiguration of remaining roads to reduce their hydrologic connectivity to surface waters are needed to reduce downstream nutrient loading.* 3) *Analysis of the effects of management actions on nutrient loading to immediate downstream receiving waters, including lakes, wetlands, reservoirs, mainstem rivers, estuaries, and the nearshore marine, are needed in environmental assessments, environmental impact statements, watershed analyses, and ESA consultations for aquatic species.*

Livestock Grazing. Whereas forestry predominates in the Northwest Forest Plan area, grazing affects a significant portion of the area as well; for example, 22 percent of BLM lands were subject to livestock grazing in the early 2000s (BLM 2008). A larger area was affected by historic grazing, where soil impacts may persist. Livestock grazing has large impacts on streams (Al-Chokhachy et al. 2010) because livestock tend to concentrate in streams, floodplains and alluvial valleys (see Beschta et al. 2013 for a recent synthesis). Besides direct disruption of wetlands and streambeds, and the suppression of woody vegetation, soil compaction by grazing in both riparian and upland areas degrades runoff quality and adversely alters flow regimes and watershed functions such as soil water storage and nutrient retention.

In addition to these direct impacts, new research shows that managing for livestock can indirectly alter ecosystem trophic cascades. For example, livestock depredation on open range led to programs to extirpate large native carnivores. Reduced numbers of carnivores release native ungulates and other herbivores from predation, leading to declines of riparian vegetation and stream conditions even outside of livestock-grazed areas (Beschta and Ripple 2012). Removing livestock grazing from federal lands has high potential to increase the resilience of watersheds and streams to environmental stresses, including climate change (Beschta et al. 2013, 2014). Measures to reduce the ecological impacts of livestock grazing, primarily by fencing streamside areas and moving cattle frequently from site to site, have met with variable success (Rhodes et al. 1994). Implementation of these methods is limited by the high capital cost of building and maintaining extensive fencing, the wages of field personnel to manage herds, and the cost of necessary environmental review and monitoring. Livestock grazing in forests is a commercial use that is not restorative, and often is marginal economically. We conclude that *livestock grazing should be excluded from Riparian Reserves, Key Watersheds, and other lands where conservation is the primary management objective.*

Chemical Use in Forests. Only very recently has science begun to directly tackle the difficult questions of fate, effects, and toxicity of pesticides and other chemicals associated with forestland uses on stream biota. Toxic contaminants come from various sources, including storm water runoff from roads (particularly those that discharge directly to surface waters pipes and ditches) (McCarthy et al. 2008, Feist et al. 2011). Herbicides are applied to tree plantations and roadsides to

control unwanted vegetation. Until recently these activities were limited by court order on BLM and USFS lands, but now they are increasing in extent and frequency, as well as continuing on adjacent private forest lands. The NMFS is reviewing the science concerning potential harm to listed species of Pacific salmon from application of commonly used pesticides. For example, use following label restrictions of the herbicide 2,4-D was determined to jeopardize Pacific salmon (NMFS 2011). Forest fire retardants that are aerially dropped in large quantities during wildfire suppression operations often reach surface waters, where they may be toxic to salmonids (Buhl and Hamilton 1998, Gaikowski et al. 1996).

While the science on toxic chemicals is certainly advancing, we have five interim recommendations based on existing knowledge: 1) *Minimize application of chemicals for forest management purposes in time and space;* for example, hand-application should be favored over aerial application when there is no feasible alternative to pesticide use. 2) *Weigh the full range of environmental trade-offs between the perceived benefits of chemical use and its possible harms in each case before a decision is made to use chemicals in forest management.* 3) *Implement wide, un-thinned forested buffers in Riparian Reserves to help reduce exposure of fish and aquatic life to toxic chemicals.* Thinned or narrow buffers can allow greatly increased aerosol penetration (chemical) from slopes to streams, and narrower buffers may also allow more transport of toxins in runoff. 4) *Reduce road density and the hydrologic connectivity of roads to surface waters to help control toxins* that originate from road use and maintenance, as well as those that are applied up-slope but find their way to streams via surface runoff. 5) *Analyze the possible effects of management actions in affecting the delivery of toxic chemicals to streams in every NEPA document and ESA consultation.*

Climate Change: Consequences and Adaptation. Anticipated climate change will alter the way we expect ecosystems to respond to forest management actions (Dale et al. 2001, Mote et al. 2003). In general for this region, hydrologic model predictions stepped-down from regional and global circulation models project increased stream and lake warming (varying magnitude across the seasons); more intense winter precipitation events, including flood and wind disturbance of riparian forests; earlier snow pack melting except for the highest elevation watersheds; and likely increased intensity and duration of droughts (Battin et al. 2007, Dalton et al. 2013). In very general terms, most climate change scenarios suggest larger and higher severity wildfires than seen in recent decades, and generally elevated evapotranspiration that could further reduce low summer streamflows. Luce and Holden (2009) documented a widespread pattern of declining summer streamflow over recent decades at gauging stations across the Pacific Northwest.

Climate changes will likely exacerbate existing (ongoing) trends in watershed degradation by affecting key processes or factors (stream thermal regimes, surface flows, groundwater and floodplain connectivity, landslide rates, fuels, fire, invasive species, and post disturbance human responses, to name but a few). Most climate change adaptation strategies call for strategic removal of non-climate stressors, because these will likely be more tractable or remediable than climate stressors (ISAB 2007, Furniss et al. 2010). No formal review of the ACS has apparently been conducted by the USFS or BLM to determine what, if any, science-based changes to the ACS best address future climate scenarios. It seems unlikely, however, that even a cursory review of the climate literature would lend support to proposals to remove or diminish currently protective provisions of the ACS.

The current ACS requirements are integral to assuring streams, wetlands, and other water bodies have the best possible resilience in the face of increasing climate stress. Extensive forested north-facing slopes can moder-

ate some climate influence on watersheds, and localized springs, and extensive shallow alluvial aquifers that store water seasonally can moderate summer streamflows and both summer and winter temperatures (Poole and Berman, 2001, Isaak et al. 2010, Wondzell 2011). Complex natural riparian vegetation communities and natural accumulations of large wood (resulting in concentrations of stored sediment) in and near floodplains are instrumental in creating and maintaining conditions that support hyporheic flow exchange. Wide Riparian Reserves provide not only shade, but essential protection and support for the natural processes that maintain and regenerate the suite of hydrologic and geomorphic elements that help buffer streams against climate forcing.

Intact watersheds are often seen to be less vulnerable to storms, floods, droughts, wildfire, and other extreme events, and are expected to be more resilient to future climate change than highly altered watersheds. Streams and rivers affected by reduced alluvial groundwater storage and diminished hyporheic buffering, fragmentation and loss of biological habitat connectivity, and a less intact native biota, are likely to respond more quickly and with greater volatility to climate change, as are engineered systems such as roads and dams. Watershed resilience in the face of climate change can best be maintained by protecting and restoring the suite of natural processes and conditions that characterize natural forested riparian areas and floodplains (Seavy et al. 2009, Furniss et al., 2010). This is exactly what the ACS was originally designed to accomplish. Whittling away riparian protections on the basis of narrowed, single-factor considerations such as proximate stream shade undermines the comprehensive protection of stream and riparian processes that the ACS was designed to maintain and restore. Finally, under changing climate, some management practices that seemed to produce desirable outcomes in the past may not do so in the future. For example, the putative effectiveness of forest thinning at altering fire behavior could become even more uncertain if weather extremes become more of a top-down driver of fire behavior (see Martinson and Omi 2013) in future climates (Dale et al. 2001, Westerling et al. 2006).

Our overall recommendation is that 1) *ACS protections for Riparian Reserves should be sustained and strengthened to better protect and restore natural ecosystem processes that confer resilience to climate change,* as detailed in our other recommendations. In addition, 2) *an interagency scientific conservation design effort is needed to expand and reconfigure some present Key Watersheds to ensure they better encompass specific areas that are likely to be topographic and hydrologic buffers to future climate change impacts.* Finally, we recommend that 3) *the direct and indirect effects of management actions on the integrity and capacity of stream and watershed ecosystems for resilience to climate change be analyzed in every environmental assessment, environmental impact statement, watershed analysis, and ESA consultation.*

Monitoring and Adaptive Management.

Environmental monitoring data often prove to be useful, but we cannot always anticipate how those data will be useful. Monitoring can be especially valuable when coupled with available data from historical records and time series sampling (such as streamflow gauging and temperature recorder data strings) (Wissmar 1993, Wissmar and Beschta 1988). Substantial progress has been made in the past 20 years on sampling design and methods of data collection for monitoring streams, watersheds and regions of watersheds (Steel et al. 2010). Twenty years after FEMAT, there are greatly expanded technological capabilities for spatially explicit data reporting and analysis, and numerous and increasingly robust methods to integrally evaluate considerations of ecological scale, geographical context, spatial and temporal continuity, and biological connectivity in data design and analysis.

The Northwest Forest Plan designated large

Adaptive Management Areas where alternative means of management and conservation might be implemented and closely monitored. For many reasons this option failed. Public involvement was required, but in most cases the public could not agree on the need for trial and testing of specific management hypotheses (Gray 2000). Managers and scientists also sometimes disagreed on hypotheses to test or what practices should be implemented. Lacking coherent large-scale experimental proposals drawing broad social support, funding never materialized. These failures are by no means endemic to the NFP—they characterize many, if not most aspirational attempts at formalized, large-scale adaptive management (Walters 1997).

We note, however, that ongoing management across multiple ownerships and with a multitude of natural background conditions creates a broad array of natural experiments that already exist on the landscape. Scientists can probably continue to learn much of what we need to know by creative monitoring of extant natural experiments. However imperfect they may be, natural experiments are more beneficial than waiting for planned, large-scale experiments that have proven exceedingly difficult to execute (and are almost always far from ideal themselves in terms of design and resources).

The existing monitoring program for aquatic resources in the Northwest Forest Plan area (Aquatic and Riparian Effectiveness Monitoring Program, AREMP, http://www.reo.gov/monitoring/reports/watershed/aremp/aremp.htm) in our view is constrained by certain design and sampling protocols that limit AREMP's capacity for drawing inferences about changes in habitat condition, living system condition, and biophysical processes over time. Whereas AREMP is intended by design to detect trends in some riparian or stream conditions over large areas, interpreting causal relations for responses requires information about changes in physical conditions and biota at specific locations over time. Further, AREMP design is based on delineated hydrologic units some of which do not represent hydrographically complete watersheds; this confounds identifying linkages between watershed condition and stream biotic and physical responses (Omernik 2003). Considering the scope of natural and man-caused variability in the field, Anlauf et al. (2011) suggested that AREMP incorporates a statistically insufficient number of sites to yield useful confidence intervals needed for reliable assessments of many measures of stream condition. Effectiveness monitoring generally fails when the design or data preclude process or cause-effect inferences, or when assumed fundamental relationships between habitat indices and biological populations and assemblages remain untested. Outside of the specific confines of AREMP, some useful new understanding has emerged from regionally extensive monitoring programs on federal lands in the Pacific Northwest (e.g., Hough-Snee et al. 2014, Meredith et al. 2014). In our view, these studies, far more specifically than AREMP, focus on iterative explicit hypotheses about cause-and-effect relations to inform the query and analysis of field survey data

We recommend three policy shifts in how monitoring is employed under the ACS. First, as a standard management practice, require *some form of effectiveness monitoring and expert review of stream and watershed responses for every forestry, range, mining, recreation development, or active management project.* Every project that could potentially affect watershed and stream conditions should integrally include collection of a field data set that sheds some light on key post-project biophysical conditions influenced by the project. Agency actions should help to increase the certainty of outcomes at particular sites. Agencies should first engage experts that could check collective awareness of the reliability of conventional assumptions about the effects of manage-

ment actions. Expert's perspectives would and increase the likelihood of the agencies identifying unanticipated outcomes that warrant broader study and management consideration. Expert review of project outcomes is needed to discourage the institutional habitat of assuming *a priori* that project outcomes are more certain and unequivocally beneficial than they often are.

Secondly, agencies should review existing programs of comprehensive regional and watershed-scale effectiveness monitoring programs, and develop comprehensive monitoring strategies to optimize return on the capital investment in monitoring. *We call for an interagency scientific panel to review the status and effectiveness of trend monitoring efforts, and identify data sets that could be useful in drawing inferences for improved monitoring programs.* New monitoring programs should be capable of assessing the effects of management actions and climate change on aquatic ecosystems and biological resources associated with BLM and USFS lands. They should be robust to both anticipated and unanticipated environmental changes.

Third, agency-driven improvements in monitoring programs should include *increased emphasis on tracking ecological conditions, including explicit biological condition measures, and the ability to establish with some certainty that trends in Key Watersheds result from specific management actions or choices (which may include deferral of active management).* Key Watersheds are especially critical for the medium- and long-term conservation success of the ACS, and may be disproportionately important to the survival and recovery of ESA-listed and other sensitive species. The special need to focus sustained time-trend effectiveness monitoring in Key Watersheds again raises the concern that re-delineation of Key Watersheds with each new piece of legislation or management planning cycle could disrupt long-term monitoring efforts. Pursuant to our third recommendation, we also recommend that agencies retain some degree of flexibility in allocation of monitoring resources to allow for occasional more directed and intensive investigation where assessments indicate that surprising and ecologically important outcomes have occurred.

CONCLUSIONS

In this report we examine selected new and emerging science that is relevant to the future of the ACS, and touch on concepts that should be integral to whatever might replace the ACS in the future. We believe more exhaustive consideration of the topics we raised--and a broadened consideration of others, including the functions of riparian and watershed reserves for conservation of terrestrial wildlife species--will only strengthen our conclusion that the founding rationale, basic architecture, and core conservation elements of the ACS remain sound. We also maintain that some specific improvements in ACS protection and conservation provisions are warranted.

New science raises many concerns about the adequacy of implementation of the ACS by the federal agencies. These issues include including post-fire and other logging after disturbances, logging and fuels treatments in riparian areas, the degree of riparian protection for headwater streams, the adequacy of past efforts for road system downsizing and remediation, the adequacy of conservation priorities for and delineations of Key Watersheds, the effectiveness of grazing management, and whether current monitoring is as useful as it should be.

This report raises concerns about anticipated climate change. While climate change does not fundamentally alter the basic facts of good conservation and responsible management, it both theoretically and materially raises the level of concern about many specific management issues, including the potential effective-

ness of restoration actions, the effectiveness of riparian areas as stream buffers, and implications for the burden of proof for management actions that balance known environmental problems against presumed restorative benefits. Most watersheds in the region are of mixed federal and other ownership. Because progress in protection and restoration on private lands has been limited (Stout et al. 2012), federal lands will likely continue to be the focus of watershed protection and aquatic habitat conservation, and related climate change initiatives for the foreseeable future.

Finally, an improved monitoring program will be necessary to ascertain that conservation of aquatic ecosystems and resources is in fact occurring, especially in the face of increasing physical and biotic stresses imposed by changing climate and human population growth. It will be of continued or increasing importance to evaluate the degree to which Riparian Reserves can serve as effective buffers against the cumulative effects of logging, roads, and other disturbances on forest lands catchment-wide. This question has assumed greater importance as research in disturbed ecosystems worldwide has demonstrated that watershed condition can sometimes affect fish assemblages more strongly than does riparian condition (Roth et al. 1996; Wang et al. 2003; 2006; Sály et al. 2011; Marzin et al. 2012).

We conclude that attempts to reduce protections to watershed, riparian, and freshwater ecosystems by weakening major components of the ACS and other related conservation elements of the Northwest Forest Plan are not justified by new and emerging science. Improved ecosystem protections--and better monitoring of outcomes--are warranted across all land ownerships, including federal forest lands, if freshwater ecosystems and their biota, including salmon and other sensitive species are to be effectively conserved in an era of increased ecological stress and changing climate.

Wildfire management decisions outweigh mechanical treatment as the keystone to forest landscape adaptation

Tucker J. Furniss[1*], Nicholas Povak[2,3], Paul F. Hessburg[2,4], R. Brion Salter[2], Zhuoran Duan[5] and Mark Wigmosta[5,6]

Abstract

Background Modern land management faces unprecedented uncertainty regarding future climates, novel disturbance regimes, and unanticipated ecological feedbacks. Mitigating this uncertainty requires a cohesive landscape management strategy that utilizes multiple methods to optimize benefits while hedging risks amidst uncertain futures. We used a process-based landscape simulation model (LANDIS-II) to forecast forest management, growth, climate effects, and future wildfire dynamics, and we distilled results using a decision support tool allowing us to examine tradeoffs between alternative management strategies. We developed plausible future management scenarios based on factorial combinations of restoration-oriented thinning prescriptions, prescribed fire, and wildland fire use. Results were assessed continuously for a 100-year simulation period, which provided a unique assessment of tradeoffs and benefits among seven primary topics representing *social*, *ecological*, and *economic* aspects of resilience.

Results Projected climatic changes had a substantial impact on modeled wildfire activity. In the *Wildfire Only* scenario (no treatments, but including active wildfire and climate change), we observed an upwards inflection point in area burned around mid-century (2060) that had detrimental impacts on total landscape carbon storage. While simulated mechanical treatments (~ 3% area per year) reduced the incidence of high-severity fire, it did not eliminate this inflection completely. Scenarios involving wildland fire use resulted in greater reductions in high-severity fire and a more linear trend in cumulative area burned. Mechanical treatments were beneficial for subtopics under the *economic* topic given their positive financial return on investment, while wildland fire use scenarios were better for *ecological* subtopics, primarily due to a greater reduction in high-severity fire. Benefits among the *social* subtopics were mixed, reflecting the inevitability of tradeoffs in landscapes that we rely on for diverse and countervailing ecosystem services.

Conclusions This study provides evidence that optimal future scenarios will involve a mix of active and passive management strategies, allowing different management tactics to coexist within and among ownerships classes. Our results also emphasize the importance of wildfire management decisions as central to building more robust and resilient future landscapes.

Resumen

Antecedentes El manejo moderno de tierras enfrenta incertidumbres sin precedentes relacionadas con el clima futuro, los nuevos cambios en los regímenes de fuegos, y retroalimentaciones ecológicas no anticipadas. El mitigar esta incertidumbre requiere de una aproximación al manejo de paisajes cohesivo, que utilice métodos simples para optimizar los beneficios, mientras se evaden riesgos sobre un futuro incierto. Usamos para ellos un modelo de simulación del paisaje basado en procesos (LANDIS-II), para pronosticar el manejo del bosque, su crecimiento, los efectos del clima, y dinámica de futuros fuegos, y filtramos los resultados usando una herramienta de soporte de decisiones, lo que nos permitió examinar las retroalimentaciones entre estrategias de manejo alternativas. Desarrollamos escenarios plausibles de manejo futuro basados en combinaciones factoriales de prescripciones de restauración mediante raleos, quemas prescriptas, y el aprovechamiento de incendios naturales. Los resultados fueron determinados de manera continua en un período simulado de 100 años, lo cual proveyó una valoración única de retroalimentaciones y beneficios entre siete tópicos primarios que representaron aspectos sociales, ecológicos y económicos de la resiliencia.

Resultados El cambio climático proyectado tuvo un impacto substancial en el modelado de la actividad de incendios. En el escenario de solamente incendios (sin tratamientos, pero incluyendo los efectos de incendios y el cambio climático), observamos un punto de inflexión ascendente en un área que se quemaría alrededor de mediados de este siglo (2060), que mostró impactos detrimentales en el almacenamiento de carbono a nivel de paisaje. Cuando simulamos los tratamientos mecánicos (~3% del área por año), si bien se redujo la incidencia de fuegos de alta severidad, esta inflexión no se eliminó completamente. Los escenarios que implicaron el uso de incendios naturales produjo una gran reducción en incendios severos y una tendencia más lineal en la acumulación del área quemada. Los tratamientos mecánicos fueron beneficiosos para los subtópicos que estaban bajo el tópico económico, dados sus retornos financieros relacionados con la inversión, mientras que el escenario de uso de los incendios naturales fue mejor para el subtópico ecológico, primariamente por una mayor reducción en los incendios de gran severidad. Los beneficios entre los subtópicos sociales fueron mixtos, reflejando la inevitabilidad de las retroalimentaciones en los paisajes de los que dependemos para los diversos y contrabalanceados servicios ecosistémicos.

Conclusiones Nuestros resultados proveen de evidencia de que el mejor escenario a futuro es el que implica una mezcla de estrategias pasivas y activas, lo que permitirá la coexistencia dentro y entre distintas clases de propiedad, y reconociendo la importancia de las decisiones de manejo del fuego como una actividad central en los esfuerzos para construir, a futuro, paisajes más robustos y resilientes.

Background

Land management in the modern era faces unprecedented uncertainty regarding future climatic changes, novel disturbance regimes, and unanticipated ecological feedbacks (Millar et al. 2007; Millar and Stephenson 2015; Hessburg et al. 2015, 2021; Schuurman et al. 2022). Wildfire poses both a challenge and a solution to these projected changes (Dombeck et al. 2004; North et al. 2015), and building climate-adapted forest landscapes will require restoring active wildfire regimes and reducing the fire deficit across much of the intermountain west (Moritz et al. 2014; Schoennagel et al. 2017; Hessburg et al. 2019). A challenge to this is that most landscapes of the intermountain west comprise a mosaic of public and private lands, large wildland areas, and extensive development in the wildland-urban interface (WUI). Employing a truly adaptive landscape management strategy requires participation across boundaries at scales large enough to restore a dynamic mosaic of forest and non-forest vegetation types that contribute to the resilience and self-regulation of active fire landscapes (Hessburg et al. 2015; Larson et al. 2022; Ager et al. 2022).

Recent investments in restorative forest treatments (e.g., US Forest Service Wildfire Crisis Strategy; USDA Forest Service 2022) are a necessary and long overdue part of the solution (Belavenutti et al. 2021), but fuel treatments alone are likely insufficient to alter fire regimes in the wildland-dominated landscapes of the west (North et al. 2015; Hessburg et al. 2015). Fuel treatments can reduce fire risk and improve resilience within the treated area (Stephens et al. 2012; Furniss et al. 2022a), but building resilient landscapes requires a multifaceted approach incorporating a combination of mechanical treatments, prescribed (Rx) fire, and wildland fire use (Miller 2003; van Wagtendonk 2007; North et al. 2012, 2015; Calkin et al. 2015; Stephens et al. 2016). Restoring natural wildfire regimes is a central part of the solution (Young and Ager 2024), as we are simply unable to duplicate the spatial scale and ecological complexity of wildfire effects (e.g., Furniss et al. 2020) with even our most sophisticated silvicultural tools.

Intact wildfire regimes function as a self-stabilizing ecological feedback process, contributing to landscape resilience by maintaining a shifting mosaic of forest

structure and age classes across the landscape (Hessburg et al. 2005, Berkey et al. 2021; Povak et al. 2023). Landscape-scale resilience is therefore an emergent property of complex and interconnected systems, and it is only evident at spatial scales greater than individual forest patches and temporal scales greater than individual fires (Falk et al. 2019; Hessburg et al. 2019). We cannot fully evaluate the resilience of a landscape without evaluating forest succession and disturbance dynamics at these grander scales (tens of thousands of hectares; tens or hundreds of years). This is where landscape simulation models excel, as they facilitate simulation of land management, forest growth, and disturbance dynamics at spatio-temporal scales that are not feasible with field-based studies (e.g., Ager et al. 2022; Young et al. 2022; Furniss et al. 2023; Povak et al. 2023).

Landscape simulation models can be used to simulate different management paradigms over long (10–100 year) timescales, enabling us to evaluate feedbacks and unanticipated dynamics that may emerge (Loehman et al. 2017; Scheller et al. 2019; Ager et al. 2020; Keane et al. 2022). Numerous studies have successfully used simulation modeling to compare the effects of different land management strategies, often in factorial arrangements, on future landscape resilience (Loudermilk et al. 2014; Keane et al. 2018; Krofcheck et al. 2019; Ager et al. 2022; Abelson et al. 2022; Young and Ager 2024). A common challenge that these studies face is in distilling the output of these complex models, as results may vary widely in both space and time. Decision support systems (DSSs) are often used here to synthesize the outputs, compare results across different simulated management strategies, and to make results more actionable for managers that are developing landscape adaptation strategies (Vogler et al. 2015; Abelson et al. 2022; Povak et al. 2020, 2022; Day et al. 2024).

In a recent study, Furniss et al. (2023) used a spatial decision support model to explore tradeoffs and synergies (sensu Maron and Cockfield 2008) in space, identifying areas in a large study domain in north-central Washington State that have the greatest potential for treatments to be effective. In this study, we use that same decision support model to explore tradeoffs in time over a 100-year simulation window, and we evaluate factorial combinations of treatment types to evaluate which alternative landscape management strategies optimize socio-ecological benefits. Specifically, we used a landscape simulation modeling approach to provide a time-series of landscape-level resource benefits provided by several alternative management strategies ranging in the frequency, intensity, and type of treatments applied to the landscape.

We used this simulation model and decision support system to investigate several questions related to management strategies designed to improve future landscape health and ecosystem functioning. These guiding questions included:

1) How do climate adaptation-oriented mechanical treatments, Rx fire, and wildland fire use compare in their potential to improve landscape resilience?
2) How do these different management tactics compare in their potential to produce benefits among a wide range of social, economic, and ecological values?
3) In landscapes dominated by wildlands (as in the present study), can thinning and Rx fire in a portion of the landscape stabilize future wildfire regimes across the landscape as a whole?

We hypothesized that future management scenarios involving thinning alone would perform best among *Economic* topic areas, while thinning plus Rx fire would perform well among *Social* and *Ecological* topic areas. We expected scenarios involving wildland fire use scenarios to perform best among *Ecological* topic areas. We also expected that thinning plus Rx fire would produce significantly better results than a "no treatment" scenario involving no management other than future wildfire activity calibrated to current levels of suppression effectiveness.

Methods

Study area

This study was conducted in a large landscape (4524 km^2) on the east side of the Cascade Range in Washington State (Fig. 1). The study domain was defined by the hydrological boundaries of the Wenatchee and Entiat River sub-basins. The model was run on a landscape that included a 5-km outer buffer (6078 km^2 total area) to simulate possible edge effects and immigration of wildfires, and this buffer was then trimmed prior to our analysis.

The study domain is characteristic of many mountainous landscapes of the interior Pacific Northwest, with steep terrain, high heterogeneity in forest communities, and historically active fire regimes (Hessburg et al. 2019). Climate in this region is humid continental with warm, dry summers and cold, wet winters. Further details about the study region may be found in Furniss et al. (2022b).

Simulation modeling

We simulated forest dynamics, tree growth, regeneration, and wildfire dynamics using LANDIS-II (Scheller et al. 2007) with the NECN (Scheller et al. 2011) and SCRPPLE extensions (Scheller et al. 2019). LANDIS-II

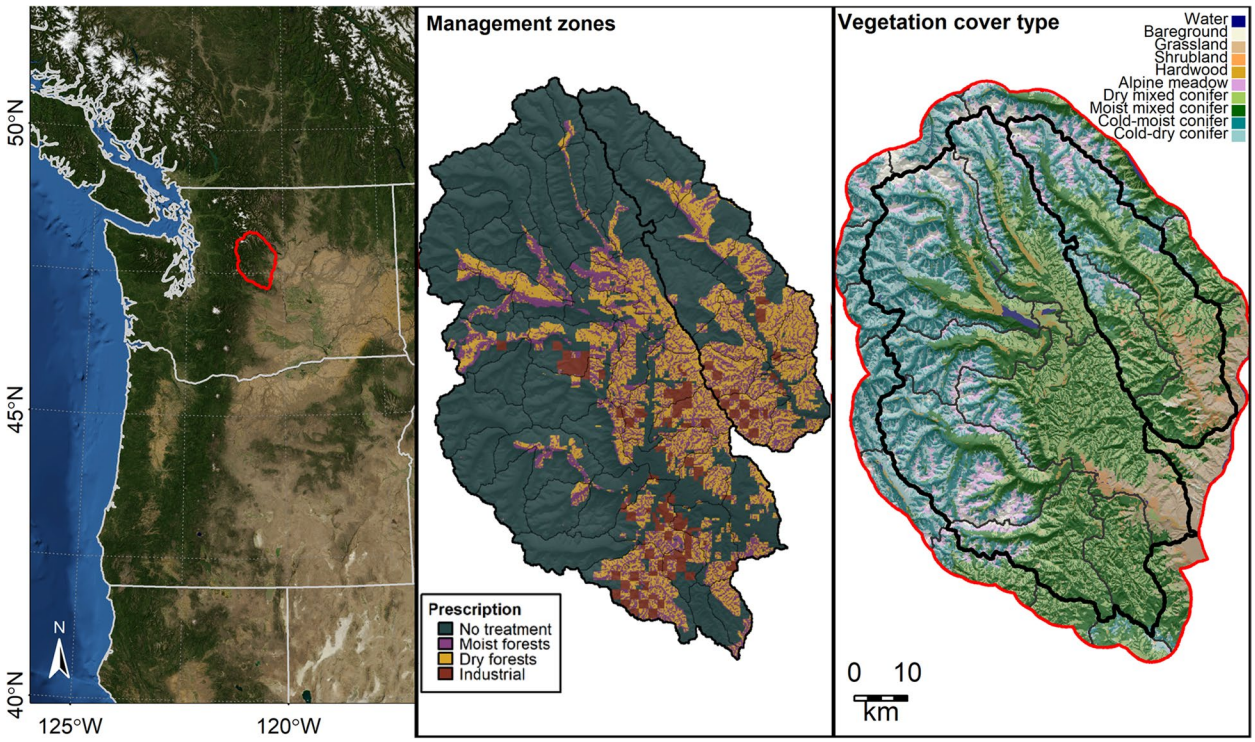

Fig. 1 Location of the study domain on the east slopes of the Washington Cascades (left). The study landscape is dominated by wilderness and roadless areas (54%), with the remainder comprising a mix of actively managed forests, private industrial timber lands, and wildland-urban interface (center). Vegetation in the study domain is heterogeneous, spanning from grass and shrub-dominated vegetation types in the lowlands to subalpine forests and alpine vegetation at the upper elevations (right). The dominant forest types on the landscape are dry and moist mixed-conifer, dominated by ponderosa pine and Douglas-fir, respectively, that occur on opposing aspects throughout most of the mid-elevations. The thick black lines in the right panel denote the boundaries of the Wenatchee and Entiat sub-basins, while the red perimeter represents a 5-km buffer that was included in the simulations to control for edge effects

is a spatially interactive forest landscape model that has been widely used to simulate climate effects on forest ecosystems and wildfire dynamics (Flatley and Fulé 2016; Loudermilk et al. 2017; Flanagan et al. 2019; Krofcheck et al. 2019). We coupled LANDIS-II with DHSVM (Wigmosta et al. 1994), a spatial distributed hydrology model for mountainous terrains that we then used to evaluate hydrologic functioning under various future management scenarios. Outputs from these models were analyzed in a decision support framework that leveraged fuzzy logic to integrate numerous ecological indicator metrics and evaluate positive and negative changes in overall ecosystem functioning (Reynolds et al. 2014; Povak et al. 2022, 2023; Furniss et al. 2023).

The initial vegetation layer for our LANDIS-II model was derived from TreeMap (Riley et al. 2021), a full-coverage raster of imputed Forest Inventory and Analysis (FIA) plot codes that could be used to develop tree lists for each 90-m pixel in the landscape. Edaphic characteristics were generated from the NRCS gSSURGO database (Soil Survey Staff 2020), and topographic layers were derived from the USGS 3D Elevation Program (Stoker and Miller 2022).

Wildfire ignitions were calibrated using the Fire Program Analysis Fire-Occurrence Database (FPA-FOD; Short 2017), and fire size and severity were calibrated to observed wildfire activity in the Monitoring Trends in Burn Severity (MTBS) database (Eidenshink et al. 2007). We used this combined empirical dataset (FPA-FOD and MTBS) to calibrate model behavior to observed patterns in wildfire frequency, area burned, and patch size distributions by severity class (Furniss et al. 2022a, b). We used the FPA-FOD alone to calibrate the frequency of small fires (< 400 ha) which are not present in the MTBS dataset. Simulated ignitions that did not spread produced fires that were 0.81 ha in size, an unavoidable consequence of the grain size of our 90-m raster grid.

We ran the wildfire and harvest extensions (SCRPPLE and Biomass Harvest, respectively) at an annual timestep, while the forest succession extension (NECN) had to be run at a 10-year timestep due to computational limitations. Each succession timestep took 3–5 h to run, so we used 10-year timesteps to keep each simulation within a

reasonable runtime (~48 h per simulation). Changing to 5- or 1-year timesteps would have vastly increased our processing time, reducing our ability to run the required number of scenarios and iterations of each scenario.

Regeneration was simulated using species-specific seed dispersal kernels and establishment probabilities which are based on available light, which is in turn determined by vegetation structure and composition at each site. Seed dispersal is determined by the presence of mature cohorts in adjacent cells, with maximum dispersal distance and probability given by species-specific parameters. Subsequent growth and mortality is determined by additional parameters that give the range of optimal climatic conditions for each species. This is the primary way that tree growth and mortality respond to different climate inputs. Further details about regeneration and vegetation succession may be found in published documentation for NECN (Scheller et al. 2011). A comprehensive description of our LANDIS-II model development and calibration work, including species parameters, can be found in Furniss et al. (2022b).

Management scenarios

To compare the tradeoffs between alternative management strategies, we designed six different management scenarios by using additive combinations of wildfire, mechanical harvest, Rx fire, and wildland fire use (hereafter, WFU). These eight scenarios were as follows: (1) *Wildfire Only*, (2) *Wildfire* + *WFU*, (3) *Wildfire* + *Rx*, (4) *Wildfire* + *Rx fire* + *WFU*, (5) *Wildfire* + *Harvest*, (6) *Wildfire* + *WFU* + *Harvest*, (7) *Wildfire* + *Rx* + *Harvest*, (8) *Wildfire* + *Rx fire* + *WFU* + *Harvest*. Additionally, we ran a *No Disturbance* scenario that simulated forest growth in the absence of wildfire and harvest, which we used to quantify the upper limit of biomass accumulation in the absence of all disturbances. All scenarios were run under a RCP8.5 climate change forecast (details under "Climate data," below). We refer to these scenarios without the RCP8.5 prefix for readability.

We ran five iterations of each management scenario to account for variability due to stochastic timing and spatial extent of treatment patches and wildfires. The number of simulations was chosen to provide a reliable estimate of uncertainty while remaining computationally feasible, a common tradeoff among simulation modeling studies. We generated simulation envelopes using the maximum and minimum values from the five iterations for each metric, and we used the average value to generate a mean trend line for each management scenario.

Vegetation pathway groups (PWGs)

The LANDFIRE biophysical settings (BpS, https://landfire.gov/bps.php) raster was used to allocate PWGs across the study area and to assign broad vegetation types (Povak et al. 2022). These data represent vegetation types that were likely present prior to Euro-American colonization, based on the biogeoclimatic conditions and characteristic disturbance regime (Rollins 2009). We used the BpS group level attribute to assign each 90-m cell into the following categories: water, snow/ice, rock, barren, grassland, shrubland, hardwood/riparian, alpine meadow, dry or moist mixed conifer forest, and dry or moist cold conifer forest conditions. The cold forest and mixed conifer forest BpS classes were further differentiated into dry-mixed (DMC), moist-mixed (MMC), cold-dry (CDC), or cold moist (CMC) conifer forest conditions based on topographic position, aspect, and elevation. Further details about the classification heuristic may be found in Furniss et al. (2023). The vegetation PWG map was not used to limit species composition or define successional trajectories. It was simply used as to create ecologically and biophysically similar areas (termed "ecoregions" in LANDIS-II) for downscaling the 4-km climate inputs. We defined these areas using a spatial intersection of vegetation PWG and HUC10-level watershed, resulting in 177 unique ecoregions that were used to extract area-weighted means from the 4-km future climate surfaces (details in "Climate data," below). Ecoregion assignment was static through time.

Management patches

We developed topographically entrained management patches using a 30-m digital elevation model (DEM) from the USGS National Elevation Data repository. Patches were primarily defined using a landscape topographic template as described by Hessburg et al. (2015) to spatially allocate forest restoration treatments across the study area. This template was further subdivided by hydrologic divides, land ownership, and land use allocation. Hydrologic divides were derived from nested Hydrologic Unit Codes (HUC) 10 (~20–80,000 ha) and 12 (~10–40,000 ha, Seaber et al. 1987).

All raster-based input layers were resampled to 90-m resolution, and a minimum mapping unit (MMU) of 4 ha (five contiguous cells) was applied to create management treatment patches. All raw and derived input spatial layers were clipped to the study area. The spatial patches and attributes were then processed through a series of spatial intersections where the MMU was enforced at each step to best maintain the integrity of the input data.

Treatments

For scenarios involving mechanical harvest, we simulated low and variable density thinning-based restoration treatments (Graham et al. 1999) using the Biomass Harvest extension (Gustafson et al. 2000). We partitioned the

landscape into wildlands, actively managed public lands, and industrial timber lands (Fig. S1, Table S1). We further sub-divided actively managed public lands into dry forests and moist forests. This produced four management zones within which we applied a single treatment prescription. Treatments occurred at the patch-level, where patches were selected at random and evaluated for their eligibility for treatment. If eligible, treatments were applied, and additional patches were selected until the target treatment rate (% area per year) was reached. Ineligible patches included patches in wildland areas and patches that had been recently treated (10 years for dry forests, 30 years for moist forests). We used random patch selection because there was not a way to optimize patch selection using an ecological basis in this version of the Biomass Harvest extension. Patches were developed by grouping pixels that shared similar ownership, topographic setting, and PWG.

In dry forests, treatments were designed to reduce surface fuels, retain medium and large sized trees, and to shift composition toward climate- and fire-adapted species (Hessburg et al. 2015; Stephens et al. 2013). This was achieved by thinning from below, removing young stems of all species and mature stems of shade-tolerant species. Slash and non-live surface fuels were reduced by 90% to simulate post-harvest pile and broadcast burning, but these simulated pile-burns were not counted when summarizing annual area burned. Treatments were applied to adjacent patches until treatment areas were between 20 and 100 ha to reduce wildfire risk at scales larger than individual patches. Target treatment area was $3\% \cdot \text{year}^{-1}$ to achieve fuel reduction efforts as quickly as possible.

The moist forest treatment was designed to increase heterogeneity and diversify habitat by creating small gaps and openings. This involved variable density thinning (75% reduction) among all size classes, for immature trees < 120 years old, across all species present in small patches (< 3 ha). Harvest gap size was set at 30% of each forest patch. Surface fuels were reduced by 50% to simulate slash piling and burning. The target treatment area was set at $1\% \cdot \text{year}^{-1}$ of available patches to maintain a sustainable level of biomass extraction throughout the simulation period.

Industrial forest lands were treated with clearcutting on a 35–50-year rotation to simulate the trend of moving toward short rotation industrial forestry in the twenty-first century. The treatment rate was set at $4\% \cdot \text{year}^{-1}$, and surface fuels were reduced by 50% to represent slash piling and burning.

Wildfire suppression and wildland fire use scenarios

We tuned the suppression levels in our *Wildfire Only* scenario to match the fire event size and severity patch size distributions based on empirical fire activity from 1984 to 2019 found in the monitoring trends in burn severity (MTBS, Eidenshink et al. 2007) dataset. To calibrate frequency of fires smaller than 400 ha, we used the spatial wildfire occurrence (FPA-FOD; Short 2017) dataset. During this period, suppression was the default response to wildfire, and suppression efforts were applied to most fire events. As such, we applied an intermediate amount of suppression effort using the SCRPPLE extension to create a "suppression-as-usual" fire suppression scenario. Under this scenario, suppression was most effective under mild and moderate fire weather conditions, natural ignitions were suppressed with the same vigor as accidental ignitions, and suppression efforts were strongest in developed areas and in the WUI. The level of suppression in the model was calibrated in conjunction with the other fire spread parameters to produce a simulated fire regime consistent with observed fire activity in terms of fire frequency, severity, and patch size distributions (Furniss et al. 2022b). This scenario should therefore be thought of as a "suppression-as-usual" suppression strategy, which is notably different from a "no action" strategy. Instead, it may be thought of as an intensive suppression scenario, with its own set of merits and consequences.

We simulated alternative future wildfire management scenarios by redistributing how suppression was applied, both geographically and temporally. We first defined four suppression zones on the landscape, and we applied variable levels of suppression depending on ignition type, fire weather index (FWI), and location on the landscape (Table S2). For management scenarios involving wildland fire use (*WFU*), we reduced suppression effort by 95% under mild weather conditions and 25% under moderate weather conditions to allow more natural wildfire ignitions to burn when weather conditions were not severe. Under extreme weather conditions, slightly more suppression effort was applied (average of 10%), representing the increased availability of resources that could be saved by letting most wildfires burn with minimal intervention. The net effect of this redistribution was that less suppression was applied overall in the WFU scenarios, while slightly more suppression was applied to ignitions occurring under extreme weather conditions. This approach is consistent with other recent studies that have used the suppression parameters in SCRPPLE to simulate alternative future wildfire management scenarios (e.g., Abelson et al. 2022).

Our implementation of WFU is not necessarily representative of wildland fire use as implemented in real-world landscapes. Instead, it was intended to be an idealized form of WFU that could be possible in a future "post-suppression" wildfire management paradigm. The assumption that WFU could make suppression more

effective under extreme weather conditions is contingent upon the idea that suppression resources stay the same (or increase) and are deployed with lower frequency but greater intensity by having increased availability of suppression resources that would be diverted from other areas throughout the region where fires were allowed to burn under moderate weather conditions. This assumption requires wildland fire use to be the default response across the region. Wildland fire use has never been tested at such a broad scale (van Wagtendonk 2007) and doing so would require a paradigm shift in wildfire management policy, culture, and legal liability (North et al. 2015).

Climate data

We generated future climate inputs using the MACAv2-METDATA CCSM4 dataset (Abatzoglou and Brown 2012), a spatially downscaled dataset containing daily climate forecasts at a 4-km resolution for the contiguous United States. We developed a baseline climate scenario by resampling historical climate from 1980 to 2010, with 3-year temporal autocorrelation (future years were drawn in sets of 3 re-ordered historical years) to create a synthetic forecast representing contemporary climate normals. This baseline climate forecast was not intended to predict plausible future weather streams, rather it provided a baseline with which we could compare the RCP8.5 climate forecast that we used to simulate the effects of climate change. We chose to use the RCP8.5 emissions scenario to simulate climate change as evidence suggests that this scenario will continue to be a good fit for anticipated climate changes for at least the next several decades (Schwalm et al. 2020).

Hydrology modeling

We used the Distributed Hydrology Soil Vegetation Model (DHSVM; Wigmosta et al. 1994) to simulate streamflow and snowpack dynamics at a daily resolution for the full 100-year simulation period. By updating the vegetation layers in DHSVM annually, we were able to create dynamic vegetation inputs that responded to forest growth, treatments, and wildfire events in LANDIS-II. We updated four vegetation parameters in DHSVM at annual intervals: canopy height, canopy fractional coverage, leaf area index (LAI), and vegetation type. LANDIS-II outputs are only available every 10 years (LAI, biomass, and age). Thus, we used linear interpolation of the decadal outputs to estimate intermediate values for each year. We ran DHVSM with a 90-m cell size to match the spatial resolution of the LANDIS-II model.

We modeled height and fractional coverage (which are not directly available from LANDIS-II) using generalized linear mixed effects models using the lme4 package in R (Bates et al 2015). We used FIA plot data to fit these models, and we applied the models to LANDIS-II outputs to estimate canopy height and cover for DHSVM (Fig. S1). The canopy height model used ln(age) and ln(biomass) to predict individual tree height, with random intercepts and slopes for age by species and PWG ($R^2 = 0.78$). Cover height for each cell was calculated as the 90th percentile of individual tree height. The fractional cover model used a third-order polynomial of stand biomass, stand age, and elevation to predict fractional coverage, with random slope and intercepts for biomass by PWG ($R^2 = 0.67$).

The DHSVM model was calibrated using annual meteorology data derived from the 1/16 degree (~6×6 km grid cells) Livneh dataset (Livneh et. al. 2015). Initial snow parameters were calibrated using empirical data from nearby SNOTEL stations (Trinity Snow Telemetry site). The model was then further calibrated using streamflow records (USGS gauges 12,456,500, 1,245,800) for the Wenatchee and Entiat sub-basins from the water years 1997–2003 and 1966–1971, respectively. Future climate forecasts were derived from the MACA Livneh climate dataset (Abatzoglou and Brown 2012).

Decision support system

We evaluated the performance of each management scenario using a custom decision support tool (DST) designed to assess ecological functioning and ecosystem services among seven primary topic areas: Sustainable Biomass, Economics, Carbon Storage, Water, Wildfire, Forest Health, and Landscape Integrity. We selected these topics to represent a broad range of important ecosystem services that are of central importance to managers and local stakeholders throughout the western US (Povak et al. 2023). For each topic area, we developed a set of 3 to 7 indicator metrics (e.g., C storage and fluxes for Carbon, peak snow water equivalent and late season flow volume for Water, etc.) that were used to assess the quality of ecosystem health and functioning (Table S3, also see Furniss et al. 2023). For each indicator metric, we assigned a logical premise that was evaluated using fuzzy logic to translate metric values into "strength-of-evidence" (SOE) scores, which use a −1 to +1 scale to represent the degree to which each metric satisfies a proposition. Fuzzy logic may be thought of as simply a way to standardize disparate unit scales onto a −1 to 1 scale, in contrast to Boolean logic which only allows values of 0 and 1. With fuzzy logic, scores can range from −1 to 1 with a SOE score of +1 indicates strong support for a proposition (e.g., carbon sequestration is maximized), a score of 0.75 indicating strong support (e.g., carbon sequestration is high), and a SOE score of −1 indicates poor support for the same proposition (e.g., carbon sequestration is minimized). Importantly, we centered all SOE scores relative to the *Wildfire Only* scenario so that positive values indicated that

a given scenario performed better than the *Wildfire Only* scenario, while a negative score indicated that the *Wildfire Only* scenario outperformed the treatment scenario.

We grouped the primary topics into three partially overlapping groups (also see Table S3) representing key facets of resilience: *Economic* (Economics and Sustainable Biomass), *Social* (Sustainable Biomass, Carbon, Water, and Wildfire), and *Ecological* (Water, Wildfire, Forest Health, and Landscape Integrity). When all primary topics were grouped together, we referred to the SOE scores as *Overall* benefits.

All metrics were initially evaluated spatially using raster outputs from LANDIS-II and DHSVM. We then used these spatial maps to build a *spatial* DST that allowed us to evaluate what parts of the study landscape had the greatest potential for treatment synergy (Furniss et al. 2023). To evaluate trends in ecosystem function over time, and to compare the effects of various alternative management scenarios, we built an *aspatial* DST by aggregating the spatial SOE scores at the patch, HUC12, and PWG level. We summarized these scores using area-weighted averages of HUC12 scores to generate landscape-level scores, for each scenario, in each year. In contrast to the spatial DST that quantified potential benefits at the end of the simulation, these aspatial SOE scores allowed us to evaluate how potential benefits changed throughout the simulation period, at the landscape scale.

We further evaluated SOE scores for each topic at simulation year 10, 50, and 100 to distill general patterns over time. We plotted these scores using heatmaps, with scenarios assigned to rows and topics assigned to columns. We built dendrograms for the scenarios to generate groupings of similar scenarios. We used the *heatmap.2* (v3.1.3) function in R with the default clustering parameters (Warnes et al. 2022).

Software versions

Landscape simulations were generated with LANDIS-II v7.0 (Scheller et al. 2007) using the NECN v6.8 (Scheller et al. 2011), SCRPPLE v3.2.1 (Scheller et al. 2019), and Biomass Harvest v4.4 (Gustafson et al. 2000) extensions. All data pre-processing, post-processing, and subsequent analyses were performed in R v4.1.3 (R Core Team 2020) using *terra*, *whitebox*, *vegan*, and *tidyr* packages.

Results

Effects of climate change on wildfire and biomass dynamics

In the absence of wildfire and mechanical harvesting, biomass accumulated over the full 100-year simulation period, and climate effects on projected biomass accretion were negligible (Fig. 2). When we added wildfire disturbance, stark differences between future climate scenarios became evident. While area burned per year under the baseline climate scenario was relatively steady (i.e., average annual area burned was similar at the beginning and the end of the simulation), there was a notable increase in area burned between under the RCP8.5 climate scenario, particularly for moderate- and high-severity classes (Fig. 3). Cumulative area burned diverged around years 2060–2070 where annual area burned under the RCP8.5 scenario began to increase more rapidly compared to area burned under the baseline climate. Average area burned (*Wildfire Only* scenario, RCP8.5 climate) before the inflection point (2020–2060) was 1687 ha · year^{-1}, while after the inflection (2080–2120) it grew to 11,237 ha · year^{-1}. Consequently, the vast majority of area burned (and area burned at high severity) occurring during the latter half of the simulation (21% from 2020 to 2070 versus 79% from 2070 to 2120). This inflection point was evident even when the climate forecast was shuffled (i.e., random ordering of years from the RCP8.5 climate projection; Fig. S2), indicating that the inflection was not caused by an underlying trend in the RCP8.5 climate forecast (dotted line in Fig. S2).

These increases in wildfire activity had a significant impact on aboveground biomass in all vegetation types (Fig. S3). Under the baseline climate scenario, potential biomass losses from wildfire did not offset forest growth, allowing biomass to accumulate throughout the simulation period (albeit at a lower rate compared to the *No Disturbance* scenario; Fig. 2). Under the RCP8.5 scenarios, however, biomass levels in all tree-dominated vegetation types peaked around 2060, then declined for the rest of the simulation (Fig. S3). The timing of this biomass decline aligns with the inflection point observed in moderate- and high-severity area burned (Fig. 3), suggesting that direct climate effects on biomass (hence carbon storage) were negligible and were instead primarily mediated by future wildfire dynamics. The reduced biomass may also be an indication of wildfire-driven type conversion, which would result in a persistent reduction in carbon storage potential even if future wildfire activity were to stabilize, but we were not able to test that directly.

Management impacts on ecosystem functions and services

We generated landscape-level mean SOE scores to evaluate potential benefits under each treatment scenario over the entire 100-year simulation period. Recall that positive values indicated that a given treatment scenario performed better than the *Wildfire Only* scenario (with RCP8.5), while negative values indicated a poorer than *Wildfire Only*.

Primary topic results revealed intuitive short-term and long-term tradeoffs between management scenarios

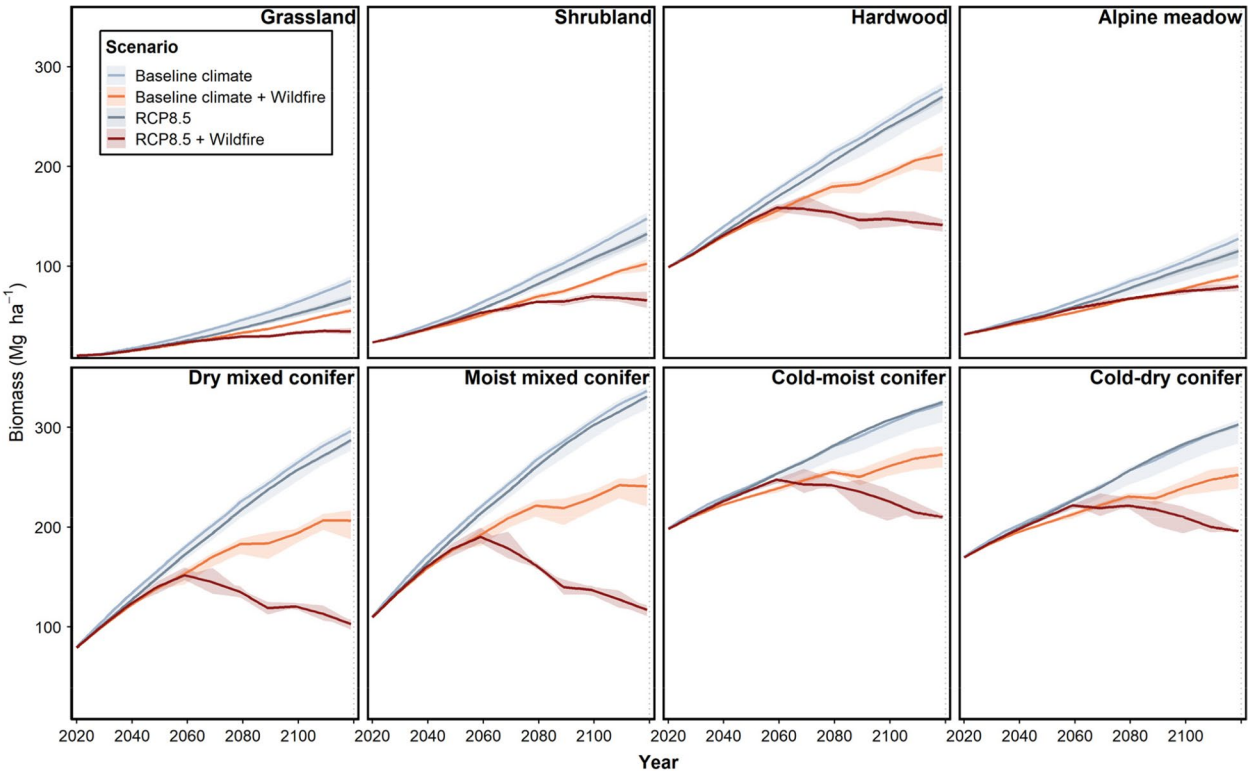

Fig. 2 Biomass accumulation per vegetation type under a *No Disturbance* scenario (cool colors) and the *Wildfire Only* scenario (warm colors). Each scenario was run under two climate forecasts: a baseline forecast representing late twentieth century climate ("Baseline climate") and a more realistic forecast based on a RCP8.5 emission scenario ("RCP8.5"). Direct effects of climate change on biomass accumulation were minimal. Wildfire had a substantial impact on biomass under the baseline climate scenario (orange lines), and an even greater impact under the RCP8.5 scenario (red lines)

(Fig. 4). In the short term (2020–2040), scenarios involving forest thinning (green lines in Fig. 4) generally performed best among Economic, Sustainable Biomass, and Water topics, with reduced benefits among the ecological categories including Forest Health, Carbon Storage, and Landscape Integrity. Existing timber stocks were depleted relatively quickly in the context of ongoing wildfires and small available treatable area, which reduced the size of potential benefits for the latter part of the simulations (Fig. 4).

Longer term benefits among all primary topics were strongly influenced by the inflection point in wildfire activity under the *Wildfire Only* scenario (under the RCP8.5 climate scenario). The rapid increase in area burned under *Wildfire Only* around 2060 (Fig. 3) led to an overall decline in benefits among most topics, and this decline contrasted with relative increases in the benefits among the other management scenarios (Fig. 4).

High interannual variability in area burned statistics, and a limited number of iterations of each scenario, precluded identifying significant differences among management scenarios at an annual resolution (Fig. 4). However, main treatment effects were observed for cumulative area burned by severity class (Fig. 3). Harvest treatments resulted in a slight reduction in cumulative area burned at high severity, while WFU produced a much more significant decrease in cumulative area burned at both moderate and high severity (Fig. 3).

When *Overall* benefits were assessed, all treatment scenarios except *Wildfire + Rx fire* performed better than the *Wildfire Only* by the end of the simulation (Fig. 5). *Economic* benefits were greatest in the scenarios involving harvest, but these benefits declined after available biomass for harvest was depleted in the context of ongoing wildfires and small treatable area (~ 2050; Fig. 5). *Social* benefits were greatest for scenarios that involved Harvest and/or WFU, which was surprising given that these scenarios tended to have the lowest benefits around mid-century. This dip was primarily driven by the depletion of carbon stocks associated with harvesting and elevated wildfire activity (Figs. 3, S2, S3). Yet as carbon and biomass stores recovered and area burned under the *Wildfire Only* scenario began to rise (Fig. 3), benefits associated with the treatment scenarios began to increase rapidly.

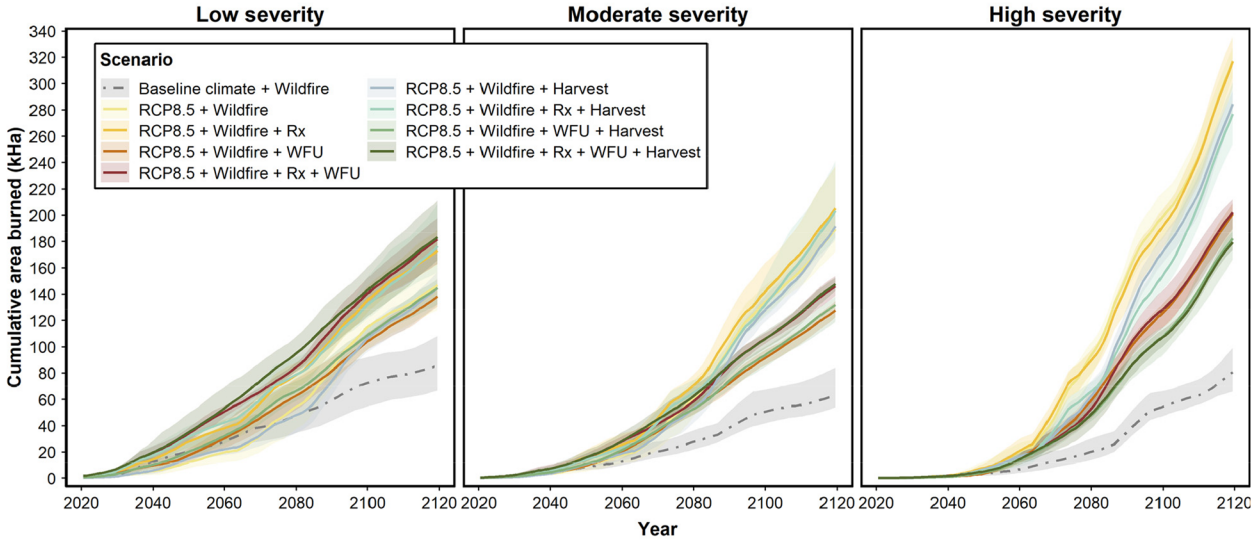

Fig. 3 Simulated area burned by severity class under historical conditions ("Baseline climate"), future ("RCP8.5") climate, and alternative management scenario (*Wildfire Only* = "RCP8.5 + Wildfire"). Model uncertainty is represented by the simulation envelopes (shaded regions) which were generated by running five iterations of each scenario. The shaded regions represent the highest and lowest values, while the solid lines represent mean values from the five simulation runs. Cool colors indicate scenarios with mechanical harvest treatments, while warm colors indicate scenarios without harvest. Darker colors indicate scenarios with wildland fire use (WFU). Differences in area burned at moderate and high severity were pronounced for the WFU scenarios, while harvest scenarios conferred a slight reduction in area burned at high severity

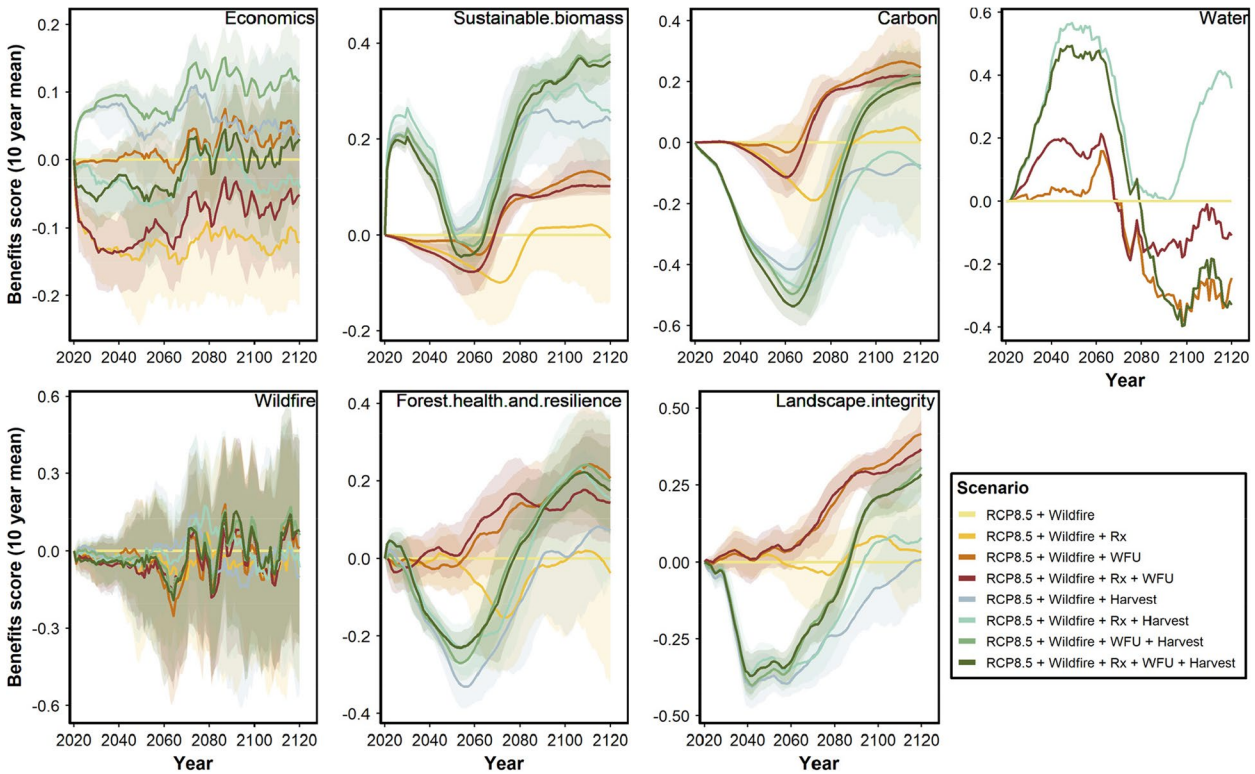

Fig. 4 Potential treatment benefits among seven primary topics for eight alternative future management scenarios. Benefits were assessed relative to the "no treatment" (*Wildfire Only*) scenario. Model uncertainty is represented by the simulation envelopes (shaded regions) which were generated by running five iterations of each scenario. The shaded regions represent the highest and lowest values, while the solid lines represent mean values from the five simulation runs

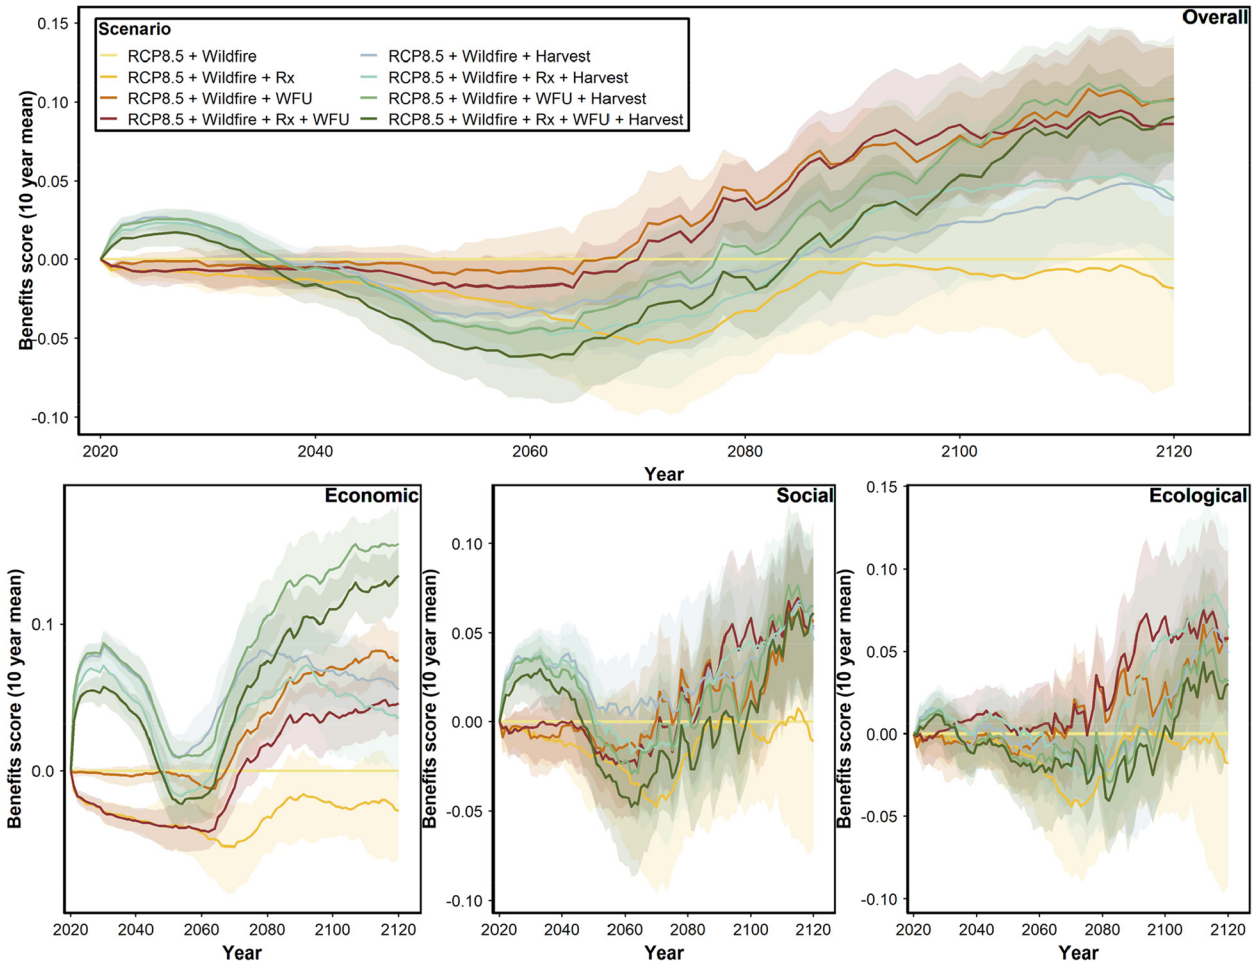

Fig. 5 Potential treatment benefits for eight alternative future management scenarios. Benefits were assessed relative to the "no treatment" scenario (*Wildfire Only*). Model uncertainty is represented by the simulation envelopes (shaded regions) which were generated by running five iterations of each scenario. The shaded regions represent the highest and lowest values, while the solid lines represent mean values from the five simulation runs

Ecological benefits showed a similar trend, although the mid-century dip was not as evident (Fig. 5).

To investigate the relative influence of Harvest versus WFU treatments, we examined the reduction in area burned due to harvest (i.e., *Wildfire Only* minus *Wildfire + Harvest*; *Wildfire + WFU* minus *Wildfire + WFU + Harvest*). Interestingly, mechanical treatments (*Harvest*) reduced area burned relative to the *Wildfire Only* scenario, but only if WFU was not applied. In the WFU scenarios, the addition of mechanical harvest did not have a discernable effect on area burned (Figs. S4 and 3).

Discussion

Scenarios involving harvest did perform best among the *Economic* categories as we expected, but the addition of Rx fire did not improve benefits to *Social* and *Ecological* topics. Wildland fire use emerged as the single most influential management tactic, and scenarios involving WFU performed well among all categories because it was most effective at curbing the amount of future high-severity fire. This was a surprising result, and it highlights the importance of wildfire as a foundational process governing the functioning and health of forest landscapes. We were also surprised by the variability in benefits across the 100-year simulation period. Even though our simulations applied the same management strategies throughout the entire simulations, future landscapes and the benefits they conferred were vastly different at year 50 versus year 100. These extended timeframes carry a great deal of uncertainty, of course, but the point remains that management actions with short-term benefits can be inconsequential or even detrimental in the long term (Young and Ager 2024). This is an important perspective for land managers and policymakers to consider. Estimating the consequences of current actions over decadal and

century timescales is not easy, but it is necessary when managing large landscapes with the potential for feedbacks and complex disturbance dynamics.

Future wildfire dynamics

Future wildfire dynamics and low available treatment area were central to the interpretation of all results of this simulation modeling study. The *Wildfire Only* management scenario under the RCP8.5 climate change demonstrated a positive feedback cycle that began mid-century (~2060), driving a marked increase in high-severity wildfire (Figs. 3, S2). Importantly, this feedback was not evident among all management scenarios, indicating that it was caused by something that differed between scenarios rather than something intrinsic to the model itself. The inflection point was present in the *Wildfire Only* scenario and given that our DST results were assessed in contrast to the *Wildfire Only* scenario, the impacts of these emergent wildfire dynamics were pervasive.

The inflection point in future area burned was a striking result of this study. For context, average area burned under RCP8.5 climate before the inflection (2020–2060) was 1687 ha·year^{-1}, corresponding to represent the 60th percentile of area burned under the baseline climate scenario, which was calibrated to empirical fire activity. Average area burned per year after the inflection point, however, was 11,237 ha · year^{-1}, corresponding to the 98th percentile of area burned under a historical climate. In other words, an average fire year during the later half of the century would represent the most severe fire year from the first half of the century. This demonstrates the potential for wildfire to create positive feedbacks that can have profound and lasting impacts on the structure, function, and resilience of large landscapes.

There are two plausible reasons for this inflection point. First, the climate forecast could have an inflection in temperature around this period, and the inflection in fire activity may simply be responding to that increase in temperature (i.e., first order effects of climate on fire spread rates). Second, the inflection could be due to a positive feedback cycle between area burned and resultant patterns of landscape contagion and susceptibility to large fire spread. Both of these explanations have support from empirical studies (Halofsky et al. 2011; Abatzoglou et al. 2021; Povak et al. 2024), providing some reassurance that this trend was not an anomaly of our model.

We distinguished between these two explanations using the randomly shuffled RCP8.5 scenario. If the inflection point was climate driven, cumulative area burned for that scenario would have been linear (because we removed any underlying structure in the climate data by shuffling the years). Instead, we saw that both shuffled and non-shuffled RCP8.5 scenarios exhibited an inflection point (Fig. S2), indicating a tipping point where positive feedbacks between wildfire and surface fuels began to rapidly accelerate reburn frequency. This finding is consistent with recent empirical work that has documented increasing wildfire activity due to both climate and fuels (Coop et al. 2020; Hagmann et al. 2021; Abatzoglou et al. 2021; Povak et al. 2023; Prichard et al. 2023), and it is further evidence for the importance of pattern and structure in determining the contagious potential of wildfire (Povak et al. 2023). The exogenous influence of climate was clearly important as well, but these results indicate that climate alone did not account for the wildfire regime change that can emerge when high-severity fire initiates a positive feedback cycle with endogenous controls on fire behavior.

These dynamics are a feature, not a fault, of simulation modeling approaches with dynamic fire models (e.g., Ager et al. 2022; Young et al. 2022; Prichard et al. 2023). As wildfire activity is determined by process-oriented algorithms within a given model, fire regimes are allowed to evolve over the simulation period rather than being constrained by a pre-defined fire size distribution. Dynamic fire modeling allows simulated fire activity to respond to changes in fuels, climate, and landscape patterns, capturing dynamics that are foundational to the emergence of wildfire regimes in real landscapes (Agee 1998; Scholl and Taylor 2010; Hessburg et al. 2019).

Alternative management scenarios

Our *Harvest* treatments produced benefits in the form of economic returns and biomass production, but even these restoration-oriented thinning treatments did little to alter projected trends in wildfire activity. Treatments were primarily effective over the next several decades before existing biomass stores were depleted (around 2050), after which point treatments continued but were less economically viable. Around this time, simulated wildfire activity began to increase rapidly. Despite the *Harvest* treatments reducing surface fuels, total area burned under the *Wildfire + Harvest* scenario was not substantially lower than the *Wildfire Only* scenario (Fig. 3).

The near-term impacts of harvest were overwhelmed by the self-regulation of wildfire that eventually emerged in the WFU scenarios (Fig. 3). Interestingly, this led to more similarity between the WFU scenarios compared to the Harvest scenarios by the end of the simulation period (Fig. 6). In other words, the *Wildfire + Harvest* scenario was more similar to the *Wildfire Only* scenario than it was to the *Wildfire + Harvest + WFU* scenario. Similarly, *Wildfire + WFU* was more similar to the *Wildfire + WFU + Harvest* than to *Wildfire Only* scenario (Fig. 6). Harvest effects were prominent early in the

simulation, but the effects of wildfire use eventually grew to dominate the scenario differences by the end of the century.

Wildland fire use

Wildland fire use (*WFU*) scenarios had profound impacts on wildfire activity that permeated to all other landscape metrics. Allowing more wildfire to burn in the wildlands produced benefits among the Water topic, at least for the first half of the century (Fig. 4). Benefits to other topic areas were slow to emerge, but the reduced amount of high-severity wildfire in the *WFU* scenarios (Fig. 3) eventually translated into greater carbon storage (Fig. S3), Landscape integrity (Fig. 4), and Ecological benefits (Fig. 5). This finding is particularly notable because most of the carbon is stored in the upper elevation wilderness areas (~200 Mg ha^{-1} in "Cold Moist Conifer" vs. ~100 Mg ha^{-1} in "Moist Mixed Conifer") where the *WFU* scenarios involved less suppression effort under *all* circumstances, even during extreme fire weather conditions. These results underscore the importance of wildfire management as a primary tool in the management toolbox (North et al. 2015; Barros et al. 2018; Young et al. 2022; Ager et al. 2022), highlighting the potential for managed wildfire use to alter fire regimes and mitigate high-severity area of future fires (e.g., Barros et al. 2018; Young and Ager 2024). Choosing how and when to suppress wildfire is the primary tactic available in large landscapes with substantial proportions of wilderness and roadless areas (Miller 2003; van Wagtendonk 2007; North et al. 2012; Stephens et al. 2016), and this study demonstrates that those wildfire management decisions can match or even exceed the impact of more active management tactics such as thinning and Rx fire.

Mechanical treatments

Interestingly, mechanical adaptation treatments (*Harvest*) only reduced area burned in the absence of a *WFU* suppression paradigm (Fig. S4). In the *WFU* scenarios, mechanical harvest resulted in a slight reduction in area burned (mean value was below 0), but this trend was not significantly different (simulation envelope overlapped 0). These results suggest that while active management can mediate future wildfire behavior, the effects of different management tactics are not necessarily cumulative, indicating diminishing returns in benefits. The same level of benefits was achieved through restoration via either mechanical methods (*Harvest* scenarios) or through alternative wildfire management paradigm (*WFU* scenarios), but applying harvest *and* WFU as well did not produce additional benefits (Fig. 5). The *Wildfire + WFU* scenario was equivalent in overall benefits to the *Wildfire + WFU + Harvest* scenario, as applying harvest increased benefits among Economic and Sustainable biomass topics while reducing benefits to Carbon and Landscape integrity (Fig. 4). Results indicate that tradeoffs among management strategies are inevitable. Therefore, managers and policy makers must decide how

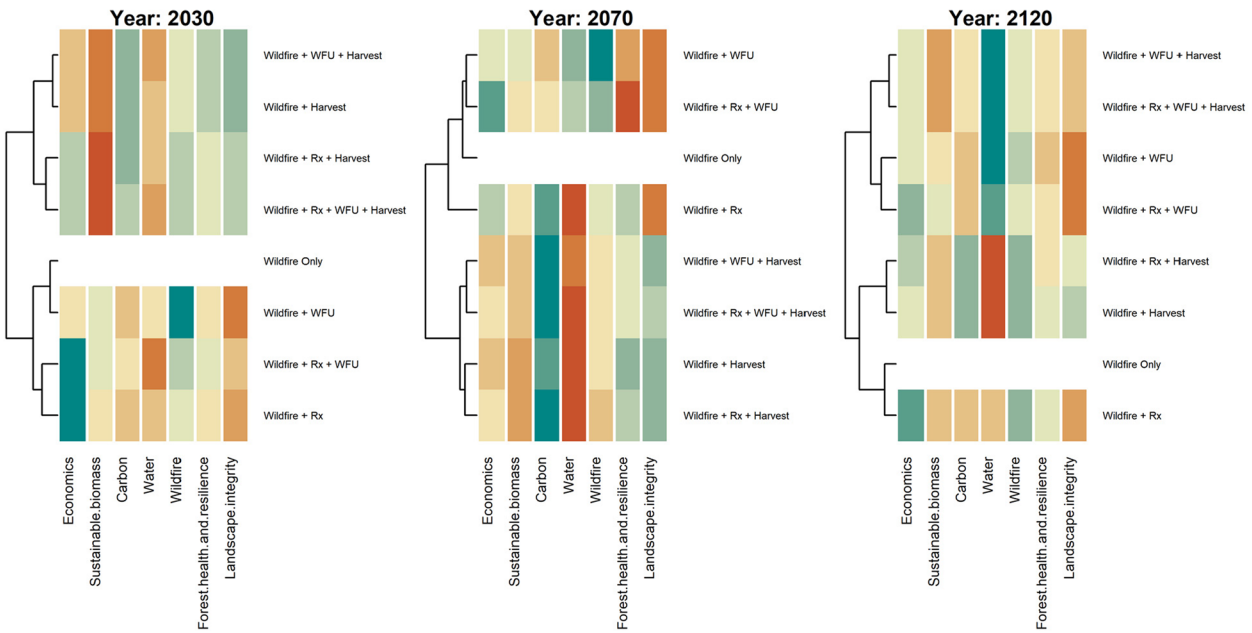

Fig. 6 Heatmap and dendrogram showing benefits among the seven primary topics (red = strong support, blue = weak support) and clustering of scenarios based on dissimilarity at three timesteps (simulation year 10, 50, and 100)

to distribute benefits, identify opportunities to manage for multiple resources at once, and determine when and where to prioritize benefits among certain topics (e.g., Ager et al. 2016; Povak et al. 2022; Furniss et al. 2023).

Prescribed fire

The Rx fire scenarios showed very little distinction from their comparison scenarios without Rx fire. This result was surprising, given that the rate of Rx fire was equal to the rate of harvest being applied (~5000 ha·year^{-1}). One explanation is that Rx fire was applied to the wildlands as well as the actively managed parts of the landscape, so the Rx fire treatments were more diffuse and therefore perhaps less impactful to overall landscape functioning. We scaled this annual rate to approximate the actual amount of Rx fire being applied in this landscape today. Our findings suggest that this level of Rx fire is wholly insufficient to alter wildfire behavior in such a large landscape. Rx fire is an effective management tool to reduce fuels at the patch-scale but generating benefits for landscape resilience will likely require far more Rx fire application and/or more wildland fire use.

Wildfire, fuel reduction, and carbon storage

Mechanical fuel reduction efforts mediated wildfire severity (Fig. 3), but these deferred losses to wildfire were offset by C losses due to harvest. This resulted in similar levels of residual biomass between the *Wildfire Only* and *Wildfire + Harvest* scenarios at the end of the simulation period (Fig. S3). This provides an interesting complement to prior studies that have shown restoration treatments (e.g., thinning + Rx fire) to be an effective way to increase forest C storage by mitigating future wildfire severity (Loudermilk et al. 2017; Young and Ager 2024). This potential for long-term benefits to forest C storage is well-established in the literature, but achieving net C gains requires carbon losses due to treatments to be effectively offset by reduced fire-related C emissions and increased productivity of residual trees. The efficacy with which restoration treatments reduce fire severity is contingent upon many factors including the timing and location of treatments (Loudermilk et al. 2014; Krofcheck et al. 2019), landscape configuration and forest conditions, and dominant fire regimes. Achieving net C gains through restoration treatments is therefore most likely in areas that are vulnerable to high-severity fire (Krofcheck et al. 2019), forests with high densities of small trees, and in places that will strategically impede fire flow.

In this study, simulated thinning treatments did not reduce fire severity enough to offset the C losses due to the thinning treatments themselves (Figs. 3, 4). In other words, scenarios without mechanical harvest resulted in higher C storage potential, with the *Wildfire + WFU* scenario showing the greatest C storage at the end of the simulation (Fig. S3). We may have achieved net C gains if simulated thinning treatments had a greater impact on fire severity and area burned, as was evident in the WFU scenarios (Fig. 3). It is also possible that post-treatment growth responses were not well represented in the model, which would have also influenced simulated carbon storage. Nonetheless, this result from our simulations reflects a real-world challenge in mitigating wildfire activity using thinning treatments: wildfire is not a deterministic process. Many treated areas never see fire, and other treated areas may burn at high severity due to top-down influences. Treatments can effectively mitigate fire severity, but it is difficult to know exactly when and where treatments may be most likely to maximize their intended benefits.

Interannual variability

For both Wildfire and Water topics, interannual variability between years was far greater than variability between management scenarios (Fig. S5). Differences between scenarios were evident when we used the *Wildfire Only* scenario as a reference, but examining the raw SOE scores revealed a great deal of noise from year to year. This noise may be largely attributed to annual climate fluctuations, as both Wildfire and Water topics were very sensitive to the timing of precipitation and within-year temperatures (via increased wildfire activity and decreased snowpack retention, respectively). Additionally, we were not able to generate simulation envelopes for the Water topic because we only performed a single DHSVM run per scenario due to computational limitations. Since DHSVM is a deterministic model and the climate stream fed into DHSVM was the same for all scenarios, all the scenarios tracked each other very closely (Fig. S5). The Wildfire topic, in contrast, was driven by wildfire activity in LANDIS-II which is stochastic and therefore produced noticeable differences between different runs of the same scenario (hence the wide simulation envelopes). For example, one iteration of *Wildfire Only* may have had a big fire year in year 10 while another iteration had a big fire year in year 11, leading to wide simulation envelopes and making differences between scenarios on a year-to-year basis difficult to detect (Fig. 4). We were able to tease out differences between management scenarios by evaluating cumulative area burned by severity which allowed differences in wildfire behavior to accumulate through time, highlighting the differences between scenarios that were evident over long enough time scales (Fig. 3).

Tradeoffs in space and time

Our simulation modeling revealed that ecosystem responses to future management scenarios are highly

dynamic, and potential benefits are unstable over time. Fluctuations in ecosystem functioning point to the importance of underlying feedbacks and destabilizing processes in shaping future landscapes. These second-order landscape dynamics were evident in the inflection point in area burned under *Wildfire Only*, the rise and fall of available biomass under the *Harvest* scenarios, and the high Carbon scores for the *WFU* scenarios. These results emphasize the importance of adaptive land management strategies that periodically re-assess management tactics in response to ever-changing ecological challenges. They also provide a way to visualize the uncertainty that managers and policy makers must reconcile (e.g., Miller 2007; Lynch et al. 2022), demonstrating how scenarios that appear best in the short term can yield less-desirable outcomes over longer time spans (e.g., Young and Ager 2024).

Limitations and future research

Caution must be exercised when interpreting the results of decision support systems. The relative ranking of various scenarios is highly sensitive to the selection of evaluation metrics and the structure of the DST logic model. Results of the DST modeling are sensitive to the number of topics and the weight given to each of the topics in the final assessment. This is a strength of fuzzy logic models: they can be adapted to reflect stakeholder values and the relative importance of different topics of interest. It is likely that these seven topics would not carry equal weight if this model were to be applied in a management context. Equal weight was applied by using union operators in the logic model (Reynolds et al. 2014). Accordingly, the overall benefits scores associated with each management scenario would change to reflect the concerns and values of managers and the local community. We used the *Social*, *Economic*, and *Ecological* groupings to get at this, as these topic groupings reflect what the decision support model results would look like if it were to include only a subset of topics.

Another difficulty in interpreting our results is that the fuzzy logic model translated absolute values into a relativized scale, which is necessary to be able to aggregate diverse units of measurement into the primary topic areas. However, this translation may obscure the magnitude of treatment effects because we set the fuzzy logic breakpoints to the 10th and 90th percentiles of observed delta values to represent the middle 80th percentile range of values. For the mean annual flow metric, for example, differences in mean annual flow between scenarios each year were very small, yet these small differences still received scores ranging from − 1 to 1. This allowed us to evaluate differences between scenarios, but it obscured the fact that year-to-year variability in mean annual flow was far greater than the within-year variability due to scenario differences (Fig. S5).

This study builds upon a growing body of research leveraging decision support systems to evaluate tradeoffs and synergies among important ecological and social values, both in space and over time, to project future landscape dynamics and management effects (Reynolds et al. 2014; Abelson et al. 2022; Maxwell et al. 2022; Povak et al. 2022; Furniss et al. 2023). A significant advancement made here is the integration of LANDIS-II with a distributed hydrology model (DHSVM), enabling us to quantify impacts of forest treatments on snowpack and streamflow dynamics. An important next step will be to make this integration more accessible, perhaps through the development of a new model extension, and to consider ways to couple the models to improve hydrology dynamics (hence water availability) within LANDIS-II.

Conclusions

We found that most alternative future management scenarios produced discernable benefits among *Economic*, *Social*, and *Ecological* primary topic areas. These gains were both robust and fragile, with the *Wildfire Only* scenario having the greatest overall performance part way through the simulation (2040–2070), then declining as positive feedbacks in wildfire activity under this scenario caused a steep increase in high-severity fire. Simulated management actions were able to mitigate this high-severity fire feedback, with both mechanical forest treatments and wildland fire use tactics reducing high-severity area burned and resulting in better overall landscape health. Unsurprisingly, mechanical treatments were more beneficial for *Economic* categories while wildland fire use alone was better for some of the *Ecological* topics. Benefits for the *Social* topics were somewhere in between, reflecting the inevitability of tradeoffs among countervailing needs such as carbon storage and streamflow enhancement. These tradeoffs highlight the need for diverse and cohesive landscape management strategies, as no single management scenario will produce optimal results across the board.

Tradeoffs are at the very core of wicked problems; positive outcomes in some areas yield negative cascades in others. Disentangling these problems requires managers and stakeholders to identify shared values, priorities, and tolerable tradeoffs, and to apply a mix of methods that reflect the diversity of desired benefits associated with various management strategies. This study demonstrates what these future scenarios can look like, underscoring the importance of both active and passive management strategies—and wildfire management decisions in particular—in building more robust and resilient future landscapes.

Natural range of variation

ABSTRACT

Widespread habitat degradation and uncharacteristic fire, insect, and disease outbreaks in forests across the western United States have led to highly publicized calls to increase the pace and scale of forest restoration. Despite these calls, we frequently lack a comprehensive understanding of forest restoration needs. In this study we demonstrate a new approach for evaluating where, how much, and what types of restoration are needed to move present day landscape scale forest structure towards a Natural Range of Variability (NRV) across eastern Washington, eastern Oregon, and southwestern Oregon. Our approach builds on the conceptual framework of the LANDFIRE and Fire Regime Condition Class programs. Washington–Oregon specific datasets are used to assess the need for changes to current forest structure resulting from disturbance and/or succession at watershed and regional scales.

Across our analysis region we found that changes in current structure would be needed on an estimated 4.7 million+ ha (40% of all coniferous forests) in order to restore forest structure approximating NRV at the landscape scale. Both the overall level and the type of restoration need varied greatly between forested biophysical settings. Regional restoration needs were dominated by the estimated 3.8+ million ha in need of thinning and/or low severity fire in forests that were historically maintained by frequent low or mixed severity fire (historical Fire Regime Group I and III biophysical settings). However, disturbance alone cannot restore NRV forest structure. We found that time to transition into later development structural classes through successional processes was required on approximately 3.2 million ha (over 25% of all coniferous forests). On an estimated 2.3 million ha we identified that disturbance followed by succession was required to restore NRV forest structure.

The results of this study are intended to facilitate the ability of local land managers to incorporate regional scale, multi-ownership context into local forest management and restoration. Meeting the region-wide restoration needs identified in this study will require a substantial increase in the pace and scale of restoration treatments and coordination amongst governments, agencies, and landowners.

1. Introduction

Ecological restoration has become a dominant paradigm for the management of many public forests across the United States (USDA Forest Service, 2012a,b). Ecological restoration is "the process of assisting the recovery of an ecosystem that has been degraded, damaged, or destroyed" (SER, 2004). Within western states, this present focus on restoration is largely in response to the widespread degradation of terrestrial and aquatic habitats and uncharacteristic fire, insect, and disease outbreaks resulting from a century or more of wildfire suppression, intensive harvesting, grazing, and mining (Brown et al., 2004; Franklin et al., 2008; Hessburg and Agee, 2003; Hessburg et al., 2005; North et al., 2009; Peterson et al., 2005; Schoennagel et al., 2004). $40 million has been appropriated annually for the ecological restoration of federal forests through the Collaborative Landscape Restoration Program (CFLRP; H.R. 5263, fs.fed.us/restoration/CFLRP). In addition to CFLRP, the USDA Forest Service has undertaken a number of initiatives in recent years to increase the pace and scale of forest restoration including but not limited to implementing a new forest planning rule (USDA Forest Service, 2012a), the Watershed Condition Framework (USDA Forest Service, 2011a), and a bark beetle strategy (USDA Forest Service, 2011b). Similarly, state governments in Oregon, Washington and elsewhere are promoting both the ecological and economic benefits of forest restoration. For example, the Oregon Federal Forest Health Package (SB 5521 passed by the Oregon Legislature in 2013) is providing nearly $2.9 million for technical assistance and scientific support needed to increase the pace and scale of collaboratively developed management efforts and to pilot a new business model that contributes funding directly to help increase the pace and scale of implementing restoration work on national forests.

Despite highly publicized calls to increase the pace and scale of forest restoration (Rasmussen et al., 2012; USDA Forest Service, 2012b) we lack a comprehensive understanding of forest restoration needs. In many, but not all, of the interior Pacific Northwest forest ecosystems previous studies have documented patterns of departure from historical conditions (e.g., Everett et al., 2000; Hagmann et al., 2013; Haugo et al., 2010; Hessburg et al., 2005, 2000b; Heyerdahl et al., 2014; Perry et al., 2011; Wright and Agee, 2004). However these studies are not able to provide a systematic evaluation of where, how much, and what types of treatments are needed to restore forest structure at regional scales (100,000s–1,000,000s of ha). Until recently most restoration planning and implementation has occurred at scales of watersheds or smaller ($\leqslant$5000 ha). Although there has been a gradual increase in the size of proposed projects, small project areas are still often used. Because the overarching objectives of forest restoration are frequently to influence ecological processes such as disturbance regimes and habitat connectivity operating at very large spatial scales (10,000's–100,000's of ha), a broader spatial perspective is required to evaluate the overall magnitude of ecological and planning needs. Without an understanding of regional scale restoration needs it is difficult to accurately quantify the magnitude of restoration funding needs for state and national entities or to set the context for prioritization of limited land management resources. It is also difficult to determine the cumulative, regional scale impact of current restoration efforts and evaluate whether these efforts are "making a difference". Consequently, evaluation of restoration needs requires a perspective larger than individual watersheds or even individual national forests, and that considers forested lands across all ownerships within a region.

In this study we demonstrate a new approach for evaluating where, how much, and what types of treatments are currently needed to restore a Natural Range of Variability (NRV) in forest structure across eastern Washington, eastern Oregon, and southwestern Oregon. NRV is defined as a frequency distribution of ecosystem characteristics, including the appropriate spatial and temporal scales for those distributions and a reference period, typically prior to European settlement. These ecosystem characteristics may encompass a wide suite of terrestrial and aquatic considerations (Keane et al., 2009; Landres et al., 1999; Morgan et al., 1994; USDA Forest Service, 2012a); here we focus on forest structure.

We acknowledge the limitations of focusing on forest structure as an indicator of ecosystem health, and the NRV as the reference condition. Many biotic and abiotic components must be considered for comprehensive restoration of forest ecosystems, including forest structure. Nevertheless, forest structure presents a tractable coarse filter to which many other aspects of biodiversity (e.g., terrestrial wildlife habitat, riparian and aquatic habitat, herbaceous diversity and productivity, and fire, insect, and disease frequency and severity) respond (Agee, 1993; Hessburg et al., 1999; Johnson and O'Neil, 2001; Peterson et al., 2005). Ideally, we would also evaluate future range of variability (FRV) reference conditions that describe the expected response of forest ecosystems to climate change (Gartner et al., 2008; Keane et al., 2009). FRV is an emerging concept, but FRV reference models are not yet consistently available at a regional scale. While the specific impacts of climate change are uncertain, restoring to a NRV is assumed to increase forests' resilience and adaptive capacity (Agee, 2003; Hessburg et al., 1999; Keane et al., 2009; Millar et al., 2007; Stephens et al., 2013; Stine et al., in press). Finally, NRV does not necessarily represent desired conditions for federal forests, which reflect social and economic concerns as well as ecological ones. Nevertheless, NRV represents a strong foundation for developing desired conditions because it represents the ecological capability of the landscape (USDA Forest Service, 2012a).

2. Methods

2.1. Study area

We assessed forest vegetation restoration needs for the approximately 11,619,000 ha of forest across eastern Washington and eastern and southwestern Oregon, USA (Fig. 1). This geography generally includes the extent of historically frequent fire forests within the USDA Forest Service's Pacific Northwest Region. These forests cover very broad climatic, edaphic, and topographic gradients with widely varying natural disturbance regimes. They range from *Tsuga mertensiana forests* and parklands along the crest of the Cascade Range with a mean annual precipitation of 1600–2800 mm per year and historical fire return intervals of several centuries to dry *Pinus ponderosa* forests in southeast Oregon with mean annual precipitation of 355–760 mm per year and historical fire return intervals of less than 10 years (Agee, 1993; Franklin and Dyrness, 1973). Our challenge was to develop an approach that can be applied across this vast extent encompassing large environmental gradients with data that are consistent and meaningful.

2.2. Core concepts and data sources

We built upon the conceptual framework of the LANDFIRE and Fire Regime Condition Class (FRCC) programs (Barrett et al., 2010; Rollins, 2009) and incorporated Washington–Oregon specific datasets. Our assessment of forest vegetation restoration need is based on four primary data inputs: (1) a classification and map of forested biophysical settings, (2) NRV reference conditions for each biophysical setting, (3) a delineation of "landscape units" for each biophysical setting, and (4) a map of present day forest vegetation structure.

2.2.1. Mapping forested biophysical settings

Biophysical settings are potential vegetation units associated with characteristic land capabilities and disturbance regimes (Barrett et al., 2010). Many different forested biophysical settings are found across Washington and Oregon based on vegetation, soils, climate, topography, and historic disturbance regimes (Keane et al., 2007; Pratt et al., 2006; Rollins, 2009). They provide the framework for describing fire regimes. We mapped biophysical settings across Washington and Oregon using the 30 m pixel Integrated Landscape Assessment Projects' Potential Vegetation Type (PVT) dataset (Halofsky et al., in press), which compiled previous potential forest vegetation classification and mapping efforts including Simpson (2007) and Henderson et al. (2011). We also incorporated subsequent refinements to PVT mapping in

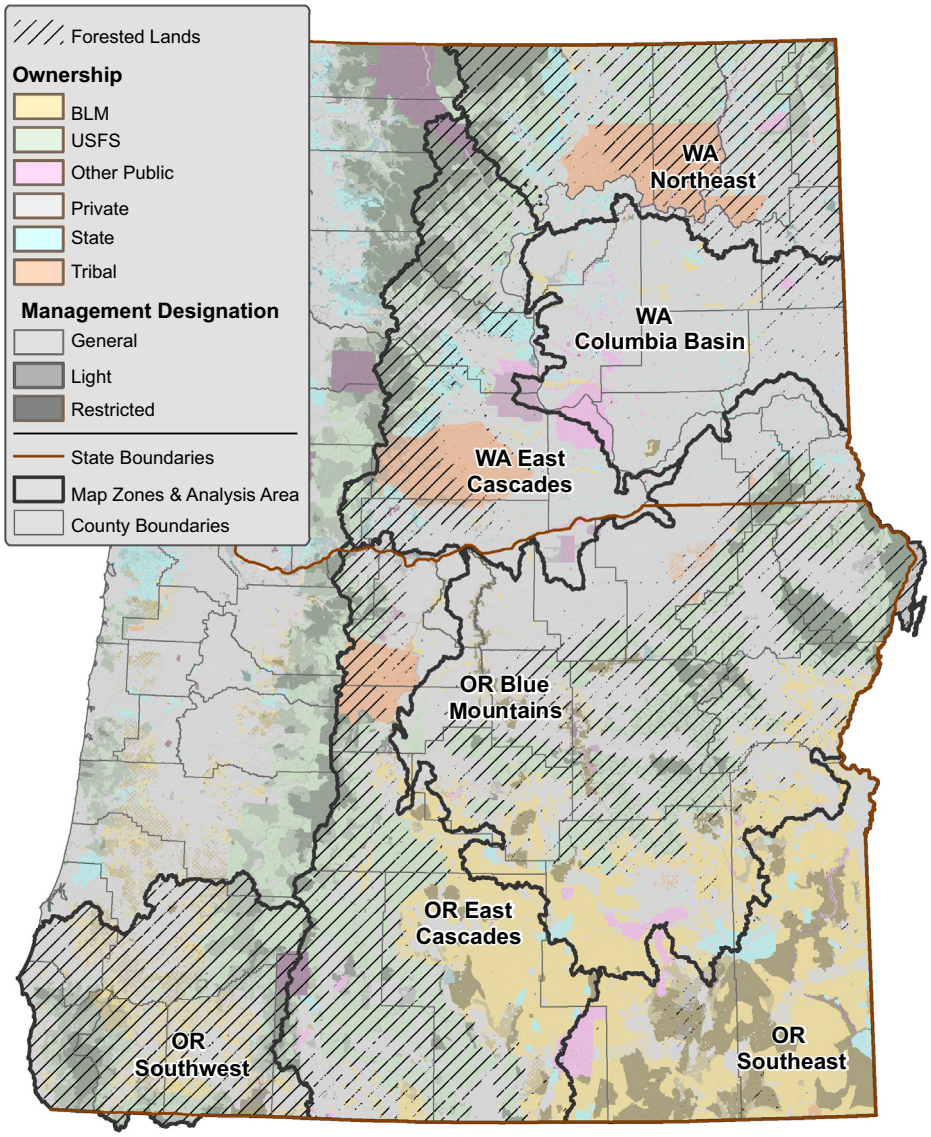

Fig. 1. Map Zones, forest ownership and forest extent in eastern Washington and eastern and southwestern Oregon.

southwestern Oregon (E. Henderson, Oregon State University, unpublished data).

A biophysical setting model from either the LANDFIRE Rapid Assessment or the later LANDFIRE National program (Rollins, 2009; Ryan and Opperman, 2013) was assigned to each PVT mapping unit (Appendix A.1). Assignments were made by staff in the US Forest Service Pacific Northwest Region Ecology Program based upon the geographic, environmental, and biological characteristics of the biophysical setting models and the PVT mapping units. We defined forests across our study area as those described as a "forest" or "forest and woodland" land cover class in the biophysical setting model. National Forest System lands are typically considered "forest" if they have >10% tree canopy cover, and this generally coincides with forest, and forest and woodland land cover classes (USDA Forest Service, 2004).

2.2.2. Natural range of variability reference conditions

Each biophysical setting model is composed of a suite of 3–5 successional/structural stages (s-classes). These classes typically include: (A) Early Development, (B) Mid-Development Closed Canopy, (C) Mid-Development Open Canopy, (D) Late Development Open Canopy, and (E) Late Development Closed Canopy. The definition of each s-class in terms of species composition, stand structure, and stand age is unique for each biophysical setting (Appendix A.2). The percentage of a biophysical setting in each s-class will differ depending on disturbance frequencies and/or intensities. The LANDFIRE and FRCC conceptual framework assumes that, given natural processes, a biophysical setting will have a characteristic range of variation in the proportion in each s-class and that an effective indicator of "ecological condition" for a given landscape is the relative abundance of each s-class within biophysical settings (Barrett et al., 2010; Keane et al., 2011).

NRV reference models describe how the relative distribution of s-classes for a biophysical setting were shaped by succession and the frequency and severity of disturbances prior to European settlement and provide a comparison to present-day forest conditions (Keane et al., 2009; Landres et al., 1999). LANDFIRE biophysical setting models are used to develop NRV estimates through the use of state-and-transition models incorporating pre-European settlement rates of succession and disturbance. Rates were determined through an intensive literature and expert review process (Keane et al., 2002, 2007; Pratt et al., 2006; Rollins, 2009).

The distribution of s-classes for each biophysical setting which results from running state-and-transition models for many time-steps (Appendix A.3) does not represent a specific historical date, but instead approximates characteristic conditions that result from

natural biological and physical processes operating on a landscape over a relatively long time period. NRV is frequently represented by a single value, the mean relative abundance of each s-class from a collection of Monte Carlo state-and-transition model simulations (e.g., Low et al., 2010; Shlisky et al., 2005; Weisz et al., 2009). However, we extended this method by developing and using ranges for each s-class resulting from the stochastic variation around the mean within the state-and-transition models. The main source of this stochastic variation was the random draw to determine whether or not a transition occurred at each time step. We ran 10 simulations for each biophysical setting state-and-transition model over 1000 cells and 1000 annual time steps (Provencher et al., 2008; Forbis, 2006). Simulations were started with an equal proportion in each s-class and it took 200–400 years for the initial trends to stabilize. We calculated the range for each s-class as ±2 standard deviations from the mean abundance from the last 500 time steps (Provencher et al., 2008). Simulations were modeled using the Vegetation Dynamics Development Tool (ESSA Technologies, 2007).

2.2.3. Landscape units

Following the LANDFIRE and FRCC conceptual framework, we defined discrete landscape units to compare present-day forests to modeled NRV reference conditions (Barrett et al., 2010; Pratt et al., 2006). Landscape units varied in size based upon their associated historical fire regimes (Hann and Bunnell, 2001; Hardy et al., 2001) as described in each biophysical setting model (Appendix A.2). To be meaningful, landscape units must be large enough to fully contain the extent of historical disturbance events and scale of other ecological dynamics, but small enough to allow detection of present day disturbance events or management activities (Keane et al., 2009; Landres et al., 1999). In a simulation study focusing on landscapes in northern Utah, USA, Karau and Keane (2007) report an optimal landscape size of ~11,500 ha for assessing vegetation dynamics within low and mixed severity fire regime biophysical settings. Historically high severity fire regime systems require much larger landscapes to evaluate vegetation dynamics. Within the Oregon Coast Range, Wimberly et al. (2000) recommend landscapes of 300,000 ha or larger to compare modeled historic and current levels of late-successional stands within forests with a high severity fire regime.

In comparison to these previous studies, we used slightly larger landscape units to ensure appropriate estimates of restoration need. Restoration needs within historical Fire Regime Group I (FRG I; Table 1) biophysical settings were calculated within watersheds (10-digit/5th level hydrologic units; average ~46,000 ha). Within historical Fire Regime Group III (FRG III; Table 1) biophysical settings we used subbasins (8-digit/4th level hydrologic units; average ~285,000 ha). For these two scales, we used watershed and subbasin delineations from the US Geological Survey Watershed Boundary Dataset (Simley and Carswell, 2009; http://nhd.usgs.gov). Finally, restoration need within historical Fire Regime Groups IV and V (FRG IV & V; Table 1) biophysical settings was assessed within "map zones" (Fig. 1; average ~3.5 million ha) modified from the Integrated Landscape Assessment Project "Model Regions" (Halofsky et al., in press). We created "map zones" by setting the boundaries of the ILAP Model Regions to subbasin boundaries in order to maintain consistent nesting of our landscape units.

Table 1
Historic fire regime groups from Barrett et al. (2010).

Fire regime group	Frequency	Description
I	0–35 years	Generally low severity fires replacing less than 25% of dominant overstory; can include mixed-severity fires that replace up to 75% of the overstory
II[a]	0–35 years	High-severity fires replacing greater than 75% of the dominant overstory vegetation
III	35–200 years	Generally mixed-severity, can also include low-severity fires
IV	35–200 years	High-severity fires
V	200+ years	Generally replacement-severity, can include any severity type in this frequency range

[a] There are no forested biophysical settings classified as Fire Regime Group II within our analysis regions.

2.2.4. Present-day forest structure and composition

We characterized present-day forest vegetation with the gradient nearest neighbor imputation (GNN; Ohmann and Gregory, 2002) datasets produced by the US Forest Service Pacific Northwest Research Station and Oregon State University Landscape Ecology, Modeling, Mapping, and Analysis research group (www.fsl.orst.edu/lemma). The 30 m pixel GNN datasets derive from a process integrating regional inventory field plots, environmental gradients, and Landsat imagery. Within Oregon and Washington the GNN datasets have become a common regional-scale measurement of present-day forest conditions (Moeur et al., 2011). Due to the Landsat imagery used to produce the GNN datasets "present-day" is year 2006 within southwest Oregon, eastern Oregon Cascades, and eastern Washington Cascades and year 2000 in all other map zones (Fig. 1).

To compare present-day forest vegetation to the NRV reference conditions, we mapped the current distribution of s-classes for each biophysical setting using GNN data. S-class mapping was based upon tree canopy cover and tree size thresholds provided for each s-class in the biophysical setting model descriptions (Appendix A.2). Quadratic mean diameter has been used in previous applications of the GNN data to classify forest size class (Moeur et al., 2011). However, simply using the GNN dataset's reported quadratic mean diameter to represent forest stand size class has been found to over represent the abundance of large and extra-large size class stands in eastern Oregon and Washington forests (M. Hemstrom and K. Mellen-McLean personal observations). Consequently, we used total canopy cover accounting for canopy overlap, and a combination of canopy cover and trees per acre by size class to classify GNN data into successional stages. We first applied a customized decision process developed to assign one of the 7 regional forest stand size classes (USDA Forest Service, 2004) to each pixel based on the GNN plot-related attributes of trees per acre by diameter class and canopy cover by diameter class (Appendix A.4). We then assigned biophysical setting s-classes by size class and total canopy cover. The first two steps of the size class decision process sets a density threshold for the number of trees >50.8 cm or >76.2 cm diameter breast height in order for a pixel to be classified as large or extra-large, respectively. These threshold values vary by biophysical setting from approximately 20–50 trees per hectare and were determined by US Forest Service Pacific Northwest Region Ecology Program specialists. We evaluated our "GNN size class decision process" using stand exam and forest inventory and analysis plot data from the Mahleur National Forest. Estimated abundance of large and very large size classes using our "GNN size class decision process" were very close to levels based stand exam and plot data (76,897 ha. versus 74,244 ha respectively; M. Hemstrom unpublished data). In contrast, simply applying the GNN dataset's quadratic mean diameter measure grossly overestimates the abundance of large and very large size classes (234,327 ha; M. Hemstrom unpublished data) compared to stand exam and plot data. All size class and s-class assignments were made using custom Python scripts (Python Software Foundation) within ArcMap 10.1 (Environmental Systems Resources Institute, 2013).

2.3. Forest restoration needs analysis

We assessed forest restoration needs based on the present-day relative abundance of s-classes compared to NRV reference conditions. Within each biophysical setting and landscape unit (stratum), we determined which s-classes were overrepresented and which were underrepresented, then how many hectares would need to transition to a different s-class in order to move the present-day distribution of all s-classes to within the NRV reference distribution (mean ± 2 SD). We categorized these specific transitions between s-classes as resulting from implementation of "disturbance only", "succession only", or "disturbance then succession" restoration categories based upon the identity of the excess and deficit classes (Fig. 2). Our analysis considered the following possible restoration categories and the resulting transitions between s-classes.

2.3.1. Disturbance only

- **Thinning/low severity fire**: Transitions between mid and late development closed canopy to open canopy s-classes through the removal of small and medium sized trees. May be accomplished through fire or mechanical treatment.
- **Opening/high severity fire**: Transition from any mid or late development s-class to "Early Development" through removal of the major proportion of medium and large trees, generally to create a clearing. May be accomplished through fire or mechanical treatment.
- **Overstory Thinning**: Transition from late development to mid development open canopy s-class through removal of overstory cohort trees and retention of smaller understory cohort trees. This transition is likely to be accomplished through mechanical treatment, insects, or disease.

2.3.2. Disturbance then succession

- **Thinning/low fire + grow with fire**: This is a two-step transition that first requires fire or mechanical treatment to transition from mid development closed canopy to mid development open canopy followed by growth with fire to transition to a late development open canopy s-class.
- **Other disturbance + growth**: Transition to mid development closed canopy from any other mid or late development s-class. The specific pathway of this uncommon transition varies by biophysical setting, but includes both disturbance and growth for all biophysical settings.

2.3.3. Succession only

- **Growth with fire**: Transitions from "Early Development" to "Mid Development Open Canopy" or from "Mid Development Open Canopy" to "Late Development Open Canopy" in Fire Regime Group I or III biophysical settings. These transitions are considered succession only as fire disturbance is not immediate required to alter the successional trajectory.
- **Growth without fire**: All other transitions from earlier to later development s-classes, typically maintaining or resulting in a closed canopy

We defined all possible transitions between s-classes within each biophysical setting (Fig. 2) described in terms of the unique characteristics of each biophysical setting's state-and-transition model and s-class descriptions. All transition definitions for a biophysical setting are captured in that setting's "rules table" (Table 2, Appendix A.5). When a transition between s-classes required more than one discrete step based upon that biophysical setting's state-transition model, we defined both a "primary" and a "secondary" transition (Fig. 2 and Table 2).

The restoration needs calculations were conducted in a stepwise fashion for each strata. For each strata, we first calculated the excess or deficit abundance of each s-class when compared to that biophysical settings' NRV reference condition. In order to incorporate the full range of conditions represented by NRV, excesses are calculated from the upper edge (mean + 2 SD) of the biophysical setting's NRV while deficits are calculated from the lower edge (mean – 2 SD; Fig. 3). Using the upper and lower edges of NRV provides a more conservative estimate of restoration need based upon the variability a biophysical setting may experience over time. Based upon the first transition (e.g. row 1) in that biophysical setting's rules table (Table 2) we determined if there was an over-abundance of hectares in the "excess" s-class and an under abundance in the "deficit"

		Deficit S-Class *Currently under-represented compared to reference condition*				
Excess S-Class *Currently over-represented compared to reference condition*		Early Devl.	Mid Closed	Mid Open	Late Open	Late Closed
	Early Devl.		Grow without fire	Grow with fire	Grow with fire	Grow without fire
	Mid Closed	Opening / high fire		Thin / low fire	Thin / low fire + grow with fire	Grow without fire
	Mid Open	Opening / high fire	Other disturbance + growth		Grow with fire	Grow without fire
	Late Open	Opening / high fire	Other disturbance + growth	Overstory thinning		Grow without fire
	Late Closed	Opening / high fire	Other disturbance + growth	Overstory thinning	Thin / low fire	

= Disturbance Only
= Succession Only
= Disturbance then Succession

Fig. 2. Default transitions used in calculations of forest structure restoration need. If there is an excess in the vertical s-class and a deficit in the horizontal s-class for particular strata (biophysical setting × landscape unit), then each intersecting cell represents the hypothetical transition needed to restore forest structure to the Natural Range of Variability (NRV). See Appendix A.3 for NRV reference conditions for each biophysical setting and Appendix A.5 for specific restoration transition definitions for each biophysical setting.

s-class. If no, we skipped that transition step. If yes, we "moved" hectares from the excess to the deficit s-class, such that the deficit s-class does not become overabundant and the excess s-class does not become under abundant relative to the NRV reference condition. These "moved" hectares were then considered "restoration hectares" and were added to the tally for that particular transition category. We then recalculated the excess or deficit abundance of each s-class following the hypothetical redistribution of acres between s-class in the previous step. Based upon the second transition in that biophysical setting's rules table (row 2) we determined if there was an overabundance in the "excess" s-class and a under abundance in the "deficit" s-class. If yes, we "moved" hectares following the same procedure as for the first priority transition and added them to the tally of restoration hectares. If no, we skipped this transition step. This process was then repeated for all transition steps for all 1729 strata. Calculations were conducted using a custom Python script (Python Software Foundation) within ArcMap 10.1 (Environmental Systems Resources Institute, 2013).

We determined the order of operation for each biophysical setting's rules table based on the following logic. First we considered disturbance transitions that were analogous to the predominant historical disturbances within that setting (e.g., thin/low fire for FRG I biophysical settings). Second we considered other disturbance transitions that were less common based on the biophysical setting's historical disturbance regime. Third we considered successional transitions analogous to that setting's historical growth dynamics. Fourth we considered other multi-step disturbance treatments, and fifth we considered multi-step successional treatments. To assess the potential bias introduced by the order of transitions we compared the number of all disturbance and all successional restoration hectares per biophysical setting and landscape unit combination calculated with the specified order of operation (Appendix A.5) versus a randomized order of operation. The absolute difference (mean ± 1 SD) in all disturbance and in all succession restoration hectares was inconsequential (1.8 ± 3.5% and 2.3 ± 4.8% of total hectares respectively per biophysical setting and landscape unit, $n = 1729$).

2.4. Forest ownership and management

Understanding how restoration needs differ amongst forest ownerships and management designations is essential to an integrated landscape scale approach to ecological restoration across ownerships. We intersected our assessment of forest restoration need with forest ownership and management allocations spatial data compiled by Halofsky et al. (in press). We considered six ownership categories (US Forest Service, US Bureau of Land Management, State, Other Public, Tribal, Private), and three levels of forest management intensity (Restricted, Limited, General). Restricted management includes forests where mechanical treatments are typically not allowed, such as Wilderness Areas, National Parks, Inventory Roadless Areas, and Research Natural Areas. Limited management includes forests in which mechanical treatments may be allowed with certain limitations, such as late successional reserves. General management refers to lands where mechanical treatments are allowed.

We used an "equal distribution" approach to determine restoration need by forest ownership and management designation at the level of map zones. Our restoration need calculations provide the percentage of total hectares for each present day sub-strata (landscape unit × biophysical setting × s-class) currently "in need" of disturbance and/or successional restoration. We also determined for each present day sub-strata the number of hectares within each ownership × management designation category. We then made the assumption that the overall percentage of a sub-strata in need of each restoration need transition applied equally across ownership × management designation categories. Consequently, we calculated the number of hectares in need of each restoration need transition for each ownership × management designation × sub-strata. Finally, we summed these values to total active and growth restoration need per ownership and management designation category per map zone. We recognize in some areas with mixed federal and private lands (e.g., checkerboard ownership configurations), a more generalized and variable allocation of restoration needs by landowners could emerge.

3. Results

3.1. Regional-wide trends in forest restoration need

We found that approximately 41% (4,742,000 ha) of all coniferous forest in eastern Washington and eastern and southwestern Oregon was in need of a transition to a different s-class in order to restore forest structure to a NRV reference condition (Table 3,

Table 2
Default restoration transitions "rule table" for biophysical settings with historic low or mixed severity fire regimes. Table describes the primary and secondary actions needed to transition from the excess to the deficit s-class. See Appendix A.5 for a complete list of rules tables for each biophysical setting.

Order	Excess S-Class	Deficit S-Class	Primary Actions	Secondary Actions	Category
1	Mid closed	Mid open	Thin/low fire		Disturbance Only
2	Late closed	Late open	Thin/low fire		Disturbance Only
3	Mid closed	Late open	Thin/low fire	Grow with fire	Disturbance then Succession
4	Late open	Mid open	Overstory thinning		Disturbance Only
5	Late closed	Mid open	Overstory thinning		Disturbance Only
6	Mid closed	Early	Opening/high fire		Disturbance Only
7	Mid open	Early	Opening/high fire		Disturbance Only
8	Late open	Early	Opening/high fire		Disturbance Only
9	Late closed	Early	Opening/high fire		Disturbance Only
10	Early	Mid open	Grow w/fire		Succession Only
11	Mid open	Late open	Grow w/fire		Succession Only
12	Early	Mid closed	Grow w/o fire		Succession Only
13	Mid closed	Late closed	Grow w/o fire		Succession Only
14	Mid open	Late closed	Grow w/o fire		Succession Only
15	Late open	Late closed	Grow w/o fire		Succession Only
16	Mid open	Mid closed	Other disturbance	Growth	Disturbance then Succession
17	Late open	Mid closed	Other disturbance	Growth	Disturbance then Succession
18	Late closed	Mid closed	Other disturbance	Growth	Disturbance then Succession.
19	Early	Late open	Grow with fire	Grow with fire	Succession Only
20	Early	Late closed	Grow without fire	Grow without fire	Succession Only

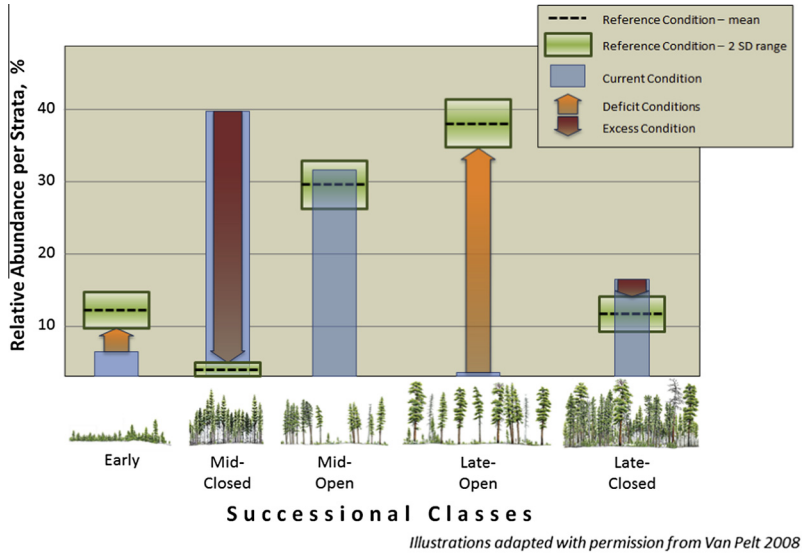

Fig. 3. Example of how the comparison of excess and deficit s-classes to natural range of variability reference conditions (NRV) are determined for a strata (biophysical setting × landscape unit). This example depicts the Dry Douglas-fir biophysical setting within the Oregon Blue Mountains – Upper Tucannon watershed (HUC 1706010706). See Appendix A.3 for NRV reference conditions for each biophysical setting. Forest illustrations adapted with permission (Van Pelt, 2008). (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

Figs. 4 and 5). Across these regions Disturbance then Succession was the most common restoration need category (20% of all forests, 5,678,000 ha) followed by Disturbance Only (14%, 3,920,000 ha) and Succession Only (7%, 2,120,000 ha; Table 3). On the largest individual ownership, the US Forest Service, approximately 38% (2,412,000 ha) of coniferous forests was in need of transition to a different s-class. Only (16%) of the overall restoration needs and 14% of the Disturbance Only plus Disturbance then Succession restoration needs on US Forest Service lands were within Restricted management areas. Across all US Forest Service Forests, the Disturbance Only and Disturbance then Succession categories were roughly equivalent at 15% and 17% of all national forests respectively (Table 3). Overall restoration need was higher on Bureau of Land Management, State, and Private forests (52%, 45%, and 45% of forests per respective ownership) with Disturbance then Succession, the most common restoration need category on these ownerships (Table 3).

Both the overall level and the type of restoration need varied greatly between forested biophysical settings. Specific restoration need transitions are illustrated in Fig. 2. Historical FRG 1 forests were both the most abundant (5,627,000 ha) and had the greatest overall restoration needs (2,857,000 ha, 51% of all FRG I forests, Table 4). Restoration needs within FRG I forests were dominated by the "thinning/low severity fire followed by growth" transition in the mid-development closed canopy s-class (1,695,000 ha, Table 4). We also found a substantial need for "thinning/low severity fire only" in the mid development closed canopy and late development closed canopy s-classes (390,000 and 261,000 ha respectively, Table 4). Forests historically characterized as FRG III were slightly less abundant (4,947,000 ha) and had lower overall restoration needs (33% of all FRG III forests; Table 4). "thinning/low severity fire followed by growth" in the mid-development closed canopy s-class was again the most commonly needed restoration transition (420,000 ha; Table 3). Other commonly needed transitions were "opening/high severity fire" in mid-development closed canopy s-classes (215,000 ha) and "thinning/low fire only" in late development closed canopy s-classes (223,000 ha). Historical FRG IV & V forests were the least common (1,045,000 ha) and had the lowest overall restoration needs (23% of all FRG IV & V forests, Table 4). Within FRG IV & V forests restoration needs were evenly divided between the Disturbance Only and Succession Only categories in the early and mid-development s-classes (Table 4).

3.2. Comparisons of forest restoration need among map zones

Across eastern Washington and eastern and southwestern Oregon we found the highest proportion of restoration need in the Oregon Southwest (1,321,000 ha, 51% of all forests) and

Table 3
Forest structure restoration needs by ownership for eastern Washington and eastern and southwestern Oregon. See Appendix B.2 for detailed summaries of restoration need by forest ownership–management and Map Zones.

Forest owner	Total	Disturbance only[a]		Disturbance then succession[b]		Succession only[c]	
	ha.	ha.	%	ha.	%	ha.	%
US Forest service	6,381,000	960,000	15	1,074,000	17	378,000	6

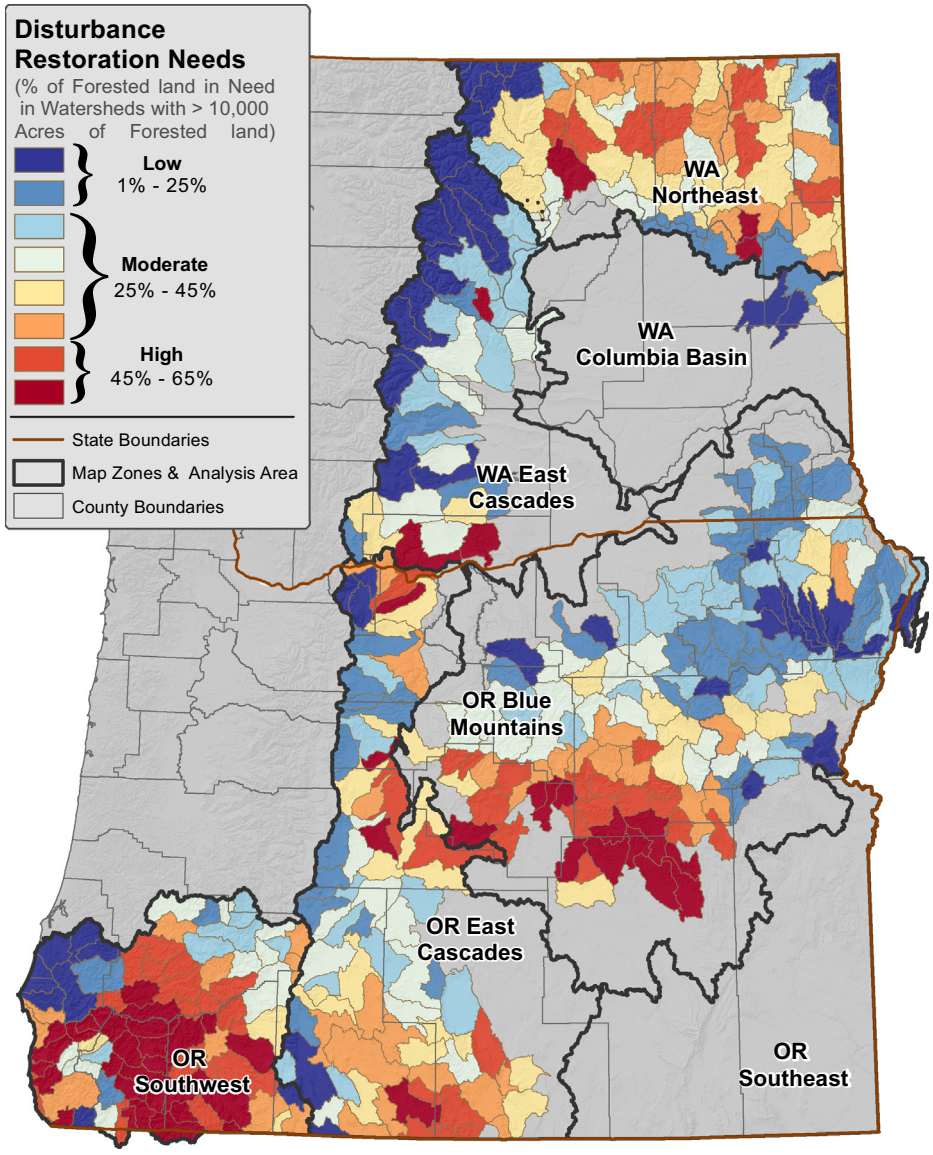

Fig. 4. All disturbance restoration needs as a percentage of forests within 10-digit/5th level hydrologic unit watersheds. Includes the thin/low fire, opening/high fire, overstory thin, thin/low fire + growth, and other disturbance + growth transitions. Within Map Zone labels WA = Washington and OR = Oregon. See Appendix B.4 for restoration need summaries per watershed.

Washington Northeast (955,000 ha, 46% of all forests) map zones (Table 5, Figs. 4 and 5). In contrast to other zones, the majority of overall Disturbance restoration needs (Disturbance Only plus Disturbance then Succession) in Oregon Southwest and Washington Northeast occurred off US Forest Service lands (Fig. 6) and were concentrated in the historically low severity fire regime forests (Fig. 7). Additionally, in both map zones the overall Succession restoration needs (Succession Only plus Disturbance then Succession) were nearly as great as the overall Mechanical/Fire restoration needs (39% vs. 33% and 23% vs. 25% of all forests in the map zone respectively; Table 5).

Compared with these map zones, the overall proportions of restoration need were slightly lower within the Oregon Blue Mountains (1,095,000 ha, 38% of all forests) and Oregon East Cascades (866,000 ha, 36% of all forests; Table 5). Restoration needs within the Oregon Blue Mountains were dominated by the Disturbance then Succession category (696,000 ha, 24% of all forests) while the Oregon East Cascades have equivalent levels of the Disturbance Only and Disturbance then Succession categories (382,000 ha, 16% and 401,000 ha, 17% respectively, Table 5). Within both zones the majority of overall Disturbance needs are on US Forest Service lands (648,000 ha, 69% and 519,000 ha, 66% respectively; Fig. 6) and were found across the FRG I and III biophysical settings (Fig. 7). This is in contrast to the Oregon Southwest and Washington Northeast zones, where sum total of needs were greatest outside the national forests.

We found the lowest overall levels of restoration need within the Washington East Cascades (476,000 ha, 30% of all forests). Similar to the Oregon East Cascades, the Washington East Cascades had equivalent levels of the Disturbance and the Disturbance then Succession (each approximately 190,000 ha/12% of all forests; Table 5). US Forest Service lands contributed only 40% (152,000 ha) of overall Disturbance restoration needs (Fig. 6), and were concentrated in the historically FRG I forests (Fig. 7).

The Oregon Southeast and Washington Columbia Basin map zones were dominated by non-forested ecosystems. Although levels of overall restoration need as a percentage of total forested area are similar to other map zones (Oregon Southeast 44%, Washington

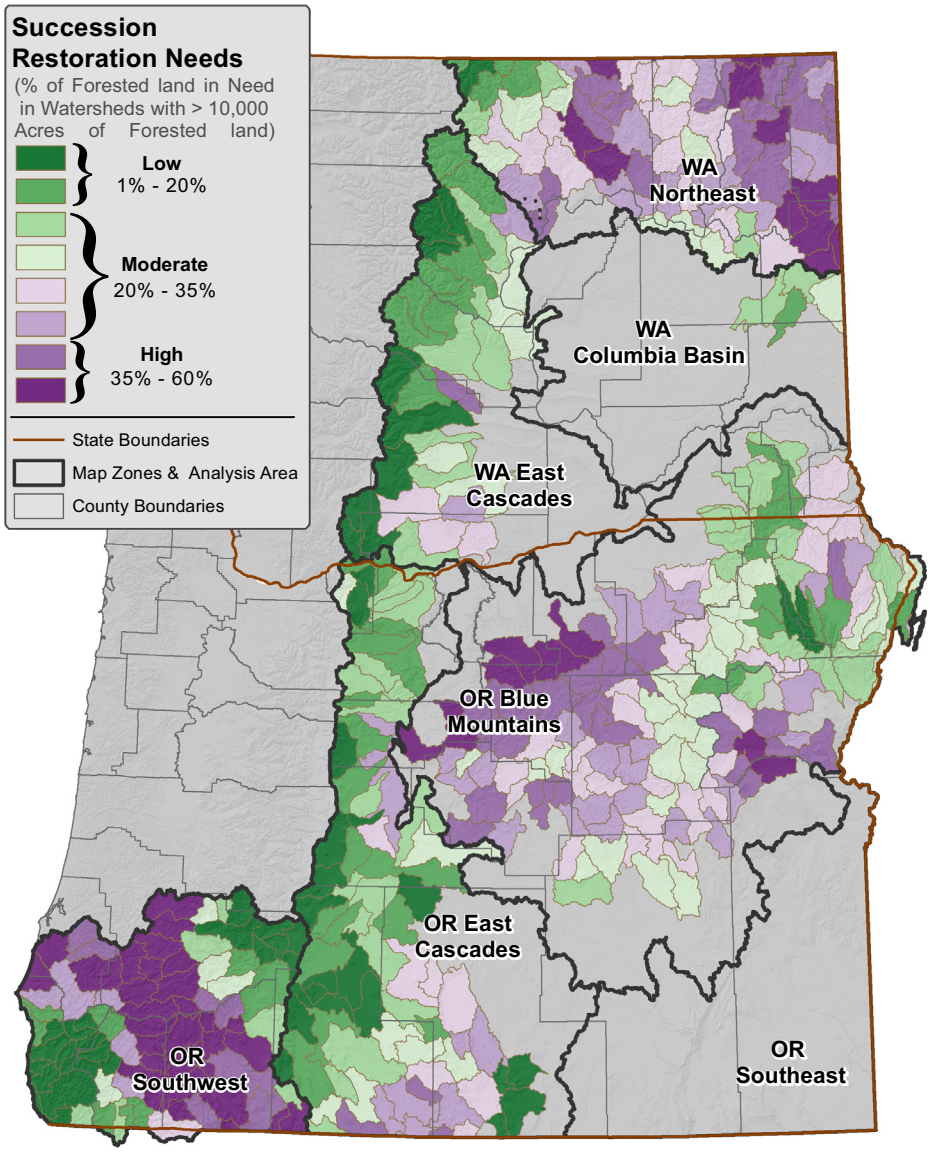

Fig. 5. All succession restoration needs as a percentage of forests within 10-digit/5th level hydrologic unit watersheds. See Appendix B.4 for restoration need summaries per watershed.

Columbia Basin 37%), they contribute little to the regional-wide restoration needs (Table 5).

4. Discussion

4.1. Interpreting regional restoration needs

We found that forest structural restoration needs across eastern Washington and eastern and southwestern Oregon were dominated by the need for thinning and/or low severity fire transitions within forests historically characterized by low and mixed severity fire regimes (FRG I and III biophysical settings; Table 4). These basic findings reflect the commonly understood impacts of wildfire suppression and past management on historically fire-dependent forest ecosystems across western North America (Noss et al., 2006). However, we found substantial variation in restoration need per watershed (5th field hydrologic units) across our region with results ranging from less than 5% to greater than 80% of all forests within individual watersheds in need of disturbance transitions. The variation we observed in restoration needs was driven in large part by the distribution of forest biophysical settings, but also by patterns of forest ownership and management. We found the highest levels of restoration need at both map zone and watershed scales in locations dominated by FRG I biophysical settings and with forest ownerships that likely focused primarily on timber production, resulting in a preponderance of early and mid-development closed canopy successional classes.

Within the vast majority of the watersheds we evaluated, disturbance alone cannot restore NRV forest structure. Deficits in late development forest structure were clearly evident; succession into later development s-classes was required in over half (66%) of the total restoration needs across the region. However, the predominant late development successional classes and the successional pathways to these classes vary amongst biophysical settings and may require repeated disturbances. The map zones with the highest proportion of overall disturbance needs (Oregon Southwest and Washington Northeast) also had the highest successional restoration

Table 4

needs (Figs. 4 and 5). In most locations, restoration programs must focus on both the application of mechanical treatments and fire while also conserving and promoting old trees and late development forest structures (Franklin and Johnson, 2012; Franklin et al., 2013; Stine et al., in press).

The historical dynamics and present day management of historical mixed severity fire regime forests has received particular attention recently by the science and management communities (e.g., Halofsky et al., 2011; Perry et al., 2011; Stine et al., in press). The complex nature of mixed severity fire regimes and long history of management for many of these forests were reflected in the variety of specific restoration transitions needs that we identified for FRG III biophysical settings (Table 3). Stine et al. (in press) argue that due to greater productivity, restoration needs within historical mixed severity fire regime forests may be even greater than historical low severity fire regime forests. While we identified a greater proportion of total forested area in need of restoration within historical FRG I forests, FRG III forests may certainly be prioritized in local restoration programs due to higher site productivity and concurrent higher fuel levels, and greater risk of high severity fire and insect/disease mortality (*see* Section 4.2).

Similarly, the historic role of high severity fire and the importance of complex early seral habitats in western forested landscapes have also received significant recent attention by the science and management communities (Hutto, 2008; Swanson et al., 2011). As a proportion of overall restoration needs, the opening/high severity fire transition was most common in historically mixed and high severity fire regime forests (e.g., FRG III, IV, & V biophysical settings). All disturbance restoration need transitions in this paper, and particularly the opening/high severity fire transition, should be interpreted with respect to historical spatial patterns at patch and landscape scales. Stand level reconstructions of frequent fire forests in western North America emphasize high levels of fine scale spatial heterogeneity in the form of individual trees, tree clumps, and openings within forest stands (Churchill et al., 2013; Larson and Churchill, 2012). At landscape scales, reconstructions of historical patch sizes from the eastern Washington Cascades reveal distributions following a negative power law, with many small ($\leqslant$10s ha) and few very large patches (1000s ha+; Hessburg et al., 2007, 2000a; Perry et al., 2011). Consequently, the majority of opening/high severity transitions that we report, particularly within historical low severity fire regime forests (e.g., FRG I biophysical settings), are likely to be represented as smaller within-stand openings. Within FRG III, IV, and V biophysical settings, the opening/high severity fire transitions may also represent larger patches of early seral habitat.

4.2. Management implications

In recent years there have been numerous calls by local, state, and federal governments, agencies, and stakeholder groups to increase the pace and scale of forest restoration treatments across Oregon and Washington (State of Oregon, 2011; The Nature Conservancy, 2012; USDA Forest Service, 2013). We have identified approximately 1.7 million ha presently in need of disturbance (including disturbance then succession) to restore forest structure NRV on US Forest Service lands outside of wilderness and inventoried roadless areas (e.g., "USFS-Restricted", Appendix Table B.2). Within our analysis area the US Forest Service averaged approximately 12,000 ha per year of hazardous fuels treatments between 2004 and 2013 and had a total of nearly 19,000 ha of forest vegetation improvements in 2013 (US Forest Service Pacific Northwest Region; unpublished data). Assuming that these treatments are additive and address disturbance restoration needs identified in this study, at these treatment rates it will take over 50 years to meet the identified disturbance restoration needs on these US Forest Service lands. These assumptions are not likely to be true for all of the recorded treatments. Furthermore, this rough comparison does not take into account the extremely important influences of wildfire, managed or otherwise, and other unplanned disturbance events or the natural growth and succession of forests. The US Forest Service Pacific Northwest Region is increasing the rate of restoration treatments, notably in the Blue Mountains. For example, acres treated in the Pacific Northwest Region increased 22% from Fiscal Year 2012 to Fiscal Year 2013 (US Forest Service Pacific Northwest Region; unpublished data). Our results indicate that such an increase in treatment rate on federal forests is warranted. However, region-wide restoration needs cannot be met through focus on unreserved US Forest Service lands alone. Coordination amongst governments, agencies, and landowners and application

Table 5

See Appendix B.2 for detailed summaries of restoration need by forest ownership–management and Map Zones.

of the entire "toolbox" (e.g., mechanical treatments, prescribed fire, managed wildfire, protection) will be required.

A primary motivation behind this study is to facilitate the ability of local land managers to incorporate regional scale, multi-ownership context into local forest management and restoration. This assessment, however, is not a replacement for the evaluation of local landscapes (1000s–10,000s of ha) and development of local landscape prescriptions. With that understanding, the results from this study may inform local landscape evaluations and development of local landscape restoration prescriptions (e.g., Hessburg et al., 2013). For example, our results provide managers with the ability to place local treatments within regional context based on relative restoration needs by biophysical settings and s-classes (Appendix B.3). Land managers may also use our results to estimate and compare overall treatment need amongst potential project areas through our watershed level summaries (Appendix B.4). However, local landscape evaluations are still required to develop on the ground restoration treatments. Ideally, these local

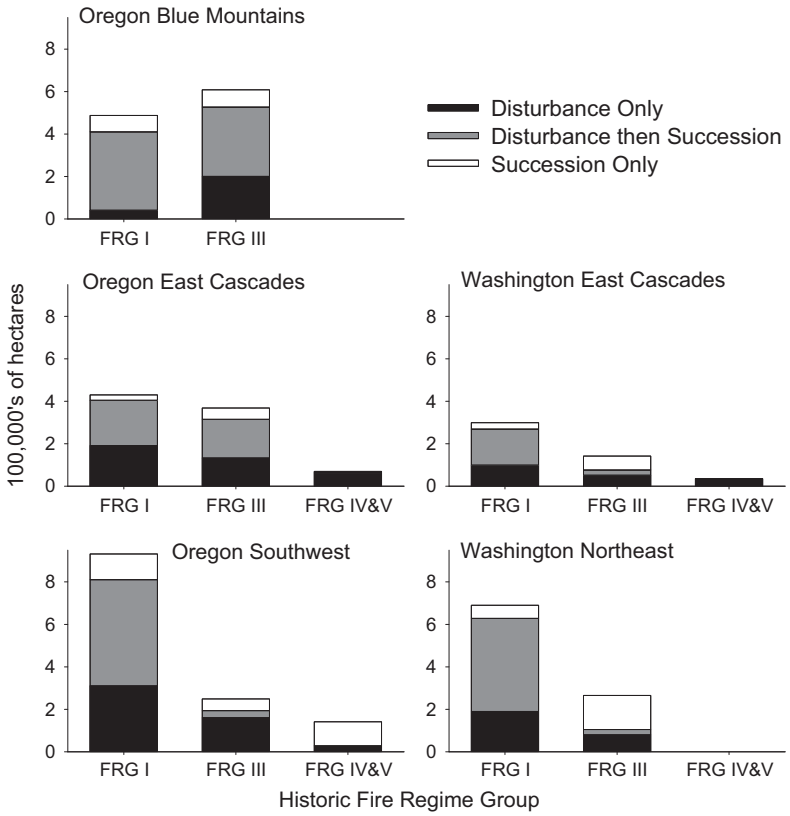

Fig. 7. Forest structure restoration need by forested biophysical setting historic fire regime groups (FRG; Table 1) per Map Zone for eastern Washington and eastern and southwestern Oregon. "Disturbance Only" includes the thin/low fire, opening/high fire and overstory thinning transitions. "Disturbance then Succession" includes the thin/low fire + growth and other disturbance + growth transitions. "Succession only" includes the grow with fire and grow without fire transitions. See Appendix B.3 for detailed summaries of restoration need by forest biophysical settings and Map Zones.

evaluations also incorporate important factors not included in our analysis such as tree species composition, forest patch size, shape, and configuration, aquatic ecosystem conditions, and specific habitat requirements. Additionally, local adjustments to the state-and-transitions models, such as changing disturbance probabilities to reflect the impact of climate, insects, disease and other natural cycles (sensu Forbis, 2006), could help refine the NRV estimates presented here. Consequently, local landscape evaluations require measurements of forest structure and composition at finer spatial resolutions (e.g., lidar, high resolution aerial photography) than are presently available for our regional scale analysis.

Forest restoration programs must consider not only patterns of vegetation and habitat, but also ecological processes such disturbance, hydrology, and migration. Our evaluation of forest restoration needs considers only half of the Fire Regime Condition Class assessment; forest structure but not contemporary fire/disturbance history (Barrett et al., 2010). However, a fundamental principle of landscape ecology is the linkage between ecological patterns and processes (Turner et al., 2001). Restoration of pattern in forested landscapes, from local to regional scales, facilitates the restoration of ecological processes. Consequently, the restoration needs identified in this study help to set the stage for the restoration of ecological processes. Finally, as better data on historical disturbance becomes available, more refined estimates of ecological departure, and associated indications for treatment, may be possible.

4.3. Appropriate uses of restoration needs results

We expect that both the results of this analysis and the conceptual framework we have introduced will be useful in providing regional context for local restoration treatments, conducting regional scale prioritizations, and assessing the scope and scale of current restoration programs. However, such uses require an understanding of the data and assumptions upon which this analysis was built. The restoration transitions we report are broad characterizations; they do not represent specific sivicultural prescriptions and are limited by both the accuracy and resolution of the current forest structure and potential vegetation type mapping we used, and by the simplified classification of each biophysical setting into five s-classes. Similarly, there are many aspects of ecological restoration, including but not limited to tree species composition and aquatic ecosystems, which our narrow focus on forest structure did not consider. Given these limitations, our results should not be interpreted below the resolution of individual watersheds (5th field hydrologic units, average ~46,000 ha).

In addition, the restoration transitions we report in this study do not directly correspond to the concepts of "active restoration" and "passive restoration" which are referenced in other discussions of forest restoration (e.g., Morrison and Lindell, 2011). Active restoration typically refers to direct intervention or manipulation, such as mechanically thinning a forest stand, whereas passive restoration typically refers to no action, such as letting a natural fire ignition burn. Yet both of these scenarios, mechanical treatment and letting a natural ignition burn, may be included in our disturbance transitions. Whether active or passive restoration means are used within a specific location to achieve identified disturbance restoration needs depends upon forest ownership and management allocation for that location. We recognize that there are many significant differences in the ecological outcomes of mechanical treatments versus prescribed fire versus wildfire (Schwilk et al., 2009). Furthermore, fire is frequently required following mechanical treatment in order to meet ecological and/or forest fuels objec-

tives (Schwilk et al., 2009). However, we consider that either mechanism is capable of achieving the coarse s-class transitions that we report in this study.

As our understanding of historical and future ecosystem dynamics, classification and mapping of biophysical settings, and measurement of current conditions across Oregon and Washington improves, new data may be incorporated into our conceptual approach to revise the results presented here. Our conceptual approach is also applicable to other regions. The basic concepts of our approach may be applied anywhere that the foundational inputs of biophysical setting classification and mapping, reference conditions, landscape units, and mapping of current conditions is available. There is great value having a consistent approach to evaluating where, how much, and what kinds of forest restoration are needed across regional scales.

Acknowledgements

Abstract. Forest landscapes across western North America (wNA) have experienced extensive changes over the last two centuries, while climatic warming has become a global reality over the last four decades. Resulting interactions between historical increases in forested area and density and recent rapid warming, increasing insect mortality, and wildfire burned areas, are now leading to substantial abrupt landscape alterations. These outcomes are forcing forest planners and managers to identify strategies that can modify future outcomes that are ecologically and/or socially undesirable. Past forest management, including widespread harvest of fire- and climate-tolerant large old trees and old forests, fire exclusion (both Indigenous and lightning ignitions), and highly effective wildfire suppression have contributed to the current state of wNA forests. These practices were successful at meeting short-term demands, but they match poorly to modern realities. Hagmann et al. review a century of observations and multiscale, multi-proxy, research evidence that details widespread changes in forested landscapes and wildfire regimes since the influx of European colonists. Over the preceding 10 millennia, large areas of wNA were already settled and proactively managed with intentional burning by Indigenous tribes. Prichard et al. then review the research on management practices historically applied by Indigenous tribes and currently applied by some managers to intentionally manage forests for resilient conditions. They address 10 questions surrounding the application and relevance of these management practices. Here, we highlight the main findings of both papers and offer recommendations for management. We discuss progress paralysis that often occurs with strict adherence to the *precautionary principle*; offer insights for dealing with the common problem of irreducible uncertainty and suggestions for reframing management and policy direction; and identify key knowledge gaps and research needs.

Key words: Climate Change and Western Wildfires; climate warming; forest landscape changes; Indigenous fire use; landscape realignment; landscape resilience; landscape resistance; social-ecological systems; wildfire regime changes.

Introduction

Western forests are rapidly changing

Starting in the mid-1980s, area burned in seasonally dry forests of western North America (wNA) began a steady rise (Westerling et al. 2006), despite increasing investment in fire suppression (Calkin et al. 2005). Seasonally dry forests are those pine, dry or moist mixed-conifer, and cold forests that are available to burn most years during the wildfire season (refer to forest type definitions and discussion in Hessburg et al. 2019). Increased burned area is attributed to combinations of warmer seasonal temperatures, longer wildfire seasons, drier summers, below-average winter precipitation and earlier snowmelt, and increasing human ignitions (Westerling et al. 2006, Morgan et al. 2008). The incidence of large wildfires has likewise increased across wNA over the last three decades (Schoennagel et al. 2017, Parks and Abatzoglou 2020), while burned area in the Inland Northwest and American Southwest has risen most noticeably over the last two decades (Westerling 2016). These increases are occurring not only in dry pine and mixed-conifer forests, but also in moist and cold

Manuscript received 18 November 2020; revised 17 February 2021; accepted 3 March 2021; final version received 6 July 2021. Corresponding Editor: David S. Schimel.
[6] E-mail: paul.hessburg@usda.gov

forests, and in nearby nonforest vegetation (preforest, grassland, shrubland, and sparse woodland; Parks et al. 2015). Based on climate change predictions, burned area in wNA will at least double or triple by mid-century (McKenzie et al. 2004, Westerling et al. 2011).

While increase in burned area is strongly associated with climatic warming, changes to other aspects of wildfire regimes (Table 1) more directly reflect the influence of human activities. For example, in many wNA forests, land and resource management decisions and actions led to abrupt and persistent declines in fire frequency (and hence, burned area) beginning more than 170 yr ago. Decreased fire frequency led to increased continuity and accumulation of live and dead fuels (Stephens et al. 2009), both of which contribute to increases in fire severity as burned area increases (Parks and Abatzoglou 2020). Likewise, while human-caused ignitions continue to contribute to increasing burned area (Balch et al. 2017), they also reflect contemporary land development and access patterns. With ongoing fire suppression, lengthening wildfire seasons, and the increased likelihood of extreme fire weather, fire effects are broadly becoming more severe than those experienced in the last two centuries (North et al. 2015, Parks and Abatzoglou 2020). As a result, forests developing after large contemporaneous wildfires little resemble forests evolving under a more characteristic wildfire regime (Keane et al. 2002, Hessburg et al. 2005, Coop et al. 2020).

The challenge of larger and more intense wildfires

The increasing impacts that large and intense wildfires will have on social and ecological systems will be the major challenge facing managers of seasonally dry forests over the 21st-century. Prolonged smoke production and human health effects, chronic soil erosion and mass wasting, degraded water supplies, loss of cultural and natural resources, increased greenhouse gas emissions and reduced carbon storage are all growing issues (Spies et al. 2014). Management capacity to influence how much area burns will be somewhat limited (cf. Taylor et al. 2016), but fuel reduction treatments, including prescribed burning, coupled forest thinning and prescribed burning, and managed wildfires, are proven methods to influence the ecological impacts of wildfire, and mitigate impacts of extreme fire events on social systems (Taylor et al. 2016; Prichard et al. 2021). To date, mechanical fuel reduction treatments have been applied to small portions of wNA forested landscapes (Barnett et al. 2016, Vaillant and Reinhardt 2017, Kolden 2019, Kolden and Henson 2019). One reason is that land allocations amenable to mechanical treatments (via their enabling legislation) represent a dwindling fraction of public lands (Fig. 1); another is a lack of sufficient experience with prescribed burning and managing wildfires in front or backcountry locations. However, scaling-up a broad variety of fuel reduction treatments can tip landscape dynamics in favor of more benign fire behavior and effects (Stevens et al. 2014, Parks et al. 2016, Taylor et al. 2016, Ager et al. 2020).

Table 1. Components of an active fire regime.

Component	Definition
Amount	total amount of area burned annually or decadally
Distribution (severity)	distribution of severity class patch sizes
Distribution (event areas)	distribution of fire event patch sizes
Frequency	average fire return interval, and variation around the mean
Spatial distribution	the geographic distribution of fires†
Intensity	the energy release from surface and crown fires at the flaming front
Duration	the length of time fires burn‡
Seasonality	the time of the year when fires burn

Note: Components may vary by climatic period.

†The spatial distribution of fires is dictated by biophysical setting, climate, and weather conditions, forest or nonforest type, ignition probability, and the propensity for reburning.

‡The period of fires is dependent on the climate, weather, and fuel bed characteristics.

The assertion of regional-scale adaptation needs

The need for broad-scale climate and wildfire adaptation across wNA is predicated on two main assertions. The first is that most seasonally dry forest landscapes, and some drier coastal forests (Hessburg et al. 2019), have significantly changed over at least the last two centuries under the influences of curtailed Indigenous burning before 1850 (Kay 2000, Stewart 2002); wildfire exclusion (beginning with domestic livestock grazing in the mid-1850s, Belsky and Blumenthal 1997); and decades of selection cutting of large, old, early seral tree species (Hessburg and Agee 2003, Lydersen et al. 2013). The resultant stand- to landscape-scale changes in forest structures and fuels have left these seasonally dry forests vulnerable to the direct and indirect effects of climate warming, drought, and wildfire (Allen et al. 2002, Noss et al. 2006, Keane et al. 2018, Bryant et al. 2019, Hessburg et al. 2019). The second assertion is that climate change and wildfire adaptation treatments implemented at large regional landscape scales can effectively moderate many ecosystem transitions, conserve greater area and heterogeneity of forest successional conditions (Moritz et al. 2013, Coop et al. 2020), better foster native biodiversity (Raphael et al. 2001, Bisson et al. 2003, Isaak et al. 2010, Rieman et al. 2010), and maintain essential and desirable ecosystem services and processes (e.g., see Dale et al. 2001, Millar et al. 2007, Hurteau et al. 2014).

Public land management: political and paralyzed

As with many topics in conservation biology (Soulé 1985), active or intentional management of public

19395582, 2021, 8, Downloaded from https://esajournals.onlinelibrary.wiley.com/doi/10.1002/eap.2432, Wiley Online Library on [30/12/2022]. FIG. 1. Map of forested areas and their primary public land management allocations in the western United States. Federal wildlands include administratively withdrawn roadless areas, congressionally designated wilderness, and terrestrial habitat reserve networks. General forest areas are those remaining that are ostensibly amenable to mechanical thinning and prescribed burning treatments. Riparian reserves are generally not shown due to map scale, but they represent a significant area in general forest. The inset map at top right shows an example of riparian reserves in the Swan sub-basin of northwest Montana. Riparian buffers are 100 m on either side of perennial streams and 30 m on ephemeral streams. Most federal wildlands and national parks are available in concept for using managed wildfires and prescribed burning as fuel reduction treatments, but application of these tools remains uneven. Data sources for map development are (1) for forested areas, National Land Cover Database, NLCD (2006); https://www.mrlc.gov/data/nlcd-2006-land-cover-conus) for inventoried Roadless Areas (2001), https://www.fs.usda.gov/detail/roadless/2001roadlessrule/maps/?cid=stelprdb5382437, USDA-FS internal enterprise data layer name: S_USA. InvRoadlessArea_2001; (2) for Northwest Forest Plan Land Use Allocations (2013), https://www.fs.fed.us/r6/reo/landuse/, USDA-FS internal enterprise data layer name: S_R06.NWFP_LandUseAllocation_2013; (3) for designated Wilderness Areas (2020), USDA-FS internal enterprise data layer name: S_USA.Wilderness; (4) for Other National Designated Areas (2020), USDA-FS internal enterprise data layer name: S_USA.PADUS_DESIGNATION; (5) for US National Atlas Federal and Indian Land Areas (last updated 2004), USDA-FS internal enterprise data layer name: S_USA.OtherNationalDesignatedArea.

forestlands often devolves into value-laden discussions and politicized views of appropriate contexts and frames of reference (Peery et al. 2019). Here, we define intentional management as the planned application of silvicultural and prescribed fire treatments and managed wildfire to meet a variety of specific landscape-level objectives in predefined conditions and contexts. This can include opportunities in Indigenous communities for more decentralized stewardship practices related to resource tending, subsistence activities, and spiritual or

19395582, 2021, 8, Downloaded from https://esajournals.onlinelibrary.wiley.com/doi/10.1002/eap.2432, Wiley Online Library on [30/12/2022]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

religious observances (Norgaard 2014). In contrast, under passive management (i.e., continued fire suppression with little intentional forest or fuel management), many assume that existing conditions and processes will naturally sort out an effective remedy without benefit of intentional management (Carey 2006).

Owing to extensive 20th-century harvest of large trees and old-growth forests, public trust in forest management eroded. In response, an emphasis emerged to conserve the victims of that history, large trees and old forests, and native species and their habitats, by minimizing further forest management actions. This emphasis is commonly underscored with policies that emphasize riparian and terrestrial habitat reserves and related conservation areas (Spies et al. 2019, Stephens et al. 2019), by legal injunction of active management projects (Prichard et al. 2021), and by maintaining a relatively small footprint of areas available for active management (Fig. 1). Opposition to active forest management is reflected in statements like "active forest management is unwarranted because the effects of fire exclusion and forest changes are overstated; . . .is ineffective and counterproductive; . . . should be focused on the wildland urban interface; or wildfires alone can do the work of fuel treatments." On the other hand, support for active management from the commercial sector suggests that "forest thinning alone can mitigate wildfire severity; forest thinning and prescribed burning can solve the problem; or managed wildfires hold no real promise." Each statement polarizes debates and oversimplifies the problems and the solutions (Prichard et al. 2021). Given rapid climate change and a legacy of excluding most natural and Indigenous ignitions, effective forest landscape restoration and adaptation strategies are more complex and nuanced than any of these statements imply.

Advocacy and objectivity: is it one or the other?

The polarization and politicization of scientific evidence impedes implementation of effective land management plans, policies, and management by raising the volume of the disagreement; obscuring the line between facts, opinions, and legal requirements; creating the impression that knowledge is more uncertain than it is; and increasing the time to resolution. Wellerstein (2018) argue that the premise of science as apolitical is simply a myth, since all science takes place and is supported within a highly political environment. Nonetheless, when scientists affiliate themselves with one-sided or partisan views and activism, they inevitably minimize their value and that of the applied science (Lackey 2007, Pielke 2007).

Scientists are increasingly asked to comment on forest policy and management recommendations. Facilitating communication among stakeholders of public land management by providing practical access to the best-available science can more effectively ensure scientifically credible decision-making (Komatsu and Kume 2020). However, while some encourage scientists to be responsible informants for species or ecosystem conservation (e.g., Lach et al. 2003), others worry that their objectivity in conservation or ecological research may be compromised (e.g., Scott et al. 2007), especially during volatile times, and with arguments that are already polarized or politicized.

Garrard et al. (2016) argue that scientists are not compromised when they transparently evaluate policies or recommendations for their consistency with the best available science, its weight of evidence, and any associated uncertainties. A systematic evaluation of best available science would include careful examination of Indigenous and western data, information, knowledge, and wisdom from a variety of locally and regionally relevant sources (Varghese and Crawford 2020). Garrard et al. (2016) further suggest that in the face of serious societal, economic, or existential issues, "the standard of debate about conservation is impoverished when scientists with relevant knowledge remain silent outside the pages of their academic journals."

Peery et al. (2019) provide a framework for evaluating agenda-driven science and a case example of controversy in the scientific literature that has impacted management of the California spotted owl and its habitats. They discuss professional norms for scientist engagement with management and policy issues and conclude "that intentionally engaging in activities outside of these professional norms to promote desired political outcomes, as part of either the production or dissemination of science . . .constitute[s] agenda-driven science."

Recent controversy involving the creation and dissemination of agenda-driven science is creating uncertainty for forest managers and policy-makers throughout wNA. Contributing to the controversy are publications that challenge the significance of forest condition and wildfire regime changes, and the advisability of proactive management without addressing the core arguments (e.g., compare Hessburg et al. [2020] and Mildrexler et al. [2020] and their discussion of trade-offs between wildfire dynamics, carbon sequestration, and forest adaptation to climate warming). To aid those engaged in designing, evaluating, and implementing science-based adaptation options, we examine the strength of evidence pertaining to these topics.

We first provide a framework for characterizing and evaluating changes in forest conditions and fire regimes in Hagmann et al. (2021). We then review the strength of evidence documenting changes or lack thereof. Similarly, in Prichard et al. (2021), we review the strength of evidence surrounding the usefulness of various passive and active management treatments to provide remedies to current conditions. We then discuss 10 key questions related to application of methods as viable treatments.

Forest Conditions and Wildfire Regimes

Advances in fire and landscape science over the past several decades enable rigorous multi-proxy and multi-

19395582, 2021, 8, Downloaded from https://esajournals.onlinelibrary.wiley.com/doi/10.1002/eap.2432, Wiley Online Library on [30/12/2022]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

scale assessments of variation in historical fire regime and forest vegetation conditions. These insights build on more than a century of assessment of changing fire behavior and forest landscape conditions. Beginning in the 1930s, fire histories based on tree-ring and fire-scar records have provided high-resolution, cross-dated, multi-centenary evidence of the spatial point patterns of fires, which have enabled precise interpretations of fire frequency associated with recorder trees. While fire-scar records remain a primary means of exploring historical fire ecology, more recently developed methodologies and multi-proxy assessments have expanded the potential to evaluate broader temporal and spatial patterns. New insights into complex relations between variations in climate, fire, and vegetation emerge from multi-proxy and trans-disciplinary studies that combine sedimentary pollen and charcoal records (Higuera et al. 2007), large-scale tree cohort analyses (Schoennagel et al. 2011), early 20th-century land system inventories and surveys (Hagmann et al. 2013, 2014, Levine et al. 2017), landscape reconstructions from historical black and white photographic imagery (oblique, panoramic, stereo photo pairs, Hessburg et al. 1999, 2000, Stockdale et al. 2015, 2019), forest inventories and land system surveys (Williams and Baker 2012, cf. Fulé et al. 2014, Odion et al. 2014, cf. Stevens et al. 2016), and simulation modeling of landscape succession and disturbance regimes (Keane et al. 2004, 2018, McGarigal and Romme 2012). Additionally, trans-disciplinary studies that employ fire-scar research, climate, archaeological, and ethnographic studies show that many different Indigenous cultures were significant contributors to the magnitude and extent of fire influence on the wNA landscape (e.g., see Taylor et al. 2016, Lightfoot et al. 2013).

Over the past two decades, a series of publications using novel techniques has suggested that 19th- to 21st-century changes in western forests and their fire regimes have been less substantial than a much larger and more diverse body of scientific evidence has long indicated. Hagmann et al. (2021) provide a comprehensive review of these papers and studies that directly evaluated them. They show that methods and inferences in these articles failed independent validation by other research groups and lend their support to the findings of the larger body of evidence.

The evidence for change in forest conditions

Hagmann et al. (2021) relied on several hundred research articles from research groups throughout wNA that examined historical changes to seasonally dry forests patterns and processes to illustrate key departures from conditions that existed prior to European colonization. They found that changes in forest successional landscapes are significant in all forest types, whether dry, moist, or cold. Changes are prominent at tree, patch, and local and regional landscape levels, and these changes explain important shifts in numerous habitats and ecosystem processes. Conditions of nonforest vegetation (grasslands, shrublands, sparse woodlands) are likewise altered as a consequence of fire exclusion and forest encroachment. While some forest and nonforest ecosystems may not have been directly altered by fire exclusion, the magnitude of changes suggests that it is likely that all were indirectly impacted by alteration of the landscape ecology and disturbance regimes that surround them. Based on a preponderance of scientific evidence, there can be little doubt that long-term fire exclusion and other associated social-ecological influences contributed to extensive modification of landscapes across wNA, and that the magnitude of the departures in fire regimes and landscape conditions has increased the vulnerability of contemporary forested landscapes to fire and drought-related stressors.

The evidence for change in fire regimes

Hagmann et al. (2021) also review the evidence for changes in the dimensions of fire regimes (Table 1). Fire exclusion has reduced fire frequency in all forest types, with the degree of change generally declining with increasing elevation, owing to orographic effects on moisture and temperature, and topo-edaphic effects on insolation. As a consequence, surface and ladder fuel abundance generally increased in historically fuel-limited frequent-fire forests, while forest cover at higher elevations expanded and became more successionally homogenized (Fig. 2). In both cases, crownfire vulnerability increased. Long-term fire exclusion reduced the total amount and spatial distribution of wildfires resulting in a nearly universal fire deficit in forests (Parks et al. 2015, Parks and Abatzoglou 2020).

Adapting Forests to Wildfires and Climate Change

Prichard et al. (2021) address 10 key questions surrounding active forest management, address the assumption that historical fire regimes were "natural" rather than cultural, and describe conditions where specific management actions are appropriate and effective for adapting current forests to wildfires and climate change. The authors again use a strength of scientific evidence approach to show why the answers to the 10 questions are relatively straightforward. In addition to evaluating the efficacy of diverse treatments to moderate expected fire severity, they discuss these questions in the context of their consistency with more holistic climate- and wildfire-adaptation strategies that are designed to achieve many social and ecological benefits. Moreover, they discuss how methods designed to achieve a single objective often fail given contemporary goals for multi-objective landscape management. We summarize their responses to the 10 questions here.

1) *Are the effects of fire exclusion overstated? If so, are treatments unwarranted and even counterproductive?*

19395582, 2021, 8, Downloaded from https://esajournals.onlinelibrary.wiley.com/doi/10.1002/eap.2432, Wiley Online Library on [30/12/2022]. FIG. 2. Top photo: View from atop Slate Peak in northeastern Washington, looking southwest, 1934, George Clisby photograph, National Archives, Seattle, Washington, USA. The 1934 panoramic view shows extensive evidence of prior wildfires, varied age classes of cold forest, and recently burned and recovering areas. In the same view nearly eight decades later (bottom photo, 2013, John Marshall Photography), note the complete absence of recent fire evidence, widespread ingrowth creating denser forests, loss of nonforest, and lack of forest successional heterogeneity.

Prichard et al. (2021) dispute all parts of this question. They reveal four crucial components in their answer, not the least of which is that increasing forest resilience and resistance to wildfires and climate change provides positive societal and ecosystem benefits, which overwhelm uncertainties about prior historical conditions. They also show that intentional forest management is effective and corrective where practiced, but its pace and footprint are insufficient to current needs.

2) *Is forest thinning alone sufficient to mitigate wildfire hazard?* Whether forest thinning achieves adaptation objectives depends on several factors, including its timing, location, rate, and spatial scale. Reducing canopy layering and density limits crownfire potential, but unless the abundance and connectivity of surface fuels and fuel ladders is also reduced, thinning can have limited effectiveness in mitigating wildfire severity, and may make matters worse. In forest thinning for adaptation to climate change and wildfires, emphasis is placed on residual forest structure, composition, and understory fuels rather than on the trees that are removed (Larson and Churchill 2012, Churchill et al. 2013).
3) *Can forest thinning and prescribed burning achieve climate adaptation?* Coupled thinning and prescribed burning treatments are proven approaches to mitigating wildfire severity in many seasonally dry forests, but they are not appropriate to all forest types, land allocations, and conditions. These treatments require regular maintenance application of prescribed or cultural burning to maintain low surface fuel levels and remove developing fuel ladders. The vast scale of ongoing fuel reduction necessitates wise use of naturally ignited future fires during moderate fire weather as well.
4) *Should active forest management, including forest thinning, be concentrated in the wildland urban interface (WUI)?* Fuel treatments in the WUI are critically important as is reducing continued development in high fire danger areas (Balch et al. 2017, Radeloff et al. 2018). People living in the WUI have ample incentive to reduce their vulnerability to wildfires (Cohen 2000), and many resources are available to

19395582, 2021, 8, Downloaded from https://esajournals.onlinelibrary.wiley.com/doi/10.1002/eap.2432, Wiley Online Library on [30/12/2022]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

help them do so (Syphard et al. 2012; *resources available online*).[7,8] However, this logic, concentrating treatments in WUI, fails to address interconnectedness between social and ecological systems in landscapes beyond the WUI. Examples include wildfire emissions and broad-scale smoke movement in the atmosphere; water quality and quantity provided by municipal watersheds distant from population centers; ember attack on WUI areas from wildfires burning several kilometers away; wildfire effects on power, WIFI, and broadband transmission and distribution networks; and tribal connections to ancestral territories and resources. It also avoids core decisions related to human social values for forested landscapes and long-term ecosystem dynamics. Alternatively, intentional forest management both within and beyond the WUI offers the greatest social and ecological benefits.

5) *Can wildfires on their own do the work of fuel treatments?* Many forests are experiencing rapid WUI expansion, leaving land managers and citizens increasingly unwilling to accept the risks of managed wildfires In the backcountry, some wildfires are allowed to burn under specified conditions to achieve incident and resource management objectives. However, the effects of fire exclusion are varied and extensive, and managed wildfire is a spatially imprecise tool. To increase predictability of outcomes, application during benign to moderate fire weather may be preferred; this, however, necessitates numerous follow-up treatments to meet objectives, and it broadens the period of landscape vulnerability to more extreme wildfires. Considering the narrow seasonal operating window and spatial imprecision concerns, managed wildfires cannot be a cure-all, but can be one of several options in a broader toolkit.
6) *Is the primary objective of fuel reduction treatments to assist in future firefighting response and containment?* The central objective of fuel treatments is to moderate fire behavior when fire inevitably returns, not to stop fire spread or reduce ignitions If fuel treatments simply improve suppression success, less area is burned in the short term but more area will escape control in the future, resulting in deferred risk and contributing to larger and more often severe wildfires.
7) *Do fuel treatments work under extreme fire weather?* Many studies show that fuel reduction treatments are effective at moderating subsequent fire severity, even under extreme weather Far fewer experimental or empirical studies challenge this premise. Moreover, there is strong evidence that some prior burn and reburn mosaics reduce landscape contagion, which limits subsequent spread and severity of wildfires.
8) *Is the scale of the problem too great? Can we ever catch up?* Given the scale of the area burned by wildfires each decade compared to area treated, some surmise that fuel treatments are futile Nevertheless, a large body of work shows that fuel reduction treatments, including portions of some past wildfires, effectively mitigate subsequent fire behavior and effects. It follows that strategies can be developed to increase rather than decrease the role of fuel reduction treatments. The key to defining the locations, spatial scale, timing, rate of treatment, and methods used is the desired forest–nonforest conditions that result, their degree of adaptation to changing climate and fire regime conditions, and the degree of comfort with spatial uncertainty of outcomes. Moreover, coupling Indigenous cultural burning, fuel reduction, and prescribed fire treatments furthers Indigenous fire stewardship and food security (Sowerwine et al. 2019*a*,*b*), and recovers opportunities for tribal engagement in resource management within their ancestral territories (Long and Lake 2018, Long et al. 2020).
9) *Will planting more trees in wNA forests help to mitigate climate change?* Widespread tree planting has been proposed as a key climate change mitigation (Bastin et al 2019). This premise has poor scientific support in many fire-prone regions of the world (e.g., Grainger et al. 2019, Lewis et al. 2019, Veldman et al. 2019). An increasing body of evidence reveals that proactive management to restore more resilient forest and nonforest structure and composition over large areas, and diversifying tree planting species mixes, can more effectively maintain or increase carbon stores relative to the effects of modern wildfires (e.g., see Hof et al. 2017).
10) *Is post-fire management needed or even ecologically justified?* Prior to fire exclusion, historical landscapes in seasonally dry regions of wNA were the product of complex mosaics of low-, moderate- and high-severity fire patches, which yielded highly variable patterns of surviving forest and scattered fire refugia (ie., unburned patches that functioned as seed sources for postfire tree regeneration in their vicinity). After contemporaneous wildfires, this mosaic is often simplified by large high-severity fire patches, and fire refugia are operationally burned out in closing suppression actions. Within one to two decades after a high-severity fire, dead wood accumulations contribute to uncharacteristically high surface fuel loads. Post-fire removal of the dead understory stems (i.e., those that had previously colonized the landscape during the lengthy period of fire exclusion) by harvest or reburning can mimic this historical reburn influence, thereby minimizing surface fuels in some developing new forests (Stevens-Rumann and Morgan 2016), and reducing future wildfire vulnerability (Coppoletta et al. 2016). The ecological justification for this post-fire removal of the smaller dead understory trees can be

observed in the low surface fuel loads associated with the frequent reburning of pre-management era landscapes and modern-day wilderness areas. It is also clearly revealed in intentional Indigenous cultural burning practices. Indigenous fire stewardship actively mediated post-fire landscape effects to stagger the availability of desired resources and species over time, and ensure their quality, quantity, and abundance (Boyd 1999, Lake and Christianson 2019).

Strategies for Adapting Western Landscapes

Changes in forested landscapes throughout wNA are somewhat unique geographically, as are the stories of change. To consider appropriate climate and wildfire adaptation strategies, managers are compelled to evaluate current vegetation and fuel conditions, the influences that precipitated changes in conditions, the magnitude of the changes, ecological and social constraints to adaptation, patch to landscape vulnerability to changing climatic and wildfire regimes, and nonnative species and any sensitive or endangered species concerns.

Stephens et al. (2010) recommend four strategies for adapting western landscapes to changing climatic and wildfire regimes, and they can be applied in a variety of contexts. They define *resistance* work as that which mitigates expected wildfire effects and protects valued resources, while *realignment* work modifies existing conditions to restore key ecosystem patterns and the processes they drive. Creating *resilient* conditions improves the natural capacity of an ecosystem to respond favorably when unplanned disturbances occur. Finally, they present *response* work as any intentional facilitation to achieve socially and ecologically desirable results that are otherwise difficult to achieve. Each of these strategies can play a role in proactive management going forward. Where their application also considers Indigenous cultural adaptations to climate, vital ecosystem processes, and active cultural use of fire, there will be greater likelihood that resulting vegetation conditions are strongly linked to culturally valued resources and services (Power et al. 2018).

Whether reactive or proactive fire management

Modern wildfire suppression extinguishes essentially all fire starts except those that overwhelm fire suppression capacity and can only be extinguished when aided by a significant change in the weather (North et al. 2015). Fires burning under extreme fire weather often burn vast areas, much larger than the current footprint of managed wildfires and other fuel treatment projects. As a consequence, wildfires that escape initial suppression efforts burn under the most extreme fire weather conditions and do most of the vegetation management in wNA ecosystems (Calkin et al. 2005, North et al. 2015). Appropriately designed thinning, burning, and managed wildfire treatments, that are tailored to topo-edaphic conditions would be helpful additions to this scenario (sensu Taylor and Skinner 2003, Hessburg et al. 2015). Such treatments would prepare landscapes for wildfires that will inevitably follow.

Managing wildfires that burn under extreme fire weather is a blunt management response, which most often results in failure to meet resource management or conservation objectives. Science-based strategies for forest and fuel management are well known, but lack of social license and sufficient financial and personnel resources currently limit fuel reduction programs to a small percentage of wNA forestlands (Hessburg et al. 2020). Increasing costs of fire suppression and lack of control during large fire growth days reveals a reactive management posture that is progressively prone to failure, despite ever-increasing investments (North et al. 2015, Stephens et al. 2020). Thus, a business-as-usual approach to wildfire in fire-prone regions will not solve the current wildfire dilemma (Moreira et al. 2020). Strategic management of regional landscapes is needed that establishes topographically sensible (sensu Povak et al. 2018 and Taylor and Skinner 2003), fire-maintained, control and anchor points (e.g., see Wei et al. 2019). This would improve fire manager usage of future wildfires as adaptation tools.

A more proactive and evidence-based management goal is to restore active wildland fire regimes and landscape resilience to climate change, and actively enable future wildland fires, prescribed and cultural burning, and managed wildfire to provide a higher standard of social-ecological work. To achieve this goal, massive progress and investment are needed (Madeira and Gartner 2018) to transition management from a reactive to a proactive, forward-looking stance. Such an approach allows for the direct adaptation of wildfire regimes by intentionally crafting landscape patterns that drive more benign fire behavior and less severe drought effects. This will require radically increasing the areal extent of restorative and adaptive fuel reduction treatments as is appropriate to conditions and land allocations. It will also require increased use of natural wildfire ignitions (as above) under moderate fire weather conditions, to recapture the once extensive moderate influences of wildfires, and then maintain that progress with controlled (prescribed and cultural) burning and thinning as needed.

The nested character of regional landscapes holds adaptation clues

The hierarchical organization of historical wNA landscapes influences countless ecosystem functions, including scale-dependent spatial and temporal controls that drive wildfire behavior and effects, and the cross-connection between levels of organization. Characteristics of this organization and its influence on ecosystem

19395582, 2021, 8, Downloaded from https://esajournals.onlinelibrary.wiley.com/doi/10.1002/eap.2432, Wiley Online Library on [30/12/2022]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

functions can inform realignment of current systems with early 21st-century and projected future climates (Hessburg et al. 2016, 2019). Three important ideas associated with that nested structure are that (1) at a fine spatial scale, species traits and adaptations drive within-patch structure, composition, and response to disturbances; (2) cross-connections between fine-scale patch structure and composition and meso-scale landscape patchworks influence fire frequency and severity because they form the percolation surface where disturbance propagates, and the manner of propagation; and (3) cross-connections between non-forest and forested landscapes mediate broad spatial patterns of fire behavior attributes and their effects. These three ideas help shape a scientifically supported landscape adaptation framework (Hessburg et al. 2015, 2019).

Additionally, we are learning through integration of western science with traditional ecological knowledge that Indigenous fire use and broader landscape stewardship practices were upheld in tribal communities as human services for ecosystems. Indigenous tribes acknowledged and promoted multi-generational contributions to foster landscape resistance and resilience. Trans-generational fire use also promoted post-fire recovery of landscapes and habitats where culturally valued drought-tolerant, fire-adapted plant species were adversely influenced by a fire (Huffman 2013).

Beyond the Precautionary Principle

The precautionary principle holds that when the potential for adverse effects is unknown or difficult to quantify; the burden of proof rests on the proponent of an activity to demonstrate that lack of harm is the most likely outcome. However, it is virtually impossible to demonstrate lack of harm for most any activity, including no action, especially in a rapidly changing environment. Moreover, one-sided, or single-issue application of the principle can overlook desired ecosystem services, species, and processes that proactive work could have protected. Given human influence on climate and wildfire regimes the world over, a no-action alternative that purports to let so-called natural processes like modern wildfires operate unfettered is grossly misleading. These processes are operating within a human-influenced template globally, and their regime characteristics and fuel conditions have been altered by humans, increasing the likelihood that large portions of many modern wildfires are unnatural.

Modern wildfire management dominated by fire suppression is perceived by many as a no-action alternative when compared to active restoration and adaptation in planning and management. However, active suppression of 98% of wildfire ignitions (North et al. 2015) hardly qualifies as no action, as we have shown earlier. The small proportion of wildfires that escape containment all too often rapidly and indiscriminately convert forest to non-forest conditions. This is an altogether unevaluated planning outcome, and the recovery of forest structure and processes can take decades to centuries, if it occurs at all. Furthermore, fire suppression costs currently exceed US$2 billion annually, not including loss of life and property, and detrimental impacts to lifeways, human health, and livelihoods, while the total annualized economic burden of wildfires ranges from US$71 billion to US$347 billion (Thomas et al. 2017; data *available online*).[9]

The precautionary principle is indeed useful guidance, but it must be applied equally to what are often mistakenly perceived as no-action alternatives. Lacking this clarity, broad application of the precautionary principle as a conservation approach can result in greater long-term harm than more ecologically intuitive remedies, as can be seen within the Northwest Forest Plan area of the eastern Cascade and Klamath Mountain regions (Spies et al. 2019, Stephens et al. 2019). There, networks of late-successional reserves (LSRs) for the northern spotted owl in seasonally dry, historically frequent-fire forests increase the likelihood of their elimination by extreme wildfire events (Henson et al 2013, Spies et al. 2018, 2019). There is simply too much at stake to require unattainable certainty about potential risk of harm or losses (Wood and Jones 2019).

The precautionary principle can become the "paralyzing principle" given irreducible uncertainty about risk of loss associated with action and no-action alternatives (Sunstein 2003). The loss of ˜30 million mature and old pine trees during a recent extreme drought in south-central California (Asner et al. 2016) is a stark reminder of the pitfall of requiring unduly high certainty despite decades of established science showing the efficacy of treatments that foster resilient forest structure and composition (Henson et al. 2018, Fettig et al. 2019). Absent 150–170 yr of frequent fires, overgrown forest density conditions produced a massive and predictable die-off event, facilitated by tree-killing bark beetles and drought, that proactive implementation of climate- and wildfire-adaptation strategies could have mitigated (Stephens et al. 2018, Fettig et al. 2019). Remedying such conditions would have required careful consideration of changes over the period of fire exclusion, the effects of climatic changes looking forward, and any related ESA (Endangered Species Act) concerns.

Dealing with uncertainty

There is much uncertainty to science, including that surrounding our knowledge of historical and contemporary forest ecology, future conditions, and adaptive forest management. In that light, active forest management projects with objectives of restoring more resilient and resistant structure and composition can be assessed using a set of questions to address the relative

[9] https://www.nifc.gov/fireInfo/fireInfo_documents/SuppCosts.pdf.

19395582, 2021, 8, Downloaded from https://esajournals.onlinelibrary.wiley.com/doi/10.1002/eap.2432, Wiley Online Library on [30/12/2022]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

uncertainty associated with proactive versus reactive treatment alternatives. For example, in the context of changing wildfire regimes and climatic conditions, what are the uncertainties, trade-offs, and likely consequences to U.S., Canadian, and Mexican Indigenous and non-indigenous people, infrastructure, ecosystems, native species and habitats of

1) Restoring active fire regimes to dry, moist, and cold forest ecosystems,
2) Continued fire suppression in these same forest types,
3) Proposed proactive, reactive, and no-action management alternatives,
4) Post-fire forest regeneration under action and no-action alternatives, and
5) Post-fire harvest/non-harvest of the younger fire-killed trees to mimic reburns?

Reframing Management and Policy

As demonstrated in literature reviews, the disturbance ecology of an ecosystem may still be the most valuable lens through which climate-related events and outcomes may be understood (Long 2009, Newman 2019, Franklin and Johnson 2013). Over millennia, Indigenous fire use in many areas amplified fire frequency to reduce the likelihood of more extreme wildfires and their effects on culturally valued resources and conditions. This culturally modified disturbance regime increased the resilience and resistance of vegetation and landscape conditions to changing climatic conditions and associated disturbances.

More recently, ecological forestry principles recognize the value of management planning that incorporates the influence of natural disturbance processes on forest dynamics (Franklin et al. 2018). Additionally, as shown by Indigenous experience, natural lightning ignitions can be supplemented to achieve desired conditions. In uncertain times, management might better focus on the long-term persistence of that native biodiversity that evolved within the local, culturally enhanced, disturbance regime, and will likely go extinct with rapid or extreme changes to those regime properties (Newman 2019). Where possible, adapting local landscapes to conserve key aspects of culturally enhanced disturbance regimes could be vital to preserving functioning ecosystems and to the native biodiversity that requires non-extreme disturbance for its continued existence (Franklin and Johnson 2012, North et al. 2014), even where single-species conservation and broader ecosystem goals may appear to be in conflict at other scales (Henson et al. 2013).

Managers and scientists have repeatedly proposed management directions that incorporate knowledge of disturbance ecology and methods that adequately mimic and recover local disturbance regimes; however, socioeconomic challenges have impeded widespread implementation of these strategies (Long 2009). Effective direction would be proactive rather than reactive, recognizing that just as with human society, all desired ecological outcomes are not possible in the same place, at the same time.

Recommendations

In this light, what constitutes adaptation of wNA forests in these uncertain times? Is bias for action rather than inaction recommended?

Scientific knowledge is always growing and incomplete. However, a preponderance of evidence suggests that proactive management can prepare many landscapes for future wildfires and the maintenance work they can provide. This would also reduce emphasis on high-maintenance solutions and the overarching and increasingly burdensome role of wildfire suppression and its expenditures.

Emphasize whole landscape and multi-scale adaptation.—Stand management as applied to western U.S. and Canadian public lands typically emphasizes forested areas where there are commercial opportunities for mechanical treatments in specific stands of trees. This focus misses many locations where proactive treatments may be most useful to adapting an entire landscape. Conducting whole landscape evaluations of forest conditions, fire regime departures, and expected future climate and weather conditions can powerfully aid in defining those places that would most benefit from adaptation treatments (North et al. 2009, Hessburg et al. 2013, 2016, Meyer et al. 2021).

Ongoing collaborative partnerships also recommend that emphasis on timber volume production from public lands has a negative influence on partner support for projects and trust maintenance (Hessburg et al. 2020), and it tends to force the hand of managers to rank commercial treatments over others that may be more truly adaptive. Alternatively, management and planning that emphasizes area restored and adapted could build trust and a broader base of support, while still providing timber volume to sustain rural mills and economies (Rummer et al. 2005). Increasingly, collaborative restoration partnerships with Indigenous communities, having tribes as part of the leadership and management, can increase opportunities for reinstating tribal stewardship practices, with tribes, local communities, and the broader society as beneficiaries of active management that achieves shared values (Lake et al. 2018, Long and Lake 2018).

Large and old trees.—Most research reveals that broadly conserving large and old fire-resistant trees and replacing those that were removed or killed by harvest, drought, insects, pathogens, and wildfires provides a strong backbone of resilient structure and habitat to seasonally dry pine and mixed-conifer ecosystems (Spies et al. 2018, 2019).

19395582, 2021, 8, Downloaded from https://esajournals.onlinelibrary.wiley.com/doi/10.1002/eap.2432, Wiley Online Library on [30/12/2022]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

Clumped and gapped trees.—As is appropriate to local seasonally dry forest types, restoring tree clump and gap patterns, and increasing area of these conditions will provide a solid patch-to-local landscape bet-hedging strategy in a warming future with increasing burned area (Larson and Churchill 2012, Churchill et al. 2013, LeFevre et al. 2020).

Successionally heterogeneous forests.—Successional heterogeneity, whether fine-, meso-, or coarse-grained, was an historical consequence of patterns of environmental productivity and fire–climate interactions with vegetation. It reinforced a continual shifting of diverse but similar patterns of heterogeneity at each scale of observation. As is appropriate to forest types and physiographic domains, restoring and maintaining forms of this heterogeneity will encourage a wider variety of wildfire and habitat outcomes, and reduce the need for aggressive fire suppression in many areas (Perry et al. 2011). This can be accomplished by adapting current spatial patterns of seral stages to more frequent burning and reburning (Stephens et al. 2020). Indigenous and Western knowledge can jointly aid in determining how best to adapt current and projected future conditions.

Using the topo-edaphic template.—Throughout wNA, topography, geomorphology, lithologies, and soils provide the template for spatially varying forest cover types, structural conditions, and their variations (Taylor and Skinner 2003, Hessburg et al. 2015). Fire exclusion and other influences have weakened connections to this template. Realigning spatial patterns of nonforest and forest successional pattern conditions (e.g., open vs. closed canopy, fire-tolerant vs. intolerant species) to this template will aid in adapting landscapes to changing climatic and wildfire regimes. For example, restoring non-forest and low-density forest cover patches to south-facing slopes and ridgetops and higher-density forest cover patches on north aspects and valley bottoms are examples of strengthening connections to the topographic template (Hessburg et al. 2015, 2019). These underlying conditions continually co-create the environments for disturbance and revegetation as the climate changes (Taylor and Skinner 2003, Hessburg et al. 2015, 2016).

Forests and their nonforests.—Meadows, shrublands, savannahs, and preforest conditions result from natural succession, disturbance dynamics, and reburning (Prichard et al. 2017). Restoring more characteristic nonforest-forest patterns in and among all forest types at fine, meso, and broad scales could significantly realign primary ecosystem processes, carbon storage, and hydrologic regimes with the warming climate (Shakesby and Doerr 2006). As recent history has shown, many pre-fire-suppression era nonforest areas throughout wNA became forested absent active fire regimes during the mild mid-20th-century climatic period (Hessburg et al. 2019).

Research Needs

The reviews of Hagmann et al. (2021) and Prichard et al. (2021) show deepening understanding of the fire and landscape ecology of wNA forests; however, substantive knowledge gaps remain. Here, we discuss the following research needs that emerged from this review:.

1) *Fortifying future vegetation and wildfire projections with insights from landscape ecology research* Most continental to regional projections of climate influence on biotic conditions and physical processes use a range of intuitive climatic drivers to explain responses to warming (Rosenzweig et al. 2008, Parks et al. 2015, Abatzoglou and Williams 2016). Outcomes are presented as ostensibly unaffected by bottom-up or meso-scale spatial variation in biotic, environmental, disturbance history, or topoedaphic conditions inherent to the system(s) of interest. From the standpoint of landscape ecology theory and practice, this approach misses key cross-scale interactions between the climate system and highly varying biophysical settings, which are known to modify climate system inputs and alter spatial and temporal patterns of realized conditions (Wu and Loucks 1995). Hurteau et al. (2019) for example, showed that future projections of burned area under climate change, which accounted for interactions among prior fires on surface and canopy fuel availability, reduced area burned by 14.3% in the Sierra Nevada compared to projections where only climate drivers were considered. Hybrid research and modeling are needed among climate change scientists and landscape ecologists to improve projections of vegetation and burned area changes, and species ranges.
2) *Multi-proxy evidence is more informative than single proxy* Observing and integrating knowledge of the multi-level dimensions of forest landscapes and their wildfire regimes provides deeper insight into how patterns influence processes, and it improves change detection (Hagmann et al. 2021). Some regions are already represented by multi-level studies, but in some cases, they could be better integrated. Multiscale and multi-proxy historical reconstructions are still needed for other regions of wNA to better understand variations in forest–nonforest relations and successional heterogeneity that are better aligned with changing climatic and wildfire regimes. With these insights, managers and policy-makers will be better able to understand how warming and drying may affect adaptation strategies.
3) *More wildfire–forest dynamics carbon research is needed* Recent studies show that strategies for adapting current forests to wildfires and climate change may result in more terrestrial carbon storage than business-as-usual scenarios. The reason is that large fuel buildup under fire exclusion renders forest carbon stores vulnerable to large, high-severity fire

19395582, 2021, 8, Downloaded from https://esajournals.onlinelibrary.wiley.com/doi/10.1002/eap.2432, Wiley Online Library on [30/12/2022]. events (Liang et al. 2018, Hurteau et al. 2019). This nascent inquiry area deserves significant investment and increased scope to determine suitable landscape management strategies, and where they may best apply.

4) *Disturbance–fish-and-wildlife-habitat connections* As Newman (2019) suggests, native species and their habitats are tied to disturbance regimes of local and regional landscapes. Our current knowledge of these species-disturbance regime linkages is weak in many areas and could be much better understood. Even where 25 yr of research is available for one of the most intensively studied bird species, that knowledge is not preventing population declines for Northern Spotted Owls (Spies et al. 2019, Stephens et al. 2019). As a result, Henson et al. (2018) advocated a coarse-filter approach that incorporates disturbance ecology in management for spotted owl habitat. Understanding and managing spatial domains to restore these more functional disturbance regimes is an intuitive coarse-filter conservation strategy for terrestrial and aquatic species.
5) *A role for decision support tools* Predicting future vegetation, climate, and wildfire conditions, and trade-offs among various habitats and resources across a set of potential management scenarios is intellectually and computationally challenging. Considering the large number of data layers, the one-to-many and many-to-one interactions among conditions represented by these layers, and variation in these relationships by scenario thwarts careful evaluation by even the best planning intellects. Decision support tools are designed for this complex and integrated planning environment and are useful for evaluating trade-offs among changing conditions, outcomes, and management scenarios (Kangas and Kangas 2005, Reynolds et al. 2014). Using such tools, managers and scientists can observe trade-offs and related positive and negative cascades associated with varied management scenarios and discover their primary drivers.
6) *Innovation and investment in multi-party monitoring and adaptive management* Adaptive forest management has been recommended by scientists and managers for decades (Lee 1999), however, it has functioned more as an abstraction than an applied reality (Bormann et al. 2007). While adaptive management provided the core of Indigenous landscape management methods (Anderson 2013), there are several key reasons for delayed application in contemporary management. Adaptive management depends on watchful learning; what we today call ecosystem monitoring, which can be time consuming and expensive, and results often come after lengthy delays. Sufficient monitoring is rarely budgeted for, and consequently, an adaptive process is inhibited. Without agreement on the monitoring questions and goals of management, disputes remain unresolved. Innovation and investment are needed in this area to develop better methods of multi-party goal setting, and efficient and inexpensive means of monitoring; for example, multi-scale photography or remote sensing in addition to intensive plot and survey application. Another monitoring approach proposed by Tribes is to use cultural keystone species as indicators of ecosystem integrity and function (Garibaldi and Turner 2004). Results from monitoring a representative subset of forest conditions and projects could be extrapolated to similar conditions. This would enable more rapid learning and implementation, which are core concerns. Effective learning of this sort will become more essential as expanding human populations search for better ways to live sustainably on increasingly dynamic wNA landscapes.

Conclusions

Here, we have described how policy and management choices of the last two centuries yielded forest conditions throughout much of wNA that are vulnerable to the effects of rapid climatic warming, including increasing fire and drought severity. We summarized core messages of Hagmann et al. (2021) and Prichard et al. (2021), detailing widespread changes in forested landscapes and wildfire regimes since the influx of European colonists, and addressing popular questions about the capacity of management practices to reverse or mitigate the worst effects of these changes. We address concerns about the influence of agenda-driven science and reiterate that the *precautionary principle* can become the *paralyzing principle* given uncertainty about the risk of losses associated with action and no-action alternatives. We discussed the near impossibility of demonstrating lack of harm for most any action, including inaction, especially in a rapidly changing environment.

We provided recommendations for reframing forest and fire management and their related policy underpinnings, emphasizing (1) whole landscape and multi-scale adaptation; (2) protection of large and old fire- and drought-tolerant trees and old forests; (3) restoration of clumped and gapped tree patterns at fine and meso spatial scales; (4) creation of successionally heterogeneous forests; (5) use of topography to realign current conditions to the biophysical template; and (6) restoration of nonforest conditions. Climate change will create more nonforest and more young open canopy forest conditions (Parks et al. 2016, Hessburg et al. 2019, Coop et al. 2020); the opportunity for management is to place those conditions and patch sizes in locations that provide the greatest social and ecological benefits while conserving and recruiting old trees and old forest where possible.

Some today call for cultivating pyrodiversity to advance biodiversity (Parr and Andersen 2006, Taylor et al. 2012, Bowman et al. 2016). However, not all heterogeneity is equally well adapted to the topography, soils, and varied environmental settings and fire

19395582, 2021, 8, Downloaded from https://esajournals.onlinelibrary.wiley.com/doi/10.1002/eap.2432, Wiley Online Library on [30/12/2022]. regimes of wNA landscapes, and thus may endanger native biodiversity. Climate and wildfire adaptation requires structural and compositional patterns and pattern variations that are in synch with biophysical settings, reinforce the desired fire regimes, and reduce undesirable impacts of climatic warming to socioecological communities.

We close our review with a short list of research needs. Key among them is the need to better understand the disturbance regimes that native plants and animals evolved with and through which persistence occurred even as we act proactively to restore pattern–process interactions and adapt these landscapes to warming climate. Most legal battles concerning forest management today are about native biodiversity, old tree or old forest conservation, conservation of threatened and endangered species, and impacts of timber harvesting. Yet, native species and their habitats are tied to disturbance regimes of local and regional landscapes and their pattern variations. Our current knowledge of these species-disturbance regime linkages is weak, yet these dynamics might become a focal means of biodiversity conservation (Henson et al. 2013).

Finally, we discussed how some of these climatic and fire regime effects were common to landscapes inhabited by the Indigenous people of wNA, and in closing, we return to those ideas. Because of significant vulnerabilities linked to native wildfire regimes, Indigenous people intentionally managed wildfire for millennia to provide a broad variety of life-supporting resources, food and medicine security, protect lifeways, sacred places, and deeply held traditions, and to increase personal safety. This intentional management was a transgenerational commitment; prior generations took responsibility for the quality and abundance of desired conditions they passed on to subsequent generations. Since the mid-1850s, the majority of EuroAmerican colonists and present-day citizens have neither practiced this intentional management nor passed on a transgenerational commitment. Yet, we are ever more dependent as a society on the ecosystem services that functional fire-adapted landscapes provide. Given the known risks of modern wildfires and climate change, embracing the role of fire and a return to intentional transgenerational management is of critical importance.

Acknowledgments

The authors acknowledge constructive reviews by Keith Reynolds, Jamie Rosen, Derek Churchill, Gavin Jones, and two anonymous reviewers. We are grateful to David Schimel for the invitation to publish this small collection of papers, and to Brion Salter for cartography. We appreciate funding by the U.S. Fish and Wildlife Service, The Wilderness Society; The Nature Conservancy, Oregon; Conservation Northwest; The Ecological Restoration Institute; Washington State Department of Natural Resources; USDA-FS, the Pacific Northwest and Pacific Southwest Research Stations, and the California Department of Forestry and Fire Protection in support of these reviews.

Carbon dynamics of Oregon and Northern California forests and potential land-based carbon storage

Tara Hudiburg,[1] Beverly Law, David P. Turner, John Campbell, Dan Donato, and Maureen Duane

Department of Forest Science, Oregon State University, Corvallis, Oregon 97331 USA

Abstract. Net uptake of carbon from the atmosphere (net ecosystem production, NEP) is dependent on climate, disturbance history, management practices, forest age, and forest type. To improve understanding of the influence of these factors on forest carbon stocks and flux in the western United States, federal inventory data and supplemental field measurements at additional plots were used to estimate several important components of the carbon balance in forests in Oregon and Northern California during the 1990s. Species- and ecoregion-specific allometric equations were used to estimate live and dead biomass stores, net primary productivity (NPP), and mortality. In the semiarid East Cascades and mesic Coast Range, mean total biomass was 8 and 24 kg C/m^2, and mean NPP was 0.30 and 0.78 kg C·m^{-2}·yr^{-1}, respectively. Maximum NPP and dead biomass stores were most influenced by climate, whereas maximum live biomass stores and mortality were most influenced by forest type. Within ecoregions, mean live and dead biomass were usually higher on public lands, primarily because of the younger age class distribution on private lands. Decrease in NPP with age was not general across ecoregions, with no marked decline in old stands (>200 years old) in some ecoregions. In the absence of stand-replacing disturbance, total landscape carbon stocks could theoretically increase from 3.2 ± 0.34 Pg C to 5.9 ± 1.34 Pg C (a 46% increase) if forests were managed for maximum carbon storage. Although the theoretical limit is probably unattainable, given the timber-based economy and fire regimes in some ecoregions, there is still potential to significantly increase the land-based carbon storage by increasing rotation age and reducing harvest rates.

Key words: carbon cycle; climate regime; coarse woody debris, CWD; inventory data; management; mortality rates; net primary production; west-coast forests, USA.

Introduction

The amount of carbon sequestered by forest ecosystems plays an important role in regulating atmospheric levels of carbon dioxide (Canadell et al. 2007, Denman et al. 2007). Factors affecting the amount and rate at which forests sequester carbon include climate, disturbance, management, land use history, and species composition (Peet 1981, Harcombe et al. 1990, Law et al. 2004, Krankina et al. 2005, Gough et al. 2007). Pending and future forest management policies are attempting to offset anthropogenic carbon dioxide emissions by increasing and maintaining land-based sinks of carbon (IPCC 2007). Thus, it is important to quantify current and potential forest carbon pools and fluxes, and to understand factors that account for geographic variation.

Of particular interest is examination of age-specific trends. Commonly accepted patterns of live biomass accumulation and NPP in relation to stand age show a stabilization or decline as stands age (Bormann and Likens 1969, Odum 1969, Peet 1981). These patterns have been identified using a variety of small-scale ecological studies that tend to select homogeneous stands (McCune and Menges 1986). However, because federal inventory plots are located in all types of stands (including transitional forests, uneven-aged stands, and areas that have experienced partial disturbances), the patterns of growth that emerge from inventory data may not follow idealized trends. The distinction between patterns elucidated from a sample of forest plots selected based on defined structural criteria, and a sample of stands selected regularly from the entire population is important when validating process models applied across landscapes (e.g., Jenkins et al. 2001). For this reason the patterns of carbon pools and fluxes over time, identified in inventory data, are uniquely powerful in that they can reveal collective trends (i.e., average values) in addition to idealized trends (i.e., upper bounds or maximum values).

In this study, data from supplemental field plots (i.e., foliage and fine-root metrics) and federal inventory data (FIA) were used to examine patterns of NPP, mortality, and live and dead carbon stores in different ecoregions of Oregon and Northern California, USA. The objectives were to: (1) identify age-related patterns of mean and maximum live biomass, dead biomass, NPP, and mortality; (2) determine the influence of forest type,

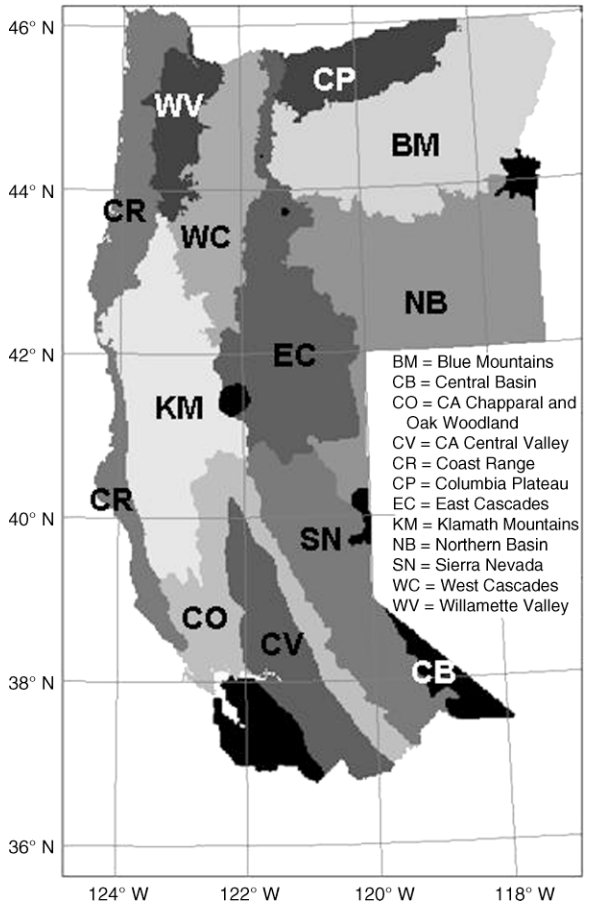

FIG. 1. ORCA study region (Oregon and Northern California, USA) divided by Omernik Level III ecoregions (Omernik 1987); different shades of gray show the different ecoregions.

ecoregion (climate), and ownership (management) on these patterns; (3) quantify total and theoretical forest carbon stocks and NPP over the study region; and (4) investigate the potential for increased land-based carbon sequestration in Oregon and Northern California forests. We examined differences in carbon pools and fluxes due to species composition, climate, and management indicated by forest type, ecoregion, and ownership, respectively. We used the patterns to determine the current land-based total stocks (excluding forest floor and soil carbon) and NPP, as well as the theoretical stocks and NPP in the absence of stand-replacing disturbance. The theoretical estimates are representative of the potential for carbon sequestration in this region through management practices. This study complements studies by Hicke et al. (2007) and Van Tuyl et al. (2005) by including additional carbon pools and fluxes (dead wood and shrub biomass, NPP, and mortality), examining possible causes of variation due to management and climate, and by further refining the estimates of carbon stocks using supplemental data and species- and ecoregion-specific allometrics.

METHODS

Study area

The ORCA project is part of the North American Carbon Program (NACP), where the goal is to quantify and understand the carbon balance of North America. The study area is the entire state of Oregon and the northern half of California (Fig. 1). The disturbance history of the region includes frequent windthrow near the coast, relatively short harvest cycles, and centuries-long fire cycles west of the Cascade crest, moderate-length harvest cycles with more frequent natural fire cycles to the drier east, and livestock grazing in the Great Basin.

The area was divided into 12 ecoregions using the U.S. EPA Level III Omernik classification scheme (Omernik 1987). The ecoregions are classified according to similar biotic and abiotic characteristics, including dominant land cover type, climate, soils, and topography. They encompass several cover types such as chaparral, juniper woodlands, coastal Douglas-fir and hemlock, and true fir alpine forests. Age-related patterns of biomass accumulation, NPP, and mortality were only examined for the dominant six ecoregions (Table 1). Totals and means were calculated for all ecoregions (Appendix: Tables A1 and A2). Approximately 50% of this area is forested land, with 56% under public ownership and 44% under private ownership (Table 1). There is a steep west to east climatic gradient, with annual precipitation ranging from 2510 mm in the Coast Range to 120 mm in the Central Basin.

Data were used from several different inventories collected by federal and state agencies and our field crews. Within plots, allometric calculations were made for each individual tree, shrub, and woody detritus record and summations were made to obtain plot total live and dead biomass carbon estimates per unit ground area and an NPP and mortality estimate per unit ground area per year.

FIA database

The federal inventory program (FIA, Forest Inventory and Analysis) has undergone recent changes in sampling protocols starting in 2001. Historically, states were measured in subsections with a complete inventory of the states completed within 10–12 years (referred to as periodic inventories). The last complete inventory (1991–1999) in Oregon and California is summarized in the Integrated Database version 2.0 or IDB (Waddell and Hiserote 2005). Under a more recent protocol (annual inventory), portions of each subsection are completed each year, with a complete inventory expected by 2010. We chose to use the earlier periodic database because it is the most recent complete cycle and thus more representative of the study region. Our results thus approximate conditions in the mid-1990s.

§ The first value is the percentage of total plots in private vs. public ownership. The second value after the comma is the percentage of total plots that are >200 years old in private vs. public ownership.

There were 14 188 plots with live tree data and 12 380 plots with woody detritus and understory data within the study area boundary (Fig. 1). The inventory design consists of 0.404-ha (1-acre) plots systematically placed across the landscape, encompassing a representative range of stand ages, disturbance histories, ownerships, and land cover types. The inventory data include tree diameter (dbh), actual height, wood increment, age, and species. Understory woody shrub data include percent cover, height, and species. Coarse woody debris and snag data include diameter, decay class, and species. We excluded plots that did not have enough increment data (1290 plots) to suitably calculate a stand age or a radial growth. One or more condition classes were assigned to plots that had more than one ownership, forest type, or disturbance history. Because we were interested in differences due to ownership and forest type, we chose to use plots with only one condition class. There were 4143 multi-condition plots distributed throughout the study area. A separate analysis of live biomass that included the multi-condition plots was done to determine if exclusion of these plots affected the overall results. The ecoregion means for total live biomass were slightly higher in the majority of areas, equivalent in some, and lower in the Coast Range by 0.90 kg C/m^2 (Appendix: Table A3). The regression of the 5-year age bin means for all plots vs. the corresponding single-condition bin means had values ranging from $r^2 = 0.75$ in the Blue Mountains to $r^2 = 0.91$ in the West Cascades.

After exclusions, 8755 plots remained with live tree and understory data, of which 8135 plots had measured woody detritus data. These plots were used to analyze NPP, mortality, and biomass for age-related trends as influenced by ecoregion, management, and forest type. To evaluate and augment the federal inventory plots, we also used data from 170 supplemental field plots systematically dispersed among the ecoregions in the study area. Although these 1-ha plots cover a larger spatial area, the subplot and transect layouts, measurement protocols, and data collected met or exceeded the minimum standards of the federal inventory. Our plot locations were selected using a hierarchical random sampling design based on climate, forest type, and age (Law et al. 2006). The additional sampling was designed to allow a more comprehensive assessment of the carbon stocks and fluxes (Law et al. 2004, Sun et al. 2004, Van Tuyl et al. 2005, Law et al. 2006) by measuring foliage and soil carbon and nitrogen, leaf retention time, foliage and fine-root biomass and production (on selected plots), leaf area index, and litter stocks.

Stand age

Plot stand age was computed as the mean of the oldest 10% of trees (Spies and Franklin 1991, Van Tuyl et al. 2005). In cases where there were fewer than three trees in the oldest 10%, a mean of all aged trees on the plot was used. Stands older than 600 years were grouped into a single age class to account for an increasing trend in within plot variation. Although this method is the appropriate metric to best detect trends in growth and mortality, it is different than age based on time since disturbance and does not include effects of delayed establishment that vary widely (and probably with ecoregion, forest type, and ownership).

Ownership and forest types

Ownership was used as a surrogate for management practices because anthropogenic disturbances (i.e.,

clearcut harvest and thinning) have been more common on privately owned lands than on publicly owned lands in this region (Spies et al. 1994, Cohen et al. 2002). Public lands are defined as all non-private lands (federal, tribal, state, county, and so on). Private lands include small ownerships to large industrial properties.

Inventory plots were assigned a forest type code based on the dominant species on the plot. We grouped forest types into seven classes: (1) fir/Douglas-fir/hemlock, (2) larch and cedar/sequoia/redwood, (3) juniper, (4) spruce, (5) pine, (6) hardwoods, and (7) non-stocked. Non-stocked forest types are assigned to plots with a large percentage of ground area that is unsuitable for growth (i.e., rocky substrates).

Biomass

A database of volume and biomass allometric equations was compiled from prior studies (e.g., Means et al. 1994, Law et al. 2001, Van Tuyl et al. 2005) and new literature. We aimed to apply as many species-specific and ecoregion-specific equations as possible. Biomass estimates for trees included bole, bark, branch, foliage, and coarse roots (Appendix: Table A4). Species-specific wood densities (Maeglin and Wahlgren 1972, Forest Products Laboratory 1974) from wood cores obtained on our 170 supplemental plots were used to convert bole and coarse-root volume to biomass. For standing dead trees, wood densities were reduced according to decay class (Waddell 2002). Tree component biomass estimates were converted to kilograms per unit of ground area by multiplying by the tree-specific trees per hectare (TPH) and by 0.51 to obtain units of carbon (Law et al. 2001). TPH is a scaling factor for each tree record that is based on the sampled area and is supplied by the IDB specifically for generating plot-scale biomass estimates (Waddell and Hiserote 2005).

Fine-root biomass was estimated using an equation from earlier studies (Van Tuyl et al. 2005; Appendix: Table A4) relating leaf area index (LAI) and fine-root biomass. LAI is not measured on inventory plots, but was calculated by dividing foliage biomass (from the allometric equations) by the leaf mass per unit leaf area (LMA). LMA was obtained from a look-up table of species-specific values derived from measurements on the supplemental plots in each of the ecoregions. In some cases, a species-specific value was not available so a closely related (i.e., congeneric) species was used.

The conversion of shrub volume to biomass was from a database of allometric equations based on shrubs harvested at our supplemental plots. In total, 12 species were harvested, covering a wide range of morphology, leaf type, and leaf longevity, allowing for substitution of equations for all species where an equation could not be found. Shrub volume was calculated as the product of the recorded fraction of plot cover, plot area, and height. Coarse woody debris biomass was estimated following Waddell (2002). Biomass was calculated using piece volume, species-specific wood density, and a decay-class density reduction factor.

NPP and mortality

To calculate NPP for a plot, a radial increment is necessary for every tree on the plot. Federal inventory includes stem increment cores for a subsample of the trees on each plot. For our estimates, trees on a plot were divided into dbh quartiles and the mean radial increment of cored trees in each quartile was assigned to all other trees in the same quartile (Sun et al. 2004, Van Tuyl et al. 2005).

Net primary production of all tree woody components was estimated as the difference in biomass at two points in time and was divided by the remeasurement interval (usually about 10 years). A previous dbh and height for each tree were necessary to calculate a previous biomass. Previous dbh was derived by back-calculation from current dbh and the radial increment, and previous height was recorded for remeasured trees or was modeled for unmeasured trees in the previous inventory using height–diameter regression equations from our supplemental plot data and BioPak (Means et al. 1994).

Woody shrub, foliage, and fine-root NPP were calculated using look-up tables constructed from supplemental plot data. Foliage NPP was calculated by dividing foliage biomass per tree by the average foliage retention time (average number of years of foliage that a stand carries). An ecoregion species-specific look-up table of foliage retention values was constructed from data gathered on the supplemental plots. Woody shrub NPP was calculated as a percentage increase in biomass per year. Increment disks from several shrub species were collected on the supplemental plots to produce a look-up table of average percentage increase in biomass for the species in each ecoregion. Fine-root NPP was calculated as the product of fine-root biomass and average fine-root turnover (1.2 $year^{-1}$) obtained from the literature and supplemental plot data (Keyes and Grier 1981, Campbell et al. 2004).

Mortality in kilograms of carbon per meter squared per year was only computed for trees. The IDB has assigned a mortality rate, the probability (0–1) that a given tree may die in one year due to natural causes, to each tree record. It is derived from a ratio of dead-to-live trees that were tallied on plots throughout the inventory area and developed for different groups by species and/or location (Waddell and Hiserote 2005). The amount of mortality expressed as the biomass loss per year can be estimated by multiplying the total live tree biomass by the location and/or species-specific mortality rate.

Statistical analysis

S-PLUS version 7.02 (S-PLUS 2005) was used for all statistical analysis. The questions of interest were addressed by comparing the coefficients of the response functions fit to the age-based distributions. Plots with

stand ages greater than 600 years were grouped into a single age group. Because less than 1% of plots on private land had age groups greater than 200 years, statistical analysis for comparisons between ownerships were restricted to plots aged 200 years or less for both public and private land.

Historically, private land ownership has tended to be located in lower elevation forested areas characterized by higher productivity. We confirmed this difference by comparing mean site index (a measure of site potential productivity) across ownerships for the stand area. We found a significantly higher mean site index value for private lands ($P < 0.01$, by permutation test). To isolate effects of differences in stand age distribution between ownerships from differences in site potential, the public land data set in each ecoregion was randomly subsampled using a constrained range and distribution of site indexes that was defined by private land distributions in the same ecoregion. This distribution was then used for the comparisons across ownerships.

To compare the coefficients of the fitted functions, the data for each ecoregion, ownership, or forest type were first binned into 25-year age groups and a stratified random sample of observations was chosen to ensure that the sample included data points from the entire age range. The appropriate functions were then fit to the sample data set. The sampling process and curve fitting were repeated to obtain 10 different estimates of each coefficient (used to produce a stand error) for each ecoregion and for ownership and forest type within ecoregion. A weighted one-way ANOVA using the coefficient standard errors as the weight was run for each coefficient to test for significant differences. To determine the relative influence of ecoregion, ownership, and forest type on biomass stores, NPP, and mortality across the entire study area and within ecoregion, the data were $\log_e$-transformed and linear regression models were compared using Akaike's information criterion (AIC). For the entire study area, model weights for age only, age + ownership, age + forest type, and age + ecoregion were calculated and ranked to determine the most influential explanatory variable (Burnham and Anderson 2002). Within ecoregion, model weights were calculated for age only, age + ownership and age + forest type.

Chapman-Richards functions (Pienaar and Turnbull 1973) were fit to live biomass and mortality data to compare the amount (mean and maximum) of carbon stored in biomass as a function of age:

$$\text{biomass} = a[1 - \exp(-b \times \text{stand age})]^c \quad (1)$$

where parameter a is the asymptote, or the maximum amount of biomass carbon; parameter b determines the rate in years that it takes to reach the maximum amount; and c is a shaping parameter that gives a Chapman-Richards relationship the characteristic sigmoid shape. Because we were interested in the age at which NPP peaked and started to decline, a peak function (three-parameter, log-normal) was fit to the NPP data:

$$\text{NPP} = a \times \exp\left\{-0.5[\ln(\text{stand age}/c)/b]^2\right\} \quad (2)$$

where parameter a is the asymptote or the maximum NPP; b is the rate to reach maximum; and c represents the age of initial NPP decline.

Woody detritus data can be fit with a standard decay function plus a Chapman-Richards function (Janisch and Harmon 2002). Stands typically start with large stores of legacy dead wood from prior stand development or downed wood caused by disturbance and then start to accumulate dead biomass as they age. The decay function quantifies the decay of the legacy dead wood in clearcut/burned and very young stands and the Chapman-Richards function quantifies the accumulation of dead wood as the stand ages:

$$\text{biomass} = d \times \exp(-e \times \text{stand age}) + a[1 - \exp(-b \times \text{stand age})]^c \quad (3)$$

where parameter d is the initial carbon stores and e is the decay rate in years. Although we were able to fit this function to all of the data in each ecoregion, we were unable to detect a U-shaped pattern with stand age in the smaller random samples used to compare the coefficients of the fitted function. Therefore, the data were divided into three age classes and a permutation test for a difference of means in each age class (by ecoregion or ownership) was used.

All of the above-mentioned curves were fit to both the mean values in each 5-year age bin and to the 99th percentile (hereafter "upper bound") of each age bin. Curves fit to the mean values represent the average realized trends of biomass, mortality, and NPP, whereas the curve fit to the upper bounds should represent the maximum values of stands in the ecoregion given minimal disturbance and ideal site and growing conditions. Curves fit to the upper bounds could also represent what many ecological field studies have documented and therefore what many modelers have used to parameterize and validate model results.

Regional-scale analyses

Total biomass, NPP, and mortality estimates for each ecoregion, state, and the total ORCA study area were obtained as the sum of the product of the relevant forested area using land cover data from Advanced Very High Resolution Radiometer (AVHRR) composite images recorded during the 1991 growing season (USDA Forest Service and U.S. Geological Survey 2002) and the corresponding mean values across all plots. The same procedure was used with GIS ownership coverages (from USGS National Land Cover Data 1992) to isolate patterns by public and private ownerships. Theoretical values for live biomass, dead biomass, and NPP were determined for each forest type × ecoregion combination using the parameter estimates for the maximum (parameter a) from the curve fit to the mean values of the data (note that this was from the

mean trend, not the upper bounds). Although these values should represent the maximum amounts, given a range of site productivities, and also should allow for partial disturbance, the amounts calculated assume the absence of stand-replacing disturbance through full harvest or catastrophic wildfire. Uncertainty estimates for regional stocks and NPP were calculated with a Monte Carlo procedure using the ecoregion mean and standard errors for the current values and the ecoregion parameter *a* estimates and standard errors for theoretical values. Simulations were run using a random normal distribution. We tested the independence assumption by using correlation coefficients for no correlation (0.0) and perfect correlation (1.0). Because the results did not vary significantly, uncertainty estimates for the simulations assuming no correlation are reported. Maps (ArcGIS version 9.1; ESRI 2005) of current mean and potential maximum carbon stocks and NPP were produced using the above results and a forest type land cover layer (USDA Forest Service and U.S. Geological Survey 2002).

Results

Ecoregion patterns

There is strong evidence ($P < 0.001$) that maximum amounts of live biomass and rate of accumulation differ by ecoregion (Fig. 2). The Chapman-Richards function appeared to be a good general equation to describe biomass accumulation (Appendix: Table A5), especially for the upper bounds data in the West Cascades. When fit to the mean values, the maximum amount of live biomass (*a* in Eq. 1) is highest in the Coast Range and Klamath Mountains (33–44 kg C/m^2) and lowest in the East Cascades and Blue Mountains (7–10 kg C/m^2). The rate (*b* in Eq. 1) at which biomass reaches the maximum is lowest in the Klamath Mountains, with maximum stores still increasing at 600 years. Rates are higher in the other ecoregions, yet biomass is still increasing in stands over 300 years in the Coast Range, the Sierra Nevada, and the West Cascades.

We were unable to measure the inputs to or outputs from dead biomass, but we were able to compare the dynamic balance between these processes across ecoregions as measured by the standing mass of dead wood in three age groups (Table 2). There is strong evidence ($P < 0.001$, from a permutation test) that mean dead biomass differs among ecoregions for young, mature, and old stands. The Coast Range and West Cascades had the highest mass of dead wood in all age groups (ranging from 3.1 kg C/m^2 in the young to 4.7 kg C/m^2 in the old). The East Cascades had the lowest mass of dead wood in all age groups (ranging from 0.8 to 1.7 kg C/m^2) and the Klamath Mountains and Sierra Nevada had intermediate levels (ranging from 0.8 to 2.7 kg C/m^2).

The theoretical U-shaped pattern of dead biomass over time (high levels initially after disturbance, followed by low levels as this legacy wood decays, then by high levels as new dead wood is recruited) was mostly apparent in the West Cascades when fit to the upper bounds (Appendix: Table A6), and slightly apparent in the East Cascades and Sierra Nevada (Fig. 3). The pattern was only slightly apparent in the West Cascades when fit to the mean values.

There is strong evidence ($P < 0.001$) that maximum NPP differs among ecoregions (Fig. 4). Maximum NPP peaks earliest in the Coast Range and West Cascades at about 80 years. The most obvious cases of late-successional decline in NPP for the upper-bound data were in the ecoregions with highest maximum NPP (Coast Range, West Cascades, and Klamath Mountains). Interestingly, the Coast Range was the only case of a conspicuous decline in mean NPP with age.

There was strong evidence ($P < 0.001$) that both maximum mortality and the rate at which it is reached differs among ecoregions (Appendix: Table A5). Maximum mortality was highest in the Sierra Nevada, followed by the West Cascades and Klamath Mountains for both the mean trend and upper bounds of the data (Fig. 5). Mortality appeared to increase with stand age and become less predictable in older stands. As a percentage of live biomass, mortality ranged from 0.50% in the Coast Range to 1.20% in the Sierra Nevada for stands younger than 80 years, from 0.35% in the Coast Range to 1.30% in the Sierra Nevada for mature (80–200 year old) stands, and from 0.35% in the Coast Range to 1.35% in the Blue Mountains for old stands (>200 years old).

Ownership patterns

Stand ages varied from 0 to over 1000 years, with a higher frequency of younger stands on private land than public land and more old stands on public lands (Fig. 6). Mean stand age for private ownership ranged from 83 years in the Coast Range to 146 years in the Sierra Nevada (Table 1). Public ownership mean ages ranged from 156 years in the Coast Range to 244 years in the West Cascades, where most of the land is public. There are very few stands older than 250 years on private land.

After accounting for site index, there is strong evidence that mean and maximum biomass differed between ownerships in all but the Blue Mountains and East Cascades ($P < 0.001$), with generally higher values on public lands (parameter *a* in Eq. 1, Appendix: Table A7). Dead biomass was not as consistently influenced by ownership as was live biomass (Table 2).

There is also strong evidence that mean NPP differed between ownerships ($P < 0.001$), being generally lower on public lands. Maximum NPP (parameter *a* in Eq. 2) was lower on public lands in the Coast Range, East Cascades, and the West Cascades and showed no difference in the Blue Mountains and Klamath Mountains (Appendix: Table A7). The number of years required to reach maximum rates of NPP was higher on public land ($P < 0.01$) in the Blue Mountains, East Cascades, and Sierra Nevada. Maximum mortality was

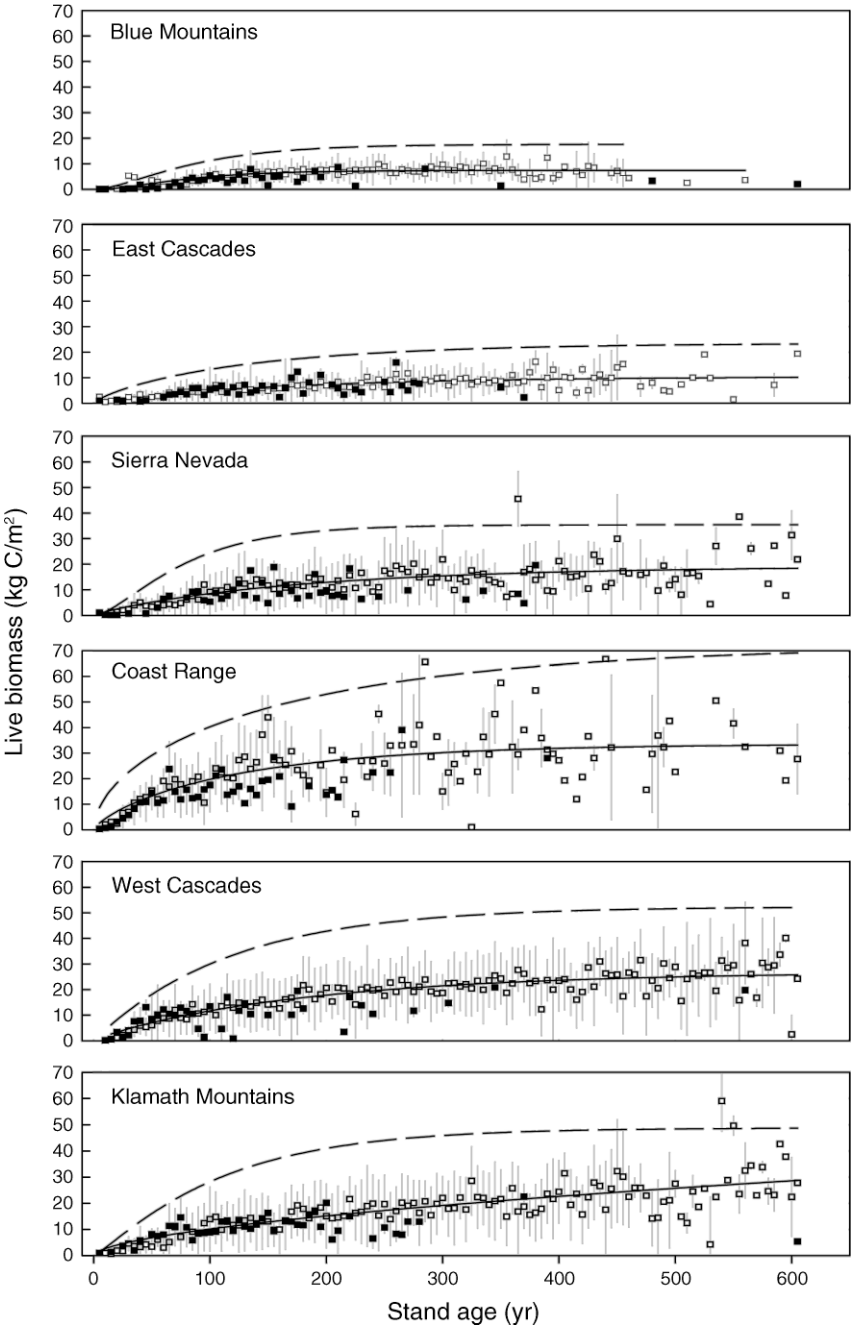

FIG. 2. Live biomass (trees and understory woody shrubs) vs. stand age. The dashed line (upper bounds) and solid line (mean trend) were fit using a Chapman-Richards function. Open (public) and solid (private) squares are the mean biomass for plots grouped into 5-year age bins. Gray vertical lines are the standard deviations in each bin. Note that, for clarity, plot mean values for the upper-bounds (99th-percentile) curve of the data are not shown on the figure.

higher on public land in the Blue Mountains and Sierra Nevada, but lower in the Coast Range.

Forest type patterns

Forest type differences were examined for live biomass and NPP. There was strong evidence ($P < 0.001$) that forest types within an ecoregion differ in maximum live biomass accumulation, maximum NPP, years required to reach maximum NPP, and age at initial decline of NPP (Appendix: Table A8). The overall variation in age-related patterns of biomass accumulation was reduced in some ecoregions when the Chapman-Richards functions were fit to the data separated by forest type. Douglas-fir forest types had the highest

TABLE 2. Estimates (mean with SD in parentheses) by age group, maximum of mean trend, and age at which maximum is reached for biomass, NPP, and mortality in each ecoregion and by ownership.

Notes: Age groups are defined as young, <80 years old; mature, 80–200 years old; and old, >200 years old (information is not available for private land for the "old" group). Ecoregion codes are as in Table 1. Means for each ownership type (last four columns) were calculated with site-index-corrected data, resulting in higher means than for the entire data set (described in *Methods: Statistical analysis*).

maximum NPP, whereas pine forest types had the oldest age of initial decline of NPP.

Regional-scale analyses

Across the entire ORCA study region and after accounting for stand age, variation in live biomass (model weights 0.0–1.0) and mortality (model weights 0.12–0.88) was most explained by forest type, whereas variation in dead biomass (model weights 0.40–0.60) and NPP (model weights 0.02–0.98) was most explained by ecoregion (Appendix: Table A9). Within each ecoregion or climate zone, forest type was the most important explanatory variable in all cases except for mortality in the Coast Range, where ownership was most important (higher on private lands).

Total live biomass of forests in the ORCA study region (4.4×10^7 ha of forest land) is estimated at 2.71 ± 0.28 Pg C, mean ± SD (Appendix: Table A1; Figs. 7 and 8a). Understory biomass ranged from 1% to 5% of live biomass in most ecoregions and exclusion would not have resulted in a significant underestimation of biomass. Private land accounts for 35% of live biomass (and 44% of the forested area), with nearly one-third of the regional biomass in the predominantly privately owned Coast Range. The total live biomass, assuming that all stands are at maximum carbon storage as determined by the mean trend of the data, would nearly double to 5.19 ± 1.34 Pg C (Fig. 8b). Although it would take hundreds of years to reach these theoretical levels in all ecoregions, land-based stocks could increase by 15% in just 50 years (i.e., if all stands increased in age by 50 years). Total dead biomass for the ORCA study regions is estimated at 0.51 ± 0.19 Pg C (Fig. 8c). Total dead biomass stores would increase by 36% to 0.80 ± 0.15 Pg C at maximum levels from the mean trend of the data (Fig. 8d). Total mortality of biomass for the ORCA study regions is estimated at 0.021 Pg C/yr. Total NPP of forest in the ORCA study region is estimated at 0.109 ± 0.001 Pg C/yr, mean ± SD (Fig. 9a) and total NPP would increase to 0.118 ± 0.002 Pg C/yr, assuming that all stands were at maximum NPP (Fig. 9b).

DISCUSSION

Trends with age

The expected age related ecological patterns (i.e., Chapman-Richards logistic growth for biomass accumulation, U-shaped pattern for dead biomass accumulation, and a marked decline in NPP with stand age)

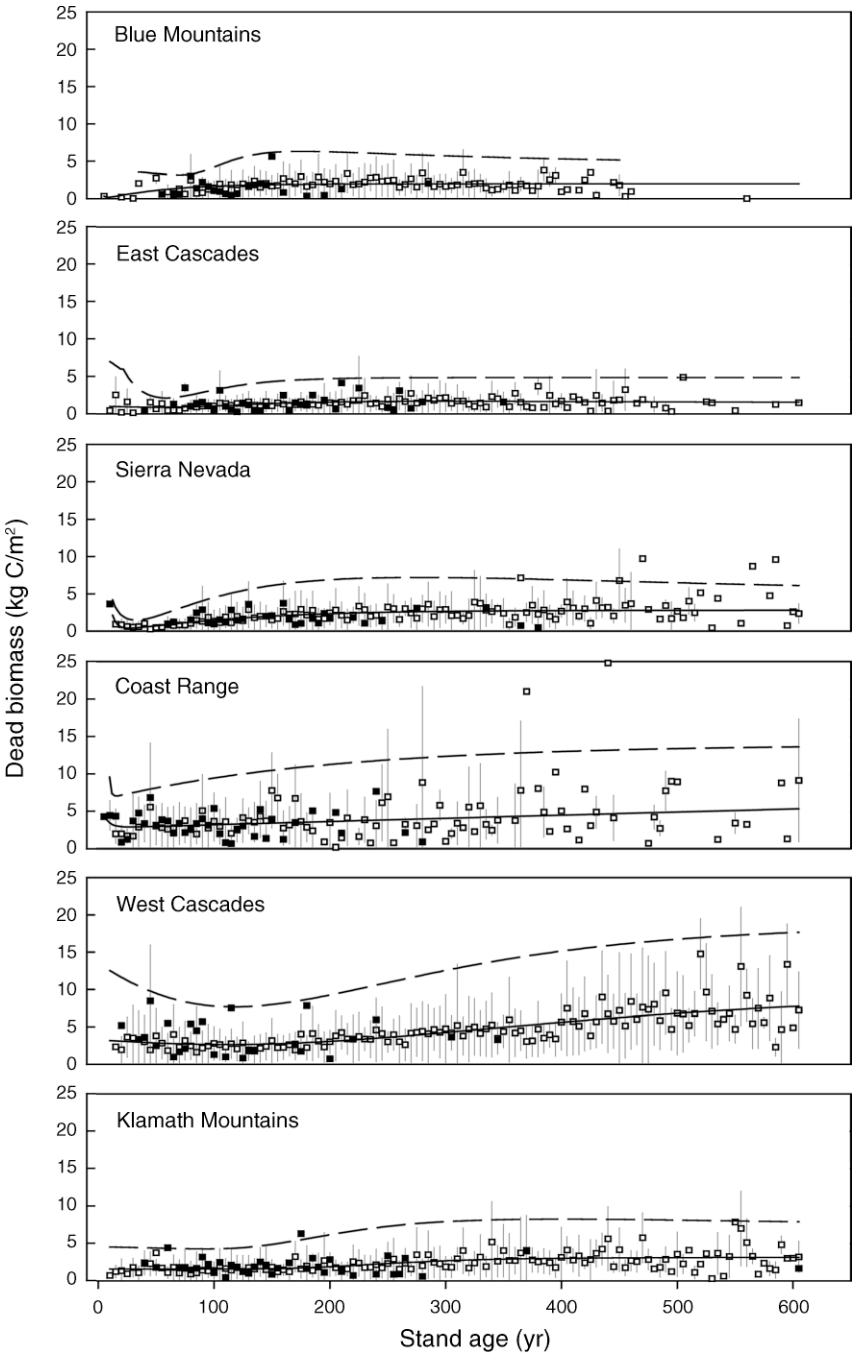

FIG. 3. Dead biomass (coarse woody debris [CWD] and standing dead trees) vs. stand age. The dashed line (upper bounds) and solid line (mean trend) were fit using a decay plus a Chapman-Richards function. Open (public) and solid (private) squares are the mean biomass for plots grouped into 5-year age bins. Gray vertical lines are the standard deviations in each bin. Note that, for clarity, plot mean values for the upper-bounds (99th-percentile) curve of the data are not shown on the figure.

were generally more distinguishable in the upper bounds of the data rather than in the age-specific mean values. In almost all cases, the West Cascades plot data were most suitably fit by these age related patterns. This is not surprising when considering that the ecological studies and data that were used to elucidate these patterns deliberately and appropriately targeted productive, smaller scale, undisturbed, mature plots, especially in the West Cascades (Acker et al. 2002, Janisch and Harmon 2002). In contrast, federal inventory sampling, by design, includes the full suite of factors that cause a given forest to grow at the full range of rates.

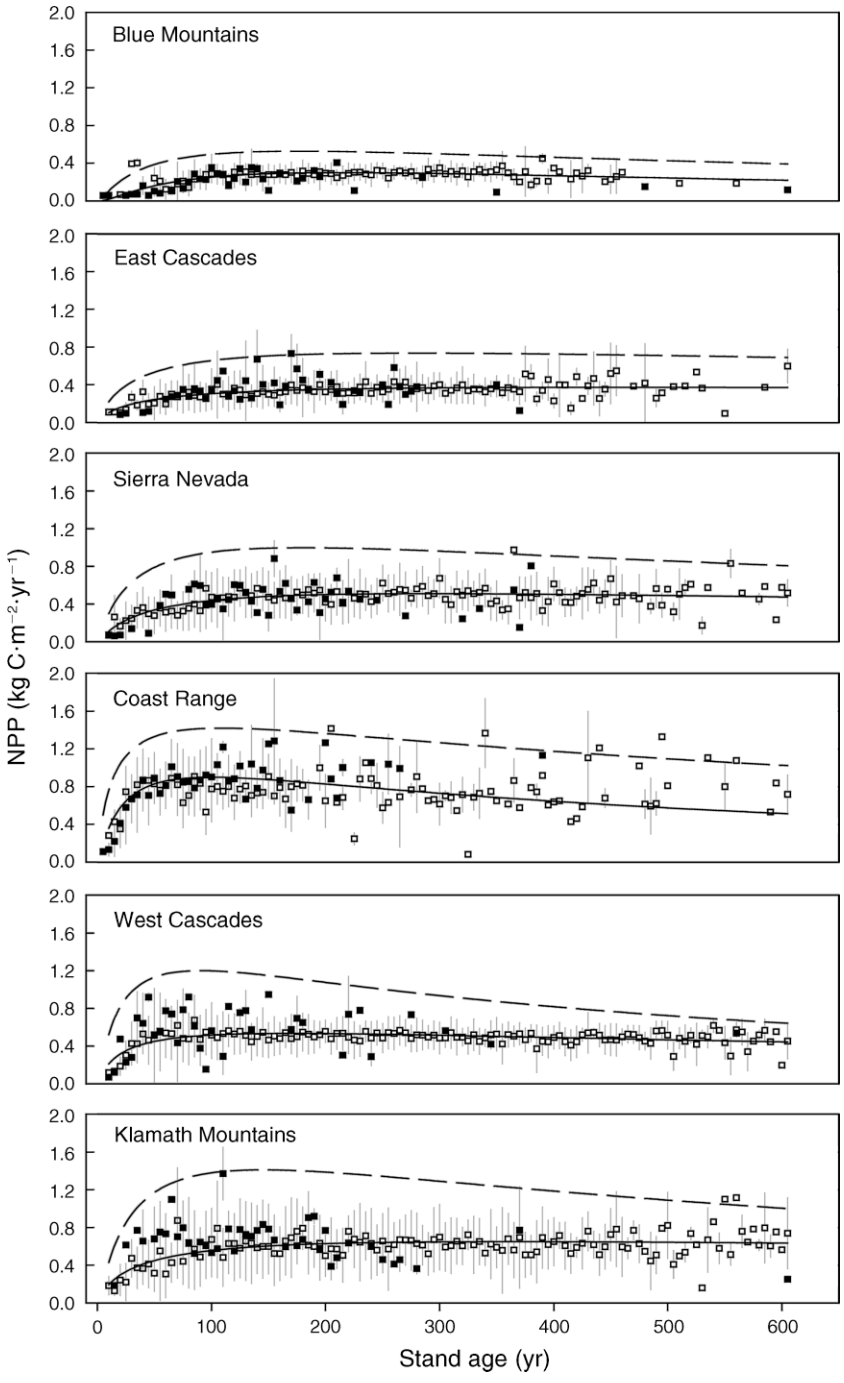

FIG. 4. Net primary productivity, NPP, of trees and understory woody shrubs vs. stand age. The dashed line (upper bounds) and solid line (mean trend) were fit using a Peak (three-parameter log-normal) function. Open (public) and solid (private) squares are the mean biomass for plots grouped into 5-year age bins. Gray vertical lines are the standard deviations in each bin. Note that, for clarity, plot mean values for the upper-bounds (99th-percentile) curve of the data are not shown on the figure.

With respect to coarse woody debris (CWD), the idealized U-shaped pattern arising from the combined and lagged effects of legacy wood decay and the recruitment of new dead wood (Harmon et al. 1986) was most apparent in the upper bounds. Coarse woody debris biomass stores may be underestimated because the federal inventory CWD data required a minimum diameter measurement of 12.5 cm, rather than the 10 cm used by ecological studies or the 7.6 cm used by fire studies. Federal inventory data also do not include

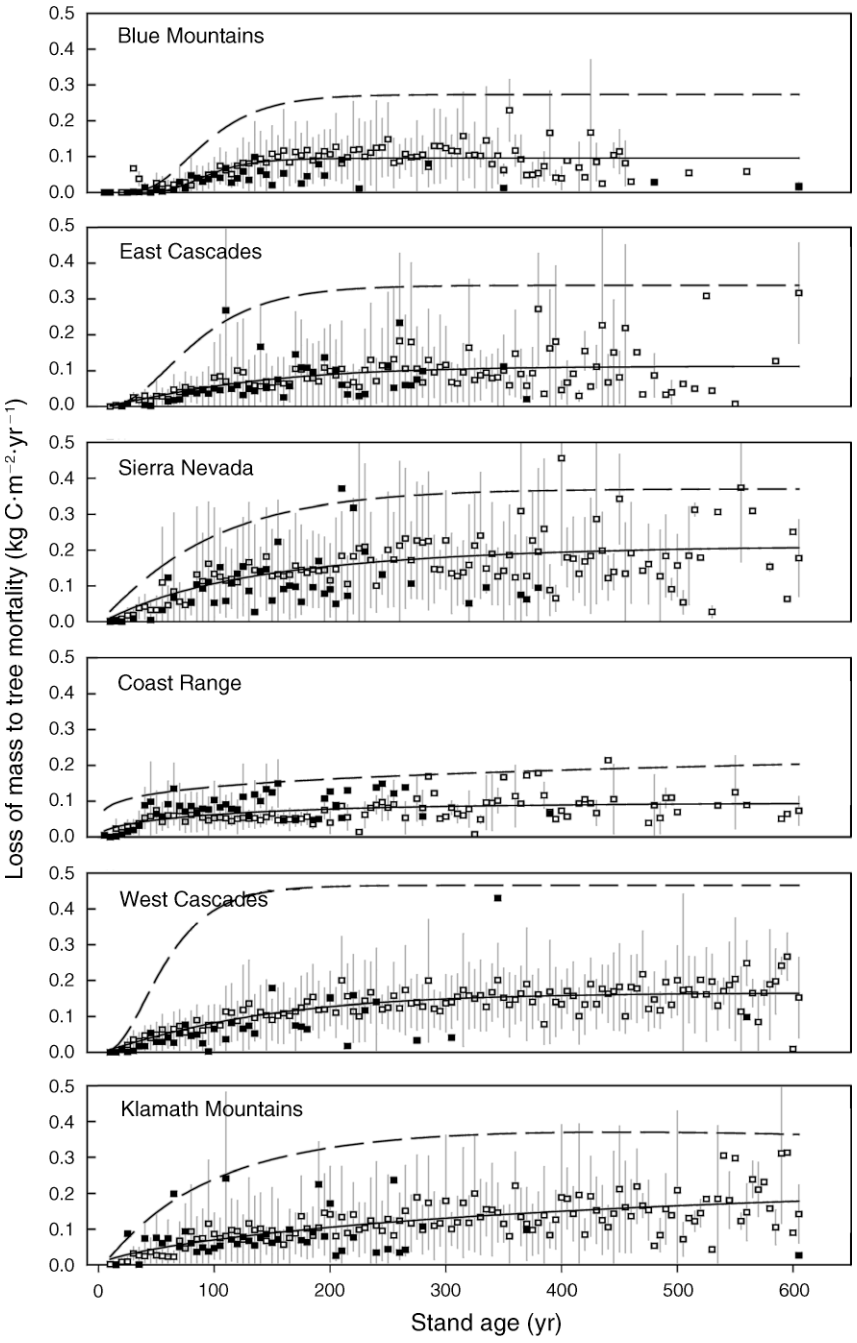

FIG. 5. Mortality of trees (loss of live carbon mass due to the death of trees) vs. stand age. The dashed line (upper bounds) and solid line (mean trend) were fit using a Chapman-Richards function. Open (public) and solid (private) squares are the mean biomass for plots grouped into 5-year age bins. Gray vertical lines are the standard deviations in each bin. Note that, for clarity, plot mean values for the upper-bounds (99th-percentile) curve of the data are not shown on the figure.

stumps, which would increase biomass in recently harvested (young) stands causing the curve to follow a more U-shaped pattern.

Because mortality affects both the inputs to dead biomass and the rate of loss from live biomass, it is important to characterize the factors controlling it. Our analysis shows mortality (expressed as an amount) increasing with stand age and stabilizing in late succession (Fig. 5). Expressed as a fraction of live biomass, we found that mortality tends not to be a constant. For example, mortality increases nonlinearly with stand age in most ecoregions and then reaches equilibrium while live biomass continues to increase. Carbon cycle models that have been applied in the

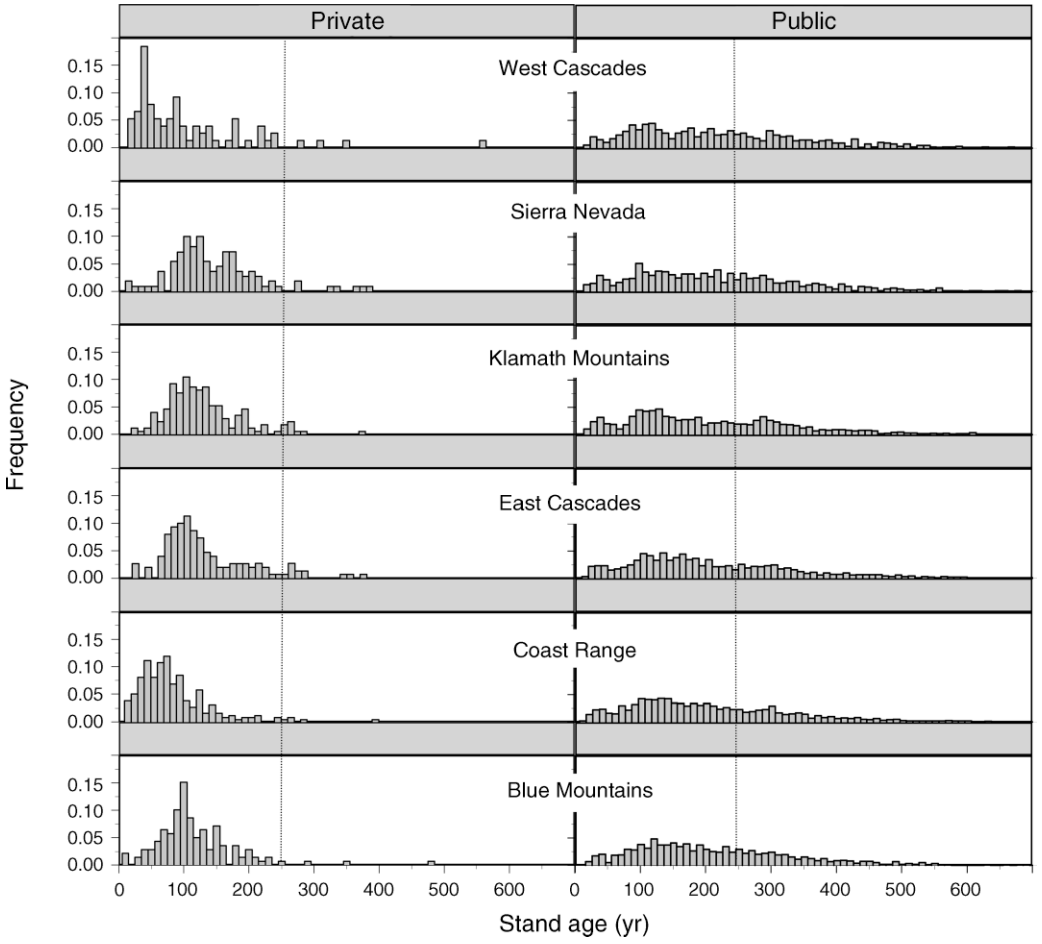

FIG. 6. Frequency distributions of stand age by ecoregion and ownership class (private vs. public). Forests on private land tend to have more stands in lower age classes than stands on public lands. The light vertical lines delineate stands older vs. younger than 250 years.

Pacific Northwest (e.g., Turner et al. 2004) often represent mortality as a fixed percentage of live biomass and our results support the implementation of a dynamic mortality function in these models.

Increased mortality and decreased net primary production have been reported as equally responsible for late-successional stabilization of bole wood biomass in the West Cascades (Acker et al. 2002).The ecological studies upon which that conclusion is based are most relevant to our upper bound lines, and our results support these findings in some ecoregions (e.g., Coast Range, West Cascades, and Klamath Mountains). In those cases, upper bound NPP peaks at approximately 80 years and then declines (Fig. 4), and mortality (Fig. 5) increases with age to a stable rate that approximates bole-wood production. The FIA data suggest that in the most productive ecoregions, biomass continues to accumulate at low rates in very old stands.

In other ecoregions, there is less marked decline in NPP with age, or no apparent decline in NPP. For instance, pine forests in the Blue Mountains, East Cascades, and Klamath Mountains experienced NPP declines at significantly older ages than did other forest types in these ecoregions (Appendix: Table A5). The traditional explanation for NPP decline with age in forests, i.e., stable GPP and increasing autotrophic respiration, has largely been rejected in PNW forests (Ryan et al. 2004). The fact that decline is most apparent in the upper bound lines and least apparent for the relatively low productivity, more open-grown, pine forest type lends support to the hypothesis that competition-related changes in stand structure (Binkley et al. 2002) may be the critical driving factor.

Ecoregion patterns

In general, wetter ecoregions west of the Cascade Mountains crest (Klamath, Coast Range, and West Cascades) had much higher NPP and biomass stores at a given age than the drier ecoregions east of the crest (East Cascades and Blue Mountains). Despite the relatively high NPP and live biomass in the Klamath Mountains, dead biomass stores were 50–60% lower than in the

Coast Range and West Cascades. Although mortality rates are generally higher for both the Coast Range and West Cascades vs. the Klamath Mountains, the difference does not account for the large difference in dead biomass stores. Dead wood biomass is either being removed or consumed in the Klamath ecoregion at a much higher rate than in other ecoregions west of the Cascade crest. One explanation is differential decomposition rates. Decomposition is thought to be higher in the Klamath than in other west-side forests because of sufficient moisture and warm temperatures, but with fewer prolonged periods of moisture saturation, which can limit log decomposition (Harmon 1992). Others have proposed that historically frequent surface fires in the Klamath (every 5–75 years) consumed much of the coarse woody debris (Skinner 2002). It is most likely a combination of faster decomposition and shorter pre-suppression-era fire return intervals that underlie the lower amounts of dead biomass in the Klamath (Wright et al. 2002).

A consideration in interpreting biomass dynamics across ecoregions is the potential influence of 20th century fire exclusion, which has likely varied among regions. In dry forest types of some ecoregions (e.g., East Cascades, Sierra Nevada), fire suppression has resulted in long recent fire intervals relative to historical fire regimes that included frequent low-intensity surface fires (Agee 1993). These long intervals may allow greater live and dead biomass accumulations than under shorter fire intervals, as well as increases in stem densities that may affect patterns of stand productivity. By contrast, in wetter ecoregions (e.g., West Cascades, Coast Range), the fire suppression era has been brief relative to characteristic fire return intervals and probably has had little effect on biomass dynamics (Noss et al. 2006). Note that the chronosequence approach taken in our study is sensitive to the changes in disturbance regime over the last century. The effect of fire exclusion (and restoration) on carbon dynamics in different forest types remains an important direction for future research.

Ownership patterns and management implications

Forest management has always been somewhat different on private and public lands in the Coast Range, West Cascades, and Klamath Mountains (Spies et al. 1994), and reduced timber cut on federal lands in these ecoregions after implementation of the Northwest Forest Plan in 1990 has intensified the differences. Private lands in these ecoregions have, on average, less live biomass per unit area than do public lands because the typical harvest rotation (80 years) is much less than the age at which maximum biomass is reached (300 years). The frequency distribution of stand age could largely explain the differences in both live and dead biomass on public and private lands (Van Tuyl et al. 2005). Mean stand age of publicly owned forests is 50–150 years older than privately owned forests and mean carbon stores are 30–50% higher. Despite the fact that

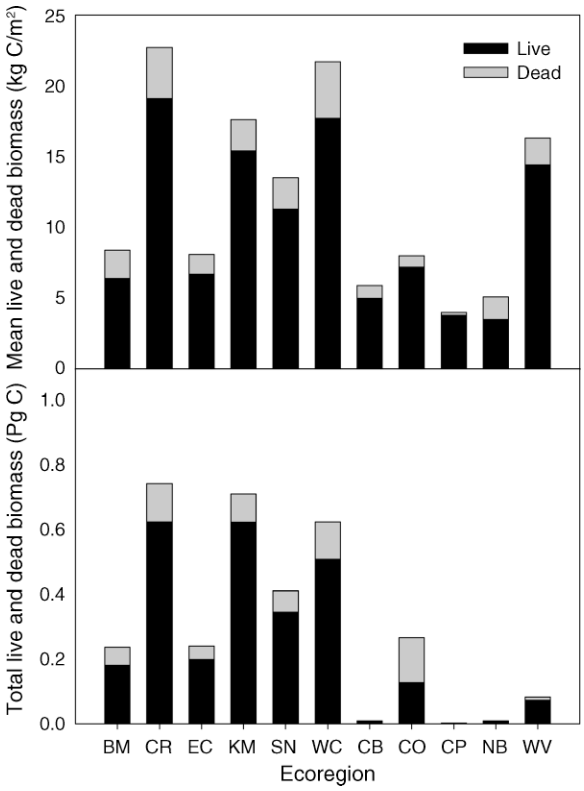

FIG. 7. Current mean and total carbon stocks in each ecoregion; mean and total live and dead biomass include trees, understory woody shrubs, and coarse woody debris.

the Coast Range has the highest percentage of private land (twice that of any other ecoregion), the lowest mean stand age, and the highest rate of removals by harvest (Law et al. 2004), it has the largest amount of biomass stored per unit area, presumably due to high NPP (climate), low natural mortality rates, and lack of recent major wildfires. Coast Range forests are among the most productive temperate forests in the world (Smithwick et al. 2002) and aboveground carbon stocks are comparable with tropical forest stocks (Houghton 2003, Sierra et al. 2007). Thus, there is high potential for increased land-based carbon storage with increased rotation age or reduction in harvest rates (Fig. 8b).

It is expected that management would affect NPP in younger stands because they are being managed for harvest and maximum wood volume production. After accounting for site index, our results supported this hypothesis, with maximum annual NPP of forests higher on private land than public land in all but the Blue Mountains and Klamath Mountains. An explanation for the lack of difference in these two ecoregions is difficult to ascertain because site index was accounted for in the analysis. There was also no difference in maximum live and dead biomass stores in the Blue Mountains. Maximum mortality is higher on public lands in the Blue Mountains, which could partially account for the decreased live biomass, but it may also

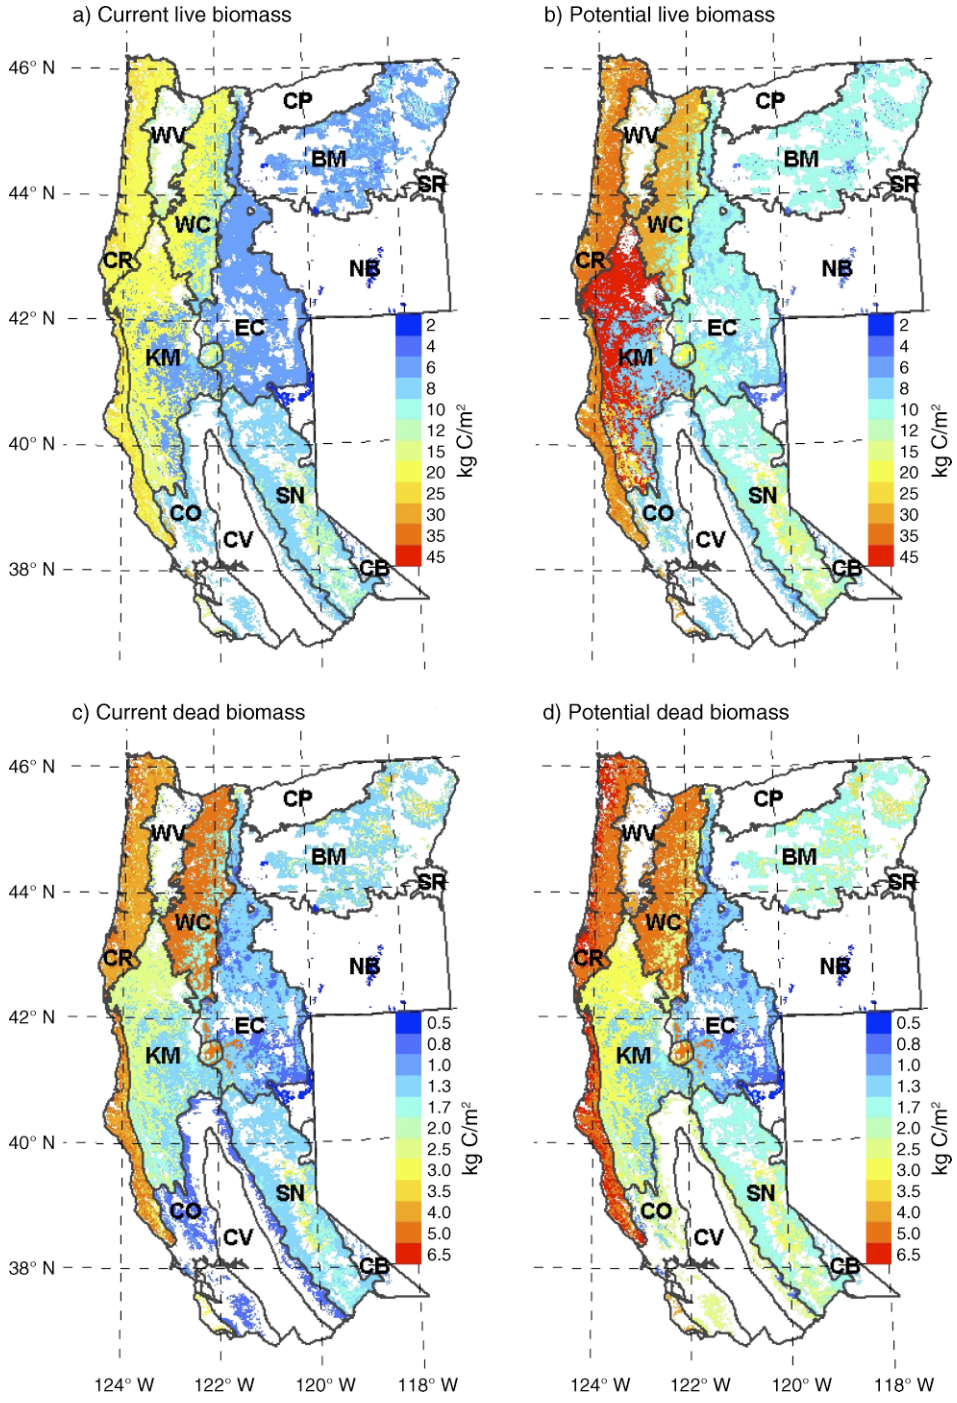

FIG. 8. Current and potential carbon stocks by forest type within ecoregion. Potential stocks were calculated using the mean trend maximums by forest type (Appendix: Table A6).

be that management practices are more similar on public and private land, as this ecoregion was also not affected by the Northwest Forest Plan.

Because ownership is associated with differences in mean biomass levels, a shift from current management on public land to a regime more like that on private land would gradually reduce mean carbon stocks on the land base. Decreasing rotation age to 50 years (i.e., mean age to 25 years) on all forested land in the Coast Range, Klamath Mountains, and West Cascades would reduce land-based live carbon stores by 53%. Some carbon can be sequestered in wood products derived from harvesting. However, due to manufacturing losses, only about 60% of the carbon harvested enters the products pool

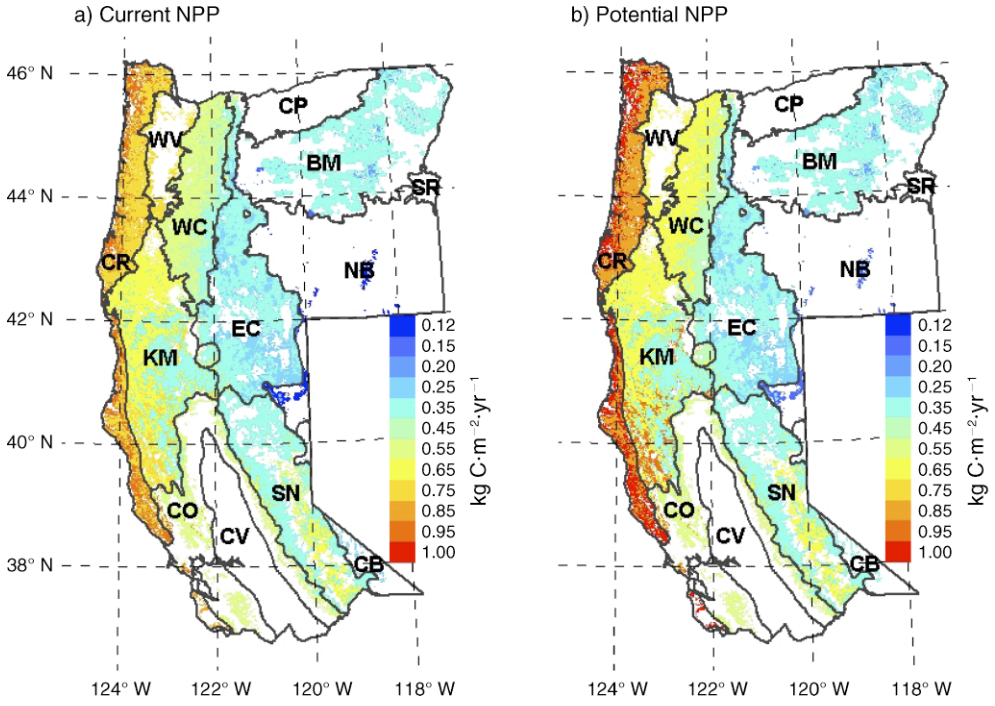

FIG. 9. Current and potential NPP by forest type within ecoregion. Potential NPP was calculated using the mean trend maximums of NPP by forest type (Appendix: Table A6).

(Harmon et al. 1996) and there are significant emissions from older products decomposing in landfills that tend to offset this carbon sink. Furthermore, with full carbon accounting there is a large carbon cost to the initial conversion of a landscape dominated by old forests to one dominated by young forests (Harmon et al. 1990).

Managing forests to maximize NPP may not have a positive effect on maximum regional carbon storage. Maximum NPP is reached much earlier in stand development than maximum biomass in all ecoregions (by hundreds of years) and limiting biomass accumulation to rotation ages based on maximum NPP would reduce land-based stocks. Examining current and potential productivity across the region is important when deciding regions where accumulation of biomass stores is most efficient. Highly productive ecoregions with infrequent fire such as the Coast Range are most likely to reach the potential stocks if managed for maximum biomass accumulation.

Modeling implications

As this study reaffirms, the processes driving forest carbon balance vary with stand age and forest type. Therefore estimates of regional carbon fluxes from modeling efforts depend in large part on our ability to accurately characterize stand age and forest type across the region (Turner et al. 2007). Including forest types as species groups in model parameterization could help further constrain model output for a specific area. Spatially explicit maps of age can be derived from remote imagery (Cohen et al. 2002), but the accuracy of these maps is dependent on pronounced canopy structural development (Law et al. 2006). Until accurate age maps can be developed for the entire region, the distribution of forest age among inventory plots is uniquely valuable in developing probabilistic-based maps of age (e.g., Ohmann et al. 2007).

Ecological studies have identified patterns of response in biomass and productivity with age that are based on homogeneous forests growing under ideal conditions, and in this study, we found that those patterns are more evident in the upper bounds of biomass or productivity for a given age rather than mean response. The structure of many process models used for scaling NEP is often developed based on ecological trends elucidated from field studies on idealized study plots or the upper bounds. Depending on exactly how a process model is structured, it may be best to parameterize it with curves fit to the upper maximum of the inventory data because these trends reflect the unconstrained behavior of vegetation in a given ecoregion. This is especially true for trends such as age-related mortality, age-related allocation, and age-related declines in NPP that need to be explicitly enforced, because these high-order trends fail to otherwise emerge in standard simulations. Mean trends in the inventory data, on the other hand, have a different, but equally important value to modeling since after incorporating the constraints of disturbance and climate across a region, model output is best validated against the mean trends apparent in the inventory data.

§ Minimum to maximum levels across study area.
|| Mean levels across ecoregions.
¶ From small-scale ecological studies (not inventory).

For this reason we advocate the separate characterization of mean and upper bound trends in federal inventory data.

Comparison with other studies

Our estimates of live and dead biomass, NPP, and mortality compare favorably with other regional studies (Table 3). Most recent federal inventory estimates of state total live and dead tree (excluding fine roots) carbon per unit area were 9–11 kg C/m^2 (Woodbury et al. 2007) in Oregon and California. Our results produce a mean of 12 kg C/m^2 (including fine roots) for both states, but range from 3 to 24 kg C/m^2 across the ecoregions. Hicke et al. (2007) reports a range of 4–20 kg C/m^2 for mean live tree biomass (excluding fine roots) at the county level in Oregon and California. When compared with the IDB estimates of ecoregion means, aboveground woody biomass varied by 5–10%.

Smithwick et al. (2002) reported that Oregon tree (including snags) and understory biomass in very old undisturbed stands averaged 63, 58, and 12 kg C/m^2 in the Coast Range, West Cascades, and East Cascades, respectively. Our estimates of the upper bounds of tree (not including snags) and understory biomass (Fig. 2) were 55, 50, and 20 kg C/m^2 for each of these ecoregions. Our East Cascade upper bounds estimate is much higher, but is based on a much larger number of plots over a more extensive area. Our aboveground wood biomass increments averaged 0.17 kg C·m^{-2}·yr^{-1} in the East Cascades to 0.50 kg C·m^{-2}·yr^{-1} in the Coast Range. In comparison with other regions, maximum live tree biomass averaged 10 kg C/m^2 in softwood forest types and wood biomass increment averaged 0.24 kg C·m^{-2}·yr^{-1} in the mid-Atlantic region (Jenkins et al. 2001). In tropical regions, total tree live-tree biomass averaged a 15 kg C/m^2 (Sierra et al. 2007) in Columbia and ranged from 11 to 13 kg C/m^2 (aboveground biomass only) across all tropical forests (Houghton 2003).

Conclusions

The potential to store additional carbon in Pacific Northwest forests is among the highest in the world because much of the area has forests that are long-lived (e.g., Douglas-fir) and maintain relatively high productivity and biomass for decades to centuries. In Oregon and Northern California (4.4×10^7 ha), total live biomass of forests is estimated at 2.71 ± 0.28 Pg C, mean ± SD (mean of 12 kg C/ha) in the period 1991–1999. Total dead biomass (which does not include fine woody debris or litter stocks) of forests in the region was 0.51 ± 0.19 Pg C, and total NPP was 0.109 ± 0.001 Pg C/yr, mean ± SD. The majority of live and dead biomass (~65%) is on public lands (53% of forested land). Trends in NPP with age vary among ecoregions, which suggests caution in generalizing that NPP declines in late succession. Contrary to commonly accepted patterns of biomass stabilization or decline, biomass was still increasing in stands over 300 years old in the Coast Range, the Sierra Nevada and the West Cascades, and in stands over 600 years old in the Klamath Mountains. If forests were managed for maximum carbon sequestration total carbon stocks could theoretically double in the Coast Range, West Cascades, Sierra Nevada, and East Cascades and triple in the Klamath Mountains (Fig. 8). Our results indicate that Oregon and California forests are at 54% of theoretical maximum levels (3.2 ± 0.34 Pg C vs. 5.9 ± 1.34 Pg C) given the absence of stand-replacing disturbance. These theoretical levels are calculated using the mean trend of the data and account for variation in site quality, climate, and partial disturbance (i.e., thinning, insect outbreaks, non-cata-

strophic fire). An increase of 15% may be possible in just 50 years. However, these levels (if reached) may be unstable in high-frequency fire regions. A more realistic management approach to increase carbon storage on the landscape would be to increase rotation ages by 30–50 years or reduce the acreage that is harvested in areas more likely to reach the theoretical levels (Coast Range, West Cascades, Klamath Mountains). Initial conditions are important when considering management options. Maintaining mature and old forests that already store large amounts of carbon is a mitigation option, as suggested by the IPCC (2007).

Acknowledgments

This research was supported by the U.S. Department of Energy Biological and Environmental Research Terrestrial Carbon Program (Award DE-FG02-04ER63917). This study is part of a regional North American Carbon Program project. Special thanks to Catharine van Ingen for her assistance with database organization and implementation, and to Microsoft for database design funding through an E-Science grant. We thank the PNW-FIA (Pacific Northwest Forest Inventory and Analysis program) regional office for their assistance and cooperation in compiling the database and Lisa Ganio, Joe Fontaine, Brendan Rogers, and Warren Cohen for editorial comments and statistical advice. We also thank two anonymous reviewers for their extensive comments, which were very helpful for revisions.

THE EFFECTS OF POSTFIRE SALVAGE LOGGING ON CAVITY-NESTING BIRDS

RICHARD L. HUTTO[1,3] AND SUSAN M. GALLO[2]
[1]*Avian Science Center, Division of Biological Sciences, University of Montana, Missoula, MT 59812*
[2]*Maine Audubon, Falmouth, ME 04105*

Abstract. We investigated the effects of postfire salvage logging on cavity-nesting birds by comparing nest densities and patterns of nest reuse over a three-year period in seven logged and eight unlogged patches of mixed-conifer forest in the Blackfoot-Clearwater Wildlife Management Area, Montana. We found 563 active nests of 18 cavity-nesting birds; all species were found nesting in the uncut burned forest plots, but only eight nested in the salvage-logged plots. All except one species nested at a higher density in the unlogged areas, and half of the species were significantly more abundant in the unlogged plots. Every timber-drilling and timber-gleaning species was less abundant in the salvage-logged plots, including two of the most fire-dependent species in the northern Rocky Mountains—American Three-toed (*Picoides dorsalis*) and Black-backed (*P. arcticus*) Woodpeckers. Lower abundances in salvage-logged plots occurred despite the fact that there were still more potential nest snags per hectare than the minimum recommended number needed to support maximum densities of primary cavity-nesters, which suggests that reduced woodpecker densities are more related to a reduction in food (wood-boring beetle larvae) than to nest-site availability. Because cavities were present in only four of 244 randomly selected trees, and because frequency of cavity reuse by secondary cavity-nesters was higher in salvage-logged than in unlogged plots, nest-site limitation may be a more important constraint for secondary cavity-nesters in salvage-logged areas. These results suggest that typical salvage logging operations are incompatible with the maintenance of endemic levels of most cavity-nesting bird populations, especially populations of primary cavity-nesting species.

Key words: *Black-backed Woodpecker, cavity-nesting birds, fire, healthy forests, salvage logging.*

Efectos de la Extracción Forestal Post-Incendio sobre las Aves que Anidan en Cavidades

Resumen. Investigamos los efectos de la extracción forestal post-incendio sobre las aves que anidan en cavidades por medio de una comparación de la densidad de nidos y los patrones de su reutilización. El estudio se realizó durante un periodo de tres años, en fragmentos de bosque mixto de coníferas quemados con y sin extracción forestal (siete y ocho fragmentos, respectivamente) en el Área de Manejo de Fauna Silvestre Blackfoot-Clearwater, Montana. Encontramos 563 nidos activos pertenecientes a 18 especies; todas las especies se registraron anidando en los fragmentos de bosque quemado sin extracción, pero sólo ocho de ellas anidaron en los fragmentos quemados con extracción. Con sólo una excepción, la densidad de nidos de todas las especies fue mayor en los fragmentos quemados sin extracción forestal y la mitad de las especies fueron significativamente más abundantes en los fragmentos sin extracción. Todas las especies que obtienen su alimento perforando la corteza o buscando en ella fueron menos abundantes en los fragmentos con extracción, incluyendo dos de las especies más dependientes de los incendios en las Montañas Rocallosas—*Picoides dorsalis* y *P. arcticus*. Las abundancias fueron menores en los fragmentos con extracción post-incendio, a pesar de contar con un número mayor de troncos por hectárea con potencial para construir nidos, en relación con el número mínimo recomendado para mantener densidades máximas de aves que anidan en cavidades. Esto sugiere que la disminución de las densidades de los pájaros carpinteros está más relacionada con una disminución en su alimento (larvas perforadoras de escarabajos), que con la disponibilidad de sitios de anidación. Ya que se detectaron cavidades en sólo cuatro de los 244 árboles seleccionados al azar, y dado que la tasa de reutilización de cavidades por parte de las especies de anidación secundaria fue mayor en los sitios con extracción que en sitios sin extracción, la restricción de sitios de anidación puede ser un factor limitante más importante para las especies de anidación secundaria en los sitios con extracción forestal post-incendio. Estos resultados sugieren que las operaciones típicas de extracción son incompatibles con el mantenimiento de los niveles

endémicos de la mayoría de las poblaciones de aves que anidan en cavidades, especialmente para poblaciones de especies de anidación primaria.

INTRODUCTION

Severe, stand-replacing fire is arguably the most ecologically important disturbance agent in conifer forests of the northern Rocky Mountains (Gruell 1983, Pierce et al. 2004). These fires generally leave a mosaic of green, unburned areas interspersed with large areas of standing dead trees, or snags (Turner and Romme 1994, Turner et al. 2003). The ecological importance of this type of forest habitat is reflected in the fact that the avian community found in forests following stand-replacing fires is comprised, in part, of species (e.g., Black-backed Woodpecker [*Picoides arcticus*], American Three-toed Woodpecker [*Picoides dorsalis*], Olive-sided Flycatcher [*Contopus cooperi*], and Mountain Bluebird [*Sialia currucoides*]) that are not only relatively abundant in, but are also relatively restricted to, severely burned forest patches (Hutto 1995, Hutto and Young 1999, Kotliar et al. 2002, Smucker et al. 2005). These species depend heavily on the abundant standing dead trees associated with severely burned forests because they provide: (1) perches from which foraging sallies are initiated, (2) food for specialized beetle larvae, which themselves serve as prey for numerous woodpecker species (Powell 2000), and (3) nesting sites (Hutto 1995).

In unburned forest, the importance of snags to cavity-nesting birds has been clearly demonstrated (Dickson et al. 1983, Marcot 1983, Scott and Oldemeyer 1983, Zarnowitz and Manuwal 1985, Schreiber and deCalesta 1992) and recommendations for snag retention during timber harvests have been incorporated into current management plans (Thomas 1979, Raphael and White 1984, Zarnowitz and Manuwal 1985, Morrison and Raphael 1993). In burned forests, however, there are still no generally accepted snag retention guidelines for postfire conditions, even though the needs of snag-dependent species in burned forests are not the same as the needs of snag-dependent species in unburned forests (Hutto 1995, 2006). The lack of snag retention guidelines for burned forests is undoubtedly a reflection of the prevailing view that forest fires are ''environmental disasters'' (Taylor 1995) and that such fires leave behind fire-damaged timber that, other than as salvaged wood, lacks value. Consequently, salvage logging is a common management practice in the western United States after high-severity, stand-replacing fires, as it is elsewhere in the world after severe disturbance events (Lindenmayer et al. 2004).

Because burned forests are valuable to snag-dependent wildlife (and other plants and animals), and because some of these species appear to be nearly restricted in their distribution to such conditions (Hutto 1995, Hobson and Schieck 1999, Nappi 2000, Kotliar et al. 2002), managers should be especially concerned about mitigating possible negative effects of salvage logging on fire-dependent plants and animals. We need information on the effects of different levels of salvage logging to be able to assess whether any level of salvage logging is compatible with wildlife needs and, if so, which kinds and minimum numbers of snags are needed to support fire-dependent species after stand-replacing fires (Hutto 1995, 2006, Nappi et al. 2004).

Unfortunately, given the inherent danger associated with severe forest fires, the prospects of obtaining information on the effects of salvage logging from multiple, independently created experimental treatment and control plots will always be limited (Hargrove and Pickering 1992, Whelan 1995, Andersen et al. 1998, van Mantgem et al. 2001). Therefore, generalizations are most likely to emerge from meta-analyses of individual studies conducted when opportunities for study after unplanned fire events presented themselves (Kotliar et al. 2002). We capitalized on one of these rare opportunities to obtain empirical data on the effects of salvage logging when a large fire burned most of the Blackfoot-Clearwater Wildlife Management Area in western Montana. By working with the State Department of Fish, Wildlife and Parks and a local timber company, we were able to design a study that included a series of otherwise similar treatment (cut) and control (uncut) plots that allowed us to: (1) assess and compare breeding, cavity-nesting bird abundance in salvage-logged vs. unlogged burned forest patches, (2) assess and compare characteristics of nest trees and randomly

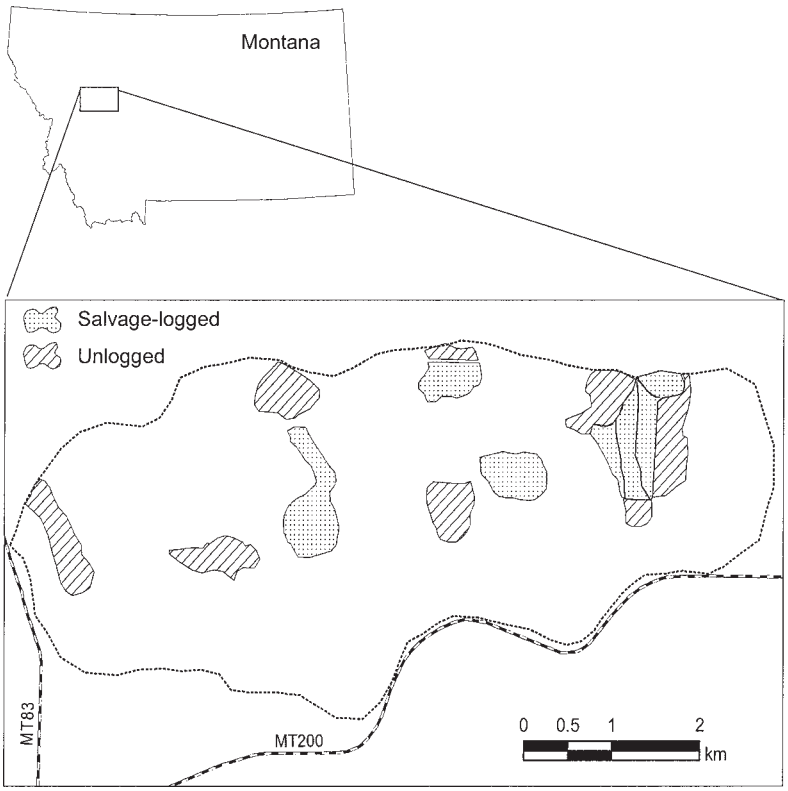

FIGURE 1. Map of the field plots used to study the effects of postfire salvage logging on cavity-nesting birds in the Blackfoot-Clearwater Wildlife Management Area, Montana. The fire boundary is indicated by the dotted line. Most of the area between plots is grassland, and MT83 and MT200 are state highways.

selected trees from salvage-logged and unlogged plots, and (3) document the reuse of cavities over a three-year period.

METHODS

STUDY AREA

This study took place on the Blackfoot-Clearwater Wildlife Management Area, which is located 80 km east of Missoula, Montana, at an elevation of approximately 1200 m. A severe fire in October of 1991 burned approximately 1600 ha of grassland and mixed-conifer forest. The burned forest areas consisted mainly of 50- to 150-year-old second-growth conifers (Douglas-fir [*Pseudotsuga menziesii*], western larch [*Larix occidentalis*], and ponderosa pine [*Pinus ponderosa*]) with occasional pockets of broad-leafed deciduous trees (*Populus* spp.). Approximately 275 ha were salvage-logged in the winter following the fire (1991–1992) in a pattern in which seven salvage-logged plots (totaling approximately 134 ha) were interspersed with eight unlogged control plots (totaling approximately 148 ha; Fig. 1). The individual plots averaged 23.9 ± 11.7 SD ha in size (range = 7–36 ha), and were delineated either on the basis of isolation of the unit or on the basis of road locations and timber harvest prescriptions provided by Champion Timber Company. The extent of salvage logging varied among plots, but in most cases all merchantable (>15 cm dbh, >4.5 m tall) fire-killed timber was removed. Most unlogged and salvage-logged forest plots were surrounded by grasslands.

NEST ABUNDANCE AND CAVITY REUSE

We located active cavity nests by searching the 15 forest plots during the breeding season from mid-May through mid-July of 1993, 1994, and 1995. We walked parallel transects (spaced at 20 m intervals) through the plots to systematically search the plots for active nests. Plots were of a size that required between one and

two days' search time to cover the entire plot. We searched plots at least twice during each breeding season, and walked transects in opposite directions from visit to visit to maximize our chances of finding all active nests. Nests were located by finding cavities directly and observing subsequent activity, following adult birds to nests, or hearing young birds in the nest. We recorded activity of adult birds at the nest (building, incubating, or feeding) at the time the nest was found and the type of cavity used (excavated or natural). The first time an active nest was found, it was considered a new nest. In subsequent years, the same nest cavities were checked for activity. Cavities active in subsequent years were considered reused nests, and cavities harboring a second pair of breeding birds of the same or a different species in a single year were classified as repeat nests.

VEGETATION AND TREE MEASUREMENTS

To characterize vegetation structure associated with the two treatments, we measured vegetation characteristics surrounding 132 randomly located trees in unlogged plots and 112 randomly located trees in salvage-logged plots. Sample trees were selected by locating random grid points on high-resolution aerial photos. If a random point fell on a tree, that tree was selected as a sample tree; otherwise the point was discarded. Random points were generated until all sample trees had been identified. Sample trees were located on the ground with the aid of aerial photos.

We recorded several characteristics associated with, and vegetation conditions surrounding, nest trees and randomly selected trees. Tree characteristics included size (diameter at breast height, measured with a dbh tape), height (measured with a clinometer), species, status (live or dead; intact or with a broken or dead top), percent bark remaining (estimated visually), and presence of a nest cavity. To assess vegetation characteristics surrounding focal trees, stakes were placed 15 m from the tree in the four cardinal directions. We made ocular estimates of the percent of bare ground (bare soil), ground cover (herbaceous plants <25 cm tall), low shrub cover (herbaceous plants >25 cm tall plus woody plants <0.5 m), and tall shrub cover (woody plants >0.5 m tall) in each quarter and then averaged the four estimates. These estimates were made from above, so the four estimates summed to 100%. Burn severity of the vegetation within 50 m of a sample tree was estimated using a subjective scale of one to five (after Hutto 1995), with 1 = 100% of the trees with green foliage or needles, 2 = most ($>60\%$) trees with green foliage or needles, and most of the rest with brown needles, 3 = 40%–60% of the trees brown-needled, and the rest either green- or black-needled, 4 = most ($>60\%$) trees black-needled, and the rest with brown needles, and 5 = all trees blackened. All vegetation measurements (including fire severity) on logged plots reflected conditions after cutting, so it was not possible to compare preharvest conditions on treatment and control plots.

STATISTICAL ANALYSES

We compared vegetation characteristics associated with the two treatments using Mann-Whitney *U*-tests for numerical data and chi-square likelihood ratios for categorical data. A Bonferonni correction for experiment-wise error was applied to adjust the *P*-value for multiple simultaneous tests. We tested for a difference in the distribution of nest abundance across species by treatment type using a chi-square likelihood ratio after combining numbers of nests across plots. Nest abundance was converted to nest density by averaging the number of nests per plot for each year of the study. We tested for differences in nest density over the three years of our study using repeated measures ANOVA. Nest densities were transformed by the inverse of the square root to achieve normality.

For each species with a minimum of nine nests, we compared characteristics of nest trees and randomly selected trees in both the unlogged and salvage-logged plots. Differences in numerical variables were tested with Mann-Whitney *U*-tests, and differences in distributions of categorical variables were tested with chi-square likelihood ratios. A Bonferonni correction for experiment-wise error was applied to all univariate tests for each species. When the same species nested in the same cavity in two or more years, the characteristics associated with that nest tree were included only once in the analysis.

For each primary cavity-nesting species, the suitability of randomly selected trees for nesting

TABLE 1. The percentage of nests found by each of three different methods and by status at the time they were found in unlogged and salvage-logged burned forest, Montana, 1993–1995. Most nests were discovered by following adult birds to the cavity, and most had either eggs or young when they were found.

	Unlogged	Salvage-logged
Method of location (n = 300)		
Following adult bird to nest	58	48
Finding cavity directly	21	23
Seeing or hearing adult or young at nest	21	29
Nest status (n = 392)		
Building, excavating, or advertising	17	18
Incubating	32	43
Feeding young	51	39

was assessed by first calculating the range of each of five characteristics associated with nest trees. If the value of a characteristic associated with a random tree fell within the range of values obtained for nest trees, that random tree was considered ''suitable'' for that characteristic. Overall suitability was then determined by combining suitability information from all the individual tree characteristics. If values of all characteristics of a random tree fell within the range of values from nest trees, that random tree was considered ''suitable'' for that species. The proportion of random trees classified as suitable for each species (all plots combined within each treatment) was then converted into an absolute number of suitable trees per hectare by multiplication with the estimated number of trees per hectare in each treatment (360 trees per ha in unlogged plots and 134 trees per ha in salvage-logged plots).

RESULTS

NEST ABUNDANCE

We found most nests between 8 and 23 June in both salvage-logged and unlogged areas. Most nests were discovered by following adult birds to the cavity, and most had either eggs or young when they were found (Table 1). Eighty-three percent of nests in unlogged plots and 77% of nests in salvage-logged plots (80% overall) were in cavities originally excavated by primary cavity-nesting birds.

We found 563 active nests distributed among 18 cavity-nesting species (Table 2). All 18 species nested in unlogged areas, whereas only eight species nested in salvage-logged areas (Table 2). The total number of active nests found in unlogged plots was almost three times higher than the total number of nests in salvage-logged plots, even though the area searched and search effort was similar between plot types (Table 2). The combined nest density was significantly higher in unlogged than in salvage-logged areas in each year of our study (treatment effect: $F_{1,13} = 8.3$, $P = 0.02$), and the mean density of all species combined increased significantly over the three years of study in both the unlogged and salvage-logged plots (year effect: $F_{2,26} = 4.2$, $P = 0.02$; Fig. 2). All cavity-nesting species except the Black-capped Chickadee (*Poecile atricapillus*) nested at a higher density in the unlogged than the salvage-logged areas, and half of all cavity-nesting species were significantly more abundant in the unlogged plots (Table 2). The most abundant species in unlogged areas (Northern Flicker [*Colaptes auratus*], House Wren [*Troglodytes aedon*], and Mountain Bluebird) were also the most abundant in salvage-logged areas, and the vast majority of nests in both salvage-logged and unlogged plots belonged to ground- and shrub-foraging species (73% and 93%, respectively) and to secondary cavity-nesting species (63% and 65%, respectively). Nevertheless, the relative abundances of all cavity-nesting species differed significantly between the two treatments ($\chi^2_{17} = 59.4$, $P < 0.001$), primarily because five timber-drilling woodpecker species and the two timber-gleaning nuthatch species nested only in the unlogged plots (Table 2).

CAVITY REUSE

Only 34% of the cavities excavated in 1993 were reused by cavity-nesting birds in 1994 (Table 3). In 1995, 36% of cavities used for nesting during either or both of the two previous years were reused. The frequency of cavity reuse in salvage-logged areas was 50% in 1994 and 44% in 1995. In contrast, the frequencies of reuse in unlogged areas were substantially lower—30% in 1994 and 33% in 1995 (Table 3). In 1995, a small percentage of cavities (2.6%) were used twice in one breeding season, and Mountain Bluebird, House Wren, and North-

TABLE 2. Total number of nests and mean nest densities (number per 40 ha ± SE) in unlogged and salvage-logged plots in burned forest in Montana. Numbers were tallied across three years from 1993 to 1995. We discovered a greater number of nests in unlogged than in salvage-logged plots for all but one species, and the mean nest densities of most cavity-nesting species were also significantly higher in the unlogged plots. Bonferonni-adjusted *P*-values are from Mann-Whitney *U*-tests for differences in mean density between the two treatments.

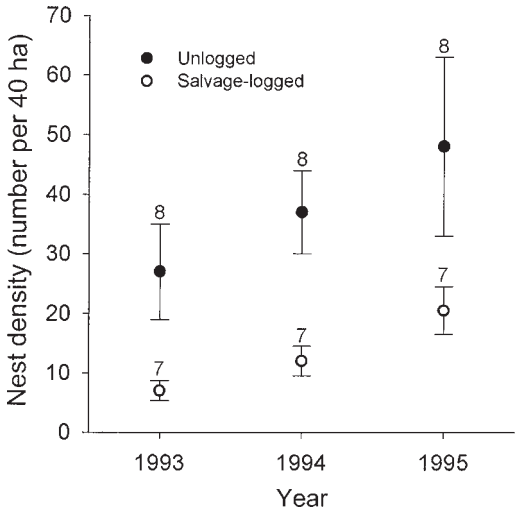

FIGURE 2. In each of the three years of study, mean nest density of all cavity-nesting species averaged over all plots was significantly higher in unlogged than in salvage-logged treatments in the Blackfoot-Clearwater Wildlife Management Area, Montana. Sample sizes appear above the error bars.

ern Flicker were the three species that most often used reused cavities for nesting. More than a quarter (27%) of Northern Flicker nests were located in previously used cavities. Although Northern Flickers may have excavated these cavities originally, it is clear they were not creating new nest cavities each breeding season.

There were 128 cavities known by observation to have been excavated by primary cavity-nesting birds. Of these, 58 were reused at least once during subsequent years, and half of those were Northern Flicker cavities being reused by flickers (Table 4). Despite the high frequency of reuse, Northern Flickers provided more cavities for other secondary cavity-nesting species than any other primary cavity-nesting species. Additionally, Northern Flicker cavities appeared to be the only cavities suitable for American Kestrels (*Falco sparverius*), possibly because flickers excavated relatively large entrance holes in relatively decayed snags. A small number of Red-naped (*Sphyrapicus nuchalis*) and Williamson's (*S. thyroideus*) Sapsuckers reused cavities excavated by Red-naped Sapsuckers (Table 4). Most of the Hairy (*Picoides villosus*), American Three-toed, and Black-backed Woodpecker cavities were reused by House Wrens and Mountain Bluebirds, which together used over a quarter of the 58 cavities originally made by primary cavity-nesting birds.

VEGETATION CHARACTERISTICS

Unlogged plots had significantly larger and taller trees, a higher density of trees, trees with more bark, higher live-tree density, and a lower proportion of intact snags than salvage-logged plots (Table 5). The burn severity surrounding randomly selected trees in unlogged plots was also slightly less than the burn severity surrounding randomly selected trees in logged plots (Table 5), although the index of severity that we used was undoubtedly affected by the removal of some green and brown-needled trees from the salvage-logged plots.

CHARACTERISTICS AND AVAILABILITY OF NEST TREES

Of the 12 species for which we found nine or more nests, all but one (Mountain Chickadee [*Poecile gambeli*]) nested in trees that were larger and taller than what was available in the salvage-logged plots; only the American Kestrel and Northern Flicker used larger trees than

TABLE 3. Numbers of new, reused (used in previous years by the same or different species), or repeat (used earlier in the same breeding season by the same or different species) nests across three years in unlogged and salvage-logged plots following fire in Montana. The proportion of cavities that were reused was higher in salvage-logged than in unlogged plots.

	Unlogged			Salvage-logged

[a] Species codes are given in Table 2.

what would be expected by chance in the unlogged plots (Fig. 3). Deciduous and broken-topped trees were also used for nesting by most species more often than would be expected due to chance (Fig. 4).

The percentage of randomly selected trees that were deemed suitable for nesting varied widely among the primary cavity-nesting species (Table 6). For some species, a single tree characteristic excluded a large number of randomly selected trees from being considered suitable. For example, Red-naped Sapsuckers nested in deciduous trees only, and because deciduous trees comprised a small percentage of random trees, the proportion of suitable nest trees for sapsuckers was close to zero in both unlogged and salvage-logged areas (Table 6). The estimated density of available nest trees ranged from zero for Red-naped Sapsuckers in salvage-logged plots, to 232 trees per ha for Hairy Woodpeckers in unlogged plots (Table 6).

Nest tree availability was not as easily assessed for secondary cavity-nesters because the presence of cavities was difficult to discern and because new cavities were undoubtedly created after we measured characteristics of randomly selected trees during the first year of our study. Nevertheless, cavities were present initially in only four of 244 randomly selected trees and only in the unlogged plots.

DISCUSSION

The densities of cavity nests in this study (14.6 and 38.6 nests per 40 hectares in salvage-logged and unlogged plots, respectively) are at the upper end of cavity nest densities that have been reported for other burned areas (Bock and Lynch 1970, Taylor and Barmore 1980, Caton 1996). Nevertheless, the higher abundance and species richness of cavity-nesting birds in unlogged compared to salvage-logged burned areas in this study is a result that is consistent with virtually all studies to date on this topic (Blake 1982, Harris 1982, Raphael and White 1984, Lyon and Marzluff 1985, Caton 1996, Saab and Dudley 1998, Haggard and Gaines 2001, Morissette et al. 2002). The single exception comes from a longer-term study in ponderosa pine-dominated communities in Idaho (V. Saab, R. Russell, and J. Dudley, USDA Forest Service, unpubl. data), where the overall density of cavity-nesting birds was observed to

TABLE 5. Vegetation characteristics associated with randomly selected trees in plots that were either unlogged (n = 132 trees) or salvage-logged (n = 112 trees) after a 1991 fire in the Blackfoot-Clearwater Wildlife Management Area, Montana. Tree sizes, tree densities, and percentage of live trees were significantly greater in unlogged than in salvage-logged plots. Means ± SE are given for numerical variables, and frequency distributions are given for categorical variables. Asterisk indicates a significant ($P < 0.05$) difference between unlogged and salvage-logged plots.

Vegetation characteristic	Unlogged	Salvage-logged

be slightly greater in salvage-logged plots in the first five years following fire, but not during the next five years. The combined density of all cavity-nesting birds increased over the three-year period of this study, primarily due to the creation of cavities by primary cavity-nesting species and the use of those same cavities in subsequent years by both primary and secondary cavity-nesters.

Of particular note is the fact that six of eight woodpecker species nested only in unlogged burned forest; they were entirely absent from salvage-logged areas. This is consistent with reports (Hutto 1995, Hutto and Young 1999) that, in the northern Rocky Mountains, two of these species (Black-backed and American Three-toed Woodpeckers) are not only more abundant in burned conifer forests than in any other vegetation type, but are also relatively restricted to such conditions. This result is also consistent with results from all of the previously cited studies on the effects of salvage logging on cavity-nesting birds. The number of Black-backed and American Three-toed Woodpecker nests decreased from the third to the fifth year after fire, which is similar to what Harris (1982), Caton (1996), Saab et al. (2004) and Saab et al. (V. Saab, R. Russell, and J. Dudley, USDA Forest Service, unpubl. data) found in their multiyear studies of postfire forests.

Preharvest tree density in salvage-logged areas (estimated by adding stump density to existing tree density) was 271 trees per ha, which was still well below the tree density in unlogged areas (360 trees per ha). It is therefore likely that salvage-logged and unlogged areas were somewhat different prior to the onset of fire and subsequent salvage-logging. There is always the possibility that some preharvest difference between plot types (e.g., a difference in average fire severity, slope, or aspect) might have contributed to the differences in bird densities between plot types; however, the presence of treatment replication in this study and the complete agreement between our results and the results of others who have looked at the effects of salvage logging strongly suggest that the significant reduction in abundance of cavity-nesting timber-drillers and timber-gleaners in salvage-logged areas was due primarily to the reduction in number of recently killed snags. This raises the question of whether it was a reduction in number of potential nest sites or some other aspect of habitat quality such as food availability that was affected most by the removal of standing dead trees.

Snags have traditionally been viewed as valuable for cavity-nesting birds exclusively in terms of their potential to be used as nest sites. Indeed, snag-management guidelines were originally based on meeting the nesting requirements of cavity-nesting birds (Thomas 1979). If nest trees were limiting bird densities in salvage-logged plots, then the density of suitable nest trees should have decreased to a number well below 6–8 trees per ha—the minimum number believed necessary to support maximum population densities of most cavity-nesting species

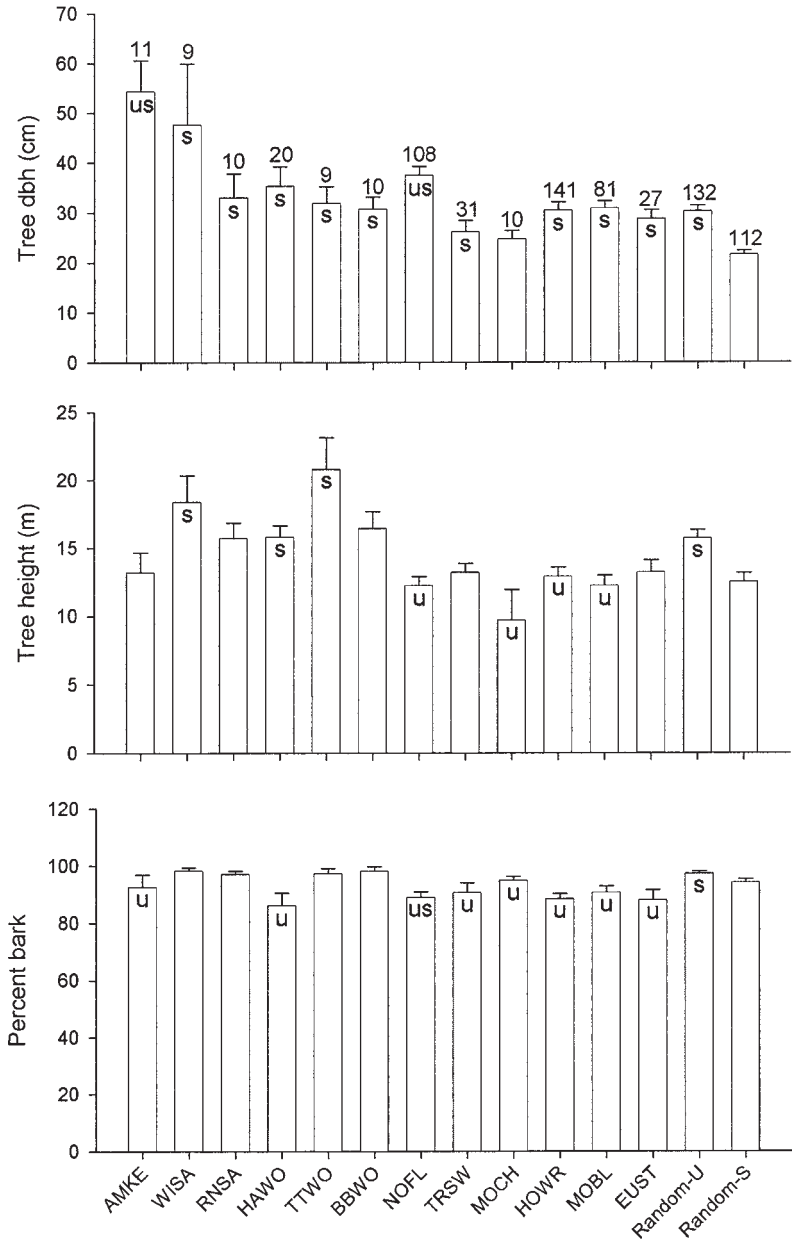

FIGURE 3. Mean nest tree characteristics (± SE) for cavity-nesting bird species (codes given in Table 2) and for randomly selected trees in unlogged (Random-U) and salvage-logged (Random-S) plots in the Blackfoot-Clearwater Wildlife Management Area, Montana. Nest trees generally differed significantly in one or more respects from randomly selected trees, especially in salvage-logged plots. Sample sizes are given above bars in the upper bar chart. Small letters indicate significant differences from randomly selected trees in salvage-logged (s) or unlogged (u) plots ($P < 0.05$, Mann-Whitney *U*-tests with Bonferonni correction for multiple comparisons).

(Thomas 1979:appendices 22, 23). We tested this hypothesis by calculating the percentage of randomly selected trees in both uncut and salvage-logged plots that could be considered suitable for nesting by each species. Most cavity-nesting species used snags rather than

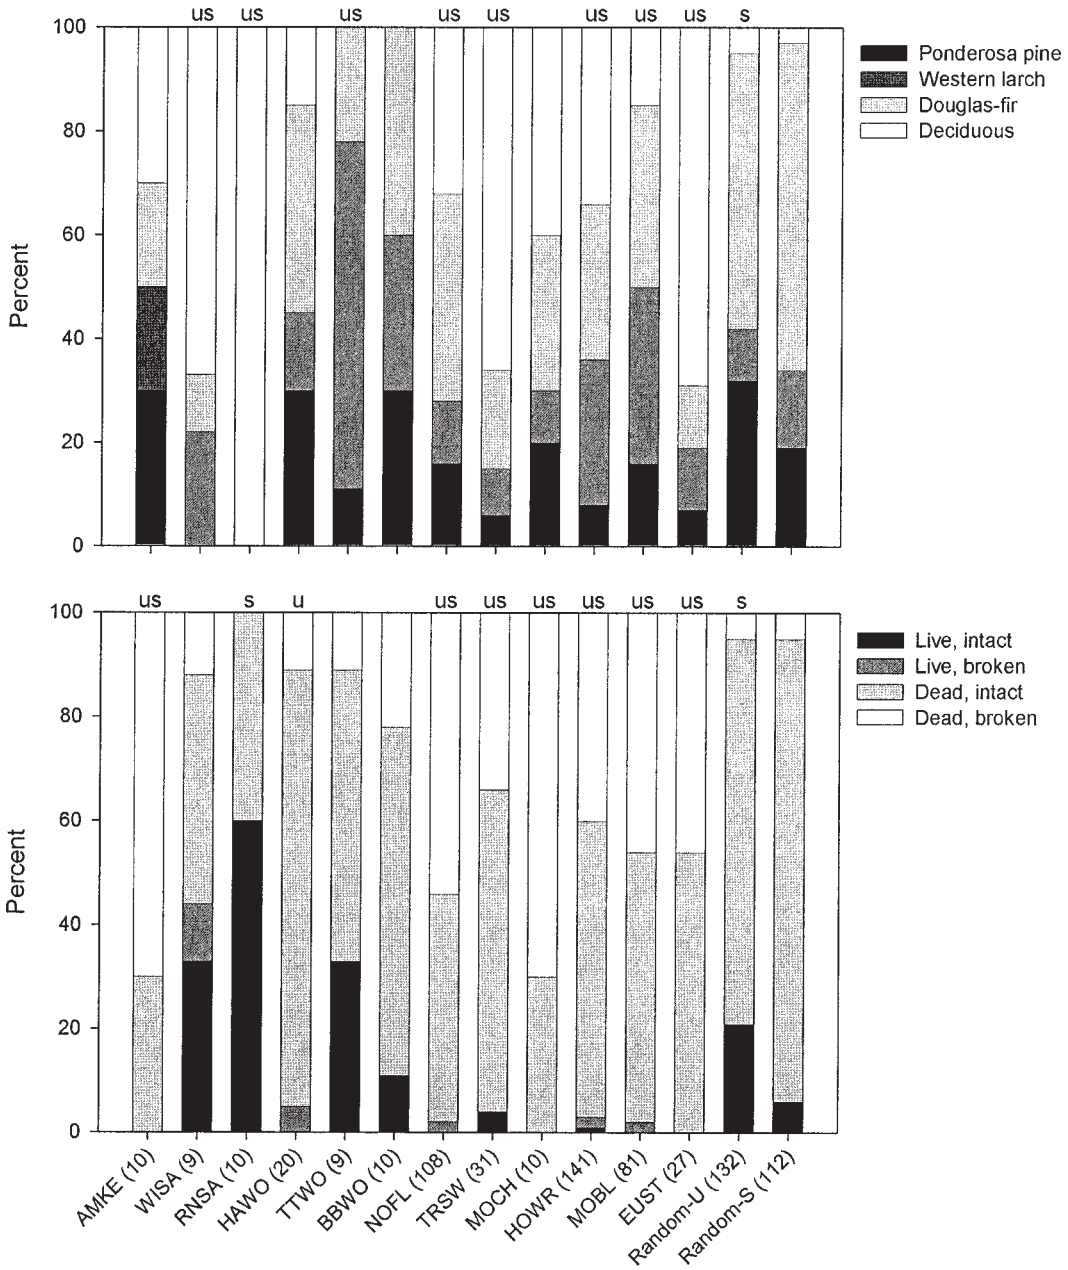

FIGURE 4. Frequency distributions of tree species and status of trees used by cavity-nesting bird species (codes given in Table 2) and of randomly selected trees in unlogged (Random-U) and salvage-logged (Random-S) plots. Most cavity-nesters used deciduous trees and broken-topped snags more than expected due to chance. Sample sizes are given at the bottom of the figure. Small letters indicate significant differences from randomly selected trees in salvage-logged (s) or unlogged (u) plots ($P < 0.05$, chi-square likelihood ratio with Bonferonni correction for multiple comparisons).

live trees for nesting, and several species used broken-topped snags more than expected based on their availability. All but one species (Mountain Chickadee) used nest trees that had significantly larger diameters than randomly selected trees in salvage-logged areas. The

TABLE 6. Percentages of randomly selected trees in unlogged (n = 132) and salvage-logged (n = 112) plots that were considered suitable for primary cavity-nesting species according to each of five different tree characteristics and all five characteristics combined in unlogged (U) and salvage-logged (S) plots in burned forest in Montana, 1993–1995. See Table 2 for Latin names of bird species. Only species with at least nine nests were included. The density of potentially suitable nest trees for each species was much greater in unlogged plots, and was greater than the minimum density needed to support maximum population densities of most cavity-nesting species in both unlogged and salvage-logged plots.

		Tree characteristic												Estimated number per ha	
		DBH		Height		Bark		Status		Species		Combined			
Species	n	U	S	U	S	U	S	U	S	U	S	U	S	U	S

Black-backed Woodpecker	10	58	21	85	77	98	93	100	99	97	93	48	14	172	19
Hairy Woodpecker	20	99	87	85	77	98	96	78	93	100	100	64	63	232	84
Northern Flicker	108	91	61	99	100	79	93	99	99	100	100	62	53	224	71
Mountain Chickadee	10	52	38	80	96	95	92	99	100	78	93	36	41	128	55

selective removal of economically valuable larger-diameter trees clearly reduced the density and average size of snags in salvage-logged areas and, therefore, reduced the amount of suitable nesting habitat. Nevertheless, the decline in density of snags that might be used as nest sites by those bird species that were most negatively affected by logging still far exceeded the 6–8 snags per ha recommended as a minimum number needed to maintain maximum population densities.

These results highlight the fact that we need to appreciate snags as food resources as well as nest-site resources and that, for timber-drilling woodpecker species in particular, the number of snags needed to meet food resource needs appears to be much greater than the number needed to meet nesting requirements. Most woodpecker species in this study are relatively "tree-dependent" foragers because they forage on dead trees for beetle larvae. Burned snags are known to serve as sources of superabundant bark and wood-boring beetle larvae (Muona and Rutanen 1994, Rasmussen et al. 1996, Hart 1998), which are the primary food resource for tree-dependent foragers in burned forests (Powell et al. 2002, Nappi et al. 2003). Salvage logging undoubtedly reduces foraging opportunities for these birds, and may be the primary reason that overall habitat suitability declines for them (Caton 1996). The total disappearance of most timber-drilling and timber-gleaning birds in this study also underscores the need for a modification of current snag management guidelines (Hutto 2006) to better recognize the importance of retaining numerous snags as sources for food (beetle larvae) in burned forests.

In contrast with primary cavity-nesting birds, secondary cavity-nesters are often thought to be limited by the availability of nest sites (Brush 1983, Brawn and Balda 1988, Walankiewicz 1991). Because two-thirds of the cavities we discovered were not reused during the three years of this study, either something other than nest sites limited the density of secondary cavity-nesting birds, or many of the apparently suitable nest cavities were not really suitable at all (see also Welsh and Capen 1992). Other animals (e.g., northern flying squirrels [*Glaucomys sabrinus*] and red squirrels [*Tamiasciurus hudsonicus*]) were observed using previously active cavities, and they are known to displace secondary cavity-nesting birds or depredate their nests. The location of cavities near other nesting birds of the same or different species may also make cavities unsuitable for nesting. For example, birds may avoid nesting near American Kestrel nests because they (or their nestlings) might experience higher rates of predation. Indeed, American Kestrels were observed to prey on other secondary cavity-nesting species in this study. Other predators known to occur in the study area, and that

could have affected the suitability of cavities for secondary cavity-nesters, include striped skunks (*Mephitis mephitis*), black bears (*Ursus americana*), and weasels (*Mustela* spp.). Other factors such as a lack of foraging opportunities could also limit secondary cavity-nesting bird densities in the face of what appear to be abundant nesting opportunities.

Assuming that secondary cavity-nesters are limited by nesting opportunities, it is noteworthy that the frequency of cavity reuse was higher in salvage-logged than in unlogged plots, possibly reflecting a greater level of nest-site limitation in the salvage-logged areas. More than 80% of the nests of secondary cavity-nesters were located in cavities excavated by woodpeckers, indicating a strong reliance on primary cavity-nesting birds for cavity excavation (see also Dobkin et al. 1995). In unlogged areas, the continuous creation of roosting and nesting cavities by primary cavity-nesting species may provide abundant new cavities for secondary cavity-nesting birds to use. In contrast, fewer breeding primary cavity-nesters in salvage-logged areas create fewer new cavities, and this may force secondary cavity-nesting birds to reuse a smaller number of older cavities, which could also affect their nest success in salvage-logged forests.

In conclusion, the cavity-nesting bird community as a whole was clearly negatively affected by salvage logging in our study area in the early years following stand-replacing fire, and the main problem for primary cavity-nesting bird species does not appear to have been availability of snags as nest sites. Rather, the reduction in numbers of trees that harbored important food resources seemed to be to the detriment of the most fire-dependent cavity-nesting bird species. Especially noteworthy was the absence of several postfire specialist woodpecker species from salvage-logged areas and the general decrease in nesting densities of timber-drilling and timber-gleaning species compared to their densities in unlogged burned areas. These results are especially important in light of recent modifications to legislation and regulations by provincial governments in Canada (cited in Nappi et al. 2003) and by the U. S. government (Healthy Forests Restoration Act of 2003) to expedite and provide incentives for salvage logging on top of already documented increases in dead tree harvest in the West (Duncan 2002). Because early postfire cavity-nesting bird communities are biologically unique, and because we lose the most fire-dependent elements of that community through salvage harvests such as the ones included in this study, the merit of postfire salvage logging should be reexamined, especially when there are other, less ecologically sensitive options available for timber harvest. Although research on the effects of different levels and styles of salvage logging are urgently needed, the findings that have already emerged from this and from other studies (McIver and Starr 2000, Kotliar et al. 2002, Beschta et al. 2004, Karr et al. 2004) are entirely consistent, and they suggest that it may be difficult to retain the ecological integrity of a burned forest in the face of most kinds of postfire salvage logging.

ACKNOWLEDGMENTS

We thank two anonymous reviewers, David Dobkin, Sallie Hejl, Paul Alaback, Elaine Caton, Vita Wright, and Jock Young for comments on earlier drafts of this paper. Financial assistance for this study was provided by a McIntire-Stennis grant from the University of Montana College of Forestry and Conservation and a student research grant from the North American Bluebird Society. Generous in-kind support was provided by the Montana Department of Fish, Wildlife and Parks, Champion Timber Company, and Richard Howe. Special thanks to Mike Thompson at Montana Fish, Wildlife and Parks for his help through all phases of this project and to Ann Mull for field assistance.

ABSTRACT

Dispersal among breeding sites in territorial animals (i.e. breeding dispersal) is driven by numerous selection pressures, including competition and spatiotemporal variation in habitat quality. The scale and trend of dispersal movements over time may signal changing conditions within the population or on the landscape. We examined 2,158 breeding dispersal events from 694 male and 608 female individually marked Northern Spotted Owls (*Strix occidentalis caurina*) monitored over 28 yr on 7 study areas to assess the relative importance of individual (sex, experience), reproductive (annual productivity, mate availability), and environmental (forest alteration, presence of competitor) sources of variation in breeding dispersal distance. Median breeding dispersal distance was 3.17 km, with 99% of all breeding dispersal events <37 km. Mean annual dispersal distances increased by 2.43 km in Oregon and 9.40 km in Washington between 1990 and 2017, which coincided with increases in annual detections of nonnative Barred Owl (*S. varia*). Frequency of breeding dispersal events, both among and within individuals, also increased over time. Female owls moved farther than males (median of 3.26 and 3.10 km, respectively), and birds with less experience (territory tenure) moved farther than those with more experience. Owls that were single in the year prior to dispersal moved 13–31% farther than those paired prior to dispersal. The greatest environmental change occurring over the course of our study was the expansion of Barred Owl populations. Breeding dispersal distance was positively related to Barred Owls in the study area and disturbance within the originating territory. While it appears that social factors continue to be important drivers of breeding dispersal distance in Spotted Owls, increased competition from Barred Owls and habitat alteration have a contributing effect. Increased breeding dispersal distances should be of concern for conservation efforts and considered in population monitoring because changing dispersal behavior may lead to higher rates of mortality and/or emigration from historical study areas.

Keywords: Barred Owl, breeding dispersal, forest disturbance, Northern Spotted Owl, *Strix occidentalis caurina*, *Strix varia*

El estatus social, los disturbios del bosque y la presencia de *Strix varia* determinan las tendencias de largo plazo de la distancia de dispersión reproductiva de *Strix occidentalis caurina*

RESUMEN

La dispersión entre los sitios reproductivos en los animales territoriales (i.e. dispersión reproductiva) está determinada por numerosas presiones de selección, incluyendo competencia y variación espacio-temporal en la calidad del hábitat. La escala y la tendencia de los movimientos de dispersión a lo largo del tiempo pueden indicar las condiciones cambiantes al interior de la población o en el paisaje. Examinamos 2,158 eventos de dispersión reproductiva provenientes de 694 machos y 608 hembras de *Strix occidentalis caurina* marcados individualmente, monitoreados a lo largo de 28 años en siete áreas de estudio, para evaluar la importancia relativa de las fuentes de variación individual (sexo, experiencia), reproductiva (productividad anual, disponibilidad de pareja) y ambiental (disturbio del bosque, presencia de competidores) en la distancia de dispersión reproductiva. La distancia media de dispersión reproductiva fue 3.17 km, con el 99% de todos los eventos de dispersión reproductiva menores a 37 km. Las distancias de dispersión media anual aumentaron 2.43 km en Oregón y 9.40 km en Washington entre 1990 y 2017, lo que coincidió con aumentos en las

detecciones anuales de la especie no nativa *S. varia*. La frecuencia de los eventos de dispersión reproductiva, tanto entre individuos como para un mismo individuo, también aumentaron a lo largo del tiempo. Las hembras de los búhos se movieron más que los machos (mediana de 3.26 y 3.10 km, respectivamente), y las aves con menos experiencia (tenencia territorial) se movieron más lejos que aquellas con más experiencia. Los búhos solteros durante el año anterior a la dispersión se movieron 13–31% más lejos que aquellos en pareja antes de la dispersión. El cambio ambiental más grande ocurrido a lo largo del tiempo de nuestro estudio fue la expansión de las poblaciones de *S. varia*. La distancia de dispersión reproductiva estuvo positivamente relacionada con *S. varia* en el área de estudio y los disturbios dentro del territorio de origen. Si bien parece que los factores sociales continúan siendo condicionantes importantes de la distancia de dispersión reproductiva en *Strix occidentalis caurina*, el aumento de la competencia por parte de *S. varia* y la alteración del hábitat tienen un efecto adicional. El aumento de las distancias de dispersión reproductiva debería ser motivo de preocupación para los esfuerzos de conservación y considerados en el monitoreo poblacional debido a que los cambios de comportamiento en la dispersión pueden llevar a mayores tasas de mortalidad y/o de emigración de las áreas de estudio históricas.

Palabras clave: dispersión reproductiva, disturbio del bosque, *Strix occidentalis caurina*, *Strix varia*

INTRODUCTION

Dispersal in territorial animals is driven by numerous selection pressures including inbreeding avoidance, competition, and spatiotemporal variation in habitat quality (Bowler and Benton 2005, Roze and Rousset 2005). There are 2 general categories of dispersal movements recognized in birds: natal dispersal, which is the movement between territories prior to the first breeding attempt, and breeding dispersal, defined as the movement of individuals between successive breeding places (Greenwood and Harvey 1982, Morrison and Wood 2009). Breeding dispersal is likely adaptive because switching breeding territories may increase access to mates or to higher-quality habitats with fewer threats or competitors. Alternatively, dispersers may also incur costs from movement to unfamiliar breeding territories, such as increased predation, resource limitation, or intra- or inter-specific aggression (Daniels and Walters 2000, Morrison and Wood 2009). Often, one sex disperses farther than the other; in mammals, male-biased dispersal is common, whereas in birds, female-biased dispersal is the norm (Greenwood 1980). Moreover, breeding dispersal movements may be short, perhaps representing a shift to an adjacent territory, or relatively far, potentially signifying emigration to another metapopulation. As a consequence, breeding dispersal involves a series of strategic decisions concerning whether or not to move, and if so, how far.

Breeding dispersal distances tend to be lower for abundant species with generalist habits, and greater for species that specialize on patchily distributed habitats (Paradis et al. 1998, Martin and Fahrig 2018). Dispersal movements may also be longer from poor-quality territories since those territories are often spatially larger (Bowman 2003). The magnitude and trend in breeding dispersal movements over time may signal population or environmental alterations. Changes within a territory such as a disturbance event (e.g., fire), the introduction of a predator (Bried and Jouventin 2007, Forero et al. 2008), or an increase in intra- or inter-specific competition may increase dispersal distances by decreasing the realized quality of a territory in terms of resource abundance, availability, and distribution (Kim et al. 2009). The abundance, availability, and distribution of resources and competitors across the landscape likely also influence the amount of time and distance required to locate a suitable territory.

The Northern Spotted Owl (*Strix occidentalis caurina*; hereafter Spotted Owl) is a long-lived territorial species with strong site and mate fidelity in both sexes (Forsman et al. 1984). Spotted Owls specialize on areas with mature coniferous forest and require old forest for nesting and roosting (Forsman et al. 2015, Davis et al. 2016, Sovern et al. 2019). The subspecies was listed as threatened under the Endangered Species Act in 1990 because of extensive loss of these forest conditions to timber harvest (USFWS 1990). Despite extensive efforts to protect old forest on federal lands under the Northwest Forest Plan (USDA and USDI 1994), Spotted Owl populations continue to decline. These declines have been linked with interspecific competition and territorial displacement by a novel invader, the Barred Owl (*S. varia*) (Dugger et al. 2016, Lesmeister et al. 2018). Forsman et al. (2002) reported a mean breeding dispersal rate of ~7% annually by color-marked Spotted Owls monitored in Oregon and Washington, USA, during 1985–1996. Investigations prior to the widespread Barred Owl expansion found that breeding dispersal in the Northern Spotted Owl and California Spotted Owl (*S. o. occidentalis*) was primarily affected by an individual's age, sex, social status (e.g., non-return of mate), and amount of habitat disturbance or alteration within their territory (Forsman et al. 2002, Blakesley et al. 2006, Gutiérrez et al. 2011).

An increased understanding of what environmental and social factors affect breeding dispersal distance in declining populations, and how these factors may change over time, can help inform conservation planning. Our primary objective was to document trends in Spotted Owl breeding dispersal distance, particularly in relation to forest disturbance and the range expansion of Barred Owls. We expected

Downloaded from https://academic.oup.com/condor/advance-article-abstract/doi/10.1093/condor/duz055/5658470 by U S Dept of Agriculture user on 11 December 2019

dispersal distance to increase with increasing forest disturbance or the increasing occurrence of Barred Owls on historical territories of Spotted Owls. We also examined the effects of sex, prior reproductive status (productivity and pair status), and territory quality (historical productivity) on Spotted Owl breeding dispersal distances. We predicted that dispersal distance would be longer for females compared to males (Clarke et al. 1997, Forsman et al. 2002, Blakesley et al. 2006, Ganey et al. 2014), inexperienced (e.g., younger) compared to more experienced birds (Forsman et al. 2002, Kim et al. 2007), single compared to paired owls (Forsman et al. 2002, Andreu and Barba 2006), birds paired with a new mate compared to those paired with a previous mate (Forsman et al. 2002, Kim et al. 2007), and unproductive owls compared to owls that successfully fledged young prior to dispersal, or were on historically productive territories (Forsman et al. 2002, Calabuig et al. 2008, Jiménez-Franco et al. 2013).

METHODS

Spotted Owl Monitoring

We analyzed all documented breeding dispersal events of marked adult Spotted Owls from 7 study areas within 5 ecophysiographic provinces in Oregon and Washington during 1990 to 2017 (Figure 1). Study areas were the Olympic Peninsula (OLY; 2,541 km^2) and Cle Elum (CLE; 980 km^2) areas in Washington and the Oregon Coast Range (OCR; 1,810 km^2), Tyee (TYE; 810 km^2), H.J. Andrews (HJA; 1,004 km^2), South Cascades (CAS; 2,372 km^2), and Klamath (KLA; 1,074 km^2) areas in Oregon (Figure 1). Study areas and ecophysiographic provinces varied in climate, vegetation, and amount of topographic relief, but all areas were dominated by conifers or mixed conifer–hardwood forests. For more details on the environmental conditions of our study areas see Forsman et al. (2011) and Dugger et al. (2016).

We studied breeding dispersal as part of a long-term monitoring program for Spotted Owls that used a standardized survey protocol for locating and monitoring individually color-marked owls (Lint et al. 1999). Surveys were conducted during the breeding season (March through August) using night call-back methods to elicit territorial responses followed by daytime visits to locate owls, resight previously banded owls, band and determine the sex and age class of unmarked owls, and document owl social status and productivity. Specific protocols have been extensively described in prior publications (e.g., Lint et al. 1999, Dugger et al. 2016) and were consistent throughout the study period with the exception of the OLY study area where monitoring was discontinued on a portion of southern historical territories in 2006 because of budgetary limitations. We generated Thiessen polygons to represent historically occupied owl territories and to calculate territory-specific metrics (Dugger et al. 2016). Polygons were created using annual activity center locations (e.g., a used nest tree) of owls during 1990–2017. Because these polygons were generated using activity centers gathered across the study period, they are representative of historical Spotted Owl annual activity centers and do not capture annual variation in territory boundaries. Thiessen polygons extended from activity center locations to a maximum of half of the median nearest-neighbor distance, or midway between the annual activity centers of owls occupying adjacent territories, whichever distance was shorter (Dugger et al. 2016).

We defined a breeding dispersal event as the movement of a territorial owl between years to a different territory where it had the opportunity to breed, regardless of whether it actually bred previously, which included both paired or single residents (Daniels and Walters 2000, Forsman et al. 2002, Seamans and Gutierrez 2007). Spotted Owls often use different nest sites within a territory (Forsman et al. 1984), so we excluded cases where movements involved use of alternate nests in the same historical territory in different years. Movements by sub-adults (age 1–2) were only included if birds were observed as territorial with a mate prior to moving (i.e. the natal dispersal had been confirmed).

For each time interval between annual observations we recorded whether or not an individual owl dispersed to a new territory and the linear distance between activity centers. We compiled a database of breeding dispersal movements that included characteristics of the owl and territory before and after the movement. For this analysis, we only looked at dispersal events, including movements that occurred to areas outside study area boundaries. We did this to reduce potential bias toward shorter dispersal distances that can occur when study area boundaries are finite (Koenig et al. 1996). However, because our annual search effort was primarily focused within study area bounds, the frequency of long-distance breeding dispersal events are still likely underrepresented.

We considered age class and number of years at a territory prior to dispersal as measures of experience. We characterized owls into 3 age classes based on known age at banding and plumage differences between birds at year 1 (S1; rectrices with white, slightly pointed tips), year 2 (S2; rectrices with white, slightly rounded tips), and >2 years (adult; rectrices with white and brown blotches, rounded tips) (Forsman et al. 1984). We generated 3 measures of experience at a territory (i.e. territory tenure pre-dispersal): (1) number of years spent on the territory prior to moving; (2) a binary variable describing if a bird was new to a territory (n = 0 yr) or had previously occupied the territory ($n \geq$ 1 yr); and (3) a categorical variable assigned as no prior experience (n = 0 yr), low experience (0 yr < n < 3 yr), or high

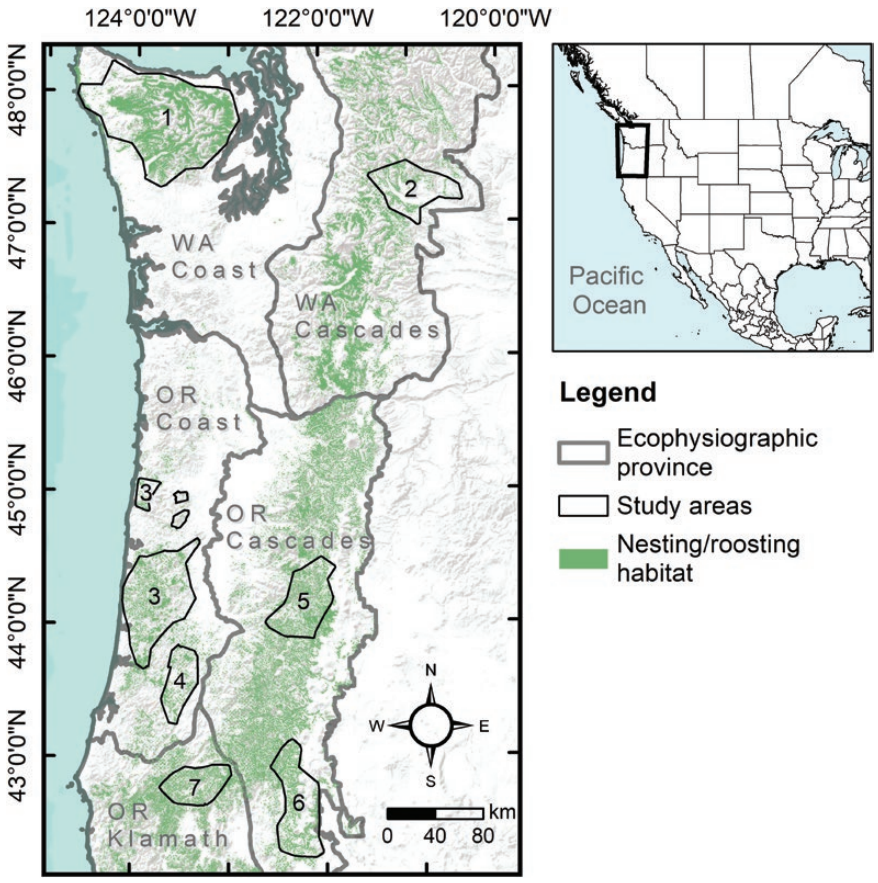

FIGURE 1. Locations of the 7 study areas (Olympic Peninsula [1], Cle Elum [2], Oregon Coast Range [3], Tyee [4], H.J. Andrews [5], South Cascades [6], and Klamath [7]) in 5 ecophysiographic provinces of Oregon and Washington used to examine trends in breeding dispersal distance in Northern Spotted Owls, 1990–2017. Also shown is the landscape distribution of suitable nesting and roosting habitat for Northern Spotted Owls as of 2012, based on a habitat suitability map developed by Glenn et al. (2017).

experience ($n \geq 3$ yr). The categorization between "low" and "high" territory experience was arbitrarily made based on category sample sizes. Because S1 and S2 birds could only have 0–1 yr of experience at a prior territory, all "experience" variables were somewhat confounded with age, thus we tested age and experience separately in models. We also generated and considered 3 potential measures of owl reproductive status prior to and after movement based on capture histories of color-marked individuals. These measures were also interrelated and considered separately in models. We recorded pair status as single, paired, or unknown, and mate status as single, paired with a new or unknown mate, paired with a mate from a previous year, or unknown. Productivity was categorized as no young fledged, successfully fledged ≥1 young, or unknown. We tested for differences in proportions of male vs. female dispersers, and in rates of productivity and pair status before and after dispersal with simple chi-square tests and report *P* values.

To address our hypothesis that dispersal distance would be shorter when individuals occupied historically productive territories, we generated an index of territory quality (TQ) based on the number of young produced from territory i within ecophysiographic province p during the study period (Blakesley et al. 2006):

$$\mathrm{TQ}_i = \frac{\sum_j (NYF_{ipj} - \overline{NYF_{pj}})}{n_i}$$

where *NYF* is the number of young fledged, j is the year with reproductive data available for each p, and n is the number of years for which reproductive data were available for a territory i. We only calculated TQ for territories for which we had at least 5 yr of productivity information available and acknowledge that this variable does not account for temporal variation in habitat quality.

Forest Disturbance

Old forest is a primary component of Spotted Owl habitat, which is susceptible to loss from timber harvest, wildfires, windstorms, insect infestations, and disease (Davis et al. 2016, Lesmeister et al. 2018). The impact of these

Downloaded from https://academic.oup.com/condor/advance-article-abstract/doi/10.1093/condor/duz055/5658470 by U S Dept of Agriculture user on 11 December 2019

disturbance events on Spotted Owls can vary with the extent and severity of the disturbance (Comfort et al. 2016, Lesmeister et al. 2018, 2019). Following Reilly et al. (2017) we partitioned disturbances into 3 severity classifications based on estimated percent basal area removal: low (<25% removal), moderate (25–75% removal), and high (>75% removal). We predicted that low-severity disturbance (e.g., primarily timber stand thinning and insect-related loss) would have less effect on dispersal distance compared to moderate- or high-severity disturbance (e.g., clear-cut harvest, stand-replacing wildfire). Low-severity wildfires have little effect on nesting habitats of Spotted Owls, which may be more resistant to high-severity wildfire compared to younger or less–structurally complex forests (Lesmeister et al. 2019). While we acknowledge that wildfire and timber harvest are not equivalent disturbances, we combined them for our disturbance metrics because of the scarcity of fire in our dataset (Appendix Figure 6). We used Google Earth Engine (Gorelick et al. 2017) and annual Landsat disturbance data in *LandTrendr* (Kennedy et al. 2010, Cohen et al. 2017) to estimate 3 annual measures of forest disturbance for each territory (i.e. Thiessen polygon) within the prior 3 yr: (1) proportion of territory with "any severity" disturbance, (2) proportion of territory with "low severity" disturbance, and (3) proportion of territory with "moderate-to-high severity" disturbance (e.g., 1990 habitat alteration proportion was generated using the sum of disturbance in 1988, 1989, and 1990).

Occurrence of Barred Owls

Although Barred Owls were not specifically surveyed, we documented over 22,500 incidental detections of Barred Owls during surveys of Spotted Owls, and detections of Barred Owls were an effective proxy for increases in the presence of Barred Owls in each study area (Dugger et al. 2016, Yackulic et al. 2019). For each year and study area, we calculated the annual percentage of historical Spotted Owl territories (Thiessen polygons) with ≥1 detection of Barred Owls at any year previous to, and including, the current monitoring year (BO; Figure 2). A subset of territories in the OLY study area were dropped from the demography study in 2006. Thus, for consistency, the Barred Owl covariate was generated across only the OLY territories monitored throughout the study.

Dispersal Distance Modeling

We used generalized linear mixed models within an information-theoretic framework to evaluate relationships between breeding dispersal distance and individual and environmental sources of variation (Table 1; Burnham and Anderson 2002, Bolker et al. 2009). We did not include movements from non-dispersers in analyses. Prior to generating models with additive covariate effects, we ranked and selected the best performing a priori univariate model structure (linear, quadratic, pseudo-threshold vs. categorical) for related groups of covariates, using Akaike's information criterion (AIC; Table 1). Our final additive model set was generated as combinations of covariates from univariate models with $\Delta AIC \leq 2$ in each covariate group. Only univariate models that scored above the null model were considered in additive models. Covariates with a Spearman's rank correlation coefficient >0.6 were not included in the same model. We observed no linear trend in disturbance variables over time within our sampled territories (Spearman's rank correlation coefficients with year <|0.01|) but the Barred Owl covariate was considered a temporal covariate (Spearman's rank correlation with year = 0.86) because the proportions of territories with detections increased over time in all study areas (Figure 2).

We fit all models using the *lme4* package in program R using a gamma distribution with a log link (Bates et al. 2015, R Core Team 2018). We included random effects of ecophysiographic province and year on the intercept in all models, including the "intercept-only" model with no fixed effects. The random effect of ecophysiographic province was included to account for regional variation in landscape and sample sizes. Year was included as a random effect to account for temporal process variance not associated with Barred Owl occurrence. Our dataset contained multiple dispersals from some individuals; however, models failed to converge when we included a random effect of individual. When we used only the data for individuals with more than one movement, the interclass correlation coefficient for distance was 0.27 (95% CI: 0.22–0.34), indicating low measurement repeatability (Wolak et al. 2012), so we retained all movements in our analyses. We considered effects in top-ranked models to be strongly supported if the 95% confidence interval (CI) for the parameter coefficient did not include zero. We report means ± standard error unless otherwise noted. Model assumptions were verified by plotting residuals vs. fitted values. To assess model fit, we report Nakagawa's R^2 for mixed effect models for the top model (Johnson 2014, Nakagawa et al. 2017).

RESULTS

We documented 2,158 breeding dispersal events during 1990–2017 from 1,302 owls (694 male, 608 female) with median breeding dispersal distance of 3.17 km. Ninety-nine percent of all documented breeding dispersal movements were ≤37 km (range: 0.04–94.55 km; Figure 3A). Sample sizes were uneven between provinces and birds in Oregon accounted for 90% of all dispersal events (Appendix Table 4). Washington birds moved farther on average than Oregon birds; mean annual dispersal distances in Washington increased by 9.40 km between

Downloaded from https://academic.oup.com/condor/advance-article-abstract/doi/10.1093/condor/duz055/5658470 by U S Dept of Agriculture user on 11 December 2019

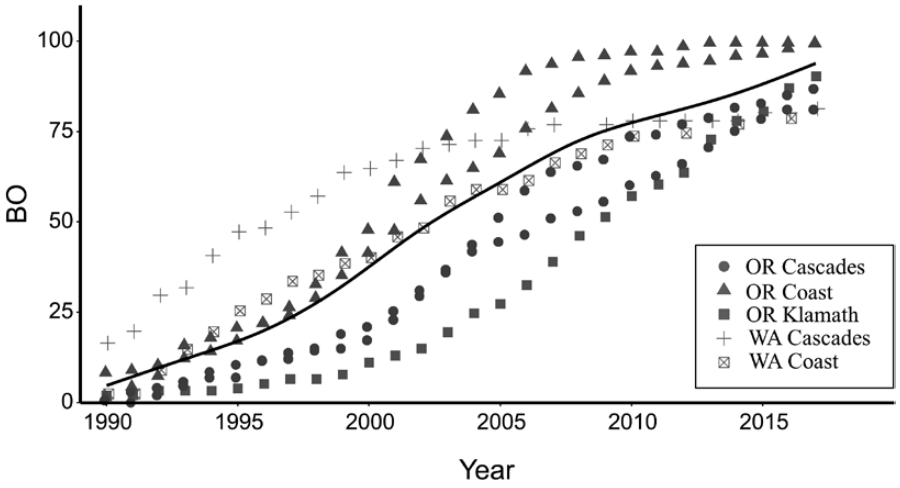

FIGURE 2. Annual trend in the percentage of cumulative Northern Spotted Owl territories with ≥1 Barred Owl (BO) detection for different ecophysiographic provinces in Oregon and Washington, USA. Spearman's rank correlation of 0.86 between year and BO (all areas combined). The solid line indicates the smoothed annual mean across provinces.

TABLE 1. Descriptions of variables and model structures considered in analyses of breeding dispersal distance for Northern Spotted Owls in Oregon and Washington, USA, 1990–2017.

Group	Variable	Structures tested against null model [a]	Used in additive model set
Sex	SEX, female or male	Categorical	SEX
Experience	EAS, experience at territory in observation prior to dispersal (years)	Linear Quadratic Pseudo-threshold [b] Categorical 2 groups Categorical 3 groups	EAS (3 groups)
	AGE, age class in observation prior to dispersal (S1, S2, Adult)	Categorical 2 groups Categorical 3 groups	
Reproductive status	PS, pair status in observation prior to dispersal (single, paired, unknown)	Categorical 3 groups	MS
	MS, mate status in observation prior to dispersal (single, paired with new mate, paired with old mate, unknown)	Categorical 4 groups	
	P, productivity in observation prior to dispersal	Categorical 3 groups	
Barred Owl	BO, annual proportion of study area territories with Barred Owl detections	Linear Pseudo-threshold	BO
Territory quality	TQ, index of territory quality of prior location (−1 to 1)	Linear	*Not used*
Habitat	D, proportion of prior territory with any severity forest disturbance in prior 3 years	Linear Quadratic Pseudo-threshold	Ln(D)
	D_MH, proportion of prior territory with moderate-to-high severity forest disturbance in prior 3 years	Linear Quadratic Pseudo-threshold	
	D_L, proportion of prior territory with low severity forest disturbance in prior 3 years	Linear Quadratic Pseudo-threshold	

[a] See Appendix Table 5 for model-selection results of initial tests of variable structures and related groups of variables.
[b] Psuedo-threshold structure was approximated using ln(x).

1990 and 2017 (Figure 3B); while in Oregon, mean annual dispersal distances increased by 2.43 km between 1990 and 2017 (Figure 3C). Sixty-one percent of owls in our dataset (n = 793) moved once. However, the proportion of repeat dispersers each year (>1 previous dispersals on record) increased over time (Figure 4), with 23% of birds (n = 300) moving 2 times, 10% (n = 131) moving 3 times, 3% (n = 40) moving 4 times, and 3% moving 5–8 times (23 moved 5 times, 10 moved 6 times, 3 moved 7 times, 2 moved 8 times).

Downloaded from https://academic.oup.com/condor/advance-article-abstract/doi/10.1093/condor/duz055/5658470 by U S Dept of Agriculture user on 11 December 2019

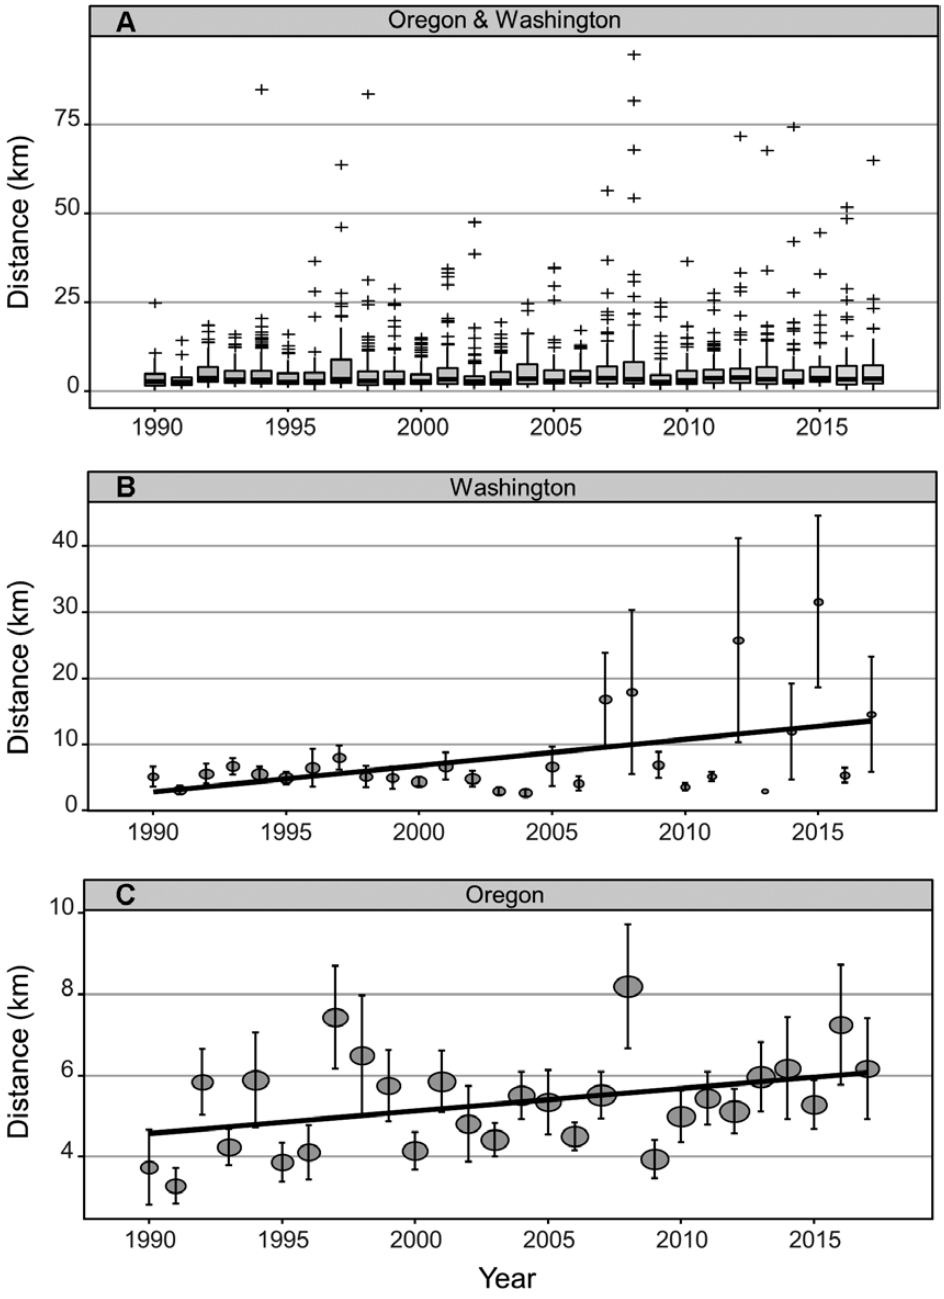

FIGURE 3. Boxplot and mean annual trend in observed breeding dispersal events in Northern Spotted Owls in Oregon and Washington from 1990 to 2017. The majority of breeding dispersal observations were <10 km from prior territories, but outliers extended as far as 95 km (**A**). Mean (± SE) breeding dispersal distances fluctuated over time with an overall positive trend, which was greater in Washington (**B**) (n = 210) compared to Oregon (**C**) (n = 1,948). The point size in panels (**B**) and (**C**) vary with annual sample size.

Ninety-two percent of all breeding dispersals were made by birds ≥3 yr old (n = 1,993; Appendix Table 4). More breeding dispersal events were observed from male Spotted Owls (54% of observed breeding dispersal events; χ^2 = 16.91, P < 0.001; Appendix Table 4). The average owl experience at the territory prior to moving was 2.06 ± 0.06 yr (range: 0–17; Appendix Figure 7). Based on the total number of territorial birds that dispersed, the percentage of birds paired and successfully producing young increased post-dispersal (χ^2 = 27.77, P < 0.001). In the year before dispersing, 18% of individuals produced young. After dispersal, 24% of dispersers produced young. The percentage of birds paired also increased post-dispersal (χ^2 = 18.45, P < 0.001). Prior to dispersal, 77% of dispersers were paired (18% single, 36% paired with prior mate, 41% paired with new/unknown mate, 5% pair status unknown).

Downloaded from https://academic.oup.com/condor/advance-article-abstract/doi/10.1093/condor/duz055/5658470 by U S Dept of Agriculture user on 11 December 2019

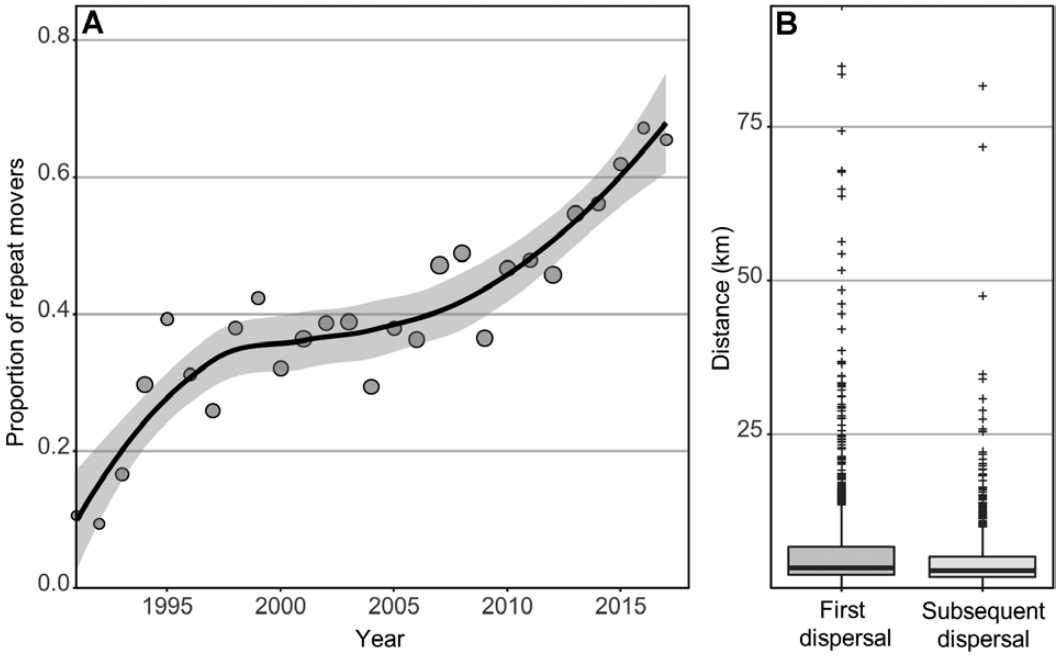

FIGURE 4. The annual proportion of individual Northern Spotted Owls dispersing more than once increased over time in our sample of 1,258 breeding dispersal events (**A**). Subsequent dispersal distances were indistinguishable from initial dispersal events (**B**). In panel (**A**), point size reflects annual sample size with the smoothed mean and standard error shown.

After dispersal, 83% of dispersers were paired (13% single, 20% paired with prior mate, 62% paired with new/unknown mate, 4% unknown paired status). Of the owls that were paired prior to dispersing, the mean experience with that mate was 1.37 ± 0.08 yr (range: 0–15 yr; Appendix Figure 7). Overall, forest disturbance was low across territories within our dispersal dataset; 75% of breeding dispersal movements originated from territories with <2% of their area disturbed at any severity in the prior 3 yr and 99% of movements originated from territories with <23% of their area disturbed at any severity in the prior 3 yr (Appendix Figure 6). Eleven movements originated from territories with >30% of the area disturbed within the prior 3 yr (max = 96.4%).

The best-supported model of breeding dispersal distance included the additive effects of sex, experience at a site prior to dispersal, the pseudo-threshold effect of disturbance at a site, Barred Owl occurrence, and mate status (SEX + EAS + ln[D] + BO + MS) with random effects of ecophysiographic province and year on the intercept (Table 2; Appendix Figure 8). Ecophysiographic province accounted for 1.2% of the overall variance and year accounted for 3.3% of the overall variance. The 95% CIs of coefficients of all covariates in the top model did not overlap zero, except for mate status "unknown" (Table 3), which was not different from mate status "single." Holding other covariates constant at their median or mode, male breeding dispersals were 20% shorter than females (exp[β] = 0.80, 95% CI: 0.75–0.86; Table 3, Figure 5). Similarly, breeding dispersals were 31% shorter when experience at territory prior to dispersal was high (exp[β] = 0.69, 95% CI: 0.62–0.76; Figure 5) compared to no prior experience at a territory, and 14% shorter when experience at territory prior to dispersal was low (exp[β] = 0.86, 95% CI: 0.77–0.95; Figure 5) compared to no prior experience at a territory. Dispersal distance was positively associated with Barred Owl occurrence (exp[β] = 1.50, 95% CI: 1.20–1.86; Figure 5) and with proportion of disturbance on the originating territory (exp[β] = 1.04, 95% CI: 1.02–1.06; Figure 5). Models with additive effects of disturbance and Barred Owl occurrence outperformed models that considered these effects independently (Table 2). We tested for an interaction between forest disturbance and our Barred Owl covariate within the top model; however, the interaction term was not supported based on AIC ranking.

DISCUSSION

We found that sex, territory tenure, pair status prior to moving, Barred Owl occurrence, and the degree of territory disturbance were all predictors of breeding dispersal distance in Spotted Owls. Our data fit the general pattern observed in birds of females dispersing farther than males, often attributed to intrasexual competition and inbreeding avoidance (Greenwood and Harvey 1982, Pusey 1987, Forsman et al. 2002). We also found that younger birds or those with less experience with mates or territories dispersed farther than older or more

[a] All coefficient statistics are presented untransformed on log-link scale.
[b] Intercept: adult female, single prior to dispersing, first year at prior territory.
Abbreviations: EAS = experience at prior territory; MS = mate status in prior year; D = proportion of prior territory disturbed (any severity) within 3 years; BO = cumulative proportion of study area with Barred Owl detection.

experienced individuals, which may reflect a competitive advantage of strong site and mate fidelity (Andreu and Barba 2006, Calabuig et al. 2008, Forero et al. 2008). In contrast to our findings, Blakesley et al. (2006) did not find differences in dispersal distance between sexes or age classes in California Spotted Owls. However, they utilized a much smaller sample size (n = 54). Generally, in territorial animals, adults (or territory holders) are able to displace younger individuals (or nonresidents) from established areas (Murray 1967). Spotted Owls do not vacate territories annually (nonmigratory). Thus, the ability of a nonresident to displace a resident individual is likely further reduced. Furthermore, since dispersal comes with inherent risk, we expected dispersing individuals to settle on the first uncontested suitable site they found (Murray 1967). Collectively, dispersal distances were negatively skewed toward short-distance dispersal events and the median dispersal distance (3.17 km) was similar to what was observed in our region previously (3.5 km; Forsman et al. 2002), which is shorter than observations of California Spotted Owls (7 km; Blakesley et al. 2006).

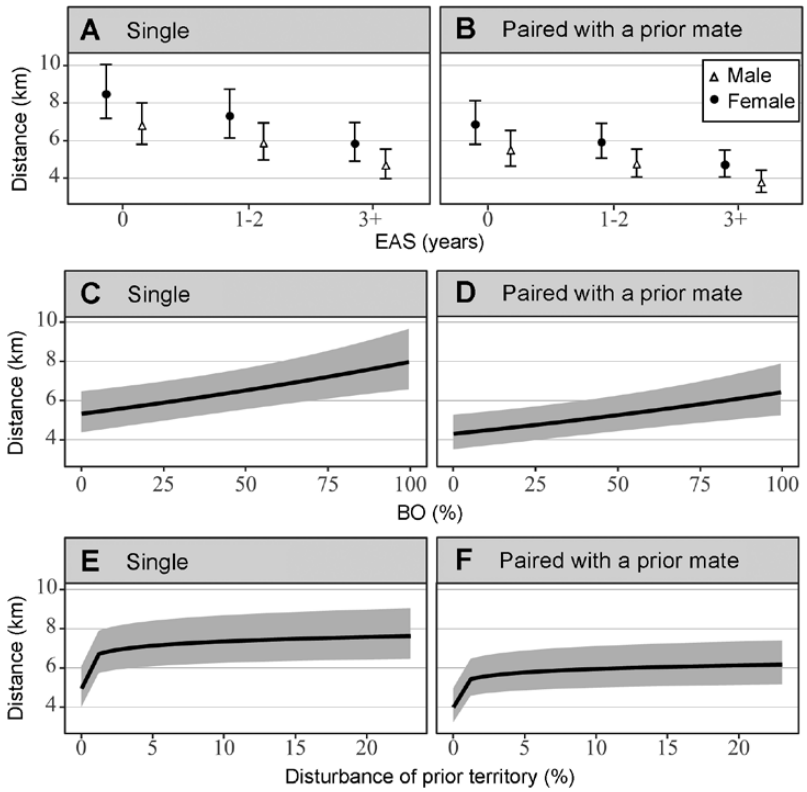

FIGURE 5. Predicted dispersal distance of Northern Spotted Owls with 95% confidence intervals for sex, prior territory experience (EAS) (**A** and **B**), Barred Owl coverage within study areas (BO) (**C** and **D**), and disturbance (**E** and **F**). Predictions were generated for Spotted Owls that were single or paired with a previous mate before dispersing, while holding other covariates at the covariate median or mode.

Animals occupying habitats with stable conditions typically show site fidelity or restricted movements between alternate breeding sites (Greenwood and Harvey 1982). Historically, this was true of Spotted Owls (Forsman et al. 2002). We found some support for increased breeding dispersal distances over time as well as an increase in the number of dispersal events by individual Spotted Owls, which could indicate a potential reduction in stability of habitat conditions for Spotted Owls in the last 20 yr. Early increases in frequency of repeat movers (1990–1995) were likely representative of study initiation effects (i.e. our ability to detect a second dispersal improved as the length of the study increased), rather than true biological increase. However, this was also a period of consistent old-forest harvest on federal lands, which may have contributed to greater dispersal movements during this time. We did not detect time trends in forest disturbance within our sampled territories, but since 1990 there was a positive trend in the proportion of Spotted Owl territories with Barred Owl detections and a correspondingly negative trend in survival and recruitment of Spotted Owl populations in our study areas (Dugger et al. 2016). Our data and analyses suggested that additive effects of habitat disturbance and competition with Barred Owls increased distances moved by Spotted Owls. We also observed higher rates of long-distance dispersal and an increased frequency of repeat dispersal events in the later years of our study, which coincided with increasing occurrence of Barred Owls.

Interspecific interactions have important implications for spatial ecology of sympatric predator communities. Interspecies competition with brown bears (*Ursus arctos*), for example, affects movement patterns of American black bears (*U. americanus*) but only when high-quality resources are spatially restricted (Belant et al. 2010). Similarly, interference competition among gray wolves (*Canus lupus*) can influence the distribution of coyotes (Berger and Gese 2007). Because of antagonistic interactions and high overlap in resource selection, Barred Owls may increase Spotted Owl breeding dispersal distance directly through conspecific territorial displacement and resource competition (Jenkins et al. 2019b, Wiens et al. 2014). Hybridization (direct competition for mates) occurs but is uncommon in our study areas (Kelly and Forsman 2004). Competition with Barred Owls has been linked to reductions in territory occupancy (Kelly et al. 2003, Olson et al. 2005, Kroll et al. 2010, Dugger et al. 2011, 2016; Yackulic et al. 2012,

Downloaded from https://academic.oup.com/condor/advance-article-abstract/doi/10.1093/condor/duz055/5658470 by U S Dept of Agriculture user on 11 December 2019

Sovern et al. 2014, Forsman et al. 2015) and apparent survival (Anthony et al. 2003, Forsman et al. 2011, Glenn et al. 2011, Diller et al. 2016, Dugger et al. 2016), both of which represent a combination of increased emigration (dispersal outside of a study area) and/or increased mortality of territory-holding adults. Barred Owls have also been associated with reduced reproduction by Spotted Owls (Olson et al. 2005, Wiens et al. 2014, Dugger et al. 2016). In contrast, Barred Owl presence was not supported as affecting natal dispersal distance in the same study populations of Spotted Owls during 1985–2013 (Hollenbeck et al. 2018). However, Hollenbeck et al. (2018) modeled annual Barred Owl presence at the individual-territory scale, which includes temporal and spatial variability associated with the lack of focused Barred Owl surveys (i.e. Barred Owl detection rates <1.0). In contrast, for this study we developed an annual index of cumulative Barred Owl presence across each study area. This cumulative index is likely a better representation of overall increases in density of Barred Owls at the study area scale, but precludes direct comparisons between these 2 studies. Elsewhere, experimentally augmented nest predation risk increased the likelihood and distance of breeding dispersal in Boreal Owls (*Aegolius funereus*; Hakkarainen et al. 2001). We do not consider Barred Owls a primary nest predator of Spotted Owls, but interspecific territoriality may disrupt Spotted Owl pair bonding and limit the availability of breeding territories for Spotted Owls, thereby leading to reductions in breeding propensity (Mangan et al. 2019), mate retention, and nesting success, and subsequent increases in breeding dispersal distances. Barred Owls may also reduce prey availability for Spotted Owls, either indirectly through changes to predator avoidance strategies used by prey (e.g., Schmidt 2006), or directly by excluding Spotted Owls from productive foraging habitats or via reductions in prey populations (Hamer et al. 2001, Wiens et al. 2014).

The decline in populations of Spotted Owls throughout the region (Dugger et al. 2016) is also likely a factor contributing to increased breeding dispersal patterns in recent years. In a review of 75 bird species, Paradis et al. (1998) found that breeding dispersal distances were longer for less abundant species than among abundant species, and dispersal distances of male Merlin (*Falco columbarius*) decreased with increased population density (Wiklund 1996). Spotted owl populations have declined on all of our study areas, and Washington study areas experienced declines earlier in the study period and more precipitously than study areas in Oregon provinces (Dugger et al. 2016), which may help explain the greater increase in mean dispersal distances in those areas. Spotted Owls occur at low densities because of their large home ranges and small populations. Spotted Owl territory size also increases with latitude (Dugger et al. 2016), which likely contributes to the reduced density and correspondingly higher mean breeding dispersal distances observed in Washington birds. Concomitant with declines in population density, it stands to reason that mate availability also declined across our study, thus increasing the distances that single birds must travel to find an available mate. As in previous studies of Spotted Owls (Forsman et al. 2002, Gutiérrez et al. 2011), the greatest proportion of dispersal movements were made by birds that failed to successfully produce young in the year prior (Appendix Table 4). However, our model with mate status was more supported than the model of productivity for predictions of dispersal distance (Appendix Table 5). Our model predicted that single Spotted Owls moved farther than formerly paired individuals, which indicates that mate availability is a primary social driver of breeding dispersal distance. Spotted Owls are a K-selected species that do not often breed every year (Stoelting et al. 2015). Thus one unsuccessful year with a mate may have less importance to a long-lived animal than the loss or lack of a mate.

We found that dispersal distance increased with increasing proportions of forest disturbance within the original territory prior to dispersal. We predicted that moderate- to high-severity disturbances would have a greater effect on distance than low-severity disturbances. However, our tests of disturbance variables, ranked "any" disturbance severity higher than "low" or "moderate-to-high" severity in predicting dispersal distances. This lack of distinction could have been because the extent of disturbances within occupied territories was small as the majority (90%) of dispersing birds had ≤7% of their territory disturbed in the 3 yr prior to movement (Appendix Figures 6 and 7). Our study areas were mostly within the late-successional reserve network under the Northwest Forest Plan (Lint et al. 1999), which has been largely successful in protecting late-successional forest on federal lands (Davis et al. 2016). When considering broadly all federal lands, most losses of Spotted Owl nesting habitat have been due to wildfire (Davis et al. 2016), but we observed relatively little loss of forest due to wildfire within our 28-yr sample of breeding dispersals. Further targeted study of breeding owl movements and survival following fire in our region are needed. Timber harvest or wildfire is unlikely to be contained within a single territory, thus it makes sense that birds that lost a proportion of their territory may need to travel farther to find an unoccupied or unaffected territory. Additionally, given dispersal distances are increasing due to Barred Owls, dispersing Spotted Owls may increasingly encounter non-habitat on lands managed outside the standards and guidelines of the Northwest Forest Plan. These areas include non-forest and intensively managed industrial forests that commonly surround late-successional reserves.

There are multiple factors influencing Spotted Owl breeding dispersal, and while it appears that social factors such as mate availability continue to be the important drivers in movement decisions, increased competition from Barred Owls and forest disturbance also have an effect. Increases in dispersal distance, when paired with increased rates of adult dispersal observed in recent years (D. B. Lesmeister and K. M. Dugger personal observations), may have important implications for studies estimating apparent survival from long-term Spotted Owl demographic data. Given Spotted Owls are moving farther and more frequently, permanent emigration from study areas is likely also increasing over time. Apparent survival models cannot differentiate between emigration and mortality, so dispersal movements that result in permanent emigration from study area boundaries can lead to underestimates of apparent survival (Zimmerman et al. 2007). Conversely, if increased dispersal distances are leading to increased movement through young industrial forests or other nonsuitable roosting cover, higher rates of mortality are also possible. Given the changing dispersal patterns we have observed, it is increasingly important to consider the impact of these behavioral changes on conservation efforts as well as long-term monitoring programs designed to detect trends in Spotted Owl populations.

ACKNOWLEDGMENTS

This study would not have been possible without the help of a small army of dedicated field biologists who collected the data on the Spotted Owl demographic study areas in Washington and Oregon. We would also like to thank R. Davis, U.S. Forest Service Spotted Owl monitoring lead, for assistance with forest disturbance parameters. The findings and conclusions in this publication are those of the authors and should not be construed to represent any official USDA or U.S. Government determination or policy. Any use of trade, firm, or product names is for descriptive purposes only and does not imply endorsement by the U.S. Government. The full data used for this analysis are available from Dryad.

Conflict of Interest Statement: The authors declare no conflicts of interest.

Funding statement: Funding for this project was provided by the U.S. Department of Agriculture Forest Service Pacific Northwest Research Station, and the U.S. Department of Interior Bureau of Land Management.

Ethics statement: All handling and marking of Spotted Owls was authorized and in compliance with regulations of the U.S. Fish and Wildlife Service, Oregon Department of Fish and Wildlife, Washington Department of Fish and Wildlife, and the Federal Bird Banding Lab. All protocols were approved by the Oregon State University Institutional Animal Care and Use Committee.

Author contributions: D.B.L., E.D.F., K.M.D., and J.D.W. conceived the research, design, sourced funding, and substantially edited the manuscript. J.M.J. developed and preformed analysis and wrote the manuscript. J.M.J., D.B.L., E.D.F., K.M.D., S.H.A., L.S.A., C.E.M., M.S.P., J.A.R., S.G.S., R.B.H., and S.A.G. conducted the research. Z.Y. developed environmental metrics and reviewed the manuscript.

Data depository: Analyses reported in this article can be reproduced using the data provided by Jenkins et al. (2019a).

Abstract
Aims Postfire logging recoups the economic value of timber killed by wildfire, but whether such forest management activity supports or impedes forest recovery in stands differing in structure from historic conditions remains unclear. The aim of this study was to determine the impact of mechanical logging after wildfire on soil bacterial and fungal communities and other measures influencing soil productivity.
Methods We compared soil bacterial and fungal communities and biogeochemical responses of 1) soils compacted, and 2) soils compacted and then subsoiled, to 3) soils receiving no mechanical disturbance, across seven stands, 1–3 years after postfire logging.
Results Compaction decreased plant-available N on average by 27% compared to no mechanical disturbance, while subsoiling decreased plant-available P (Bray) on average by 26% compared to the compacted and non-mechanically disturbed treatments. Neither bacterial nor fungal richness significantly differed among treatments, yet distinct separation by year in both bacterial and fungal community composition corresponded with significant increases in available N and available P between the first and second postharvest year.
Conclusions Results suggest that nutrients critical to soil productivity were reduced by mechanical applications used in timber harvesting, yet soil bacteria and fungi, essential to mediating decomposition and nutrient cycling, appeared resilient to mechanical disturbance. Results of this study contribute to the understanding about impacts of harvesting fire-killed trees and bear consideration along with the recovery potential of a site and the impending risk of future fire in stands with high densities of fire-killed trees.

Introduction

The effects of mechanical disturbance that occur with logging operations, such as compaction and subsoiling, on soil productivity and forest recovery are of concern worldwide, and depend upon severity, time since disturbance, and site factors (Grigal 2000; Marshall 2000; Rab 2004; Bassett et al. 2005; Yildiz et al. 2007, 2010; Hartmann et al. 2009). Successful forest regeneration following logging operations may rely upon natural forest regeneration or upon successful reforestation from nursery stock (Bassett et al. 2005; Yildiz et al. 2007, 2010; Lindenmayer et al. 2008; Perry et al. 2008). Similarly, disturbance from fire, whether prescribed or natural, varies within forest ecosystems, depending on intensity and length of time since fire (Bárcenas-Moreno and Bååth 2009; Keeley 2009; Yildiz et al. 2010). Re-establishment of understory plant diversity and ecosystem functions of natural forest communities with herbs, shrubs, and tree species mixtures may be important in sustaining long-term productivity (Fisher and Binkley 2000; Fox 2000; Rothe and Binkley 2001; Rothe et al. 2002; Talkner et al. 2009).

Fire effects upon forest ecosystems have long been of interest in understanding forest recovery and subsequent management and sustainability of forests worldwide (Kauffman and Uhl 1990; Attiwill and Adams 1993; Fox 2000; Fisher and Binkley 2000; Cochrane and Laurance 2002; Boerner et al. 2008, 2009; Perry et al. 2008). Forest wildfires have been a universal concern, including in the western United States. This has prompted the need to evaluate the effect of postfire treatments on forest ecosystem recovery (Cochrane et al. 1999; McIver and Starr 2000; Beschta et al. 2004; Sessions et al. 2004; Lindenmayer et al. 2008; Perry et al. 2008). It is well established that severe wildfire negatively impacts soil nutrient pools (Neary et al. 1999; Knicker 2007; Bormann et al. 2008; Hebel et al. 2009); however, the effect of postfire timber removal on soil productivity is not well understood and its application remains highly controversial among land managers, scientists, and the interested public (Lindenmayer et al. 2008). Postfire logging, currently underway in forests to salvage the economic value of timber killed by wildfire, may reduce burn severity to soils in the event of reburning by removing large, dead wood (Poff 1989); may increase the risk of fire (Donato et al. 2006) or fire severity (Thompson et al. 2007); or may decrease the amount of carbon (C) for long-term storage (DeLuca and Aplet 2008; Mitchell et al. 2009).

Forest harvesting equipment, including that used in postfire logging, frequently results in soil compaction, reducing soil pore size and decreasing oxygen availability and water and nutrient movement to tree roots (Dick et al. 1988; Page-Dumroese et al. 2006; Craigg and Howes 2007; Hartmann et al. 2009). To alleviate compaction, the practice of subsoiling or deep tillage is used to fracture the lower soil strata. Based on results from agricultural soils, tillage may degrade soil structure, adversely affecting microbial biomass and diversity by loss of macro-aggregates (Lupwayi et al. 2001). In forest soils, as a remedial treatment for soil compaction, subsoiling may actually ameliorate the more severe soil structure degradation from compaction. Disruption of the belowground component has immediate and potentially long-lasting effects on the below- and aboveground ecosystem (Froehlich et al. 1985; Perry et al. 1989; Neary et al. 1999; Beschta et al. 2004). However, in the case of soil compaction, subsoiling as a remedial treatment has been found to increase rooting volume, decrease bulk density, and increase aeration porosity, potentially having a positive effect on soil productivity (Otrosina et al. 1996; Carlson et al. 2006).

Soil microbes can indirectly influence soil productivity by enhancing nutrient availability for plant uptake, or reducing plant productivity through competition for nutrients with plant roots by promoting nutrient loss via leaching (Wardle et al. 2004; van der Heijden et al. 2008). For example, beneficial rhizosphere microorganisms, including mycorrhizal fungi and plant growth-promoting rhizobacteria (PGPR), such as *Rhizobium* and certain *Pseudomonas* species, can increase the availability of nutrients or plant growth substances to plants or suppress parasitic and nonparasitic pathogens (Schippers et al. 1987; Smith and Read 2008; Courty et al. 2010). Disturbances such as fire and harvesting can impact the abundance, activity, and composition of soil microbial communities (Smith et al. 2005; Smith et al. 2008; Kennedy and Egger 2010), thereby contributing to changes in nutrient cycling, organic matter decomposition rates, and ecosystem C accrual (Pietikäinen and Fritze 1995; Neary et al. 1999). While some studies in pine and mixed-conifer forests have reported minimal or

no modification of the mineral soil microbial community size or activity (Dick et al. 1988; Chow et al. 2002; Shestak and Busse 2005; Busse et al. 2006), another has shown deep and long-lasting effects of organic matter removal and soil compaction on microbial community structures (Hartmann et al. 2009). Understanding soil microbial tolerance to levels and thresholds of disturbance severity is critical to long-term forest productivity (Marshall 2000).

Our objective was to compare microbial communities in soils compacted and decompacted (subsoiled) by mechanical equipment to soils receiving no mechanical disturbance after a wildfire in a mixed conifer forest in central Oregon. In this forest, we investigated the structure, metabolism, and function of soil bacterial and fungal communities in relation to physicochemical properties. Studies incorporating approaches for assessing both structural and functional diversity in examining microbial response to wildfire (Yeager et al. 2005), soil compaction (Axelrood et al. 2002a, b; Shestak and Busse 2005; Busse et al. 2006; Hartmann et al. 2009), or both (Kennedy and Egger 2010) are varied in their approaches and responses. We hypothesized that post-fire mechanized salvage logging would compact surface soils resulting in restricted microbial- and invertebrate-habitable pore space. This would reduce organic matter turnover and nutrient (N,P) mineralization. Restricted microbial grazing by soil invertebrates would stabilize microbial populations and increase diversity in compacted soils. Subsoiling would ameliorate these effects by increasing microbial access to nutrients, but result in a loss of microbial diversity due to an increase in predation from microbivores.

Materials and methods

Study area

This study was conducted within the Booth and Bear Butte (B&B) Fire Complex, located on the east side of the Cascade Mountains of Oregon in the Deschutes National Forest. The B&B Fire burned 36,733 ha in the summer of 2003. Timber sales approved prior to the B&B Fire and subsequently harvested 1 year after the fire provided a unique and timely opportunity to study the impacts of postfire logging without the uncertainty surrounding the approval of proposed postfire-logged stands. Timber harvest and subsoiling of portions of the compacted areas occurred in summer 2004. Subsoiling (on approximately 17% of a stand) was completed on all stands within a 3-day period. Compacted areas occupied approximately 2% to 5% of a stand. Stands, ranging in size from 5 to 12 ha (Table 1), were thinned from below with a feller buncher operation that consists of a shear machine used to cut and place trees into a trail, and a rubber tire skidder machine that pulls the trees to a landing.

Stands within the study are characterized by a dominant overstory of ponderosa pine (*Pinus ponderosa* Dougl. ex Laws) and Douglas-fir (*Pseudotsuga menziesii* Mirb. Franco) with white fir (*Abies concolor* Gord. & Glend., Lindl. ex Hildebr.) or grand fir (*Abies grandis* Dougl. ex D. Don, Lindl.) occurring as co-dominants (Simpson 2007). Before logging, stands were comprised mainly of second-growth trees. Nearly all stands contain a few large, 100 to 200-year-old trees, and dense shrubs typifying early successional stages after fire and subsequent logging. Stands contain an understory of snowbrush ceanothus *(Ceanothus velutinus* Dougl.), dwarf rose *(Rosa gymnocarpa* Nutt.), common snowberry *(Symphoricarpos albus* [L.] Blake), dwarf Oregon-grape (*Mahonia nervosa* [Pursh] Nutt.), trailing blackberry (*Rubus ursinus* Cham. and Schlecht) and red huckleberry (*Vaccinium parvifolium* Sm.). Soils are Vitricryands and Vitrixerands with sandy loam texture (Table 1). Elevations of all stands are about 1,000 m (Table 1). Average air temperatures range from −1°C in the winter months to 20°C in the summer months. Average annual precipitation ranges from 50 to 150 cm. About 70% of the precipitation falls during November through April. During the driest months (July, August, and September), the average monthly precipitation is less than 2.5 cm.

Study design

The study was a randomized genuine replicate block design (GRBD) (Hinkelmann and Kempthorne 2008) consisting of seven stands representing a mix of burn severities, including one stand that occurred within the perimeter of the B&B Fire, but was spared from fire. Since most fires are spatially heterogeneous, leaving unburned or low severity burned areas as well as more severely burned areas, all seven stands were included in the study. The study was designed to

compare the effects on soil of mechanical harvesting to non-mechanically disturbed areas. Within each replicate stand, several areas representing each of the three treatments were identified: 1) compacted (compaction from heavy ground-based equipment), 2) subsoiled (compaction followed by subsoiling), and 3) no mechanical disturbance (Fig. 1).

A sampling grid with grid points every 4–6 m was established within each stand (Fig. 1). Grid points were marked with a wooden stake and all stake locations were recorded with the Global Positioning System (GPS). A 10 m buffer zone within the perimeter of each stand was not sampled to avoid potential edge effects. Compacted and subsoiled treatments were based on visual indications of soil disturbance with heavy equipment using a classification system similar to those of Craigg and Howes (2007) and Frey et al. (2009) in which the compacted treatment was identified by topsoil displaced in lateral berms, and the subsoiled treatment as areas where fracturing of the compacted soil was evident. Visual classification systems of soil disturbance have been successfully used by the British Columbia Ministry of Forests and are currently under developmental use in the U.S. Forest Service Region 6 (Pacific Northwest) (Curran et al. 2005). Treatment designations were further assessed by the ease or difficulty of pounding stakes into the ground and validated with a combination of soil strength and bulk density measurements (described below). Within each stand, plots were established at 3 grid points randomly selected from each treatment type for sampling soil physical, chemical, and biological properties (Table 2). Grid point plots were treated as genuine replicates because of their random placement on multiple discontinuous treatment areas within a stand (Hinkelmann and Kempthorne 2008) (Fig. 1). When measurements were made through time (more than one season and year), these data were treated as repeated measures and analyzed using the appropriate split-plot design. For the responses for which we did not composite the replicates we fit a mixed linear model that included fixed effects for treatment (df=2) and season (df=5). We included random effects for site (df=6) and for replicates within treatment areas within sites (df=54) and the residual error (df=300). For responses for which we composited the material from the 3 replicates for each treatment within each site we also fit a mixed linear model with fixed effects for treatment and season. The random effects included site (df=6), variation among site by treatment combinations (df=12) and the residual error (df=90). All models were fit using SAS's PROC MIXED (SAS Institute 2003). There were seven stands with

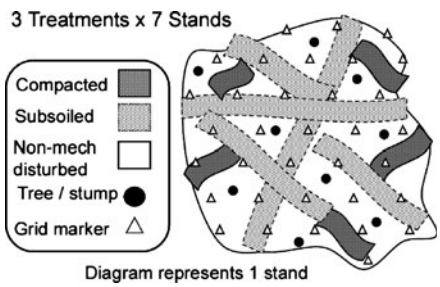

Fig. 1 Genuine replicate block study design with three discontinuous treatments within a stand 1) compacted (compaction from heavy ground-based equipment), 2) subsoiled (compaction followed by subsoiling), and 3) no mechanical disturbance. Three plots from each treatment were randomly selected for soil analyses (7 stands × 3 treatments × 3 plots = 63 plots)

[c] Combined samples within treatment × $stand^{-1}$

three treatments each and three plots of each treatment, for a total of 63 plots; each plot was sampled over seven seasons: summer and fall 2005; spring, summer, and fall 2006; and spring and summer 2007. The response variables were selected based on their ability to influence and measure soil microbes and their processes.

Soil physical properties

Soil physical properties were measured at various times and replications, as shown in Table 2. Differences in soil strength were measured at each stand in one plot per treatment in the fall of 2005 (Table 2) using the Rimik 4011 recording soil penetrometer (Rimik International Pty Ltd, Queensland, Australia) at 2.5 cm increments. Five measurements at each sampling point were taken to a maximum depth of 60 cm. Bulk density was assessed in the fall of 2005 (0–5 cm) and the springs of 2006 (5–10 cm) and 2007 (0–5 cm, 5–10 cm). Gravimetric water content (% moisture) was measured in each plot during each sampling period to calculate water-filled pore space, an attribute critical to mass flow of nutrients, as well as to limits to biological activity.

Soil chemistry, N mineralization, and incubation N

Mineral soils for chemical analysis, N mineralization, and incubation N were collected to a 10 cm depth, using a garden trowel on each plot during each summer sampling period (Table 2). Soil samples were combined by treatment per stand and then sieved (2.0 mm) and air-dried before being analyzed. Total C and N were analyzed by the dry combustion technique (Bremner 1996; Nelson and Sommers 1996) using a Flash EA112 NC soil analyzer (Thermo Electron Corporation, Milan, Italy). Cation exchange capacity (CEC) was estimated using the sum of exchangeable cations (Robertson et al. 1999) for the

summer 2005 and 2006 samplings, and the ammonium acetate method (Rhoades 1982) for the summer 2007 soils. Soil pH was measured employing the 1:2 (soil:water) dilution method using deionized water (Robertson et al. 1999). Plant available P was analyzed using the dilute acid-fluoride method (P-Bray) (Kuo 1996) at the Oregon State University Central Analytical Lab (OSU CAL). Total P was measured at the OSU CAL using a Kjeldahl digestion (Bremner 1996; Taylor 2000), followed by P determination on an ALPKEM autoanalyzer (Technicon Instruments, Saskatoon, Canada).

Nitrogen mineralization potential, the conversion of organic N in microbial biomass to inorganic N under laboratory conditions, is considered a potential estimate of biologically available N (Myrold 1987; Perry et al. 2008). Anaerobic incubation N and net minerlizable N were measured in summer 2007 at the OSU CAL using the procedure of Bundy and Meisinger (1994). After incubation at 40°C for 7 days, 50 ml of 2 M KCl was added to extract NH_4–N for 1 h. The extracted NH_4 was determined on an ALPKEM autoanalyzer (Technicon Instruments, Saskatoon, Canada).

Genetic analysis of samples

Bacterial and fungal richness was measured at each plot within each stand for the first 6 sampling periods (Table 2). At each plot, a sparse litter layer of pine needles was removed and the mineral soil sampled to a depth of 10 cm and put in a 50 ml tube. Samples were placed in a cooler, transported to the lab and stored in a −80°C freezer until further processing. Small pebbles and vegetation (not including roots) were removed from the sample prior to DNA extraction. A MoBio Power Soil™ DNA isolation kit was used to extract total genomic DNA from approximately 0.5 g of each soil sample (MoBio Laboratories, Carlsbad, CA, USA).

Soil bacteria DNA was amplified using 16S rDNA gene primers 8F (FAM) and 907R (Edwards et al. 1989; Muyzer et al. 1995) in a 50 μl reaction mix containing: 1x PCR buffer, 2 mM $MgCl_2$, 0.2 mM dNTPs, 0.2 μM Primer, 0.064% BSA. Each soil DNA extract was run twice under the following conditions: 95°C for 3 min, followed by 30 cycles at 95°C for 30 s, 55°C for 1 min, 72°C for 45 s, and ending with an extension step of 72°C for 7 min. Once amplified, the two products were pooled to capture the diversity more fully. These pooled products were then purified using a MoBio Ultra Clean DNA Clean Up kit (MoBio Laboratories, Carlsbad, CA). Restriction enzyme *Msp*I was selected over *Alu*I for terminal restriction fragment length polymorphism (T-RFLP) community analysis after comparison trials on replicate samples revealed its ability to identify the greatest amount of variation. *Msp*I consistently is considered a top performing restriction enzyme for T-RFLP of bacterial samples (Liu et al. 1997; Engebretson and Moyer 2003). Digests were run according to the manufacturer's specifications by incubating the restriction digest for 3 h at 37°C. Restricted samples were submitted to Oregon State University Center for Gene Research and Biotechnology for analysis using an ABI Prism 3100 Genetic Analyzer (Applied Biosystems Inc., Foster City, CA, USA) to run capillary gel electrophoresis. Approximately 1 ng of amplified DNA was submitted for analysis for each sample. The analysis produced one community profile for each sample, where a profile consists of peaks of varying height and base pair length. The peaks (operational taxonomic units or OTUs) can be used to determine the richness of a given sample (Liu et al. 1997). Length and fluorescence of the terminal restriction fragments (TRF) were determined using GeneScan version 2.5 and Genotyper version 3.7 software (Applied Biosystems Inc., Foster City, CA). OTUs were binned to 1 bp in width.

Methods for identifying soil fungi were followed as stated above with the following exceptions. The fungal ITS spacer region was amplified using ITS-1f (Gardes and Bruns 1993) and ITS-4 (FAM) (White et al. 1990) and the reaction mixture and thermocycling program of Dickie et al. (2002). Restriction enzyme *Hinf*I was selected over *Hae*III for T-RFLP community analysis after comparison trials on replicate samples revealed its ability to identify the greatest amount of variation. Both *Hinf*I and *Hae*III are widely used in fungal T-RFLP profiling (Avis et al. 2006; Dickie and FitzJohn 2007; Alvarado and Manjon 2009). GeneMapper software 4.0 (Applied Biosystems Inc., Foster City, CA) was used to determine fragment fluorescence, OTUs were binned to 1 bp in width, and a binary analysis of presence or absence was performed following the methods of Rinehart (2004).

Community level physiological profiles

Soils for CLPPs were collected and processed in spring 2006 to a 10 cm depth at each plot. Soil samples were combined by treatment per stand, sieved (2.0 mm) and approximately 10 g was placed in small envelopes, and stored at 4°C until processing. The physiological potential, an estimate of functional diversity of the bacterial community, can be determined through the utilization patterns of various C sources (Garland 1996; Garland et al. 1997) but obviously is biased towards culturable, aerobic and fast-growing bacteria. The CLPPs were qualitatively assessed using Biolog EcoPlates™ (Biolog Inc., Hayward, CA, USA) following the method described in Sinsabaugh et al. (1999). Plates were incubated at room temperature and color development was determined using a BioTek PowerWave X 340 spectrophotometer (BioTek Instruments, Winoski, VT, USA) at a wavelength of 596 nm. Absorbance values were recorded at 24 h intervals for 5 consecutive days (Sinsabaugh et al. 1999). The data used in this analysis are from the day 3 readings and have been standardized to the water control. The water column values (all zeros) were removed and all resulting negative values were changed to zero.

Soil respiration

Soil respiration was measured at 3 plots per treatment in each stand for the first six sampling periods (Table 2). Soil respiration data were obtained following the methods in Law et al. (2001) using a LI6200 infrared gas analyzer (LiCor, Lincoln, NE, USA). Soil respiration rates were expressed as μmol m^{-2} s^{-1} of CO_2, using the same convention and quantification as Sulzman et al. (2005).

Phosphatase enzyme activity

Phosphatase enzyme activity was assayed from soil samples collected in spring 2007 using the *p*-nitrophenyl-phosphate (*p*-NPP) assay of Tabatabai (1994) as modified by Caldwell et al. (1999). After soils were sieved (<2 mm), slurries were prepared with deionized water, and 1 ml of slurry was incubated with 1 ml of 50 mM *p*-NPP at 30°C. These assays were run without conventional buffers to measure enzyme activity under actual soil matrix conditions (pH, cation concentrations), rather than to estimate potential enzyme activities present at optimum pH with increased ionic strength. After 1 h, 0.5 ml of 0.5 M $CaCl_2$ was added and reactions were terminated by adding 2 ml of 0.5 M NaOH to the assay. Controls consisted of slurry without substrate and substrate without slurry. After centrifugation, supernatant *p*-nitrophenol (*p*-NP) concentrations were measured at 410 nm, and enzyme activities were calculated on a dry weight basis (Caldwell et al. 1999).

Statistical analyses

The mean responses for soil properties (Table 3) were compared among treatments, and when appropriate, among seasons and years. No significant treatment by season interactions were detected for any of the measured response variables; therefore, only main effects are presented. Results were considered significant at $P=0.05$ and were considered a statistical trend at $P=0.1$. The variability inherent in field studies with smaller sample numbers, such as when soil samples were composited in this study, affords practical value for using statistical trends at $P=0.1$ (Steel et al. 1997). The F statistic and α level of significance are presented in the text when not included in a table.

Multivariate statistical analyses were performed using PC-ORD version 5.0 (McCune and Grace 2002). Sample community profiles were examined using nonmetric multidimensional scaling (NMS) with the Sørensen distance measure. The medium NMS autopilot mode was selected, with 200 maximum iterations, 0.0001 instability criterion, 15 real runs, and 30 randomized runs. The final model dimensions were chosen by comparing the NMS runs with real data to Monte Carlo simulations with random numbers. The proportion of variation represented by each axis was assessed by calculating the coefficient of determination (R^2) between distances in the ordination space and Sørensen distances in the original distance matrix. The relationships between plots in ordination space and their corresponding environmental variables were assessed by over laying the variables as a joint plot. Preliminary ordinations were examined and the data set further modified, first by excluding peaks occurring in fewer than five samples and then by an arcsine square root transformation of each response in order to normalize the data

Table 3 Effects of management treatments on soil physical, biochemical, chemical, biological and biodiversity response variables, with means and ANOVA results

Means are listed with standard errors in parentheses. The F statistic is testing the null hypothesis of no difference among treatment means. Within a column, means with a common lowercase letter are not different at α=0.1. Means differing at α=0.05 are shown in bold

set. Using the blocked multiresponse permutation (MRBP, Euclidean distance, treatments or year/season as groups) and unblocked multiresponse permutation (MRPP, Sørenson distance, treatments or year/season as groups) procedures, the strength and statistical significance of group membership was tested. If data contained repeated measures, MRBP was used, otherwise MRPP was used. The *P*-value and *A* statistic (*A*) describing within-group heterogeneity compared to the random expectation, were recorded for each MRBP and MRPP analysis. Similarities of each of the bacterial and fungal communities among treatments were assessed using a nested PerMANOVA with Sørenson distance where samples were nested within site. Soil biogeochemical properties were correlated with community compositional ordinations to investigate links between community composition and functional capability for the six seasons.

NMS, where samples were ordinated in C-substrate space, was used to analyze the Biolog™ spectrophotometer data for bacteria. The data needed no further transformation after looking at initial ordinations for normalization. For outlier analysis, MRPP and PerMANOVA Sørensen distance was used.

Diversity was estimated using the Shannon-Wiener index (*H*): $H = -\sum p_i (\ln p_i)$, where p_i is the ratio of the number of OTUs for bacteria or fungi found in each sample to the total number of peaks for bacteria or fungi found in all samples for the OTU data (Magurran 1988). Biolog™ substrate diversity was similarly calculated, except that p_i was the ratio of average well color development (AWCD) on each substrate to the sum of all AWCD on all substrates. Evenness was calculated for the OTU data using: $E = H'/H_{max} = H'/\ln S$, where H is the Shannon-Wiener diversity index, S is the total number of peaks found

in all samples, and E is a number between 0 and 1 (Magurran 1988).

Results

Soil physical properties

Overall, soil strength was greatest in the compacted treatment and least in the subsoiled treatment (Fig. 2). Soil strength measurements revealed distinct differences among all treatments at most 2.5 cm increments between 7.5 and 17.5 cm and distinct differences between compacted and other treatments at all increments to a depth of 17.5 cm (Fig. 2). At levels deeper than 17.5 cm, compacted and non-mechanically treated soils did not differ in soil strength; however, the subsoiled treatment showed distinctly less resistance compared to those treatments at depths of 25–35 cm (Fig. 2). Bulk density at 10 cm taken more than 1 year after harvesting was 15% lower, on average, in the subsoiled treatment (95% (Confidence Interval (CI)=6–24%)) (Table 3).

Percent moisture was up to 85% lower in summer compared with fall and spring (95% CI=70–93%, 95% CI=74–94%, respectively) ($F_{[2,\ 111]}$=119.69, P<0.0001), but differences among treatments were not observed (P=0.18) (Table 3).

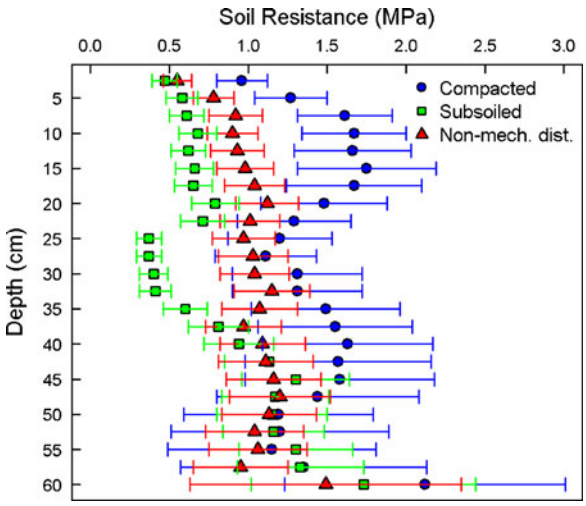

Fig. 2 Soil strength measurements by treatment. Measurements were taken at 2.5 cm increments to a maximum depth of 60 cm. Differences in soil strength were seen to a depth of 17.5 cm for most measurements. *Error bars* represent 1 SE

Soil chemistry, N mineralization, and incubation N

Differences were not observed among treatments for soil CEC, C:N, pH, total C, total N (P>0.1) (Table 3). Soil CEC was higher in summer 2005 compared to summers 2006 or 2007 ($F_{[2,\ 36]}$=16.63, P<0.0001). Plant-available P (Bray) was up to 26% lower in the subsoiled treatment compared to the compacted or non-mechanically disturbed treatments (95% CI=9–39%, 95% CI=11–41%), respectively (P<0.001) with a similar tendency for total P (P=0.1, 95% CI=−1.2–24%) (Table 3). Plant-available P (Bray) was higher in summer 2006 than in summers 2005 or 2007 ($F_{[2,\ 36]}$=18.76, P<0.0001). Compaction decreased anaerobic incubation NH_4-N by 26% (95% CI=3.5–51%) and net mineralizable (anaerobic) NH_4 by 27% (95% CI=2–50%) compared to the non-mechanically disturbed treatment (P=0.01 for both) (Table 3). Total N ($F_{[2,\ 36]}$=27.58, P<0.001) was higher in summer 2006 than in summer 2005. Increased N in the second summer led to lower C:N ($F_{[2,\ 36]}$=47.78, P<0.0001) in summer 2006 compared to summers 2005 and 2007.

Soil microbial communities

A total of 275 OTUs for soil bacteria were detected. Compaction tended to increase the mean number of bacteria OTUs, on average, by 9% and 14% when compared to both the non-mechanically disturbed and subsoiled treatments (95% CI=−0.5–19%, 95% CI=5–25%), respectively (P=0.09, Table 3). Shannon-Wiener indices for bacteria OTUs among treatments (4.0 to 4.1) suggest that bacteria OTUs in our samples were equally distributed and showed high community complexity, and evenness values of 0.70 to 0.73 suggest that OTUs were equally abundant. The average number of soil bacteria OTUs differed with respect to sampling period ($F_{[5,\ 90]}$=11.53, P<0.0001) (Fig. 3). Similarly, Shannon-Wiener indices were higher in year 1 (summer 2005, fall 2005, spring 2006) (4.0 to 4.1, with evenness values of 0.71 to 0.73) compared to year 2 (summer 2006, fall 2006, spring 2007) (3.6, with evenness values of 0.63 to 0.65).

A total of 160 OTUs for soil fungi were detected. There were no detected differences in the average number of fungi OTUs among treatments ($F_{[2,\ 12]}$=1.38, P=0.29) but differences were detected among sampling periods ($F_{[5,\ 90]}$=51.39, P<0.0001) (Fig. 3).

Fungal richness in all treatments declined after the first sampling season (summer 2005) and increased in the last sampling season (spring 2007) (Fig. 3). Similarly, Shannon-Wiener indices were higher in the first and last sampling seasons (4.0 and 4.2, evenness 0.81 and 0.83, respectively) compared to the other sampling seasons (3.4 to 3.6, evenness 0.67 to 0.72).

There were no observed differences in the cumulative number of bacteria and fungi OTUs among treatments (P=0.3 for both) (Table 3). All treatments showed a gradual increase in the cumulative mean number of bacteria and fungi OTUs over time (Fig. 4).

Variation in bacterial community composition was not detected among treatments (PerMANOVA $F_{[2,\ 105]}$= 0.61, P=0.76). NMS ordinations of the average number of OTUs showed differences in the bacterial community composition between year 1 (summer 2005, fall 2005, spring 2006) and year 2 (summer 2006, fall 2006, spring 2007) (MRPP P<0.0001, A= 0.13) and among seasons (PerMANOVA $F_{[2,123]}$=4.91, P=0.0002). Responses of CEC and percent moisture helped explain the variation in the soil sample community from summer 2005, spring 2006, and spring 2007 (Table 4). In addition to these variables, available P explained separation of the bacterial community in summer 2006 soil samples. No environmental measures explained variation in either of the fall measurement periods (Table 4).

Variation in fungal community composition was also not detected among treatments (PerMANOVA $F_{[2,105]}$=1.27, P=0.23). NMS ordinations showed differences in the fungal community composition between year 1 (summer 2005, fall 2005, spring 2006) and year 2 (summer 2006, fall 2006, spring 2007) (MRPP P<0.0001, A=0.12), and among seasons (PerMANOVA $F_{[2,123]}$=5.41, P=0.0002). Responses of CEC, total C, and percent moisture (Table 3) helped explain the variation in the soil sample community from fall 2005 and summer 2006 (Table 4). No environmental measures explained variation in summer 2005, fall 2006, or either spring measurement periods (Table 4).

Community level physiological profiles

Variation in functional diversity, as measured by absorbance values, was not detected among treatments (MRBP P=0.11, A=0.022) (Table 4). Differentiation in Shannon-Wiener indices for CLPPs for bacteria was not observed among treatments (3.0 in compacted, 2.9 in both the subsoiled and non-mechanically disturbed treatments). Ordinations of the CLPP data in species space showed that C substrate groups, amines/amides, amino acids, and carbohydrates significantly correlated with the variation in species composition in spring 2007 (Table 4); amines/amides were more correlated with axis 3 (R^2= 0.460), amino acids with axis 1 (R^2=0.634), which explains more variation than axis 3, and carbohydrates with axis 2 (R^2=−0.456). Proportion of variation (R^2) explained by each axis was 0.63, 0.16, and 0.21, respectively.

Soil respiration and phosphatase activity

Soil respiration rates tended to be higher in the non-mechanically disturbed treatment compared to both

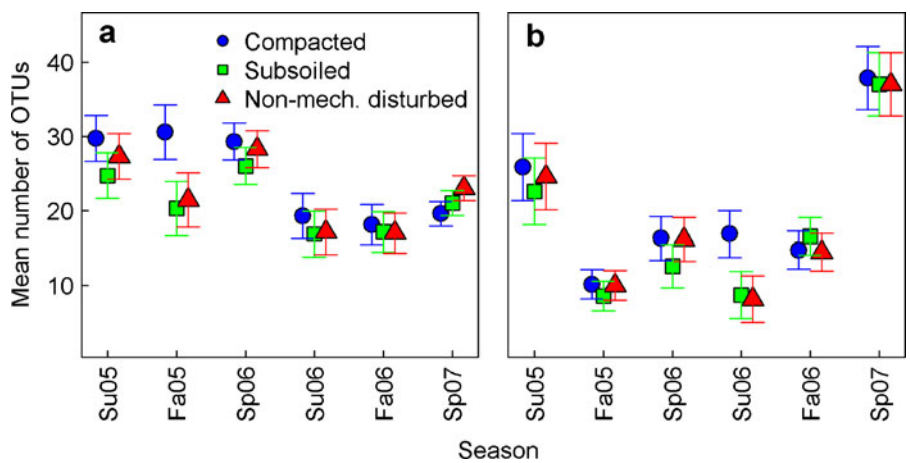

Fig. 3 Mean number of **a** bacterial (*Msp*I) and **b** fungal (*Hinf*I) OTUs differed among seasons. Bacterial OTUs tended to be higher in the compacted treatment; however there were no differences among treatments in the mean number of fungal OTUs

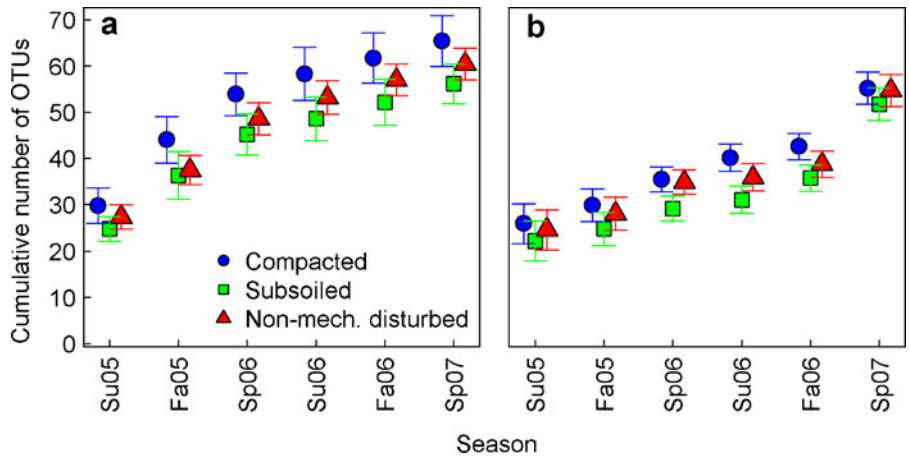

Fig. 4 Cumulative mean number of **a** bacterial (*Msp*I) and **b** fungal (*Hinf*I) OTUs by season and treatment. All treatments showed a gradual increase in the cumulative mean number of bacteria and fungi OTUs over time

the compacted and subsoiled treatments (P=0.09) (Table 3). Soil respiration rates were, on average, more than 20% lower in fall compared to summer or spring (95% CI=26–42%, 95% CI=14–33%, respectively, P<0.01 for both). Evidence suggested that phosphatase activity was, on average, 30% lower in the subsoiled treatment compared to the non-mechanically disturbed treatment (P=0.07, 95% CI= 10–51%) (Table 3).

Discussion

Following forest ecosystem disturbances, such as wildfires and logging, soil microorganisms, including fungi, bacteria, and protozoans, facilitate decomposition processes for both aboveground forest floor and wood residues, and for belowground components, such as fine and coarse roots (Stark 1972; Richards 1987; Perry et al. 2008). These important soil biota help to sustain forests by re-establishing nutrient cycling processes following forest disturbance, while also facilitating establishment of trees and understory vegetation components, which depend upon both free-living and symbiotic microbes for nutrient uptake (Paul and Clark 1996; Dighton 2003; Perry et al. 2008; Smith and Read 2008; Simard 2009; Courty et al. 2010).

The net mineralizable N mean values for all of our treatments (Table 3) shows that most of the available mineral soil N pool is being maintained in microbial tissues, based upon research used to develop the anaerobic N mineralization method employed in our study (Myrold 1987; Bundy and Meisinger 1994; Perry et al. 2008). The soil microbial biota, such as bacteria and fungi, also are important in taking up other key nutrient elements, including P and base cations from soil mineral and organic matter sources (Stark 1972; Cromack et al. 1975; Entry et al. 1992; Tiessen et al. 1994; Smith and Read 2008).

Soil organic matter is a primary source of soil N required for the decomposition of residual forest floor and woody components aboveground and fine and coarse roots belowground (Richards 1987; Tiessen et al. 1994; Dighton 2003). Fungi, due to their ability to create hyphal networks through long-lived fungal rhizomorphs and mycelial strands (Treseder et al. 2005), facilitate translocation of important nutrients such as N and P from soil sources into the residual forest floor aboveground woody components. Similar fungal networks are created by ectomycorrhizal fungi of trees, including Douglas-fir and ponderosa pine (Simard 2009; Courty et al. 2010), enabling N to be mobilized from a variety of soil organic matter sources (Lilleskov et al. 2010), soil P from organic and inorganic soil sources (Entry et al. 1992; Perry et al. 2008; Smith and Read 2008), and soil water from transport by ectomycorrhizal fungi to tree seedlings (Warren et al. 2008).

Soil N availability studies have provided a useful comparative basis in forest productivity studies (Fisher and Binkley 2000) and for evaluating forest management activities, such as thinning, fertilization or prescribed burning (Waring et al. 1992; Monleon et

al. 1997; Velazquez-Martinez and Perry 1997; Jones et al. 2010). In support of our hypothesis, compaction decreased plant-available N by 27%, on average, and NH_4–N and N mineralization by 26%, on average, compared to the non-mechanically disturbed treatment. Similarly, Lindo and Visser (2003) found decreased NH_4–N after clearcut harvesting, whereas DeLuca and Zouhar (2000) reported an increase in the levels of NH_4–N and potentially mineralizable N immediately following harvesting and prescribed fire. The anaerobic N availability index values in our study were similar to values reported by Myrold (1987) and Hebel et al. (2009) for other central Oregon forest sites (Table 3). Myrold (1987) also found a highly significant correlation (R^2=0.731) between anaerobic mineralizable N and microbial biomass N, using data from seven sites across Oregon. Based upon results of that research (Myrold 1987), the significantly higher net mineralizable anaerobic N on the non-mechanically disturbed treatment in our study (Table 3) may indicate that there was a greater microbial biomass N pool present under that treatment. Breland and Hansen (1996) postulated that N mineralization in compacted soil was reduced by increased physical protection of organic materials and microbial biomass against attack by microbivores. Busse et al. (2006) suggested that a decrease in pore size that benefits microbial community

stability may reduce plant nutrient availability. These observations are in agreement with several other studies on how soil structure affects habitable pore space for microorganisms and the turnover of soil organic matter and nutrients, such as N (Elliott et al. 1980; Battigelli et al. 2004; Li et al. 2004; Coleman 2008).

In support of our hypothesis, soils subjected to mechanical harvesting equipment after wildfire, and measured 1 year after harvesting, exhibited increased soil resistance compared to soils receiving no mechanical disturbance (Fig. 2). However, there were no observed differences in bulk density at 10 cm between the compacted and non-mechanically disturbed treatments 1 and 3 years after harvesting. Page-Dumroese et al. (2006) reported that in coarse-textured soils, bulk density measurements change relatively quickly with time and at the 10 cm depth may indicate recovery not reflected in soil strength measurements after 1 and 5 years. Frey et al. (2009) found no difference in bulk density at 10 cm between their lightly compacted and undisturbed treatments or between their moderately compacted and undisturbed treatments in two of three study sites, even though moderate compaction was characterized as topsoil displaced in lateral or side berms. Furthermore, Frey et al. (2009) reported that the physical effects of different levels of compaction from heavy logging machinery significantly changed the bacterial community structure in their severely compacted soil (approximately 32% increase in bulk density relative to undisturbed soil) and resulted in only minimal changes in bacterial OTU abundance in moderately (18% increase in bulk density) and lightly (3% increase in bulk density) compacted soils. In contrast, we did not observe variation in bacterial community composition among treatments.

In contrast to our hypothesis that subsoiling may alleviate nutrient loss due to compaction, we observed that plant-available P (Bray) was up to 26% lower in the subsoiled treatment compared to the non-mechanically disturbed and compacted treatments. This decrease would be expected to lead to decreased plant growth; however, subsoiling improved tree seedling growth compared to the compacted and non-mechanically disturbed treatments (JE Smith, unpublished data). Subsoiling also tended to decrease total P by 11%, on average, compared to the non-mechanically disturbed treatment. The decrease in plant-available and total P in the subsoiled treatment in this study may be linked to fractions of the organic matter that were not measured. Some P stored in plant residues becomes associated with the active and passive fractions of soil organic matter, where it can be stored for future release and very slowly converted to soluble inorganic forms that plants can use (Brady and Weil 2002).

The decrease in plant-available P (Bray) could be related to the 30% reduction in phosphatase activity that we detected in the subsoiling treatment, which mineralizes this P from organic forms. Dick et al. (1988) found that compaction in skid trails lowered phosphatase by 41% (and all enzyme activities assayed by 41–75%) in the 10–20 cm depth. However, there was a consistent trend that enzyme activities in the top 10 cm were lower in the compacted treatment compared to the control, but differences were small and not significant. Dick et al. (1988) did not detect differences in phosphatase between subsoiled treatments and the control. Boerner et al. (2008) found that fire and the combination of fire and mechanical treatment from harvesting lowered phosphatase activity compared to the mechanical treatment alone in a dry mixed conifer forest in Oregon. They further noted that phosphatase activity was reduced by treatments that included fire in the majority of fire and fire surrogate sites in the western United States. In contrast, phosphatase activity in our study did not differ between the one stand that escaped fire and the others that burned.

Contrary to our hypothesis, salvage logging soil disturbance did not appear to have an effect on microbial diversity; however, compaction tended to increase the mean number of bacterial OTUs by 9% and 14% when compared to the non-mechanically disturbed and subsoiled treatments, respectively. Variation in fungal richness was not detected between mechanically disturbed treatments and the non-mechanically disturbed treatment. However, the ordination approach we used revealed distinct separation in both the bacterial and fungal community composition between the first and second postharvest year that corresponded with significant increases in total and available N and available P. Tree mortality from fire and the removal of trees in our study may have led to a shift from root and rhizosphere associated bacteria and fungi to saprotrophic dominated communities. Studies suggest that overstory harvesting and the presence of living trees more greatly

influences soil microbial communities than an intact forest floor (Busse et al. 2006; Kennedy and Egger 2010). Disruption of root C transport after tree girdling or root severing leads to changes in both fungal and bacterial communities (Högberg and Högberg 2002; Brant et al. 2006; Yarwood et al. 2009) and induces the rapid growth of opportunistic saprophytic fungi that utilize dying mycorrhizal mycelia (Lindahl et al. 2010).

A trend over six sampling seasons suggested that the compacted soil contained a slightly greater cumulative mean number of bacterial OTUs (Fig. 4). A decrease in pore size may have led to less predation on the bacterial community, as suggested for compacted conditions in similar forest types (Shestak and Busse 2005; Busse et al. 2006). Soil compaction alters pore size distribution and may benefit the bacterial community by increasing the volume of habitable pores and decreasing the pore space available to larger microbivores such as nematodes and protozoa (van der Linden et al. 1989; Hassink et al. 1993; Breland and Hansen 1996). Moldenke et al. (2000) found that compaction caused by skid trails in the Deschutes National Forest in central Oregon contributed to a shift in the food web to one that utilized primarily bacteria.

Soil respiration is a direct measure of both microbial and root activity. In our study, compaction tended to reduce respiration rates and this effect was not alleviated by subsoiling. Lindo and Visser (2003) found that clearcutting significantly reduced soil respiration in the forest floor. In contrast, Concilio et al. (2005) reported increased soil respiration with selective harvesting. Ma et al. (2004) found that thinning resulted in nominal impact on soil respiration, but that burning significantly reduced soil respiration. These varied responses may be attributed to the influence of understory vegetation on soil moisture and temperature. For example, Ma et al. (2004) reported that soil respiration was reduced significantly in burned ceanothus patches, but increased in unburned but thinned ceanothus patches. Law et al. (2001) showed that soil surface CO_2 effluxes were lowest for bare soil, and highest near shrubs, some of which were N_2 fixers with higher photosynthetic rates. The increased activities shown by respiration and by phosphatase in the non-mechanically disturbed treatment, for example, may indicate the effects of increased ceanothus and other understory plant recovery and colonization. Thus, there may be greater microbial activity with more plants, such as ceanothus, but not necessarily greater bacterial diversity than is being shown in the compacted treatment. The more compacted soil may have shown greater bacterial genetic diversity, yet less activity for respiration and phosphatase.

Varied responses of microbial communities and soil physicochemical properties to compaction and other soil disturbances may be explained by the complexity of soil disturbances that occur during mechanized harvesting and to levels of soil disturbance (Shestak and Busse 2005; Busse et al. 2006; Boerner et al. 2009; Frey et al. 2009). Busse et al. (2006) suggested that soil microbial response to compaction is typically more pronounced in studies with additional impacts of soil displacement and mixing such as that which occurs with the creation of skid trails. Recent studies in 100-year-old mixed-conifer forests (Shestak and Busse 2005) and in younger pine and mixed-conifer plantations (Li et al. 2003, 2004; Busse et al. 2006) reported little or no effect of compaction on microbial community size, activity, or function. Nevertheless, negative responses by microbial communities to compaction in forest ecosystems abound (Dick et al. 1988; van der Linden et al. 1989; Torbert and Wood 1992; Li et al. 2003; Tan et al. 2005, 2008) and can be long-lasting (Hartmann et al. 2009), emphasizing the need for scrutiny and thoughtful interpretation when investigating soil microorganism response to disturbance and its relation to soil processes.

Conclusions

Postfire logging in a dry, mixed conifer forest with sandy loam volcanic soils appeared to have minimal effects on soil microbial richness. However, this short-term study revealed decreased plant-available N and P in the soil after postfire logging disturbances that could have long-lasting effects in a system that already is nutrient limited. A shift in bacterial communities corresponding with an increase in plant available N and P suggests that soil microbes in these postfire landscapes are resilient to mechanical disturbance. Clearly, effects of postfire timber harvesting on soil microbes, nutrients, and processes warrant longer term investigation. Management decisions about whether or not to harvest fire-killed trees should be balanced with

the recovery potential of a site, and the potential for high densities of fire-killed trees to increase the area of severely burned soil in the event of future fire.

ABSTRACT

Forest management guidelines are designed to protect water quality from unintended effects of land use changes such as timber harvest, mining, or forest road construction. Although streams that periodically cease to flow (nonperennial) drain the majority of forested areas, these streams are not consistently included in forest management guidelines. This paper reviews management guidelines for nonperennial (intermittent and ephemeral) streams draining temperate forests in the continental U.S., evaluates potential impacts of land use activities on ecosystem services provided by these streams, and identifies information needed to incorporate nonperennial streams into water quality protection practices. For federally administered lands, national management guidance is deliberately nonprescriptive, deferring to regional and forest-level recommendations for both perennial and nonperennial streams. Most state guidelines recommend riparian management zone (RMZ) protection for perennial streams (48/50 states) and intermittent streams (45/50 states), but only Alaska and West Virginia require RMZs around ephemeral streams. Based on the National Hydrography Dataset, an average of 58% of forested land area in the U.S. drains to nonperennial headwater streams, making these stream types the most common connectors between forested lands and the aquatic system. Land uses that modify flow regimes in these streams can affect sediment and organic matter transport and distribution, stream temperature dynamics, and biogeochemical processing. Nonperennial streams also provide material subsidies to downstream waters and serve as temporary habitats for some aquatic species. However, limited research has examined how forest land uses affect ecosystem services and biota in these streams. Therefore we highlight a set of key questions about nonperennial streams in forests, not the least of which is simply understanding where headwater stream channels are located and associated patterns of flow duration. Although many questions remain, we also note where recent advances in data collection, modeling and process-level research provide opportunities to resolve uncertainties around nonperennial streams in forested landscapes of the continental U.S.

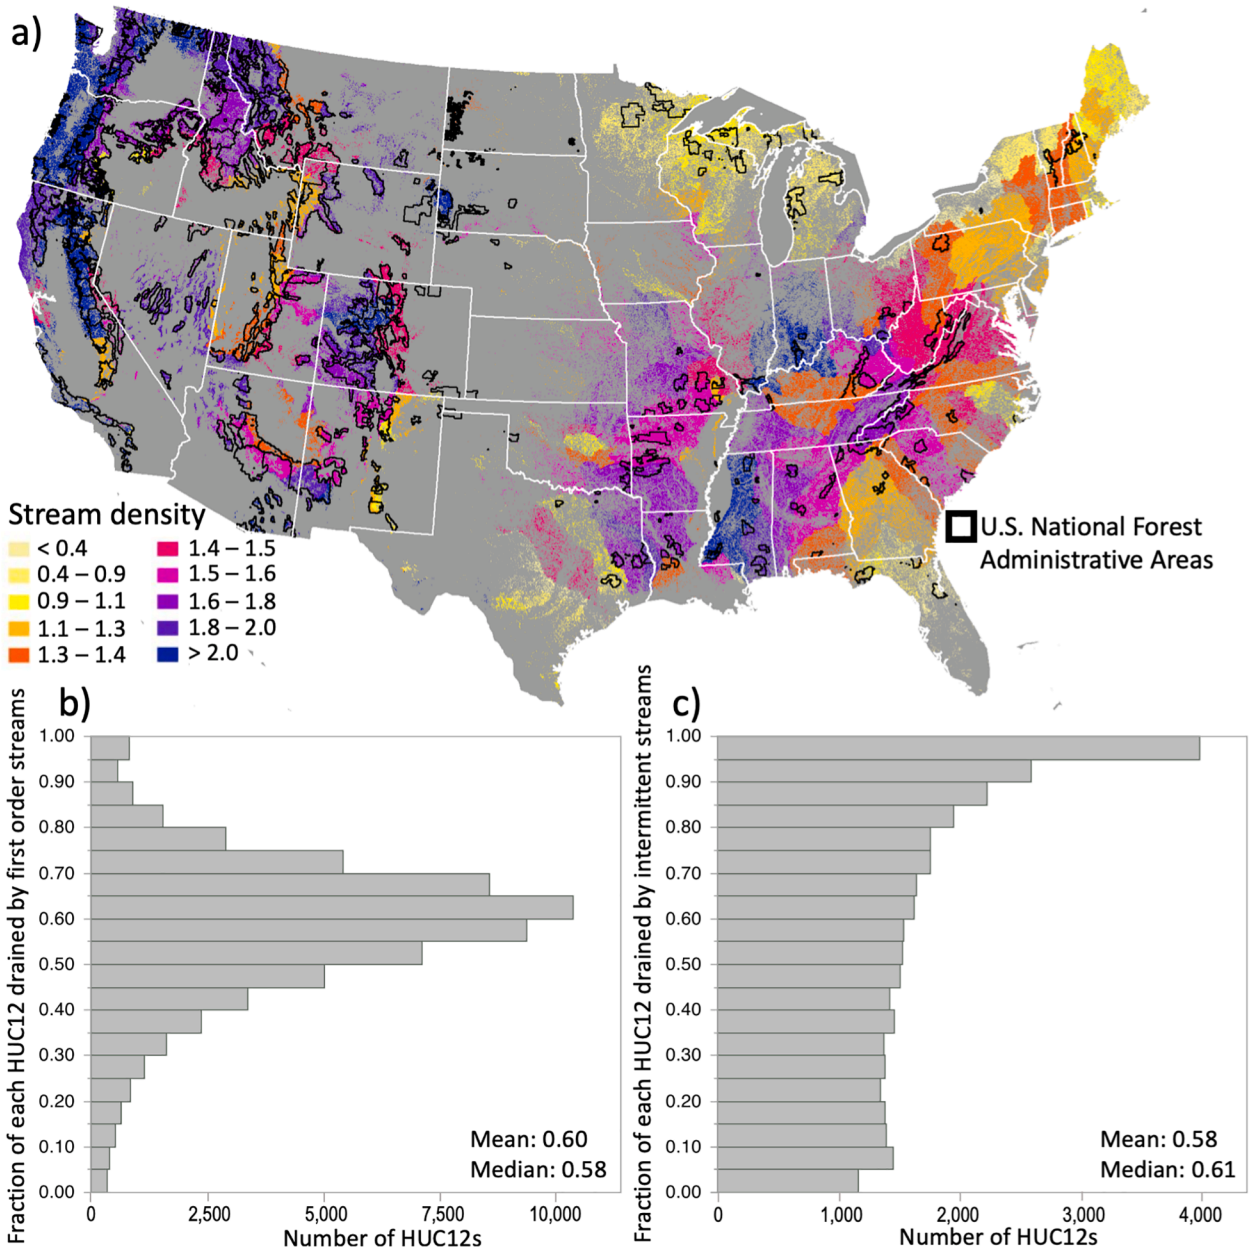

Fig. 1. Stream networks for forested watersheds of the continental U.S. showing (a) stream density (km km^{-2}), (b) fraction of forested watershed land area drained by first order headwater streams, and (c) fraction of first order streams in forested watersheds that are classified as nonperennial (intermittent or ephemeral); note that these classifications are uncertain, as described in the manuscript. Stream data from National Hydrography Dataset High Resolution (NHDHR) flowlines (USGS, 2020a) using only stream and river (Streamriver class) segments. Colored areas in (a) are forested pixels from the National Land Cover Dataset (NLCD, Yang et al., 2018), with stream densities calculated for USGS Hydrologic Unit Code (HUC) 12 watershed subdivisions aggregated to HUC4 scale for visualization. Only HUC12s with forested area > 50% are shown in (b) and (c). Black lines in (a) are boundaries of U.S. National Forest Administrative Areas. Calculations in (b) and (c) are for the same forested watersheds shown in (a), but subdivided into smaller HUC12 watershed sub-units.

1. Introduction

Forested watersheds are widely recognized as important water supply sources in temperate zones. In the United States (U.S.), streams draining land administered by the USDA Forest Service (USFS, Fig. 1a) provide more than half of the nation's water supply (Furniss et al., 2010; Brown et al., 2008). Natural resources on forested lands are managed for multiple uses such as timber harvest, grazing, mining, and recreation. Active vegetation management includes prescribed burning, pre-commercial thinning, wildfire suppression, and pesticide application. Changes in forest land uses can affect streamflow, sediment, organic matter, and thermal regimes (Wohl et al., 2015; Steel et al., 2017; Wohl et al., 2019; Segura et al., 2020), potentially disrupt aquatic and riparian ecosystems (Anderson et al., 1976; Nisbet, 2001), and ultimately degrade water quality of managed watersheds (Binkley and Brown, 1993). Accordingly, management guidelines are developed with the intent to reduce or mitigate potential impacts of land use on aquatic and riparian habitat and downstream water quality (e.g., Aust and Blinn, 2004; Ice et al., 2004; Shepard, 2006; Croke and Hairsine, 2006; Anderson and Lockaby, 2011; Cristan et al., 2016).

A major challenge for effective stream management on forested lands is lack of knowledge regarding the full extent of stream networks (Richardson and Danehy, 2007; Bishop et al., 2008). This information is critical for determining whether forest management activities will affect

Table 1
Summary of state riparian management zone (RMZ) guidelines for perennial, intermittent, and ephemeral streams, presented as number of states within each region. The states included in the four regions are shown in Fig. 3.

RMZ Details	Perennial Streams				Intermittent Streams				Ephemeral Streams			
	West Coast (n = 5)	Interior West (n = 8)	Northern (n = 24)	Southern (n = 13)	West Coast (n = 5)	Interior West (n = 8)	Northern (n = 24)	Southern (n = 13)	West Coast (n = 5)	Interior West (n = 8)	Northern (n = 24)	Southern (n = 13)
Recommended	5	7	23	13	4	7	21	13	1	1	1	1

surface water sources and downstream water quality. Locations of smaller headwater streams are often not well documented (Meyer et al., 2007; Colson et al., 2008) even though they drain the majority of land area in forests (Fig. 1b). Most current stream inventories are based on topographic maps that have limited spatial accuracy and may not correctly classify streams into perennial, intermittent, or ephemeral categories (Fritz et al., 2013; Villines et al., 2015; Hafen et al., 2020). For the purposes of this paper, we broadly define perennial streams as flowing year-round; intermittent as flowing only part of the year, with sustained groundwater contributions allowing prolonged flow, and ephemeral as flowing primarily in direct response to precipitation with variable or no inputs from shallow groundwater sources (Costigan et al., 2016; Busch et al., 2020). Collectively the intermittent and ephemeral types are nonperennial, meaning flow is not continuous in space and time (Whiting and Godsey, 2016; Jaeger et al., 2007). Current estimates indicate that these nonperennial streams make up the majority of headwater stream length in forested lands (Fig. 1c). Flow regimes in headwater streams are sensitive to changing climate (Dhungel et al., 2016), meaning that a static flow class (perennial, intermittent, ephemeral) may not capture the range of flow conditions in past, present, and future climates.

Land management decisions are based on the widely accepted premise that ecosystem services provided by streams are important, societally relevant, and worth protecting (Martin-Ortega et al., 2015; Penaluna et al., 2017). However, most of the scientific understanding of streams and their ecosystem services is based on studies of large, perennial streams (Kovach et al., 2019). Far fewer studies have focused on how land uses impact ecosystem processes in nonperennial headwater streams (e.g., Chiu et al., 2017), with fewer still attempting to relate processes in these streams to their influence on downstream perennial waters (e.g., Warrick et al., 2005). In this review we examine: (1) how current forest management guidelines apply to nonperennial streams; (2) potential impacts of forest land uses on selected processes in nonperennial streams, with a primary focus on timber harvest impacts; and (3) information needed to incorporate nonperennial streams into water quality protection practices. We focus geographically on forested headwater watersheds of the continental U.S. (CONUS) (Fig. 1a), though parts of this review may be relevant for forested watersheds across the globe.

2. Forest management guidelines for nonperennial streams

Guidelines for contemporary forest management in the U.S. are often referred to as "best" management practices (BMPs), which focus on water quality protection from nonpoint source pollution to ensure compliance with the Clean Water Act (33 U.S.C §§ 1251; Binkley and Brown, 1993; Ellefson et al., 2001). In watersheds that support rare species, guidelines also address aquatic and terrestrial habitat protection to comply with the Endangered Species Act.

A primary focus of forest management guidelines is establishing a management zone along stream segments in areas proposed for treatments to reduce chemical contamination, prevent increases in water temperature, and limit inputs of sediment, logging slash, and other large organic materials produced by forestry activities. Throughout this paper, we call these areas riparian management zones (RMZs), although many different naming conventions are used in management guidelines. On federal lands administered by the USFS, the National Core BMPs (USDA-FS, 2012) refer to streamside areas as aquatic management zones, and in regional guidance documents these areas have been termed riparian conservation areas, water influence zones, streamside management units, stream environment zones, and riparian reserves. We distinguish an RMZ from a "buffer", as some forest harvest is allowed in most RMZs, whereas "buffer" typically indicates a band of vegetation left in its pre-harvest / pre-treatment condition. The term "buffer" makes no assumptions about the composition, structure, height, or density of the vegetation left adjacent to the stream other than that it is left undisturbed by direct human activities.

On National Forests, the National Core BMPs (USDA-FS, 2012) provide general guidance for designating RMZ width and managing RMZs to protect water quality and maintain stream, aquatic, and riparian function and processes. Determining stream channel type (perennial, intermittent, ephemeral) is a key component of National Core BMP recommendations, but the guidelines are deliberately nonprescriptive, allowing managers to adapt them to local conditions. For a given region or National Forest, project-specific management plans are developed depending on local features such as presence of valued aquatic biota (e.g., species listed under the Endangered Species Act), steepness of terrain, and compliance with state, tribal, and national water quality goals. RMZ designation and BMP implementation are more prescriptively directed in forest-level management plans, with recently revised plans tending to have more specific guidance than older plans. Notable exceptions to individual forest-level or project-specific plans are the Pacific Anadromous Fish Strategy (PACFISH; U.S. Forest Service and U.S. Bureau of Land Management, 1994) and the Inland Fish Strategy (INFISH; U.S. Forest Service, 1995), which are multi-agency mandates for watershed management across vast expanses of federal lands along the Pacific Coast and in the Upper Columbia River Basin, USA. PACFISH and INFISH were developed in response to regulatory proceedings of the Endangered Species Act to protect aquatic and riparian habitat for threatened and endangered salmonid fishes. These strategies amended forest plans of 20 National Forests and 10 Bureau of Land Management Field Offices, increasing protection of intermittent streams on federal lands in the Pacific Northwest and western regions of the U.S. (Henderson et al., 2005).

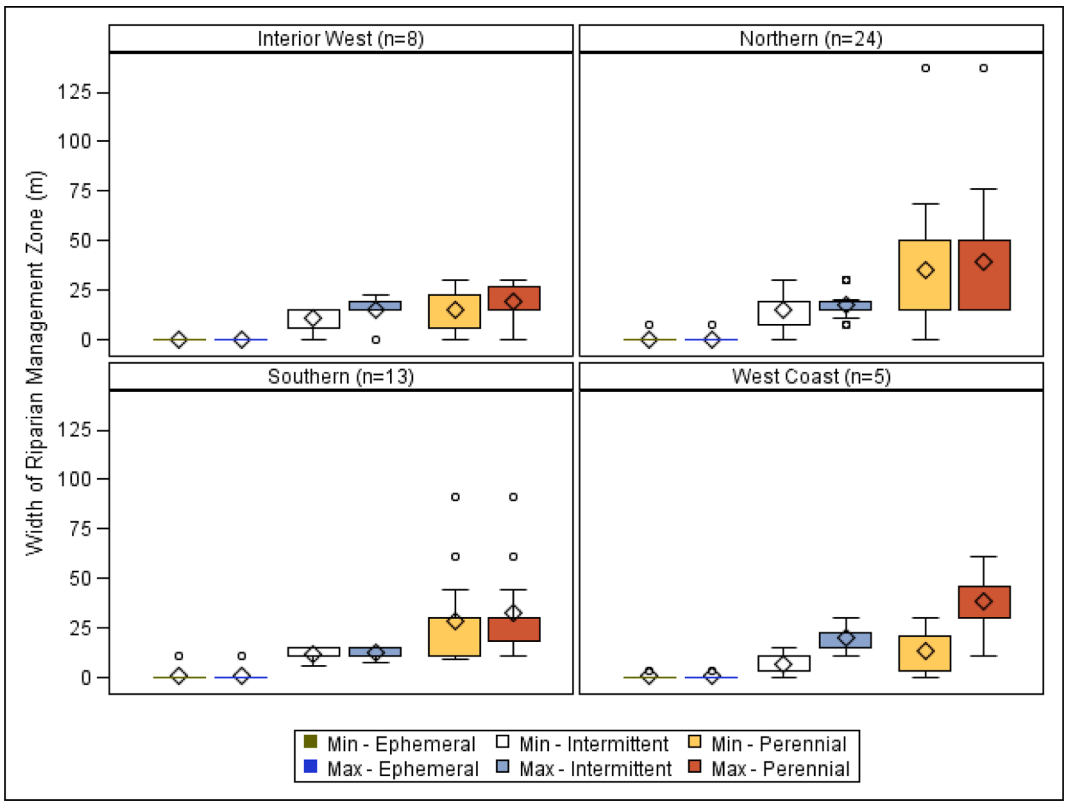

Fig. 2. Means (◊) of minimum and maximum riparian management zone (RMZ) widths surrounding ephemeral, intermittent, and perennial streams in four regions as defined by U.S. Forest Service Forest Inventory analysis (FIA, https://www.fia.fs.fed.us/regional-offices/, Fig. 3). Boxes represent the range in minimum and maximum RMZ widths among individual states in each region between the 25th and 75th percentile (the interquartile range, IQR); whiskers represent the spread of data that fall within 1.5 times the IQR, and outliers (○) are datapoints beyond 1.5 times the IQR.

Most state guidelines are more specific and prescriptive than the USFS National Core BMPs. We reviewed forest management guidelines by state and found that in most states, perennial (n = 49 states) and intermittent (n = 46 states) streams are explicitly or implicitly recognized as needing RMZ designation (Table 1). This is an increase in the number of states including intermittent streams in RMZ recommendations over the 40 that had these recommendations in 2001 (Blinn and Kilgore, 2001). Nearly all states provide forest practice guidebooks that tier to general requirements under the Clean Water Act (33 U.S.C §§ 1251), and approximately a quarter of states now have laws or statutes explicitly requiring RMZs for perennial and intermittent streams (Table 1). While 82% of states have updated guidelines over the past 20 years, only two states (Alaska, West Virginia) have revised guidelines to require RMZs for ephemeral streams; two additional states (Alabama, Montana) recommend RMZs for ephemeral streams. The minimum RMZ recommendations for intermittent streams have only changed modestly in the last two decades (Table 1).

Although we compare state guidelines using the perennial, intermittent, and ephemeral terminology (Table 1), these terms are not present in all state guidelines. For example, Washington's regulations refer to intermittent streams as "seasonal" streams. Similarly, California's guidelines include streams "capable of sediment transport", whether or not they continuously flow (California Department of Forestry and Fire Protection, 2020). Montana's streamside management zone law considers average duration of flow, with the RMZ requirements dependent on whether the streams flow fewer than six months per year (Rogers, 2006).

In most state guidelines, RMZ widths and allowable practices within RMZs are less protective for ephemeral and intermittent streams than perennial streams (Fig. 2). Recommended widths vary across regions and states depending on terrain steepness, stream size, fish occupancy, and contribution to municipal water supply (Table 1). Some state recommendations for RMZs are based on the use of the stream water (e.g., Washington, Oregon, California, Idaho, Montana), with highest level of protection for fish-bearing streams and(or) streams that are used for domestic drinking water (Washington Forest Practices Board, 2001; Oregon Department of Forestry, 2018; California Department of Forestry and Fire Protection, 2020; Barkley et al., 2015; Rogers, 2006). Where intermittent streams support fish or other species included in state guidelines, the RMZ requirements match those for perennial streams. For intermittent streams without fish, state RMZ recommendations range from including no RMZ requirement, to narrower RMZs, and in some cases RMZ widths similar to perennial streams. RMZ protections in Idaho depend on whether streamflow is present at the time of treatment operations, with reduced protection when intermittent stream channels are dry (Barkley et al., 2015). Guidelines for RMZs in Michigan vary with stream order, steepness of adjacent land, and public versus private ownership (Michigan Department of Natural Resources, 2018).

Most states allow limited harvest operations within RMZs of intermittent streams, with exceptions that prohibit some operations (Delaware, Idaho, California) or all operations (Utah, Nevada, Wisconsin, Washington, Oregon, Alaska). The requirements for retaining overstory trees can differ between intermittent and perennial streams (EMNRD, 2008; Wyoming State Forestry Division; South Carolina Forestry Commission; Stringer et al., 2018; Georgia Forestry Commission; Brogan et al., 2006; Tennessee Department of Agriculture, 2003; West Virginia Division of Forestry, 2018; Colorado State Forest Service, 2010). For ephemeral streams, some state guidelines (e.g. South Carolina, Kentucky, North Carolina, Tennessee, Michigan) recommend that disturbances be avoided within and near stream channels, but usually there are no RMZ requirements. The exception is West Virginia, which requires a reduced width RMZ for ephemeral streams as compared to

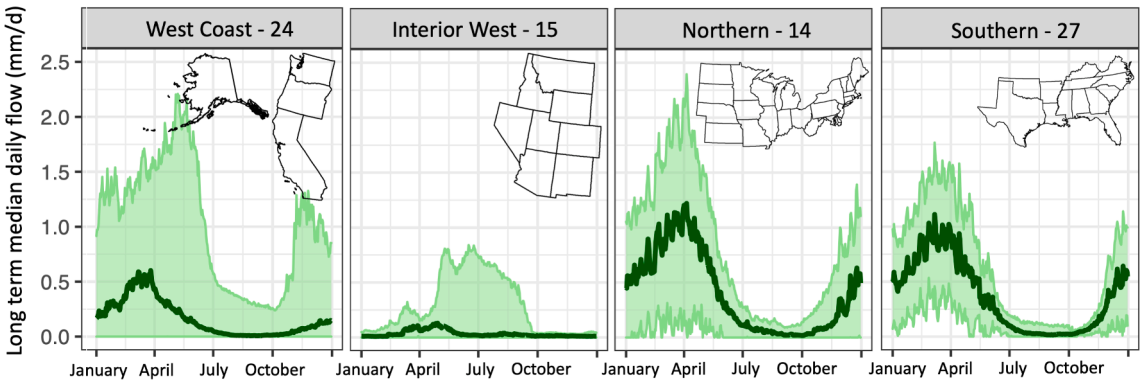

Fig. 3. Median daily flow (drainage area-normalized) for USGS reference stream gages with nonperennial flow for water years 1980–2018 (USGS, 2020b; Hammond et al., 2021). In each plot the dark line indicates the median flow for each day of year across all years of record and all nonperennial stream gages in the region, with the number above each panel indicating the number of gages used. The light green area indicates one standard deviation above and below the median. Regional subdivisions are those used by the U.S. Forest Service Forest Inventory analysis (FIA, https://www.fia.fs.fed.us/regional-offices/). Note, although Alaska and Hawaii are included in the West Coast region for Table 1 and Fig. 2, they are not part of the daily flow dataset (Hammond et al., 2021).

perennial and intermittent (West Virginia Division of Forestry, 2018). Finally, some states apply guidelines or requirements only to perennial streams (e.g., Vermont; Wilcox et al., 2019), do not specify the types of streams to consider (e.g., Nevada; Nevada State Conservation Commission, 1994; Nevada Code, 2010), or have no management guidelines at all (e.g., Arizona; Ice et al., 2004).

These varying guidelines and their level of detail regarding stream types pose contrasting management challenges. Where guidelines are explicit about the types of streams addressed in management plans, accurate information is needed on stream location, flow duration, and aquatic species present. Where guidelines are broader or more ambiguous, the decision to include a stream in a management plan is largely made at the discretion of the land manager. Management guidelines for RMZs included in state or federal forest management plans can vary in the degree to which guidelines are followed, as certain practices are considered voluntary and/or at the discretion of land managers. In other countries, examination of actual buffers used during timber harvest has shown region-wide patterns of poorly applied protections and infrequent adherence to minimum buffer guidelines for small streams when their application is voluntary or unmonitored (Kuglerová et al., 2020). Such lack of information about nonperennial stream location and use by biota could default to limited or no protection. Although BMP monitoring on federal, state, and private forest lands largely indicates the effectiveness of RMZs for perennial streams (Cristan et al., 2016), implementation and monitoring of BMPs has likely been biased toward perennial streams, given the general lack of BMP evaluation studies that focus on or even mention nonperennial streams. The variability in guidelines between states exemplifies how much management practices can vary between political jurisdictions, even though stream systems connect across political boundaries.

3. Impacts of land use and management on nonperennial forest streams

Land uses in uplands can affect streams if they change the inputs of water, sediment, and other materials to the stream network. The majority of upland area in forests drains into headwater nonperennial streams (Fig. 1b,c) rather than into higher order perennial streams, meaning that headwater nonperennial streams are often the first point of connection between uplands and stream networks. In spite of this, direct studies on the effects of land management on nonperennial streams are rare, with van Meerveld et al. (2020) recently calling nonperennial streams “Aqua temporaria incognita” to emphasize how little is known about them. In this section, we introduce how land use activities may alter streamflow regimes, sediment export, organic matter dynamics, stream temperature, and biotic ecosystems of nonperennial streams.

3.1. Streamflow regimes

3.1.1. Temporal and spatial patterns

Intermittent streamflow timing is largely driven by seasonal variability in water inputs (snowmelt, rainfall) and outputs (evapotranspiration; ET). For most streams in temperate forests of the U.S., drying is most likely during the summer and fall, when potential ET is highest (Fig. 3). In west coast forests with Mediterranean climates, the summer is commonly a time of precipitation deficit, so streams sustain flow through the summer only if they are supplied by persistent groundwater sources. Many forest streams of the drier interior West are fed by snowmelt, so highest flow is most likely during spring and summer, with driest conditions in fall and winter.

Streamflow can also be spatially intermittent, typically with reduced active (flowing) stream network extent in dry times of year. In many environments, flowing channels expand and contract seasonally, with the greatest headward extent of channels during wet times of year and (or) when ET is low (Barefoot et al., 2019; Jensen et al., 2017). Other stream networks have more stable flow locations, especially where bedrock exerts a strong control on water flow paths (Shaw, 2016; Whiting and Godsey, 2016; Lovill et al., 2018). Watersheds with varying bedrock geology may have a combination of both stable and migrating flow heads (Jaeger et al., 2007; Martin et al., 2021). Downstream of flow heads, water may move to the subsurface in stream segments with highly permeable substrates such as karst or coarse sediment deposits (Ward et al., 2018; Durighetto et al., 2020). Flow can also re-emerge downstream due to changes in channel slope, topographic convergence or valley confinement (Baxter and Hauer, 2000; Jensen et al., 2017).

3.1.2. Land use impacts

Land use activities can modify nonperennial streamflow regimes if they change the timing and/or quantity of water delivery. The timing of water delivery relates to the pathways of water from uplands to streams. In most mesic temperate forests, water reaches streams through subsurface pathways (e.g., Hewlett and Hibbert, 1967), and infiltration excess overland flow is rare. Water traveling slowly through subsurface pathways sustains flow in channels after rainfall has stopped. Land uses that reduce surface infiltration capacity can change flow paths by increasing the likelihood of infiltration excess overland flow (Wondzell and King, 2003; Larsen et al., 2009), particularly where severe ground disturbance is combined with intense rainfall (Megahan et al., 1995; Meyer and Wells, 1997; Orem and Pelletier, 2016). The ground disturbances that cause this effect may be limited to unpaved roads, skid trails

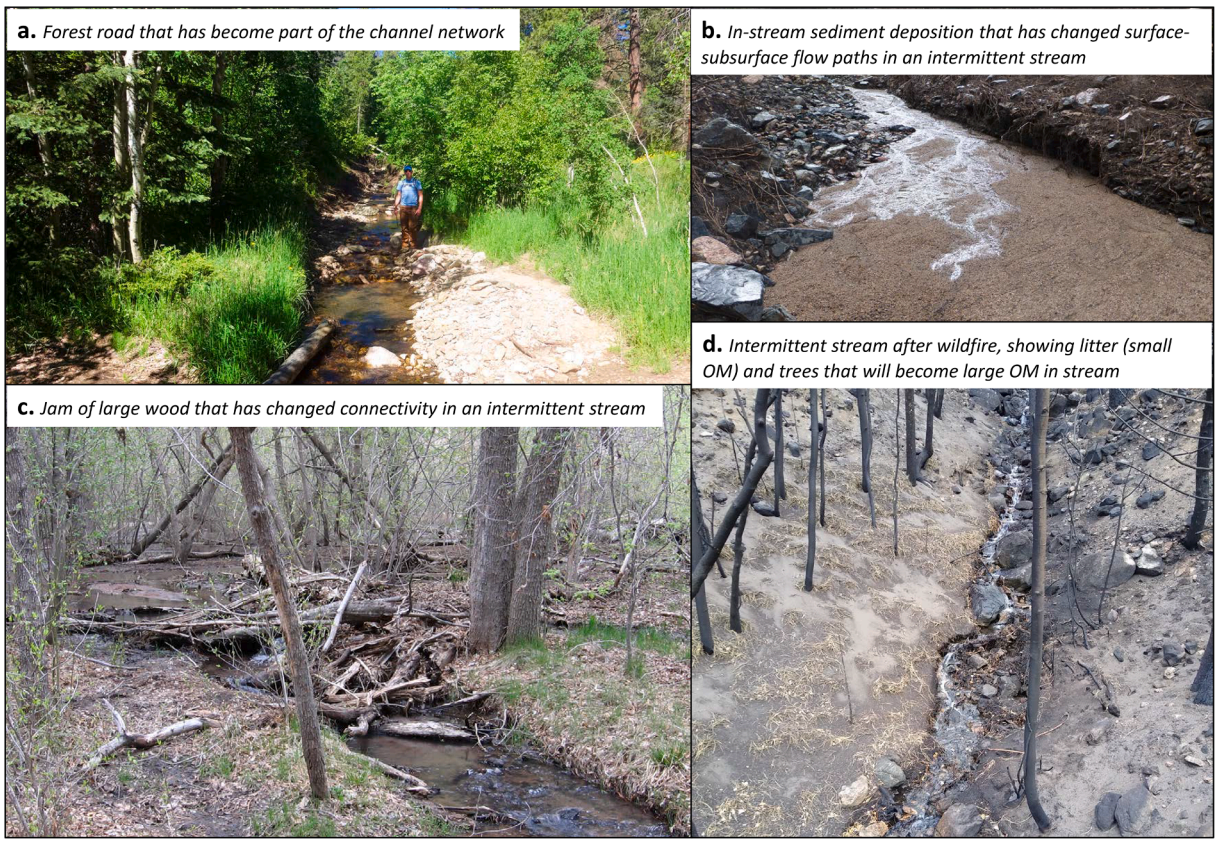

Fig. 4. Examples of nonperennial forest streams showing: (a) forest road with flowing surface water; (b) channel reach filled with recent sediment deposits, where surface flow infiltrates into the coarse sediments; (c) jam of large wood changing sediment storage and flow paths in a stream reach; (d) example of organic matter (OM) sources to stream after wildfire, including ash, litter, and eventually, burned wood when trees fall into the stream channel.

(Dickerson, 1976), or other areas where heavy equipment is operated. Cable yarding, which is commonly used for timber harvest in steep terrain, keeps heavy machinery off of slopes, and yields only small areas of compaction where logs drag. After forest harvest, a range of practices has been used historically to remove logging slash and competitive brush to prepare harvest sites for replanting, including activities like broadcast slash burning and drum chopping. Such practices can reduce infiltration and increase overland flow, at least temporarily (e.g. Hewlett and Doss, 1984; Harr et al., 1975). Post-harvest restoration activities, such as ripping or mulching skid trails and other areas disturbed by heavy equipment are now routinely used to restore infiltration capacity and reduce overland flow from disturbed patches.

Forest roads may be more permanent locations with reduced infiltration and therefore greater infiltration excess overland flow. Roads can also modify flow paths by capturing subsurface flow where roads are cut into steep slopes. Flow intercepted along cutslopes can be converted to overland flow before it would have naturally reached the stream (Wemple and Jones, 2003; Burroughs et al., 1972; Megahan, 1972; Moore and Wondzell, 2005). Depending on topography, soils, and climate, some roads capture more flow than others (Wemple and Jones, 2003; Luce, 2002). If roads capture substantial flows that are re-routed directly into streams, then the presence of roads, in effect, extends the length of the channel network, especially the nonperennial portion (Wemple et al., 1996; Croke and Mockler, 2001, Fig. 4a). By conveying overland flow rapidly to streams, roads can lead to more rapid streamflow response to rainfall.

Forest land uses can also modify the quantity of water reaching streams via changes in evapotranspiration. Trees are generally able to transpire more water than the herbaceous vegetation that grows soon after forest removal because of deeper root systems and larger leaf areas, although transpiration responses to disturbance can be highly variable (Amiro et al., 2006). The effects of changes in vegetation on streamflow have long been examined through paired catchment studies (see reviews by Bosch and Hewlett, 1982; Brown et al., 2005), which have shown that forest clear cutting over entire mesic headwater catchments leads to increases in total annual streamflow in the years immediately following forest harvest. Increases in late summer discharge have also been observed immediately after forest harvest (Perry and Jones, 2017; Robinson and Dupeyrat, 2005; Li et al., 2018) or wildfire (Kinoshita and Hogue, 2015). These types of flow changes would likely be associated with increases in flowing channel extent, with flow persisting longer in intermittent reaches.

Forest land use changes are not always detectable in streamflow, in part based on the size of the land change relative to drainage area. Prior studies have indicated that at least 20% of a catchment would need to be impacted by vegetation change before the effect would be detectable in streamflow (Bosch and Hewlett, 1982). Headwater streamflow in locations affected by vegetation change may be more sensitive than flow in larger perennial streams, for which land use changes affect a smaller portion of total drainage area. The ability to detect and quantify hydrologic effects of disturbance also depends on the magnitude of the disturbance effect relative to variability in streamflow caused by climate, and the rate and nature of vegetation recovery (Brown et al., 2005; Adams et al., 2012). Due to the heterogeneity of forest disturbances, climates, and hydrologic processes, many types and time scales of flow regime changes are possible. For example, conversion of old-growth forest to younger aged forest can cause decreased late-summer discharge in the later decades of long-running paired watershed studies because young trees may transpire more water than old-growth trees (Kuczera, 1987; Moore et al., 2004; Delzon and Loustau, 2005). Thus as forests recover from disturbance, baseflows may decline, and even be lower than the pre-disturbance condition (Perry and Jones,

2017; Segura et al., 2020; Safeeq et al., 2020; Coble et al., 2020). Natural disturbances that cause substantial forest dieoff may lead to increases, no change, or even decreases in streamflow (Adams et al., 2012; Goeking and Tarboton, 2020). Thus the effects of forest land uses on non-perennial streamflow regimes are likely to be highly variable and site-specific.

Some forested lands include areas of active or past mining, which can dramatically change the topography and alter the contributing areas to downstream rivers (Ross et al., 2016; Jaeger and Ross, 2021). Underground mining can cause land subsidence, which affects both the water reaching streams and the topographic gradients between uplands and streams (Sidle et al., 2000). In some cases, streams may be diverted below ground (Slaughter et al., 1995), while elsewhere streams may gain flow due to connections with groundwater that did not exist prior to mining (Morrison et al., 2018). The legacy effects of mining (surface and underground) and reclamation activities on streamflow patterns are highly variable and can persist for decades following mining and reclamation activities (Dickens et al., 1989; Bonta et al., 1997; Miller and Zégre, 2014). Recent modeling of reclaimed watersheds that had been surface mined indicate that changes in flow paths caused by mining would reduce streamflow during low flow periods under future climate scenarios, although this response can be mitigated by implementing different forestry reclamation approaches (Williamson and Barton, 2020).

While most forest disturbances are followed by vegetation regrowth, not all disturbances are transient. For example, although forest harvest patches are usually replanted rapidly, the road network used to access cutting units is often maintained, in which case the effects of roads on watershed hydrology persist over longer time periods. Other forest land uses such as campgrounds, day use areas, parking areas, field stations, and ski areas also have more persistent changes in forest cover. These more permanent land use conversions represent a small (<1%) portion of forested land area, but they can have localized effects on headwater streamflow regimes. For example, ski areas have been associated with sustained changes in streamflow (Wemple et al., 2007), channel network extent, and adjustments of channel morphology (David et al., 2009).

3.2. Sediment regimes

Sediment and streamflow regimes are highly inter-connected. Sediment can reach streams via erosion during overland flow, mass movements, or bank erosion (MacDonald and Coe, 2007). In undisturbed landscapes, nonperennial streams may store a large fraction of sediments produced during major storms and release these sediments gradually to downstream reaches (Dieterich and Anderson, 1998; Dewey et al., 2020), potentially limiting or moderating erosion and habitat degradation downstream. In contrast, erosion from overland flow can lead to rill and gully formation, expansion of the channel network, and more downstream sediment export (Istanbulluoglu et al., 2002; 2003; Bastola et al., 2018; Wilson et al., 2021). Although RMZs around streams are often effective at intercepting sediment from upland diffuse overland flow, concentrated flow in gullies and rills can breach RMZs (Rashin et al., 2006; Lakel et al., 2010). Where rills and gullies connect to streams, their sediment inputs can be as high as those found in streams without RMZs (Gomi et al., 2006), creating substantial changes in downstream sediment loads (Fig. 4b). If the excess overland flow that forces rill and gully incision is temporary, and vegetation recovers after disturbance, rills and gullies may disappear in a few years as side walls collapse, and channels refill with sediment (Wohl and Scott, 2017).

Roads are a ready source of chronic fine sediment to streams (Reid and Dunne, 1984; Luce and Black, 1999) and can be associated with altered stream channel morphology (Pechenick et al., 2014). Road decommissioning practices such as ripping can help restore infiltration capacity and reduce overland flow and erosion, although even after decommissioning, roads may still have reduced infiltration and elevated surface erosion compared to undisturbed forests (Luce, 1997; Sosa-Pérez and MacDonald, 2017).

Reducing surface disturbance in riparian zones is often a focus of forest management guidelines because these zones are adjacent to nearby streams. Movement of skidders or road construction equipment through riparian areas is a well-recognized source of sediment to streams, leading to restrictions on logging equipment use in RMZs (e.g. Keim and Schoenholtz, 1999). Recreational off-road vehicle use in riparian areas and stream crossings can also elevate sediment delivery to streams (e.g. Marion et al., 2014), particularly activities like “mudding” (a recreational activity involving driving off-road vehicles through mud) that disrupt soils and promote erosion of fine sediments.

Mass movements are another cause of changing sediment regimes in stream networks, in some cases leading to the greatest geomorphic changes following vegetation removal in steep uplands (Montgomery et al., 2000; Jackson and Roering, 2009). The frequency of mass movements can increase after logging (Sidle et al., 1985; Brardinoni et al., 2003; Benda et al., 2005) and along forest roads (Wemple et al., 2001; Montgomery, 1994). The sediment evacuated from steep terrain may cause substantial channel reorganization downstream by diverting or blocking channels, forming deposition fans or sediment wedges, and leading to changes in channel form (Hoffman and Gabet, 2007; Benda, 1990; Benda and Dunne, 1997). Mass movements can also lead to establishment of new channel heads by creating zones of groundwater flow convergence (Dietrich and Dunne, 1993; McNamara et al., 2006). While landslides and debris flows can be large sediment sources in many areas with steep topography, they are episodic and infrequent. Chronic, smaller magnitude sediment production is often dominated by bank erosion (Hassan et al., 2005).

Changes in the patterns of deposition and scour along streams may affect patterns of flow intermittency by shifting how water moves between the surface and subsurface. For example, deposition of fine-textured sediment within a stream can reduce hydraulic conductivity of the channel bed and hyporheic exchange with groundwater (Wharton et al., 2017). Locations of large sediment deposits can become zones of water infiltration and reduced flow duration (Ward et al., 2018; Fig. 4b).

3.3. Organic matter

Organic matter (OM) inputs to headwaters may come from wind-thrown trees, litter fall from riparian and upland vegetation, overland flow or mass wasting, leachate from organic matter in the subsurface, and dispersal of soil and canopy fauna into streams (Wipfli et al., 2007). Riparian inputs of OM per unit stream area generally decrease with increasing stream size (Conners and Naiman, 1984), making OM input particularly important in headwater streams. As with sediments, headwater nonperennial streams tend to store large amounts of OM relative to similar sized perennial streams (Dieterich and Anderson, 1998; Acuña et al., 2004), Moreover, OM decomposition rates in nonperennial streams tend to be slower due to low microbial growth rates and little physical breakdown during dry periods, as well as reduced densities of macroinvertebrate shredders (Richardson, 1990; Sabater et al., 2016). However, during flowing conditions, the resulting large standing stocks of accumulated benthic OM become available to downstream perennial reaches either gradually through seasonal flow or episodically during storm events, potentially providing increased stability to the detrital-based food webs in headwater stream networks over annual or decadal time periods (Richardson et al., 2005; Larned et al., 2010).

Coarse organic material in the form of large branches, logs, chunks of wood, and roots, can directly influence channel morphology and sediment characteristics (Fig. 4c). Studies on coarse OM specific to nonperennial streams are extremely sparse (but see Wohl et al, 2018; Galia et al., 2020 for drier climates), though prior research on forested headwater streams may not have distinguished between perennial and nonperennial streams (e.g., May and Gresswell, 2003). Because many nonperennial streams are headwaters with lower flow and smaller channel dimensions, they tend to retain much of the coarse wood that

Fig. 5. Thin RMZ retained around a nonperennial stream in an area of timber harvest.

falls in them, and more of it may initially be suspended over channels. However, episodic flash flood and debris flow events can transport substantial volumes of wood out of these channels to downstream reaches. Given the nature of these processes, we might expect the wood balance of nonperennial streams to be dominated by local inputs and decomposition, but some may occasionally release large pulses of accumulated wood to downstream segments. The changes in channel morphology caused by large wood can alter in-channel biological communities, sediment storage, and the movement and transformation of nutrients and other materials (Blaen et al., 2018; Short et al., 2015; Wipfli et al., 2007).

Smaller forms of organic material, including particulate and dissolved OM, contribute to local and downstream metabolic processes and carbon cycling (Richardson, 2019a; 2019b), with dissolved OM most likely to be transported downstream. Fine particulate and dissolved OM can be derived from direct instream growth or allochthonous inputs from riparian vegetation. Macroinvertebrates are primary consumers of fine particulate OM, and they may subsequently become food for predators. The presence of these invertebrates and therefore the breakdown of OM may be reduced when nonperennial streams are dry (Datry et al., 2011), with heterogeneous decomposition as flow paths become fragmented (Abril et al., 2016). Multiple studies have found that stream wetting and drying patterns also affect dissolved organic carbon dynamics (von Schiller et al., 2015; Hale and Godsey, 2019). Dissolved OM is available to microorganisms and constitutes a demand for oxygen that can limit habitat suitability in some intermittent streams (Larsen and Woelfle-Erskine, 2018).

Land use activities can affect all forms of OM input with subsequent implications for in-channel or downstream OM processes. The primary mechanisms of change are: 1) altering the proximal forest canopy that provides OM inputs to the stream (Fig. 4d); 2) increasing sunlight on the stream allowing greater algal growth, and 3) altering dissolved organic carbon inputs from runoff and shallow groundwater inputs from adjacent forests. Direct removal of vegetation adjacent to stream channels will substantially reduce particulate OM until vegetation regrows (Webster et al., 1992), with an even longer delay for large wood inputs (Bilby and Likens, 1980; Verry et al., 1999). Log jams may become century-scale legacies of past riparian harvest on large OM (Wohl and Goode, 2008). Roots from streamside trees also influence channel morphology; root loss after forest harvest can lead to bank failure, which can impact sediment storage and surface water expression. Changes in dissolved organic carbon inputs to streams from adjacent forest areas through runoff and leaching have complex responses to harvest, with reports of both increases and decreases depending on initial organic matter loads in the stand, moisture dynamics, changes in temperature, and time following harvest (e.g. Meyer and Tate, 1983; Laudon et al., 2011; Schelker et al., 2013; Lajtha and Jones, 2018).

3.4. Temperature

Perennial streams have been the primary focus of stream temperature research, although their temperature dynamics may be quite different from those of smaller nonperennial headwater streams (Moore et al., 2005). High stream temperatures are a water quality concern because they can limit habitat suitability for aquatic species. High stream temperatures are most likely during warmer seasons with lower flow where incoming solar radiation is a dominant energy source (Webb and Zhang, 1997, Roon et al., 2021). Consequently, loss of riparian canopy from timber harvest, removals of hazard trees, or other activities can lead to increases in warm season stream temperature (e.g. Poole and Berman, 2001).

Concerns over solar radiation and stream heating have been a primary motivation for suggesting or requiring RMZs along perennial streams. However, there have been many questions about the utility of RMZs for nonperennial channels, leading to inconsistent, optional, or ineffective application of RMZs . One example is the “compromise” of using narrower RMZs for harvest around nonperennial channels since there seems to be no “stream” to shade, and offering some nod to other values from riparian forests. Unfortunately, the riparian forest does not exist independently of the surrounding forest stand, and the thin strips prescribed for RMZs around nonperennial streams may be more vulnerable to blowdown (e.g. Jackson et al., 2001 and Fig. 5).

In some forest headwater streams, flow is supplied by shallow groundwater inputs and has relatively little opportunity for heating along the channel; in these locations, stream temperatures may be less sensitive to increased solar energy inputs from harvest or fire (e.g. Story

et al., 2003; Janisch et al., 2012; Kelleher et al., 2011; Mayer, 2012; Luce et al., 2014). Even under low flow conditions in nonperennial channels, surface water heating by solar radiation may be limited if the water is sourced by groundwater and is spatially intermittent. In some cases, subsurface flow maintains longitudinal connectivity along channels even as surface water becomes separated into disconnected pools (e.g. Ward et al., 2018). Because solar heating of subsurface water is relatively minor (e.g. Story et al., 2003), shallow groundwater inflow can cool stream temperatures during summer (Wigington et al., 2006; Larsen and Woelfle-Erskine, 2018). This can allow surface water along spatially intermittent streams and stream junctions with seemingly "dry" channels to provide locally cold habitat (Ebersole et al., 2001; Snyder et al., 2015). Temperatures of shallow subsurface water can also be sensitive to land use change such as loss of canopy to harvest or wildfire; however, the warming of groundwater is generally less than the direct warming of stream water by increased solar radiation, so even the warmed shallow groundwater inputs are still a cooling influence on peak stream temperatures (Guenther et al., 2014).

Because of the importance of groundwater for stream temperature, activities that change surface–subsurface exchanges of water along stream corridors can influence temperature regimes. Compaction of ephemeral channels during harvest (e.g. Burns, 1972), siltation of the streambed reducing down-valley transmissivity, and channel scour removing the hyporheic zone (e.g. Dunham et al., 2007) can each reduce hyporheic zone subsurface flow. This forces more flowing water to be exposed on the surface to solar radiation. Less is known about overland flow influences on stream temperatures during rain storms in forested ecosystems, although this can cause temperature spikes during summer rains in urban systems (e.g. Nelson and Palmer, 2007). Although these examples provide some insight into how disturbance may affect nonperennial stream temperatures, there is neither a formal framework nor substantial focused research on temperature in headwater nonperennial streams and their overall contribution to thermal regimes downstream perennial reaches.

3.5. Biota

Headwaters, including nonperennial streams, are vital components of upland ecosystems, potentially regulating the spatial and temporal distribution of suitable physical environmental conditions and ecosystem processes that influence terrestrial and aquatic biota (Richardson and Danehy, 2007; Studinski et al., 2012). Consequently, human-induced changes to the landscape that alter the amount, predictability, spatial distribution, and connectivity of headwater habitats can affect not only the species that intermittently use or inhabit these periodically dry stream channels, but also the species downstream in the perennial stream network (Datry et al., 2014; Leibowitz et al., 2018). Here we focus on the importance of nonperennial streams for aquatic biodiversity in general and then consider influences downstream specifically for fish, which are often the focus of management guidelines.

At the reach scale, nonperennial streams typically support lower aquatic macroinvertebrate and fish species diversity than perennial reaches due to the effects of drying on habitat availability (Poff and Ward, 1989; Stanley et al., 1997). However, recent evidence suggests that when semi-aquatic and terrestrial flora and fauna are included, biodiversity within and adjacent to nonperennial reaches is often equal to or higher than that observed for comparable perennial reaches, particularly in landscapes where seasonal drying is predictable and extensive (Larned et al., 2010). For instance, in arid landscapes, nonperennial stream valleys are oases that frequently support more productive and diverse vegetative communities than the surrounding uplands, although the processes behind these responses are not entirely clear (Katz et al., 2012). In turn, these communities create more favorable microclimates that provide primary habitat, breeding areas, temporary refuges, and movement and migration corridors for biota. Nonperennial streams can be important habitats for terrestrial invertebrates, amphibians, reptiles, birds, and mammals (Corti and Datry, 2016; Sánchez-Montoya et al., 2017).

Across river networks, nonperennial stream habitats can have a disproportionately high influence on beta- and regional diversity of both aquatic macroinvertebrate (Valente-Neto et al., 2020) and fish (Rogosch and Olden, 2019) communities. Although not fully understood, the patterns of aquatic community diversity at least partly depend on complex interactions between the length of the drying period, the spatial topology of drying within river drainages, and the predictability of drying over time (Sánchez-Montoya et al., 2018), all of which are vulnerable to changing land use. The distributions of lotic (flowing water), lentic (isolated pools), and terrestrial (dry) habitats shift seasonally thereby increasing habitat heterogeneity. Differences in communities in each phase of wetting and drying increase biodiversity at larger scales over annual cycles (Datry et al., 2014; Stubbington et al., 2017). Where seasonal drying is predictable, it can exert strong selection pressures that favor specialized behavioral, morphological, physiological, or life history adaptations that increase tolerance or resilience to drying (Lytle and Poff, 2004; Walters, 2011), sometimes resulting in higher rates of endemism and regional biodiversity (Meyer et al., 2007).

Despite the importance of nonperennial streams in maintaining biodiversity, management guidelines have focused primarily on the extent to which headwater habitats are used by fish or influence fish downstream. The role of nonperennial streams for fish has not been extensively studied in forested ecosystems (Richardson and Danehy, 2007), although in arid portions of the U.S. fish are strongly dependent on them (Minckley and Deacon, 1991; Perkin et al., 2017). Here we highlight a selected range of examples across forested ecosystems in the U.S. that demonstrate the importance of nonperennial streams for fish.

Although fish are often absent from nonperennial streams during low flow periods, several studies indicate that they do use intermmittent streams seasonally. In the northwestern U.S., fish, including salmon and trout, are known to track stream network expansions (Erman and Hawthorne, 1976; Woelfle-Erskine et al., 2017; Wigington et al., 2006). Erman and Hawthorne (1976) reported that 39–47% of nonnative rainbow trout (*O. mykiss*) spawned in a single intermittent tributary to a perennial stream in the eastern Sierra Nevada Mountains. In this study, researchers found that egg incubation, emergence, and emigration of juveniles to perennial streams occurs within the seasonal window when nonperennial streams are flowing. Emigration from these systems has not been studied extensively, but one study of eight native fish species in forested streams of the southeastern U.S. reported that the probability of emigration increased as stream networks contracted, and stream flows became intermittent (Albanese et al., 2004).

Use of nonperennial streams by many fish species in forested systems can pose important tradeoffs. These streams represent a large area of potential habitat, thus supplementing what is available to fish within the perennial network (Schlosser, 1995). In some cases, use of intermittent portions of the network allows species to avoid adverse ecological interactions with members of their own species (e.g. intraspecific competition) or other species more characteristic of the perennial network (Meyer et al., 2007). However, use of intermittent streams by fish entails risks, such as the chance that stream segments will become disconnected, dry, or otherwise unsuitable. For example, Hwan and Carlson (2016) reported that increasing intermittency was associated with declining survival in juvenile trout and salmon in a northern California stream. Thus it is not clear when use of nonperennial streams represents a net benefit to fish (e.g., Battin, 2004; Richardson, 2019a; 2019b). More research is needed to evaluate the costs and benefits of use of nonperennial streams by fish and other biota as well as the role of these streams in providing habitat and supplying cold water or trophic subsidies for different species in the context of the full range of stream types in a channel network (Richardson and Danehy, 2007; Ebersole et al., 2015).

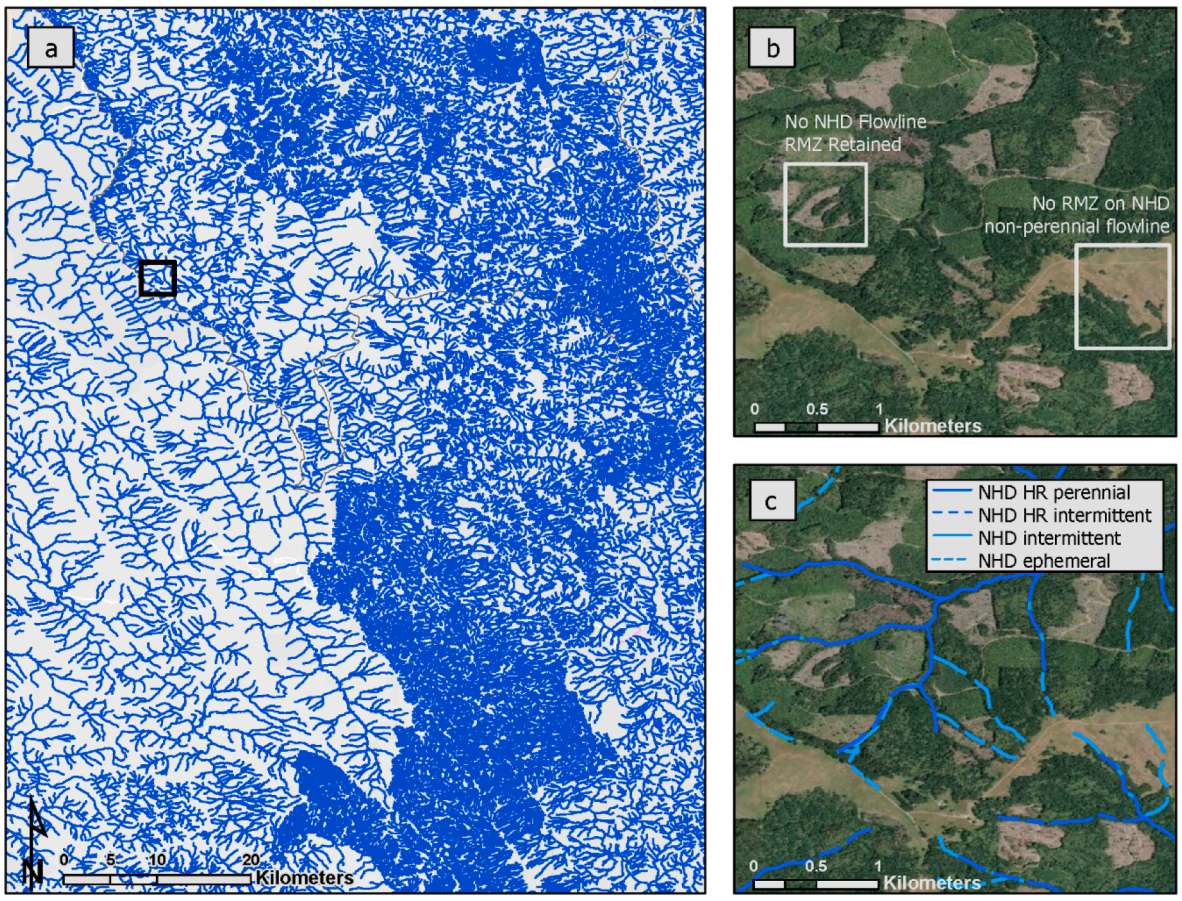

Fig. 6. Example challenges in using geospatial datalayers for management plans: (a) Inconsistencies in mapped stream density within the NHD dataset; (b and c) examples of RMZs compared to NHD HR flowlines. Some flowlines have no evident RMZ, which could be because no stream was evident in the field along these channel segments. Other locations have RMZs even though the NHD does not indicate a flowline.

4. Incorporating nonperennial streams into forest management plans

Our review and others highlight some examples of water, sediment, and organic matter connectivity between stream types and the importance of nonperennial streams for aquatic biota (Fritz et al., 2018; Leibowitz et al., 2018). Because of this connectivity, integration of nonperennial streams into forest management decisions would provide more protection for stream networks. The key aspect of management we have highlighted in this review is RMZs. Determining where to establish RMZs involves: (1) identifying nonperennial stream locations; and (2) determining stream flow duration.

A stream channel is an incised feature with a defined bed and banks (Dietrich and Dunne, 1993) generally with evidence of scour or sediment deposition from recent surface flow (Montgomery and Dietrich, 1988). If flowing water is not present, evidence of recent flow may include fluvially transported sediments, dried algae, or mesic vegetation that is distinct in species composition and(or) phenology compared to surrounding areas. In many nonperennial channels, these features are clearly visible; however, determining if a feature is a true channel is more ambiguous in other areas. For example, legacy gullies can persist for decades to centuries on the landscape without active flow; they have defined beds and banks but no recently transported sediments. Transient saturated areas may not have any clear incised channel feature (Rashin et al., 2006), even though they clearly have surface and groundwater connectivity to downstream channels. Thus the interpretation of channel presence/absence might require subjective decisions about the sensitivity of the feature to disturbance and its possible downstream impacts. For example, if a legacy gully is downstream of a heavily disturbed area that could produce infiltration excess overland flow, then an RMZ might help prevent reactivation of the gully.

Channel locations are frequently obtained from geospatial datasets. In the U.S., stream network maps are available from the National Hydrography Dataset in both Medium Resolution (NHD MR, 30 m) and High Resolution (NHD HR, 10 m) (https://www.usgs.gov/core-science-systems/ngp/national-hydrography). Because of the finer resolution of the NHD HR, this dataset generally includes more headwater streams, often considerably more. While NHD datasets are useful for illustrating regional differences in stream types (Fig. 1), they were not created in the same way across the country and can have boundary effects where stream densities vary between adjacent watersheds (Fig. 6). Field evaluations of these flow lines have found that they miss headwater streams in some regions, with prior studies reporting > 200% lower stream lengths in high resolution NHD compared to observations (Fritz et al., 2013; Villines et al., 2015; Fig. 6), while over-representing the stream network extent in others (Martin et al., 2021). There is an active stewardship program specifically aimed at updating stream information (https://www.usgs.gov/core-science-systems/ngp/national-hydrography/stewardship-and-community), and managers conducting field visits can therefore update NHD based on more detailed field reconnaissance of streams.

In addition to NHD flowlines, topographic and other geospatial data may be used to estimate stream channel locations. Techniques for mapping channels from topographic data include statistical and terrain morphology methods that search for incised features (Passalacqua et al., 2010; Sofia et al., 2011; Clubb et al., 2014; Hooshyar et al., 2016), flow routing algorithms (e.g., Moore and Grayson, 1991; Costa-Cabral and Burges, 1994; Tarboton, 1997), and topographic wetness indices (e.g.,

Beven and Kirkby, 1979; Barling et al., 1994; Hjerdt et al., 2004). These approaches have been combined with surface water features to estimate depth to groundwater, saturated areas, and potential expansion areas of surface channel networks (de Alwis et al., 2007; Ågren et al., 2015). However, topographic data alone are often insufficient for mapping stream channel networks accurately (e.g., Helmlinger et al., 1993; Orlandini et al., 2011; Hastings and Kampf, 2014) because they can miss the heterogeneity in flowpaths caused by variability in subsurface properties or by storage, infiltration, or barriers along surface flow paths (Bracken and Croke, 2007). Consequently, to design effective management plans, field site visits are usually necessary to identify surface water flow paths and their connectivity to downstream waters.

If project planning stratifies RMZs by stream channel type (perennial, intermittent, ephemeral), correctly identifying stream type poses an additional challenge. The NHD provides channel type classes, which were mainly derived from the cartographer stream type interpretation for USGS 1:24,000 topographic maps. These maps generally used solid lines for perennial streams and dashed lines for intermittent and ephemeral streams (Fishburn and Allord, 2017). Although these classes are often the best available information, classification accuracy is a notable concern because of the potential geographic inconsistencies in methods used to identify intermittent and ephemeral streams (Fig. 6). Stream type determinations are, in many cases, decades old and no longer accurate (Hafen et al., 2020).

Decisions about whether or not to apply RMZs to headwater nonperennial streams face several trade-offs. Where stream networks are dense, meaning a high length of stream per area (Fig. 1a), applying RMZs to all streams may be costly or infeasible; on the other hand, preferentially applying RMZs only to certain types of streams may require more extensive field work to determine stream type during project planning. The subjectivity in determining stream types may partly explain why implementation of RMZs is not always well aligned with management guidelines (Kuglerová et al., 2020; Fritz et al., 2020). Further, in cases of severe disturbance, erosion and mass movements can lead to creation of new channels that would not have been mapped as channels using pre-disturbance field assessments or topographic data. Thus, in addition to identifying pre-disturbance channels, managers could aim to identify locations that could develop flow and sediment connections to downstream waters. This may include topographic hollows likely to saturate during wet conditions or steep convergent slopes susceptible to rilling and gullying. Rather than prescribing fixed RMZ requirements by channel type, management plans could build on holistic watershed assessment and emphasize interventions most likely to minimize stream changes across the full channel network. Because of the heterogeneity and complexity of hydrological processes, it may not be realistic to identify fixed guidelines that apply to all landscapes. This implies the need for managers to be trained in the field, where they can observe flow locations and patterns and develop management guidelines that are most appropriate for each unique landscape.

5. Conclusions

Nonperennial headwater streams are ubiquitous on forested lands, comprising the majority of stream length. While these streams clearly influence physical and biotic processes throughout stream networks, they have proven challenging to address in a management context. Even basic information regarding the locations of nonperennial stream channels and their geomorphic and hydrologic persistence remains difficult to resolve. Accordingly, policies for managing nonperennial streams vary widely. To facilitate the path forward to addressing these issues, we conclude with a list of key questions that emerge from this review:

1. How can we identify locations within forested watersheds that are most likely to develop surface flow connectivity to stream channels after disturbance?

RMZs are most needed in locations that may produce overland flow and surface erosion after land disturbance. We need observations from streams in a variety of landscapes to determine what factors drive upland-stream connectivity and stream network expansion, both in undisturbed conditions and following different types of chronic and episodic disturbances.

2. What are the most effective methods for accurately identifying locations of stream channels and categorizing their flow durations on managed forests?

New developments in remote sensing, ground-based surveys, physically-based models and statistical models offer promising new opportunities to address this most basic question about nonperennial streams (review in Shanafield et al., 2021). Targeted efforts through community sourced field data on headwater streams (Kampf et al., 2018; Njue et al., 2019), including qualitative flow/no flow observations, can be a useful approach to meet data scarcity challenges in this portion of the stream network where streams are abundant, but data are limited. Widespread data collection is needed to improve maps of nonperennial streams across the broad range of physiographic conditions in forests.

3. To what extent do changes in flow, sediment, organic matter, and temperature regimes in nonperennial channels propagate downstream?

Nonperennial stream processes affect the larger perennial streams that are often the focus of management plans. Spatial and temporal dynamics of stream ecosystem components are inter-connected across stream networks. System-level research is needed to explore these dynamic processes in a variety of forest and stream types, both with and without management interventions.

4. To what extent do species of concern rely on nonperennial headwater streams?

Responses of aquatic and semi-aquatic species to nonperennial stream changes are difficult to anticipate, as their dependencies on these streams have not been well-studied. This equates to uncertainty regarding the vulnerability and adaptive capacity of these species to changing climate (e.g., Kovach et al. 2019) and a need for studies examining reliance of species on different stream types.

5. Where recommended, how are best management practices applied in managed forests near nonperennial streams, and how effective are these practices for protecting water quality and ecosystem services?

Relative to perennial streams, evaluations of BMP implementation for nonperennial streams are lacking. Additional monitoring studies are needed to examine RMZ effectiveness across the range of stream types and RMZ sizes. Such studies could inform decisions about which management practices to apply along nonperennial streams.

6. How will changing climate, particularly shifts in temperature and precipitation regimes, impact the spatial and temporal distribution of nonperennial streams, and how will semi-aquatic and aquatic species respond?

Nonperennial streams are sensitive to changes in temperature and precipitation, with shifts towards increased drying more likely in locations with reduced snowpack and/or reduced summer precipitation (e.g. Godsey et al. 2014; Kormos et al. 2016; Wuebbles et al. 2017). In contrast, locations with increasing precipitation / decreasing aridity may experience longer flow durations (Hammond et al., 2021). These climate-induced streamflow changes are not directly within land manager control, but understanding them is essential for developing

management strategies that maintain the resilience of streams to change. Improved understanding of all aspects of climate vulnerability in these systems could help managers craft effective climate adaptation strategies (Crausbay et al. 2020).

These broad questions have yet to be investigated systematically for nonperennial forested stream networks. Addressing them can help inform practical issues related to identifying stream types as well as shape future management guidelines. Although current management practices in the U.S. tend to include more protections for perennial than nonperennial streams, protecting nonperennial source waters may be most beneficial for the channel network as a whole because these streams are often the first point of connection between uplands and the aquatic system. Any stream in a channel network has the potential to impact ecosystem services in downstream reaches, so excluding nonperennial headwater streams from management plans can mean missing a substantial source of potential impairment to receiving waters. Streams are not static features but rather adjust to conditions within the watershed and the episodic disturbances that shape channel form. This means that streamside management in forests requires adaptive approaches that address both current and potential future changes along stream corridors.

An Ecological Perspective of Riparian and Stream Restoration in the Western United States

By J. Boone Kauffman, Robert L. Beschta, Nick Otting, and Danna Lytjen

ABSTRACT

There is an unprecedented need to preserve and restore aquatic and riparian biological diversity before extinction eliminates the opportunity. *Ecological restoration* is the reestablishment of processes, functions, and related biological, chemical, and physical linkages between the aquatic and associated riparian ecosystems; it is the repairing of damage caused by human activities. The first and most critical step in ecological restoration is *passive restoration*, the cessation of those anthropogenic activities that are causing degradation or preventing recovery. Given the capacity of riparian ecosystems to naturally recover, often this is all that is needed to achieve successful restoration. Prior to implementation of active restoration approaches (e.g., instream structures, channel and streambank reconfiguration, and planting programs), a period of time sufficient for natural recovery is recommended. Unfortunately, structural additions and active manipulations are frequently undertaken without halting degrading land use activities or allowing sufficient time for natural recovery to occur. These scenarios represent a misinterpretation of ecosystem needs, can exacerbate the degree of degradation, and can cause further difficulties in restoration. Restoration should be undertaken at the watershed or landscape scale. Riparian and stream ecosystems have largely been degraded by ecosystemwide, off-channel activities and, therefore, cannot be restored by focusing solely on manipulations within the channel. While ecological restoration comes at a high cost, it also is an investment in the natural capital of riparian and aquatic systems and the environmental wealth of the nation.

J. B. Kauffman

A fence-line contrast of a five-year-old exclosure (without livestock grazing) and an area grazed season-long on a tributary of the Deschutes River, Oregon. The cessation of those activities that are causing degradation or preventing recovery is the most important step in ecological restoration. Given the natural resilience capacity of riparian ecosystems, passive restoration such as halting excessive livestock grazing is all that is needed to restore degraded riparian ecosystems.

Traditionally, the use and management of rivers, riparian zones, and wetlands have focused on activities that led to increases in the social well-being or material wealth of a society. These included such endeavors as transportation, hydroelectric power generation, flood control, and the use of water for agricultural, industrial, and municipal uses (National Research Council 1992).

J. Boone Kauffman is an associate professor at Oregon State University's Department of Fisheries and Wildlife, 541/737-1625; Kauffmab@ccmail.orst.edu. Robert L. Beschta is a professor at the Department of Forest Engineering. Nick Otting and Danna Lytjen are graduate research assistants for the Department of Fisheries and Wildlife, Oregon State University, Corvallis, OR 97330.

As a result of these practices, as well as activities such as channelization, road construction, timber harvesting, livestock grazing, mining, and water diversion, numerous riparian zones in the western United States have been extensively altered since Euro-American settlement (National Research Council 1995, 1996). The resulting decreases in diversity, functions, and productivity of riparian and aquatic ecosystems limit their future integrity, value, and use. This is an important societal concern since riparian zones are among the nation's most highly valued, yet threatened natural ecosystems (Johnson and McCormick 1979; National Research Council 1995).

Riparian and aquatic ecosystems are currently being altered, impacted, or destroyed at a greater rate than any time in history (National Research Council 1992).

An estimated 70%–90% of all natural riparian areas in the United States have been extensively altered (Hirsch and Segelquist 1978); approximately 47.3 million ha (117 million acres) or 53% of all U.S. wetlands have been lost since the 1780s (Dahl 1990). Some widespread land uses that occur in both uplands and riparian systems exert their greatest impacts on streamside areas. For example, in the 11 western states, livestock grazing is permitted on 91% of all public lands. On the 64 million ha (158 million acres) of Bureau of Land Management-administered lands, 58% is classified in fair to poor condition (i.e., the lands have been moderately to severely desertified) as a result of long-term grazing (U.S. General Accounting Office 1988). Historical grazing impacts to riparian systems have been even more severe. On these public lands, 25,700 km (16,000 miles) of sportfishing streams have declined in quality as a result of land use practices (Armour et al. 1991).

Degradation of riparian zones and streams diminishes their capacity to provide critical ecosystem functions, including the cycling and chemical transformation of nutrients, purification of water, attenuation of floods, maintenance of stream flows and stream temperatures, recharging of groundwater, and establishment and maintenance of habitats for fish and wildlife. The most important factor contributing to the decline of aquatic biodiversity is the loss or degradation of habitats (i.e., habitat alteration, introduced species, and water pollution; Miller et al. 1989). Almost 40% of the perennial streams in the United States are affected by reduced flows, and 41% are influenced by siltation, bank erosion, and channelization (National Research Council 1992). More than half of the nation's rivers have fish communities harmed by turbidity, high temperatures, toxins, and low levels of dissolved oxygen (Council on Environmental Quality 1989). Almost 85% of historical Pacific Northwest anadromous salmon stocks are either extinct, endangered, threatened, or of special concern (National Research Council 1996). The current threat to aquatic biodiversity in North America is greater than the threat to terrestrial diversity (Naiman et al. 1995). While 11%–15% of the terrestrial vertebrates are considered rare or nearly extinct, 34% of the fishes, 65% of the crayfishes, and 75% of the bivalve mussels fall into these categories (Naiman et al 1995). To date, not a single aquatic species has been delisted through Endangered Species Act procedures because of implementation of a successful recovery plan; in fact, the majority of the listed species do not have a formal recovery plan (Williams et al. 1989). An unprecedented need exists for ecological restoration of riparian ecosystems and their closely associated aquatic ecosystems.

What Is Ecological Restoration?

Ecological restoration in riparian ecosystems is defined as the reestablishment of predisturbance riparian functions and related chemical, biological, and physical processes (National Research Council 1992). *Restoration* is the process of repairing damage caused by humans to the diversity and dynamics of indigenous ecosystems (Jackson et al. 1995). While ecological restoration attempts to return riparian zones as closely as possible to predisturbance functions and processes, scientists must recognize that ecosystems are in a constant state of flux due to ever-changing environmental conditions. These changes, sometimes coupled with irreversible human impacts (e.g., soil loss, biotic invasions, air pollution), may preclude our capability to precisely re-create ecosystem structure and functions that previously existed. Thus, the goal of restoration projects is to ensure that the dynamics of natural ecosystem processes are again operating efficiently so that both ecosystem structure and function can be recovered (National Research Council 1992).

Riparian areas are three-dimensional zones of biological, physical, and chemical interactions between terrestrial and aquatic ecosystems (Gregory et al. 1991). Because of landscape-level interactions between terrestrial and aquatic systems, ecological restoration of riparian zones requires a holistic approach whereby activities and conditions across an entire watershed should be considered. Problems affecting riparian and aquatic resources are unlikely to be solved by ignoring deleterious land management practices, either historical or current, that occur at landscape or watershed scales.

While scientists strongly recognize the need to restore or conserve native fish throughout the Pacific Northwest and other nearby regions, less appreciation exists for how local geomorphic settings and natural

hydrologic disturbance regimes interact with native riparian plant communities to create sustainable habitats (Figure 1). Restoration of degraded riparian zones and their subsequent conservation after recovery requires knowledge of how these ecosystems function as well as the attributes responsible for their composition, structure, and productivity. The character and value of riparian zones arise as a result of an infinite number of complex interactions among three fundamental ecosystem features: (1) soils/geomorphology; (2) hydrology; and (3) biota (Figure 1). The soils/geomorphology features include streambank and floodplain form and development, channel gradient, geologic substrates influencing soil and channel composition, and subsoil features of the floodplain (e.g., gravel lenses important for hyporheic or subsurface flows). Hydrological features include the frequency, magnitude, and temporal distribution of stream flow (including peak and low flows), sediment availability and transport, subsurface hydrology, and water quality. Biotic features include vegetation, vertebrates, invertebrates, and microorganisms. In addition to live plants, the vegetation component also includes dead materials (necromass) such as snags, fallen logs, and fine organic debris (litter). Anthropogenic activities that either alter these components or sever the linkages between them will disrupt ecosystem dynamics, including species composition, productivity, structure, and function.

Among the most important ecosystem linkages are those interactions among vegetation, hydrology, and substrates as they influence geomorphic features such as channel morphology and channel dynamics (Figure 1). For example, naturally occurring pool habitats typically form as a result of interactions of hydrologic disturbance regimes, substrates, and streamside vegetation. If hydrologic patterns, sediment availability, or streamside vegetation are altered by land use activities, then channel morphology will subsequently adjust to these new conditions. This is often expressed by a simplification in stream structure (e.g., loss of pools, decreased channel sinuosity, and loss of channel diversity).

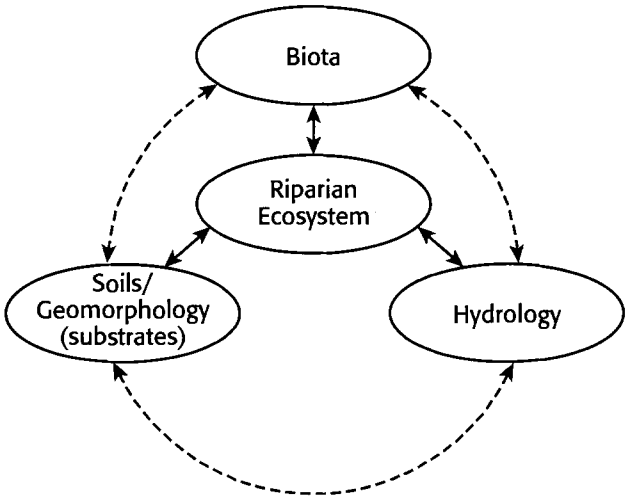

Figure 1 illustrates the linkages of the biotic, hydrologic, and geomorphic components combined to shape the unique structure and function of riparian and stream ecosystems. Each arrow represents an infinite number of biological and physical processes and interrelationships among these ecosystem features. Because of these inextricable linkages, human or natural actions that alter any one component or process will have feed-forward influences that can affect all other components of the ecosystem.

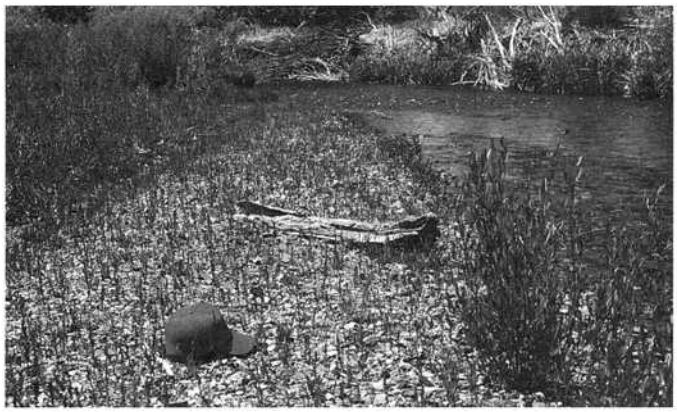

Another important interaction represented in Figure 1 is the influence of substrate characteristics and hydrology on plant community composition. For example, many riparian-obligate trees and shrubs have specific micro-site requirements for establishment. Successful natural establishment of cottonwood trees (*Populus* spp.) and willows (*Salix* spp.) commonly occurs on point bars of newly deposited, coarsely textured, well-aerated substrates within the 2- to 10-year floodplain (McBride and Strahan 1984; Bradley and Smith 1986); high flows are needed to create these conditions. Seed dispersal and germination are timed to coincide with late-spring flows when water tables are high, and fresh alluvium has been deposited (Noble 1979). Successful establishment also may be limited to areas where the rate and extent of water table decline does not exceed the biological capacity of root growth (Mahoney and Rood 1992). At the lower limits of the floodplain, establishment is often not possible because high water in subsequent years destroys the young plants (Bradley and Smith 1986).

Saturated, finely textured soils associated with low-gradient riparian zones are often sites of anaerobic conditions; such sites are typically unsuitable for the establishment of cottonwoods or willows. Under these hydrologic and geomorphic conditions, the natural plant communities are dominated by sedges (*Carex* spp.), rushes (*Juncus* spp.), or hydrophytic grasses. At the opposite extreme, where coarse materials (cobbles and boulders) occur in elevated and excessively drained situations, riparian-obligate vegetation will not establish. These conditions rarely occur naturally in western riparian ecosystems. However, they may be found after extreme human perturbations (e.g., dredge mining, channelization, or other in-channel modifications) deposit spoils on streambanks and floodplains.

Ecological restoration begins with identification of those land use practices that are damaging ecosystems or preventing recovery, followed by implementation of land management strategies that allow for natural recovery to occur (National Research Council 1992, 1996; Jackson et al. 1995). Thus, ecological restoration aims to ensure the occurrence of (1) those physical and biotic processes facilitating persistence of species through natural recruitment and survival; (2) functioning food webs and systemwide nutrient conservation via relationships among plants, animals, and detritivores; and (3) the integrity of watersheds through linkages with the hydrologic, geomorphic, and climatic disturbance regimes that shape plant and animal communities (Jackson et al. 1995).

What Isn't Ecological Restoration?

Ecological restoration results in the reestablishment of linkages between organisms and their environment. Because an entire suite of organisms, physical features, and processes comprise an ecosystem, a species-only or single-process approach to restoration will likely fail (Beschta et al.

Photos by J. B. Kauffman

The influence of restoring streamflow and halting grazing on Rush Creek, California, (1992–1996) is illustrated above. The small willow in the foreground in 1992 (left) is the same willow to the left of the third author in 1996. In 1992, a high density (50 m^{-2}) of willow seedlings, was established on the gravel bar the first year without livestock. By 1996, a dense willow community had formed, with many willows becoming more than 2 m in height.

1994; Jackson et al. 1995). For example, the reintroduction of an extirpated fish species or the installation of log weirs and large boulders into a degraded stream reach does not constitute restoration. While attempts to revive a single species are likely to target only a few of its more obvious habitat requirements, less-apparent needs and important processes and functions are often ignored. In the case of declining anadromous salmonids, a technological perspective has prevailed (Bottom 1997); first fish hatcheries, then fish ladders, and finally in-stream manipulations were looked on as solutions. However, increasingly apparent is that there is a remarkable complexity of environmental phenomena that affect salmon viability, and the cumulative losses of various biotic and physical components are what must be addressed (National Research Council 1996). By shifting the focus to the integrity of ecological processes and functions, we are more likely to successfully attain the restoration both of habitats and species of interest.

Ecological restoration also should be distinguished from architectural and mechanical approaches to ecosystem management. Such "restoration" methodologies often call for the systematic reconstruction of a stream according to specific human perspectives of what the stream "should look like." More often than not, this will not achieve the goal of ecological restoration or species recovery. Merely re-creating a form without the function or the function in an artificial configuration does not constitute restoration (National Research Council 1992). A long-term perspective regarding ecosystem sustainability is not inherent with these approaches. For example, the placement of artificial structures (boulders, rock gabions) does not replace many of the multiple functions of large, woody debris, nor does it ensure or promote the future recruitment of woody debris into the stream system. Such structures are commonly engineered and constructed with the false assumption that they and the stream channel are static. High flows can be destructive when rigid structures are placed in degraded alluvial channels (Beschta et al. 1991; Gregory and Bisson 1997). The underlying failure of this approach rests in a lack of recognition regarding the natural dynamics of high-flow disturbances, bedload transport, local scour and fill, lateral channel movements, and particularly the interactions of streamside vegetation with fluvial disturbance regimes.

Fish hatcheries, fish ladders, and barging salmon downstream in dammed rivers are artificial means of maintaining anadromous fish in systems (functions with no natural form). These approaches seldom address fundamental problems associated with restoring the habitats of natural fish runs. Such activities could be construed to be mitigation or aquaculture but not restoration since they do nothing to restore habitat or reverse barriers to migration.

Preservation

Preservation is the maintenance of intact ecosystems; it is distinct from ecological restoration, which only addresses degraded ecosystems. Ecosystems that exist in a desired natural state warrant preservation (National Research Council 1992, 1996). The protection and preservation of intact ecosystems are of great importance, both environmentally and economically. Restoring the natural structure and function of riparian and stream ecosystems requires an understanding of the complex processes and linkages between the biotic and physical components of intact systems. Intact ecosystems are necessary as reference reaches from which to compare the efficacy of restoration programs (Case 1995; Beschta 1997). Furthermore, they are sources of natural genetic material for the reestablishment or reintroduction of the native biota to nearby areas in need of restoration.

Preservation is a management strategy that entails more than simply preventing human-induced alterations. For example, management actions may be necessary to maintain natural functions and characteristics (e.g., prescribed fire, management of exotic species invasions, and large herbivore management). Measures to protect intact ecosystems (preservation) are important because they are often easier to implement, have greater rates of success, and are less expensive than restoration. Preserving intact ecosystems also may be less expensive than restoring them, just as preventative medicine is nearly always less expensive than corrective medicine (National Research Council 1992; Cairns 1993).

Various other land management approaches seek to alter and improve riparian conditions or specific habitat features, yet they may not represent ecological restoration. Activities often confused with ecological restoration include creation, rehabilitation, reclamation, mitigation, replacement, and enhancement. These activities typically emphasize altering ecosystem components for a particular human purpose (National Research Council 1992, 1996).

Creation

Creation is defined as establishing a new ecosystem that previously did not exist on a particular site. For example, developing a sustainable wetland in an area formerly occupied by upland plant communities would represent creation. Creation also includes attempts to create specific riparian features that previously did not exist on the treated site. Examples include the planting of willows or alders (*Alnus* spp.) on riparian wetland sites naturally occupied by sedges or rushes, placement of boulders in streams with floodplains comprised of fine sediment, and construction of secondary channels where none existed previously (Quammen 1986) .

Reclamation

Reclamation is traditionally defined as the process of adapting wild or natural resources to serve a utilitarian human purpose (National Research Council 1992). Historically, this often included the conversion of riparian or wetland ecosystems to agricultural, industrial, or urban uses. More recently, however, *reclamation* has been defined as the process resulting in a stable, self-sustaining ecosystem that may or may not include some exotic species. Reclaimed sites may have similar, although not identical, structure and function of the original land (Jackson et al. 1995).

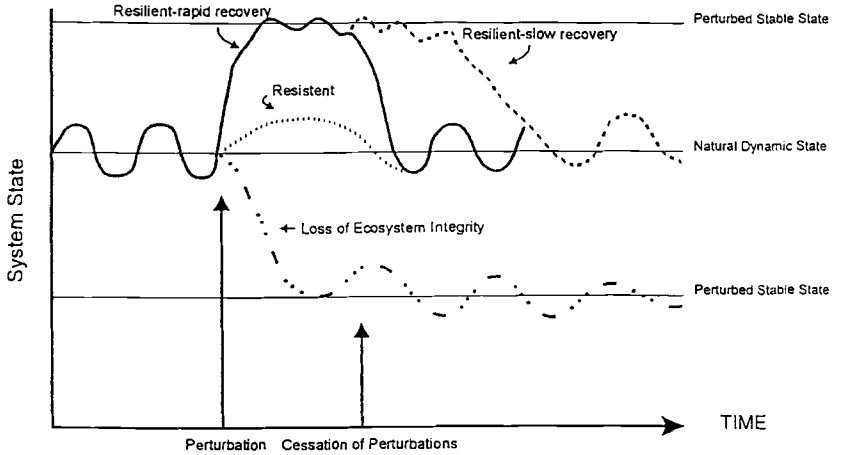

Figure 2 represents the conceptual responses of individual riparian plant communities to human perturbations and response pathways after cessation of perturbations. Resistant plant communities exhibit few deviations from natural equilibria when exposed to a perturbation. In contrast, nonresistant communities shift to a perturbed state unlike that of the natural dynamic state (i.e, changes in composition, structure, or productivity). After activities that caused ecosystem degradation (perturbations) stop, resilient communities will recover to natural system states. *Nonresilient communities* are those lacking potential for natural recovery and are characterized as having lost ecosystem integrity. In the absence of active restoration activities, they may remain indefinitely in an altered ecosystem state.

Rehabilitation

Rehabilitation implies making the land useful again after natural or anthropogenic disturbances. Restoration to predisturbance conditions and functions is not implied in the definition of *rehabilitation*. The creation of a crested wheatgrass (*Agropyron cristatum*) stand where sagebrush steppe (*Artemisia tridentata*) once existed or the planting of exotic grass species after a forest fire could be construed as rehabilitation but is not ecological restoration.

Replacement

Replacement is the substitution of a native species or ecosystem feature with an exotic species or foreign object; often, it is considered another form of rehabilitation. Examples of replacement would include the planting of nonnative trees or the placement of boulders, gabions, or weirs to substitute for natural features. The introduction of brook trout (*Salvelinus fontinalis*) or smallmouth bass (*Micropteris dolomieui*) in streams historically occupied by native salmonids is an example of ecological replacement.

Mitigation

Mitigation is an attempt to alleviate any or all of the detrimental effects or environmental damage that arise from anthropogenic actions. The construction of fish hatcheries or the modification of headwater fish habitats to compensate for losses caused by dams is a mitigation approach. Wetland creation is often suggested as mitigation for the destruction of natural wetlands from construction, fill, or other human activities. However, these constructed wetlands seldom display the structural or functional attributes of the native wetlands they replaced (Quammen 1986; M. Kentula, U.S. Environmental Protection Agency, personal communication).

Enhancement

Enhancement is any improvement of a structural or functional attribute for a species or habitat. However, when enhancement activities are focused only on a single species or specific component of an ecosystem, they may create conditions outside the context of a natural riparian and stream system. For example, in-stream structures (e.g., rock jetties, gabions, pool excavations) are often used with the objective of fish habitat enhancement. However, these structures can severely alter streambank structure, sediment transport dynamics, and hydrologic connectivity with riparian vegetation, resulting in disruptions or losses of riparian-stream linkages. When in-stream spoils, rocks, or boulders are piled on a streambank, conditions may no longer be suitable for natural establishment of riparian vegetation nor for adjustments in channel morphology to natural variations in sediment transport and stream flow. Such physical

alterations may further limit the future recruitment potential of large, woody debris as well as degrade riparian wildlife habitat. The ecological costs and benefits to physical processes, biological diversity, and ecosystem functions should be considered before such actions are initiated.

Resistance and Resilience

In undertaking restoration, it is important to understand the response of riparian ecosystems to anthropogenic perturbations (resistance) as well as the capacity to recover after cessation or removal of the problem-causing activities (resilience). *Resistance* is the capacity of an ecosystem to maintain natural function and structure after a natural disturbance or an introduction of an anthropogenic perturbation. For example, some riparian meadow plants will maintain productivity with moderate levels of livestock grazing because of their adaptive capacities or tolerance to herbivory. These would be considered *resistant communities*. In contrast, even low levels of herbivory can retard community development on gravel bars dominated by young willow or cottonwoods (Case and Kauffman, in press; Green and Kauffman 1995); these are *nonresistant communities*.

Resilience is the capacity of species or ecosystems to recover after a natural disturbance or following the cessation of an anthropogenic perturbation. Because riparian species evolved in areas with frequent fluvial disturbances, they represent classic examples of a resilient biota. Not only do many riparian plants depend on natural disturbances for establishment, but rates of recovery or establishment following disturbances can be remarkably high (Busse 1989; Gecy and Wilson 1990; Case 1995). Paradoxically, while riparian ecosystems are often resilient to natural disturbance regimes, many rapidly degrade with the curtailment of these disturbances. For example, water impoundment and diversion projects have resulted in dramatic losses in riparian floodplain forests throughout North America (Bradley and Smith 1986; Rood and Mahoney 1990; Howe and Knopf 1991).

The conceptual pathways of riparian community response to the initiation and cessation of anthropogenic perturbations are illustrated in Figure 2. A severe anthropogenic perturbation (e.g., overgrazing, clear-cutting, channelization, dams, diversions) may sufficiently alter a riparian ecosystem such that it will attain a dynamic equilibrium different than what would occur under natural conditions. A *resistant ecosystem* is one that displays few changes in composition or structure following the initiation of a perturbation. In contrast, nonresistant riparian zones or communities will change to a new system state or equilibrium typified by a different composition (e.g., dominance by exotics), different structure (e.g., losses of the woody component), altered productivity (e.g., shifts in above- and below-ground biomass), or a change in ecosystem functions (e.g., influences on water quality).

After cessation of perturbations, resilient riparian ecosystems usually show signs of recovery through measurable changes in composition, structure, or function (Figure 2). In these situations, cessation of those human perturbations that harm the riparian ecosystem may be all that is necessary to achieve restoration. Because some ecosystems recover more quickly than others, it is important to monitor changes before implementing other, often more costly, measures. Failure to wait minimally may result in wasting limited funds; at worst, it may exacerbate the extent of degradation.

When losses in ecosystem structure, composition, or function reach a sufficient magnitude, the simple cessation of perturbations may not be sufficient for ecosystem recovery (Figure 2). Factors that may diminish resilience and, hence, prevent recovery include species extinctions, introductions of exotics, excessive soil erosion, pollution, and severe changes in geomorphology or hydrology. In these situations, the ecosystem may remain degraded indefinitely even after the cessation of activities that caused degradation. In this scenario a concerted and active effort will be needed to accomplish restoration.

Rather than referring to a handbook, land managers should obtain the "blueprints" for the ultimate outcomes of planned restoration activities from intact streams.

Conceptual Approaches to Restoration

The basic goal of riparian restoration is to facilitate a self-sustaining occurrence of natural processes and linkages among the terrestrial, riparian, and aquatic ecosystems. An important initial component of any restoration plan should be an evaluation of the ecological status of existing riparian and aquatic systems. Ideally, this assessment should be conducted at the watershed scale, while still being sufficiently detailed to depict specific reaches or channel units where particular restoration activities might ultimately occur. The objectives of the initial resource analysis should be to identify (1) those reaches that are relatively intact (few anthropogenic impacts evident) and worthy of protection or preservation management strategies; (2) those reaches where restoration is feasible with changes in current land use activities or without large expenditures of money; (3) those areas that could be restored but only at high costs and with a high probability of failure, and (4) those reaches that are in a condition where restoration is not technically feasible due to extreme conditions of alteration, degradation, or sociopolitical limitations.

When planning for ecosystem restoration, it may be useful from a strategic perspective to partition riparian zones into those capable of rapid recovery, those with a slow rate of natural recovery, and those with little or no resilience capacity (i.e., loss of ecosystem integrity, Figure 2). The greatest efforts should be initially focused on the former because of a greater potential for successful restoration with lowered risk or expenditures. Only after areas

with a high-resilience capacity are improving or have been restored should restoration efforts focus on areas that have generally lost the capability of natural recovery, even after the cessation of human perturbations. However, special situations may exist in which degraded habitats of species near extinction can only be restored at high risk and cost; such areas assume a high priority for improvement.

Where possible, managers should emphasize preservation because preservation of intact ecosystems is typically less expensive than restoring degraded systems (Cairns 1993). Intact ecosystems are not only valuable sources of biological diversity, but they also provide important reference sites that land managers may seek to emulate in their restoration activities. Rather than referring to a handbook, land managers should obtain the "blueprints" for the ultimate outcomes of planned restoration activities in adjacent sites from intact streams. Because the failure rate of restoring degraded ecosystems is far greater than that of simply protecting fully functional sites, protecting and preserving intact ecosystems should represent the first priority of any watershed-scale restoration plan.

At the other extreme, many areas exist where ecological restoration in the strictest sense is neither economically, socially, nor technologically feasible (e.g., metropolitan reaches, dredged mine sites, etc.). If restoration practices are pursued in these situations, they may be costly. However, stream enhancement activities should not be ruled out in these scenarios, particularly if such activities would diminish harm to downstream or upstream riparian and aquatic ecosystems.

Reviews of instream habitat management projects throughout the western United States clearly indicate that passive restoration has been the critical first step in successful riparian restoration programs.

The domain of riparian and stream restoration lies between these two extremes (Figure 2). A successful riparian restoration program will result in the perpetuation of processes that determine ecosystem structure, function, and evolutionary trajectory. However, this operating principle is stated with the recognition that the intact wildlands of today and the future will exist in a fragmented landscape and will require specific preservation management activities such as prescribed fires, suppression of arson fires, control of biotic invasions, and maintenance of natural hydrologic disturbance regimes.

After identifying those degraded sites where restoration is deemed feasible, scientists must determine the causes of degradation and the activities preventing recovery (Beschta 1997). Also important is the identification of biotic components of the ecosystem that have been extirpated and the presence of biotic invaders that may prevent recovery. In addition to biotic considerations, scientists must determine the degree to which the hydrologic and geomorphic features of the ecosystem have been (or are being) altered. This includes determining the influences of past management activities on channel morphology, channel incision, hyporheic flows, water table dynamics, and water quality (i.e., the linkages between the terrestrial and aquatic system). From this initial analysis, not only can the extent and causes of ecosystem degradation be addressed, but potential restoration options may become evident. Obviously, even at this stage, restoration is a multidisciplinary effort.

The desired endpoints of restoration efforts are naturally dynamic and self-sustaining ecosystems (Figure 2). Given the fluctuating nature of environmental factors inherent to all natural systems, restoration managers should emphasize ecosystem processes and function rather than some preconceived landscape form. Fisheries professionals should recognize that because of the likely permanence of many exotic species, extinctions of native species, long-term changes in soil productivity due to erosion, and other severe environmental perturbations, complete recovery may not always be possible. In such cases, goals of restoration are to return a riparian system to a "potential natural community," whereby the ecosystem is naturally functioning in a manner as closely as possible to that in which it evolved.

Passive Restoration

Once professionals have decided where to implement restoration activities, the first and most critical step is to halt activities causing degradation or preventing recovery, an approach referred to as *passive* or *natural restoration* (Kauffman et al. 1993; Kauffman et al. 1995). Many riparian zones are capable of rapid recovery after human perturbations stop because the biota has evolved adaptations to survive and even reproduce despite frequent natural disturbance events characteristic of riverine systems (Barnes 1983; Wilson 1970; Gecy and Wilson 1990).

In western riparian zones the two most common examples of successful passive ecological restoration are the rewatering of streams after years of withdrawal for agricultural or municipal purposes and the cessation of livestock grazing in riparian areas. Stream flow diversion, combined with heavy livestock grazing, can result in severe degradation of riparian and stream ecosystems. With the return of perennial instream flows and the halt of livestock grazing, the recovery of riparian vegetation can be dramatic. For example, in the Mono basin of California, 24% of the area of riparian vegetation lost during a 50-yr period of water diversion (1940–1989) had reestablished after only 4 years following rewatering (Jones and Stokes Associates, Inc., and Trihey Associates, personal communication). Along these recovering streams, willow and cottonwood seedling densities were often >50 m^{-2} with annual growth rates of 0.6 to 1.5 m high (B. Kauffman and R. Beschta, Oregon State University, personal communication). Now, vegetation establishment is beginning to influence channel diversity through the creation of narrower channels, bank undercuts, and pools. In contrast, while several million dollars has been spent on engineering manipulations

in and around stream channels, the influence of those manipulations on trout densities was insignificant and actually hurt the natural restoration process of the riparian and stream ecosystem (Beschta et al. 1994; Inter-Fluve 1995; W. S. Platts, Don Chapman and Consultants, personal communications).

Livestock grazing has been perhaps the most prevalent cause of ecological degradation for many western riparian and stream ecosystems (Kauffman and Krueger 1984; Kauffman 1988; Fleischner 1994). After extensive field reviews of fish habitat improvement projects in eastern Oregon, Beschta et al. (1991) and Kauffman et al. (1993) concluded that the cessation of livestock grazing in riparian zones of eastern Oregon was the single most ecologically effective approach to restoring salmonid habitats.

While many reviews of grazing effects on riparian vegetation have been general in nature (e.g., Platts 1991; Elmore and Kauffman 1994), recent research is providing improved insights into the effects of grazing on woody riparian species. This research is important because willows, cottonwoods, and alders are significant features of terrestrial wildlife habitat, stream channel morphology, and aquatic habitat. In central Oregon, Busse (1989) found a lack of willow and cottonwood reproduction in grazed

misinterpreting ecosystem needs is common with many instream rehabilitation and enhancement programs

riparian zones of the Crooked River National Grassland. After constructing corridor fencing, she recorded a widespread and rapid rate of willow and cottonwood establishment. In northeast Oregon, similar rates of woody species recovery after cattle grazing stopped have been quantified (Green and Kauffman 1995; Case and Kauffman, in press). Three years after cattle grazing stopped on Meadow Creek (a tributary of the Grande Ronde River), Case and Kauffman (in press) reported that the average crown volume of willows increased nearly 300%. Average crown volume of black cottonwood and alder increased 800% and 200%, respectively. Comparing 10 years of no grazing with light to moderate late-season grazing use in northeast Oregon, Green and Kauffman (1995) reported significant increases in both the density and structural complexity of willows and cottonwoods in ungrazed exclosures. Although positive trends in willow density and height also occurred in the lightly to moderately grazed areas (three weeks annually late in the season), recovery rates were significantly less than those of the ungrazed areas.

Reviews of instream habitat management projects throughout the western United States clearly indicate that passive restoration has been the critical first step in successful riparian restoration programs (Beschta et al. 1991; Kauffman et al. 1993; Beschta et al. 1994). In many cases, this was all that was needed to initiate restoration of riparian ecosystems. Because of the high costs and potential for failure with active restoration and manipulation, we recommended that project managers monitor and observe the natural recovery process for an appropriate period of time (e.g., 10 years) after implementing passive restoration. Then, if managers ascertain that natural recovery is limited or not occurring, implementation of active restoration projects might begin.

Active Restoration

After implementing passive restoration, a site still may remain in an ecological state that is unlike what would occur naturally (Figures 2 and 3). These situations can occur when an ecosystem is sufficiently degraded such that the inherent capacity to recover has been lost. To achieve ecological restoration in such situations, active manipulations will be necessary.

Many factors may prevent a return to a natural dynamic system when using only passive restoration—species extinctions [particularly keystone species such as cottonwood or beaver (*Castor canadensis*)], exotic predators [smallmouth bass or bullfrogs (*Rana catesbeiana*)], exotic competitors [carp (*Cyprinus carpio*), reed canary grass (*Phalaris arundinacea*), or knapweeds (*Centaurea* spp.)], loss of hydrologic function and alteration of hydrologic disturbance regimes (e.g., diversions, regulated flows by dams, disruptions of groundwater flow patterns), and alteration of geomorphic features (e.g., channel incision, soil erosion, compaction). While some of these barriers to recovery might be easily ameliorated, others can be sufficiently severe in their magnitude and persistence that restoration may not be technologically feasible.

Biotic manipulations representing active ecological restoration include the reintroduction of beaver or plant species that have been extirpated from the area. Reintroductions are most successful when a feasibility analysis has confirmed that suitable habitat is present for the organism to be reintroduced. In the case of beaver, adequate habitat conditions include sufficient availability of forage and suitable structure of riparian plant communities. If introduced into degraded or recovering ecosystems before woody species have sufficiently reestablished, beaver can actually limit ecological recovery (Kauffman et al. 1982; Case 1995). Alternatively, when reintroduced in suitable riparian habitat conditions, the beaver can dramatically accelerate the restoration process through its influence on the hydrology, wetland extent, species composition, and quality of salmonid habitats (Naiman et al. 1988; Lowry 1993).

Vegetation plantings are a commonly proposed restoration technique. However, after passive restoration is implemented, the natural capacity for rapid reinvasion of woody species on suitable sites often makes artificial plantings unnecessary (Busse 1989; Schulz and Leineger 1990; Case and Kauffman, in press). Where shrubs and other woody species have been eliminated and the potential for natural reinvasion no longer exists, active revegetation will be required. For example, where high-flow regimes have been significantly altered (e.g., below a

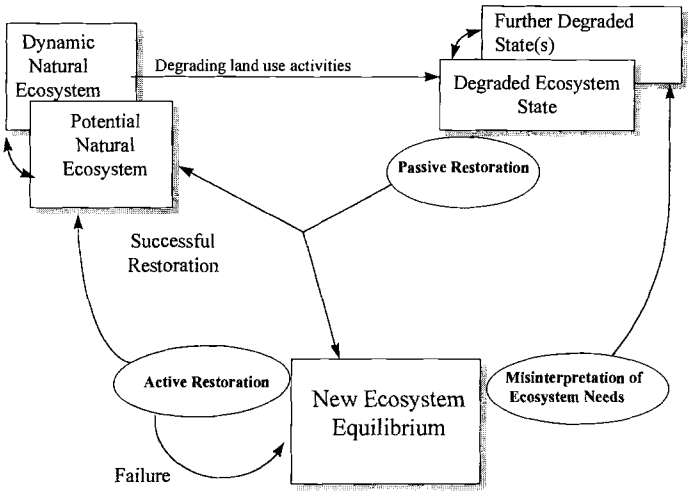

Figure 3 explores the conceptual pathways or ecosystem response to ecological restoration of western North American riparian and stream ecosystems.

major dam), the natural regeneration of riparian-obligate trees and other woody species may be severely limited (Bradley and Smith 1986; Rood and Mahoney 1990). Without a recovery of high-flow regimes, artificial revegetation will likely be necessary to perpetuate forests within the historic floodplains. Gallery forests can be naturally perpetuated only if flow management allows high-water events to create conditions for regeneration.

By definition, ecological restoration of riparian vegetation entails the planting of only native species. The use of exotic plant species to "improve" riparian habitats associated with native fisheries is tantamount to introducing brook trout (*Salvelinus fontinalis*) or some other exotic fish as a substitute for extirpated native bull trout (*Salvelinus confluentus*) populations. In addition, revegetation with native species should focus on those areas of the riparian zone that contain appropriate substrates and microclimates. The planting of willows or conifers in native sedge meadows will likely result in failure or the creation of an unnatural, unsustainable plant community.

In addition to revegetation, a suite of silvicultural options to accelerate riparian forest development can be implemented. Creation of small canopy gaps, small clearings, and placement of coarse wood debris on the floodplain to serve as nurse logs can enhance growth rates of existing trees or provide conditions for establishment of desirable trees. Overstory manipulations should be done in a patchy, irregular manner to mimic natural disturbances and forest structure. In some instances, the products of thinning can be used as a source of instream wood or nurse logs. Prescribed burning also can be an important activity when used to mimic the disturbance regime of natural fires.

Appropriate livestock grazing management is of major importance for the proper functioning of many western riparian zones, particularly where grazing is deemed a primary use (e.g., private ranch lands). While some have suggested that livestock can be used as a "tool" in riparian enhancement, there is no ecological basis to indicate that livestock grazing, under any management strategy, can accelerate riparian recovery more rapidly than total exclusion (Platts 1991; Elmore and Kauffman 1994). The passive restoration approach of livestock exclusion demonstrably has resulted in a rapid recovery of riparian vegetation (U.S. General Accounting Office 1988; Beschta et al. 1991; Kauffman et al. 1993); however, less is known regarding rates of channel morphology recovery (P. McDowell, University of Oregon, personal communications). Although moderate levels of winter grazing, late-season (autumn) grazing, or early-season (spring) grazing have been demonstrated to reduce harm by livestock in some riparian zones (Platts 1991; Elmore and Kauffman 1994), any grazing practice must include close monitoring of wood use and bank conditions so that livestock can be promptly removed before significant damage occurs. The variety of approaches to active restoration is potentially large and beyond the scope of this document, but what is important regarding active restoration procedures is that any approach reestablish the disturbance regimes and conditions so natural hydrologic, geomorphic, and biotic processes can occur. In some cases, active restoration may require removing or altering artificial structures contributing to degradation or preventing natural ecosystem processes from occurring. These practices might include obliterating roads that are contributing excessive amounts of sediment, removing instream or streambank structures (e.g., rip-rap, gabions, and anchored structures) that limit channel dynamics, reconfiguring channelized reaches to increase their sinuosity and floodplain connectivity, and removing mainstem dams to eliminate barriers to fish migration.

Instream Structures

A general deficiency of large, woody debris within streams draining forested watersheds is common throughout much of the Pacific Northwest, primarily because of historical practices of timber harvesting of riparian forests, splash damming, agricultural conversion, livestock grazing, and stream "cleaning" (i.e., the purposeful removal of wood debris). The natural recruitment of coarse, woody debris in such streams often requires much time (Gregory and Ashkenas 1990). As a result, managers often add large, woody debris. Where such practices are needed, the primary goal should be to provide natural amounts, types,

sizes, and spatial distributions of wood both in and along stream channels. During the inevitable high-water events that follow, added wood should function effectively in channel development and sediment and hydrologic routing (Gregory and Bisson 1997). Managers should place logs in or along channels so they resemble natural accumulations of debris, and should use complex wood debris (e.g., whole trees with branches and root wads if at all possible) to maximize habitat values and minimize potential for movement. The placement should enhance conditions that facilitate natural establishment of woody species (e.g., point-bar formation or nurse logs) so wood recruitment will become a self-perpetuating process. Anchoring or cabling complex pieces should be done sparingly, if at all, because it does not allow for the natural behavior of log accumulations during high-flow events. In this respect log length is critical; logs longer than the active channel width are not likely to move very far downstream (Lienkaemper and Swanson 1986).

Unfortunately, structural additions to channels (e.g., logs, boulders) are too often undertaken before anthropogenic impacts causing degradation have been eliminated or before significant natural recovery of riparian plant communities has occurred. In both situations, artificial structural additions are premature and can cause additional degradation to riparian and aquatic ecosystems. Of particular importance is the concern that placement activities should not diminish the natural regrowth capacity of riparian forests and should not severely curtail or accelerate natural channel dynamics such as channel migration, pool development, and streambank building. Riparian and stream ecosystems degraded from off-channel activities cannot be restored by focusing only on manipulations within a channel.

Throughout the western United States, inchannel placement of habitat structures has become one of the most common and widespread stream "enhancement" activities. Although instream structures have been commonly used in attempts to control channel erosion and rehabilitate fish habitat since the early twentieth century (Elmore and Kauffman 1994), systematic evaluation of their success has been limited. Furthermore, instream habitat handbooks (e.g., U.S. Forest Service 1952; Seehorn 1985, 1992) generally provide no ecological or geomorphic perspective as to where various habitat manipulations are appropriate (or inappropriate). A summary of instream enhancement projects throughout the region (Beschta et al. 1994) indicated little or no positive fisheries response to structural approaches. Clearly, the widespread practice of engineered structural modifications to streams with little or no scientific evidence of biological benefits represents a management paradox of immense proportions.

Misinterpretation of Ecosystem Needs

Active restoration should be undertaken to facilitate recovery of natural ecosystem processes (Kauffman et al. 1995). Riparian and instream activities that do not address ecosystem function and linkages are likely to fail or even exacerbate degradation of the ecosystem—a result of misinterpretation of ecosystem needs. Examples of such misinterpretation might include outplanting hatchery fish of nonindigenous genetic strains and introducing nonnative plant species. Implementation of riparian or inchannel activities that further degrade or prevent reestablishment of hydrologic, geomorphic, or biotic functions also represents a misinterpretation of ecosystem needs (Figure 3). Such activities may involve habitat manipulations such as blasting bedrock channels; adding logs and boulders in channels formed in floodplains of finely textured meadow systems; implementing in-channel engineering approaches that are heavily anchored by cable, metal rods, or boulders (structures that rely on geotextile fabrics to maintain their integrity); armoring streambanks with large boulders; and placing excavated sediments on streambanks and floodplains. Many of these approaches not only severely limit the capacity for streams to undergo natural adjustments in channel morphology and stream sinuosity through time, but they also may create conditions that suppress or stop the recovery of riparian vegetation.

Ecological restoration is a holistic approach not achieved through isolated manipulations of individual elements but through approaches ensuring that natural ecological processes occur...

Unfortunately, misinterpretating ecosystem needs is common with many instream rehabilitation and enhancement programs (Beschta et al. 1991; Kauffman et al. 1993). Stream manipulations targeted to fish habitat enhancement often exacerbate riparian and stream degradation for many reasons (Beschta et al. 1994):

- An inadequate understanding of riparian and stream ecology, particularly how stream-side vegetation and disturbance patterns shape both channels and habitat features;
- Sociopolitical pressures (e.g., it is socially or politically unacceptable to change ongoing land use practices that are causing degradation);
- Institutional limitations regarding the use of available funds (e.g., appropriations are designated only for mechanical or engineering approaches to stream manipulation with little or no appreciation of the effectiveness of improved stewardship);
- Management philosophies that emphasize immediately quantifiable project results (e.g., the number of instream structures built during a fiscal year) rather than ecological improvement or improved stewardship;
- Emphasis on a "landscaping" approach (e.g., designing channels or building structures based on preconceived plans rather than addressing factors limiting the processes that create these habitat features);
- A presumption that engineering approaches (e.g., placement of boulders, woody debris, gabions,

spawning gravels) are equivalent or superior to natural processes and structure;
- A presumption that inchannel structures can mitigate for riparian and aquatic degradation caused by land use practices (e.g., installing structures while allowing continued overgrazing, logging, or agricultural or industrial practices); and
- Current paradigms of land stewardship (e.g., a lack of a social or political land ethic that implicitly recognizes the value of natural or noncommodity products associated with naturally functioning and intact riparian ecosystems).

The rationale behind these reasons forms a common managerial paradigm: Stream, riparian, and fish habitat degradation brought about by anthropogenic activities, both locally and throughout a watershed, can be remedied solely through inchannel habitat manipulations. We suggest that the philosophy that natural habitat structure can be "improved" by engineering approaches misinterprets ecosystem needs and is an inadequate solution for fish habitat restoration. These approaches include activities that attempt to enhance fisheries habitat by eliminating natural barriers to fish passage, placing structures in intact ecosystems (old-growth forests), and putting spawning gravels or structural features such as logs or boulders in reaches where they would not naturally exist. Such activities not only carry a high risk of biological failure, but also risk a loss of capital resources, labor resources, and public credibility.

Sustainable and successful ecological restoration of degraded riparian systems is most likely to be achieved by considering the potential influences of proposed activities. Prior to the implementation of instream or riparian manipulations, the following questions should be addressed:
- Has passive restoration (e.g., changes in grazing, logging, etc.) been implemented, monitored, and evaluated prior to choosing structural manipulations?
- Will manipulations ultimately provide shade and thermally moderate stream temperature?
- Will they ultimately provide allocthonous inputs similar to that of stream-side vegetation?
- Will they ultimately provide the range of microhabitats typical of a particular stream?
- Will activities facilitate restoration of riparian vegetation that will restore natural channel morphology (e.g., overhanging banks, width-to-depth ratios, pool/riffle morphology)?
- Will they decrease time-rate dissipation of a stream's potential energy (i.e., stream power) by providing increased flow resistance from stream-side vegetation along a reach as compared with energy dissipation at localized points associated with inchannel structures?
- Will they allow for increased channel sinuosity from increased hydraulic roughness (as would occur with recovery of riparian vegetation)?
- Will biogeochemical and nutrient cycling influences on water chemistry—the results of the unique functional linkages between hydrologic and biotic features of intact riparian zones—be preserved or restored?
- Will the activities improve woody-debris recruitment and, hence, channel diversity because of enhanced vegetation establishment and growth?
- Are the restoration activities composed of naturally occurring materials? Are their characteristics and functions within the natural context of the riparian and stream reach to be treated?

Conclusions

Riparian zones are rich ecosystems in terms of biological diversity, unique biogeochemical processes, and productivity. For humans, riparian and stream ecosystems are a foci of commodity, recreational, and aesthetic values. The preservation and maintenance of intact riparian ecosystems and the restoration of degraded ones are important to local, regional, and global societies as well as to future generations.

While we recognize that ecological restoration sometimes comes at a high cost, we also note that ecological restoration is an investment in the natural capital of stream and aquatic systems and, hence, the environmental wealth of the nation. Healthy riparian ecosystems are a subsidy of nature. Conversely, degradation is the squandering of this natural wealth through the depletion of the productive capacity of ecosystems. Clearly, restoring once-productive riparian and aquatic ecosystems in the western United States is in the best long-term environmental and economic interests of the nation. Restored riparian and aquatic systems essentially will be self-maintaining and, therefore, useful in perpetuity (Cairns 1993). Because these ecosystems are a fundamental component of our life-support system, restoration should represent an important priority for both public and private landowners.

Complex ecosystems and associated habitat features cannot be created via simple and artificial construction of selected components. Ecological restoration is a holistic approach not achieved through isolated manipulations of individual elements but through approaches ensuring that natural ecological processes occur (National Research Council 1992). If society is to use, enjoy, and benefit from the wide range of values and products associated with western riparian and stream ecosystems, concerted efforts of ecological restoration should begin before their productive potential, diversity, and beauty are forever lost.

Acknowledgments

We wish to thank all of the biologists, hydrologists, landowners, and others dedicated to the restoration of the riparian and stream ecosystems of the world. Much of the research that generated the hypotheses and ideas presented in this paper was funded by the U.S.D.A. Pacific Northwest Research Station-Land and Water Interactions Team. We especially thank Peter Bisson, Nick Gerhardt, and Gordon Reeves for their helpful reviews of this paper.

REVIEW PAPER

Climate change impacts and adaptation in forest management: a review

Rodney J. Keenan

Received: 1 September 2014 / Accepted: 10 December 2014 / Published online: 14 January 2015
© INRA and Springer-Verlag France 2015. This article is published with open access at Springerlink.com

Abstract

• ***Key message*** **Adaptation of forest management to climate change requires an understanding of the effects of climate on forests, industries and communities; prediction of how these effects might change over time; and incorporation of this knowledge into management decisions. This requires multiple forms of knowledge and new approaches to forest management decisions. Partnerships that integrate researchers from multiple disciplines with forest managers and local actors can build a shared understanding of future challenges and facilitate improved decision making in the face of climate change.**

• ***Context*** Climate change presents significant potential risks to forests and challenges for forest managers. Adaptation to climate change involves monitoring and anticipating change and undertaking actions to avoid the negative consequences and to take advantage of potential benefits of those changes.

• ***Aims*** This paper aimed to review recent research on climate change impacts and management options for adaptation to climate change and to identify key themes for researchers and for forest managers.

• ***Methods*** The study is based on a review of literature on climate change impacts on forests and adaptation options for forest management identified in the Web of Science database, focusing on papers and reports published between 1945 and 2013.

• ***Results*** One thousand one hundred seventy-two papers were identified in the search, with the vast majority of papers published from 1986 to 2013. Seventy-six percent of papers involved assessment of climate change impacts or the sensitivity or vulnerability of forests to climate change and 11 % (130) considered adaptation. Important themes from the analysis included (i) predicting species and ecosystem responses to future climate, (ii) adaptation actions in forest management, (iii) new approaches and tools for decision making under uncertainty and stronger partnerships between researchers and practitioners and (iv) policy arrangements for adaptation in forest management.

• ***Conclusions*** Research to support adaptation to climate change is still heavily focused on assessing impacts and vulnerability. However, more refined impact assessments are not necessarily leading to better management decisions. Multi-disciplinary research approaches are emerging that integrate traditional forest ecosystem sciences with social, economic and behavioural sciences to improve decision making. Implementing adaptation options is best achieved by building a shared understanding of future challenges among different institutions, agencies, forest owners and stakeholders. Research-policy-practice partnerships that recognise local management needs and indigenous knowledge and integrate these with climate and ecosystem science can facilitate improved decision making.

1 Introduction

Anthropogenic climate change presents potential risks to forests and future challenges for forest managers. Responding to

climate change, through both mitigation and adaptation, may represent a paradigm shift for forest managers and researchers (Schoene and Bernier 2012). Climate change is resulting in increasing air temperature and changing precipitation regimes, including changes to snowfall and to the timing, amount and inter-annual variability of rainfall (IPCC 2013). Forests are widespread, long-lived ecosystems that are both intensively and extensively managed. They are potentially sensitive to these longer term climatic changes, as are the societies and economies that depend on them (Bernier and Schöne 2009). Climate change increases the potential consequences of many existing challenges associated with environmental, social or economic change.

Whilst forest ecosystems are resilient and many species and ecosystems have adapted historically to changing conditions, future changes are potentially of such magnitudes or will occur at rates that are beyond the natural adaptive capacity of forest species or ecosystems, leading to local extinctions and the loss of important functions and services, including reduced forest carbon stocks and sequestration capacity (Seppälä et al. 2009).

Recent global warming has already caused many changes in forests (Lucier et al. 2009). Aspects of climate change may be positive for some tree species in some locations. Tree growth is observed to be increasing in some locations under longer growing seasons, warmer temperatures and increased levels of CO_2. However, many projected future changes in climate and their indirect effects are likely to have negative consequences for forests. Observed shifts in vegetation distribution (Kelly and Goulden 2008; Lenoir et al. 2010) or increased tree mortality due to drought and heat in forests worldwide (Allen et al. 2010) may not be due to human-induced climate change but demonstrate the potential impacts of rapid climate change. These impacts may be aggravated by other human-induced environmental changes such as increases in low elevation ozone concentrations, nitrogenous pollutant deposition, the introduction of exotic insect pests and pathogens, habitat fragmentation and increased disturbances such as fire (Bernier and Schöne 2009). Other effects of climate change may also be important for forests. Sea level rise is already impacting on tidal freshwater forests (Doyle et al. 2010) and tidal saltwater forests (mangroves) are expanding landward in sub-tropical coastal reaches taking over freshwater marsh and forest zones (Di Nitto et al. 2014).

With projected future change, species ranges will expand or contract, the geographic location of ecological zones will shift, forest ecosystem productivity will change and ecosystems could reorganise following disturbances into ecological systems with no current analogue (Campbell et al. 2009; Fischlin et al. 2009). Forests types differ in their sensitivity to climatic change. Bernier and Schöne (2009) considered boreal, mountain, Mediterranean, mangrove and tropical moist forests most vulnerable to climate change. However, there has been recent debate about the vulnerability of tropical moist forests (Corlett 2011; Huntingford et al. 2013; Feeley et al. 2012), and temperate forests in areas subject to drier climates may be more at risk (Choat et al. 2012).

Adapting to these changing and uncertain future conditions can be considered from a number of perspectives (McEvoy et al. 2013). Policy and management might be directed at avoiding or reducing the impact of climate-related events, reducing vulnerability to future climatic conditions, managing a broader suite of climate 'risks' or increasing resilience and capacity in forest ecological and production systems to recover from climate 'shocks'.

Adapting forest management to climate change involves monitoring and anticipating change and undertaking actions to avoid the negative consequences or take advantage of potential benefits of those changes (Levina and Tirpak 2006). Adopting the principles and practices of sustainable forest management (SFM) can provide a sound basis for addressing the challenges of climate change. However, Innes et al. (2009) pointed out that our failure to implement the multi-faceted components of sustainable forest management in many forests around the world is likely to limit capacity to adapt to climate change. Forest managers will need to plan at multiple spatial and temporal scales and adopt more adaptive and collaborative management approaches to meet future challenges.

Whilst forest managers are accustomed to thinking in long time scales—considering the long-term implications of their decisions and factoring in uncertainty and unknowns into management—many are now responding to much shorter term social or economic imperatives. Local forestry practices are often based on an implicit assumption that local climate conditions will remain constant (Guariguata et al. 2008). Other social and economic changes will also continue to drive changes in forest management (Ince et al. 2011). For example, a growing global population, rapid economic development and increased wealth are driving demand for food and fibre crops and forest conversion to agriculture in many developing countries (Gibbs et al. 2010). Climate change mitigation objectives are increasing demands for wood-based bioenergy and the use of wood in construction and industrial systems. Increasing urbanisation is changing the nature of social demands on forests, and decreasing rural populations is limiting the availability of labour and capacity for intensive forest management interventions.

Ecosystem-based adaptation is being promoted as having the potential to incorporate sustainable management, conservation and restoration of ecosystems into adaptation to climate change (IUCN 2008). This can be achieved more effectively by integrating ecosystem management and adaptation into national development policies through education and outreach to raise societal awareness about the value of ecosystem services (Vignola et al. 2009).

Kimmins (2002) invoked the term 'future shock', first coined by Toffler (1970) to describe the situation where

societal expectations from forests were changing faster than the institutional capacity for change in forest management organisations. The pace of climate change is likely to intensify this phenomenon. Empirically based management based on traditional 'evidence-based' approaches therefore will potentially not develop quickly enough for development of effective future management options. How can managers consider rapid change and incorporate the prospect of very different, but uncertain, future climatic conditions into their management decisions? What types of tools are needed to improve decision making capacity?

This study aimed to review the literature on studies to support forest management in a changing climate. It builds on the major review of Seppala (2009), in particular Chapter 6 of that report by Innes et al. (2009).

2 Methods

The study involved a systematic assessment of the literature based on the database Web of Science (Thomson-Reuters 2014), an online scientific citation indexing service that provides the capacity to search multiple databases, allowing in-depth exploration of the literature within an academic or scientific discipline.

The following search terms were used in the titles of publications:

(forest or tree* or (terrestrial and ecosystem)) and climat* and (adapt* or impact* or effect* or respons*) and*

(forest or tree*) and climat* and vulnerabilit* or sensitivit*)*

The search was restricted to publications between 1945 and 2013. References related solely to climate change mitigation were excluded, as were references where the word 'climate' simply referred to a study in a particular climatic zone. This left a database of 1172 publications for analyses (a spreadsheet of the papers revealed in the search can be obtained from the author). References were classified into various types of studies and different regions, again based on the titles. Not all papers identified in the search are referenced. The selection of themes for discussion and papers for citation was a subjective one, based on scanning abstracts and results from relevant individual papers. The focus was important themes from key papers and literature from the last 5 years. The review includes additional papers not revealed in the search relating to these themes including selected papers from the literature in the year 2014.

3 Results

Of the published papers relating to climate impacts or adaptation selected for analysis, the vast majority of papers were published from 1986 onwards. The earliest paper dated from 1949 (Gentilli 1949) analysing the effects of trees on climate, water and soil. Most studies prior to 1986 (and even some published later) focused on the effects of trees on local or wider regional climate (Lal and Cummings 1979; Otterman et al. 1984; Bonan et al. 1992), the implications of climate variability (Hansenbristow et al. 1988; Ettl and Peterson 1995; Chen et al. 1999), studies of tree and forest responses across climatic gradients (Grubb and Whitmore 1966; Bongers et al. 1999; Davidar et al. 2007) or responses to historical climate (Macdonald et al. 1993; Huntley 1990; Graumlich 1993).

One thousand twenty-six papers specifically addressed future climate change (rather than historical climate or gradient analysis). Of these, 88 % studied impacts, effects, vulnerability or responses to climate change in tree species, forests, forest ecosystems or the forest sector (Fig. 1). The first study analysing the potential impacts of future climate change on terrestrial ecosystems was published in 1985 (Emanuel et al. 1985) with other highly cited papers soon after (Pastor and Post 1988; Cannell et al. 1989).

Twelve percent of papers (129) considered adaptation options, including 10 papers on adaptation in the forest sector. The first papers to focus on adaptation in the context of climate change were in 1996 with a number of papers published in that year (Kienast et al. 1996; Kobak et al. 1996; Dixon et al. 1996). Publications were then relatively few each year until the late 2000s with numbers increasing to 11 in 2009, 22 in 2010 and 27 in 2011. Publications on adaptation dropped to 14 papers in 2013. The ratio of adaptation-related papers has increased more recently, with 19 % of total publications on adaptation in the last 5 years. Most papers considering adaptation since the early 2000s have related to the integration of adaptation and forest management (e.g. Lindner 2000; Spittlehouse 2005; Kellomaki et al. 2008; Guariguata 2009; Bolte et al. 2009; Keskitalo 2011; Keenan 2012; Temperli et al. 2012).

Analyses of the implications of climate change for the forest sector have focused heavily on North America: Canada (Ohlson et al. 2005; Van Damme 2008; Rayner et al. 2013; Johnston et al. 2012) and the USA (Joyce et al. 1995; Blate et al. 2009; Kerhoulas et al. 2013); and Europe (Karjalainen et al. 2003; von Detten and Faber 2013). There has been a stronger consideration in recent years of social, institutional and policy issues (Ogden and Innes 2007b; Kalame et al. 2011; Nkem et al. 2010; Spies et al. 2010; Somorin et al. 2012) and the assessment of adaptive capacity in forest management organisations and in society more generally (Keskitalo 2008; Lindner et al. 2010; Bele et al. 2013a).

Regionally, there have been relatively few published journal articles on impacts or adaptation in forests in the Southern Hemisphere (Hughes et al. 1996; Williams 2000; Pinkard et al. 2010; Gonzalez et al. 2011; Mok et al. 2012; Breed et al. 2013), although there have been more studies in the grey literature for Australian forests (Battaglia et al. 2009; Cockfield et al. 2011; Medlyn et al. 2011; Stephens et al.

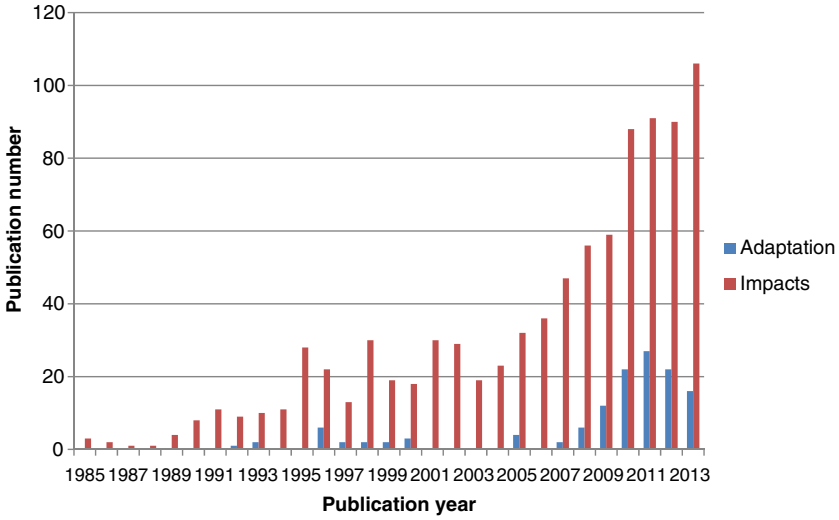

Fig. 1 Publication numbers by publication year for publications relating to climate change and forests from a search of the Web of Science database to the end of 2013 (1025 in total, 896 publications studied climate change impacts, responses or vulnerability, 129 studied adaptation)

2012). There have been some valuable analyses for the tropics (Guariguata et al. 2008, 2012; Somorin et al. 2012; Feeley et al. 2012).

Analysis of the publications identified the following key themes: (i) predicting species and ecosystem responses to future climate, (ii) adaptation actions in forest management, (iii) new approaches and tools for decision making under uncertainty and stronger partnerships between researchers and practitioners and (iv) policy arrangements for adaptation in forest management. These are discussed in more detail below.

3.1 Predicting species and ecosystem responses to future climate

Forest managers have long used climatic information in a range of ways in planning and decision making. Climate information has been used extensively to define and map vegetation types and ecological zones and for modelling habitat distributions of vertebrates and invertebrates (Daubenmire 1978; Pojar et al. 1987; Thackway and Cresswell 1992), for species and provenance selection (Booth et al. 1988; Booth 1990) and seed zone identification (Johnson et al. 2004), for forest fire weather risk assessment and fire behaviour modelling (Carvalho et al. 2008), for modelling forest productivity (Battaglia et al. 2004) and analysing the dynamics of a range of ecological processes (Anderson 1991; Breymeyer and Melillo 1991). Predicting species responses to future climate change presents a different set of challenges, involving consideration of predictions of future climate that are often outside the historical range of variability of many species. These challenges are discussed in the next section.

3.1.1 Species responses to climate

Aitken et al. (2008) argued that there were three possible fates for forest tree populations in rapidly changing climatic conditions: persistence through spatial migration to track their ecological niches, persistence through adaptation to new conditions in current locations or the extirpation of the species. Predicting the potential fate of populations in these conditions requires the integration of knowledge across biological scales from individual genes to ecosystems, across spatial scales (for example, seed and pollen dispersal distances or breadth of species ranges) and across temporal scales from the phenology of annual developmental cycle traits to glacial and interglacial cycles.

Whilst there has been widespread use of climatic information to predict future distributions in species distribution models (SDMs, Pearson and Dawson 2003; Attorre et al. 2008; Wang et al. 2012; Ruiz-Labourdette et al. 2013), understanding of the range of climatic and non-climatic factors that will determine the future range of a particular species remains limited. Many now feel that SDMs are of limited value in adaptation decision making or species conservation strategies. Some of these limitations are summarised in Table 1.

For example, models indicate significant shifts in patterns of tree species distribution over the next century but usually without any intrinsic consideration of the biological capacity of populations to move, internal population dynamics, the extent and role of local adaptation or the effects of climate and land use (Aitken et al. 2008; Thuiller et al. 2008). In a recent study, Dobrowski et al. (2013) found that the predicted speed of movement of species to match the predicted rate of climate change appears to be well beyond the historical rates of migration. Whilst modelled outputs suggest that migration rates of 1000 m per year or higher will be necessary to track changing habitat conditions (Malcolm et al. 2002), actual migration rates in response to past change are generally considered to have been less than 100 m per year. This was reinforced by model predictions that incorporate species dispersal characteristics for five tree species in the eastern USA indicated very low probabilities of dispersal beyond 10–20 km from current species boundaries by 2100 (Iverson et al. 2004).

Table 1 Limitations to species distribution models (SDMs) for predicting the impacts of climate change on forest tree species

Challenge	Examples	References
Predicting capacity of species to move	Species have historically moved much more slowly than future climate is projected to change. Humans may have a role in shifting species distributions. Fragmentation or lack of suitable habitat can limit movement	Iverson et al. (2004), Dobrowski et al. (2013), Clark (2007), Corlett and Westcott (2013)
Local adaptation	Many species have the capacity to adapt to changes in local conditions through refugia	Aitken et al. (2008)
Uncertainty in predicting future climate, particularly precipitation or aridity	Water balance and aridity can be major factor in determining future tree growth	Dobrowski et al. (2013), Wang et al. (2012)
Predicting and incorporating effects of extreme events on tree species populations	Extreme events (frost, fire, flood, high temperatures) can be a major determinant of species survival	Zimmermann et al. (2009)
Lag effects and gene flow within species	Species are generally still responding to past changes in climate and not optimally suited to current conditions	Thuiller et al. (2008), Kuparinen et al. (2010), Kremer et al. (2012)
Epigenetic effects	The growing conditions of the parents can affect the capacity of progeny to cope with drier or warmer conditions	Brautigam et al. (2013)
Biotic effects	Insect pests and diseases can be strong determinants of species distribution	Anderson et al. (2012), (Brooker et al. 2007)
Phenology and life history traits	Age to sexual maturity, fecundity, seed dispersal, or chilling or dormancy requirements	Nitschke and Innes (2008b)
Mutual benefits with plants or animals	Some species have strong interactions with other plants, animals or micro-organisms that may respond differentially to climate	Six (2009), Gilman et al. (2012)
Competition effects	SDMs generally assume open-grown conditions. Competition with other tree species can determine species distribution	Castagneri and Motta (2010)

Corlett and Westcott (2013) also argued that plant movements are not realistically represented in models used to predict future vegetation or carbon-cycle feedbacks and that fragmentation of natural systems is likely to slow migration rates.

However, these estimates do not account for the role of humans in influencing tree species distributions, which they have done for thousands of years (Clark 2007), and managed translocation may be an option for conserving many tree species, but there are significant unresolved technical and social questions about implementing translocation at a larger scale (Corlett and Westcott 2013).

Most early SDMs relied primarily on temperature envelopes to model future distribution, but factors such as precipitation and soil moisture are potentially more limiting and more important in determining distribution patterns (Dobrowski et al. 2013). Aitken et al. (2008) found that the degree to which variation in precipitation explains phenotypic variation among populations is greater in general for populations from continental than from maritime climates and greater for lower latitude than higher latitude populations. However, precipitation alone is often not a good predictor of variation and there is often a strong interaction with temperature (Andalo et al. 2005). Heat to moisture index or aridity is probably more important in determining future distribution or productivity than precipitation alone (Aitken et al. 2008; Harper et al. 2009; Wang et al. 2012). Soil properties (depth, texture and organic matter content) have a major influence on plant-available water, but few SDMs incorporate these.

Future precipitation is proving more difficult to model than temperature, due to the complex effects of topography, and there are more widely varying estimates between global circulation models (GCMs) of future change in precipitation (IPCC 2013). As such, there is more uncertainty around the extent to which moisture stress will change with warming and the extent to which natural selection pressures will change as a result. Even without changes in precipitation, increased temperatures will increase the length of growing season and potential evapotranspiration (PET) resulting in more water use over the year and greater risk plant water shortage and drought death.

Changes in the intervals of extreme events (extreme heat, cold, precipitation, humidity, wind) may also matter more than changes in the mean. Current forecasting approaches that produce future climate averages may make it difficult to detect non-linear ecosystem dynamics, or threshold effects, that could trigger abrupt ecosystem change (Campbell et al. 2009). Zimmermann et al. (2009) found that predictions of spatial patterns of tree species in Switzerland were improved by incorporating measures of extremes in addition to means in SDMs.

The risks of future climate will also depend on the management goal. If the aim is simply to conserve genetic diversity, risks of extinction or reduction in genetic diversity may be overstated by SDMs because much of the genetic variation within tree species is found within rather than among their populations, and the extinction of a relatively large proportion

of a population is generally likely to result in relatively little overall loss of genetic diversity (Hamrick 2004). Local habitat heterogeneity (elevation, slope aspect, moisture, etc.) can preserve adaptive genetic variation that, when recombined and exposed to selection in newly colonised habitats, can provide for local adaptation. The longevity of individual trees can also retard population extinction and allow individuals and populations to survive until habitat recovery or because animal and wind pollination can provide levels of pollen flow that are sufficient to counteract the effects of genetic drift in fragmented populations. Consequently, widespread species with large populations, high fecundity and higher levels of phenotypic plasticity are likely to persist and adapt and have an overall greater tolerance to changing climates than predicted by SDMs (Alberto et al. 2013).

Tree species distributions have always been dynamic, responding to changing environmental conditions, and populations are likely to be sub-optimal for their current environments (Namkoong 2001; Wu and Ying 2004). These lag effects are important in predicting species responses to climate change. In a modelling study of Scots pine and silver birch, Kuparinen et al. (2010) predicted that after 100 years of climate change, the genotypic growth period length of both species will lag more than 50 % behind the climatically determined optimum. This lag is reduced by increased mortality of established trees, whereas earlier maturation and higher dispersal ability had comparatively minor effects. Thuiller et al. (2008) suggest that mechanisms for incorporating these 'trailing edge' effects into SDMs are a major area of research potential.

Trees are also capable of long-distance gene flow, which can have both adaptive evolution benefits and disadvantages. Kremer et al. (2012) found that there may be greater positive effects of gene flow for adaptation but that the balance of positive to negative consequences of gene flow differs for leading edge, core and rear sections of forest distributions.

Epigenetics—heritable changes that are not caused by changes in genetic sequences but by differences in the way DNA methylation controls the degree of gene expression—is another complicating factor in determining evolutionary response to climate change (Brautigam et al. 2013). For example, a recent study in Norway spruce (*Picea abies*) showed that the temperature during embryo development can dramatically affect cold hardiness and bud phenology in the offspring. In some cases, the offspring's phenotype varied by the equivalent of 6° of latitude from what was expected given the geographic origin of the parents. It remains uncertain whether these traits are persistent, both within an individual's lifetime and in its offspring and subsequent generations (Aitken et al. 2008). It is suggested that analysis of the epigenetic processes in an ecological context, or 'ecological epigenetics', is set to transform our understanding of the way in which organisms function in the landscape. Increased understanding of these processes can inform efforts to manage and breed tree species to help them cope with environmental stresses (Brautigam et al. 2013). Others argue that whilst investigating this evolutionary capacity to adapt is important, understanding responses of species to their changing biotic community is imperative (Anderson et al. 2012) and 'landscape genomics' may offer a better approach for informing management of tree populations under climate change (Sork et al. 2013).

These recent results indicate the importance of accounting for evolutionary processes in forecasts of the future dynamics and productivity of forests. Species experiencing high mortality rates or populations that are subject to regular disturbances such as storms or fires might actually be the quickest to adapt to a warming climate.

Species life history characteristics are also not usually well represented in most climate-based distribution models. Important factors include age to sexual maturity, fecundity, seed dispersal, competition or chilling or dormancy requirements (Nitschke and Innes 2008b).

Competitive relationships within and between species are likely to be altered by climate change. Most models also assume open site growth conditions, rather than those within a forest, where the growth environment will be quite different. However, increased disturbance associated with climate change may create stand reinitiation conditions more often than has occurred in the past, altering competitive interactions.

Process-based models of species range shifts and ecosystem change may capture more of the life history variables and competition effects that will be important in determining responses to climate change (Kimmins 2008; Nitschke and Innes 2008a, b). These can provide the basis for a more robust assessment framework that integrates biological characteristics (e.g. shade tolerance and seedling establishment) and disturbance characteristics (e.g. insect pests, drought and fire topkill). Matthews et al. (2011) integrated these factors into a decision support system that communicates uncertainty inherent in GCM outputs, emissions scenarios and species responses. This demonstrated a greater diversity among species to adapt to climate change and provides a more practical assessment of future species projections.

In summary, whilst SDMs and other climate-based modelling approaches can provide a guide to potential species responses, the extent to which future climate conditions will result in major range shifts or extinction of species is unclear and the value of this approach in adaptation and decision making is limited. The evidence from genetic studies seems to suggest that many species are reasonably robust to potential future climate change. Those with a wide geographic range, large populations and high fecundity may suffer local population extinction but are likely to persist and adapt whilst suffering adaptational lag for a few generations. For example, Booth (2013) considered that many eucalyptus

species, some of which are widely planted around the world, had a high adaptive capacity even though their natural ranges are quite small.

However, large contractions or shifts in distribution could have significant consequences for different forest values and species with small populations, fragmented ranges, low fecundity or suffering declines due to introduced insects or diseases may have a higher sensitivity and are at greater risk in a changing climate (Aitken et al. 2008).

3.1.2 Ecosystem responses to climate

Projecting the fate of forest ecosystems under a changing climate is more challenging than for species. It has been well understood for some time that species will respond individualistically to climate change, rather than moving in concert, and that this is likely to result in 'novel' ecosystems, or groups of species, that are not represented in current classifications (Davis 1986). Forecasts need to consider the importance of these new species interactions and the confounding effects of future human activities.

Climate change affects a wide range of ecosystem functions and processes (Table 2). These include direct effects of temperature and precipitation on physiological and reproductive processes such as photosynthesis, water use, flowering, fruiting and regeneration, growth and mortality and litter decomposition. Changes in these processes will have effects on species attributes such as wood density or foliar nutrient status. Indirect effects will be exhibited through changing fire and other climate-driven disturbances. These will ultimately have impacts on stand composition, habitat structure, timber supply capacity, soil erosion and water yield.

Most early studies of forest ecosystem responses to climate change were built around ecosystem process models at various scales (Graham et al. 1990; Running and Nemani 1991; Rastetter et al. 1991). A number of recent studies have investigated the effects of past and current climate change on forest processes, often with surprising effects (Groffman et al. 2012).

Observed forest growth has increased recently in a number of regions, for example over the last 100 years in Europe (Pretzsch et al. 2014; Kint et al. 2012), and for more recent observations in Amazon forests (Phillips et al. 2008). In a major review, Boisvenue and Running (2006) found that at finer spatial scales, a trend is difficult to decipher, but globally, based on both satellite and ground-based data, climatic changes seemed to have a generally positive impact on forest productivity when water was not limiting. However, there can be a strong difference between species, complicating ecosystem level assessments (Michelot et al. 2012), and there are areas with little observed change (Schwartz et al. 2013). Generally, there are significant challenges in detecting the response of forests to climate change. For example, in the tropics, the lack of historical context, long-term growth records and access to data are real barriers (Clark 2007) and temperate regions also have challenges, even with well-designed, long-term experiments (Leites et al. 2012).

Table 2 Forest ecosystem responses to elevated CO_2 and climate change

	Faster response	Slower response
Direct	• Photosynthesis	• Litter decomposition
	• Water use/transport	• Foliar nutrient status
	• Flowering/phenology	• Genetic change
	• Regeneration	• Tree species distribution and stand composition
	• Growth and mortality	
	• Wood density/quality	
	• Frost/storm damage	
Indirect	• Increased fire frequency/intensity	• Habitat composition and structure
	• Disease impacts	• Wood supply
	• More insect pests	• Erosion and soil loss
	• Increased invasive species	• Water yield
	• Water quality	

Projections of net primary productivity (NPP) under climate change indicate that there is likely to be a high level of regional variation (Zhao et al. 2013). Using a process model and climate scenario projections, Peters et al. (2013) predicted that average regional productivity in forests in the Great Lakes region of North America could increase from 67 to 142 %, runoff could potentially increase from 2 to 22 % and net N mineralization from 10 to 12 %. Increased productivity was almost entirely driven by potential CO_2 fertilization effects, rather than by increased temperature or changing precipitation. Productivity in these forests could shift from temperature limited to water limited by the end of the century. Reyer et al. (2014) also found strong regional differences in future NPP in European forests, with potential growth increases in the north but reduced growth in southern Europe, where forests are likely to be more water limited in the future. Again, assumptions about the impact of increasing CO_2 were a significant factor in this study.

In a different type of study using analysis of over 2400 long-term measurement plots, Bowman et al. (2014) found that there was a peaked response to temperature in temperate and sub-tropical eucalypt forests, with maximum growth occurring at a mean annual temperature of 11 °C and maximum temperature of the warmest month of 25–27 °C. Lower temperatures directly constrain growth, whilst high temperatures primarily reduced growth by reducing water availability but they also appeared to exert a direct negative effect. Overall, the productivity of Australia's temperate eucalypt forests could decline substantially as the climate warms, given that 87 % of these forests currently experience a mean annual temperature above the 'optimal' temperature.

Incorporating the effects of rising CO_2 in models of future tree growth continues to be a major challenge. The sensitivity of projected productivity to assumptions regarding increased CO_2 was high in modelling studies of climate change impacts in commercial timber plantations in the Southern Hemisphere (Kirschbaum et al. 2012; Battaglia et al. 2009), and a recent analysis indicated a general convergence of different model predictions for future tree species distribution in Europe, with most of the difference between models due to the way in which this effect is incorporated (Cheaib et al. 2012). Increased CO_2 has been shown to increase the water-use efficiency of trees, but this is unlikely to entirely offset the effects of increased water stress on tree growth in drying climates (Leuzinger et al. 2011; Booth 2013). In general, despite studies extending over decades and improved understanding of biochemical processes (Franks et al. 2013), the impacts of increased CO_2 on tree and stand growth are still unresolved (Kallarackal and Roby 2012).

Integrating process model outputs with spatially explicit landscape models can improve understanding and projection of responses and landscape planning and this could provide for simulations of changes in ecological processes (e.g. tree growth, succession, disturbance cycles, dispersal) with other human-induced changes to landscapes (Campbell et al. 2009).

Investigation of current species responses to changing climate conditions may also guide improved prediction of patterns of future change in ecosystem distribution. For example, Allen et al. (2010) suggest that spatially explicit documentation of environmental conditions in areas of forest die-off is necessary to link mortality to causal climate drivers, including precipitation, temperature and vapour pressure deficit. Better prediction of climate responses will also require improved knowledge of belowground processes and soil moisture conditions. Assessments of future productivity will depend on accurate measurements of rates (net ecosystem exchange and NPP), changes in ecosystem level storage (net ecosystem production) and quantification of disturbances effects to determine net biome production (Boisvenue and Running 2006).

Hydrological conditions, runoff and stream flow are of critical importance for humans and aquatic organisms, and many studies have focused on the implications of climate change for these ecosystem processes. However, most of these have been undertaken at small catchment scale (Mahat and Anderson 2013; Neukum and Azzam 2012; Zhou et al. 2011) with few basin-scale assessments (van Dijk and Keenan 2007). However, the effects of climate and forest cover change on hydrology are complicated. Loss of tree cover may increase stream flow but can also increase evaporation and water loss (Guardiola-Claramonte et al. 2011). The extent of increasing wildfire will also be a major factor determining hydrological responses to climate change (Versini et al. 2013; Feikema et al. 2013).

Changing forest composition will also affect the habitat of vertebrate and invertebrate species. The implications of climate change for biodiversity conservation have been subject to extensive analysis (Garcia et al. 2014; Vihervaara et al. 2013; Schaich and Milad 2013; Clark et al. 2011; Heller and Zavaleta 2009; Miles et al. 2004). An integrated analytical approach, considering both impacts on species and habitat is important. For example, in a study of climate change impacts on bird habitat in the north-eastern USA, the combination of changes in tree distribution and habitat for birds resulted in significant impacts for 60 % of the species. However, the strong association of birds with certain vegetation tempers their response to climate change because localised areas of suitable habitat may persist even after the redistribution of tree species (Matthews et al. 2011).

Understanding thresholds in changing climate conditions that are likely to result in a switch to a different ecosystem state, and the mechanisms that underlie ecosystem responses, will be critical for forest managers (Campbell et al. 2009). Identifying these thresholds of change is challenging. Detailed process-based ecosystem research that identifies and studies critical species interactions and feedback loops, coupled with scenario modelling of future conditions, could provide valuable insights (Kimmins et al. 1999, 2008; Walker and Meyers 2004). Also, rather than pushing systems across thresholds into alternative states, climate change may create a stepwise progression to unknown transitional states that track changing climate conditions, requiring a more graduated approach in management decisions (Lin and Petersen 2013).

Ultimately, management decisions may not be driven by whether we can determine future thresholds of change, but by observing the stressors that determine physiological limits of species distributions. These thresholds will depend on species physiology and local site conditions, with recent research demonstrating already observed ecosystem responses to climate change, including die-back of some species (Allen et al. 2010; Rigling et al. 2013).

3.1.3 Fire, pests, invasive species and disturbance risks

Many of the impacts of a changing future climate are likely to be felt through changing disturbance regimes, in particular fire. Forest fire weather risk and fire behaviour prediction have been two areas where there has been strong historical interaction between climate science and forest management and where we may see major tipping points driving change in ecosystem composition (Adams 2013). Fire weather is fundamentally under the control of large-scale climate conditions with antecedent moisture anomalies and large-scale atmospheric circulation patterns, further exacerbated by configuration of local winds, driving fire weather (Brotak and Reifsnyder 1977; Westerling et al. 2002, 2006). It is therefore important to improve understanding of both short- and long-

term atmospheric conditions in determining meteorological fire risk (Amraoui et al. 2013).

Increased fuel loads and changes to forest structure due to long periods of fire exclusion and suppression are increasing fire intensity and limiting capacity to control fires under severe conditions (Williams 2004, 2013). Increasing urbanisation is increasing the interface between urban populations and forests in high fire risk regions, resulting in greater impacts of wildfire on human populations, infrastructure and assets (Williams 2004). Deforestation and burning of debris and other types of human activities are also introducing fire in areas where it was historically relatively rare (Tacconi et al. 2007).

In a recent study, Chuvieco et al. (2014) assessed ecosystem vulnerability to fire using an index based on ecological richness and fragility, provision of ecosystem services and value of houses in the wildland–urban interface. The most vulnerable areas were found to be the rainforests of the Amazon Basin, Central Africa and Southeast Asia; the temperate forest of Europe, South America and north-east America; and the ecological corridors of Central America and Southeast Asia.

In general, fire management policies in many parts of the world will need to cope with longer and more severe fire seasons, increasing fire frequency, and larger areas exposed to fire risk. This will especially be the case in the Mediterranean region of Europe (Kolström et al. 2011) and other fire-prone parts of the world such as South Eastern Australia (Hennessy et al. 2005). This will require improved approaches to fire weather modelling and behaviour prediction that integrate a more sophisticated understanding of the climate system with local knowledge of topography, vegetation and wind patterns. It will also require the development of fire management capacity where it had previously not been necessary. Increased fire weather severity could push current suppression capacity beyond a tipping point, resulting in a substantial increase in large fires (de Groot et al. 2013; Liu et al. 2010) and increased investment in resources and management efforts for disaster prevention and recovery.

Biotic factors may be more important than direct climate effects on tree populations in a changing climate. For example, insects and diseases have much shorter generation length and are able to adapt to new climatic conditions more rapidly than trees. However, if insects move more rapidly to a new environment whilst tree species lag, some parts of the tree population may be impacted less in the future (Regniere 2009).

The interaction of pests, diseases and fire will also be important. For example, this interaction will potentially determine the vulnerability of western white pine (*Pinus monticola*) ecosystems in Montana in the USA. Loehman et al. (2011) found that warmer temperatures will favour western white pine over existing climax and shade tolerant species, mainly because warmer conditions will lead to increased frequency and extent of wildfires that facilitates regeneration of this species.

3.2 Adaptation actions in forest management

The large majority of published studies relating to forests and climate change have been on vulnerability and impacts. These have increased understanding of the various relationships between forest ecosystems and climate and improved capacity to predict and assess ecosystem responses. However, managers need greater guidance in anticipating and responding to potential impacts of climate change and methods to determine the efficiency and efficacy of different management responses because they are generally not responding sufficiently to potential climate risks.

3.2.1 Adaptation actions at different management levels

A number of recent reviews have described adaptation actions and their potential application in different forest ecosystems being managed for different types of goods or services (Bernier and Schöne 2009; Innes et al. 2009; Lindner et al. 2010; Kolström et al. 2011), and adaptation guides and manuals have been developed (Peterson et al. 2011; Stephens et al. 2012) for different types of forest and jurisdictions. Adaptation actions can be primarily aimed at reducing vulnerability to increasing threats or shocks from natural disasters or extreme events, or increasing resilience and capacity to respond to progressive change or climate extremes. Adaptation actions can be reactive to changing conditions or planned interventions that anticipate future change. They may involve incremental changes to existing management systems or longer term transformational changes (Stafford Smith et al. 2011). Adaptation actions can also be applied at the stand level or at ownership, estate or national scales (Keskitalo 2011).

Recent research at the stand level in forests in the SE USA showed that forest thinning, often recommended in systems that are likely to experience increased temperature and decreased precipitation as a result of climate change, will need to be more aggressive than traditionally practised to stimulate growth of large residual trees, improve drought resistance and provide greater resilience to future climate-related stress (Kerhoulas et al. 2013).

An analysis of three multi-aged stand-level options in Nova Scotia, Canada, Steenberg et al. (2011) found that leaving sexually immature trees to build stand complexity had the most benefit for timber supply but was least effective in promoting resistance to climate change at the prescribed harvest intensity. Varying the species composition of harvested trees proved the most effective treatment for maximising forest age and old-growth area and for promoting stands composed of climatically suited target species. The combination of all three treatments resulted in an adequate

representation of target species and old forest without overly diminishing the timber supply and was considered most effective in minimising the trade-offs between management values and objectives.

An estate level analysis of Austrian Federal Forests indicated that management to promote mixed stands of species that are likely to be well adapted to emerging environmental conditions, silvicultural techniques fostering complexity and increased management intensity might successfully reduce vulnerability, with the timing of adaptation measures important to sustain supply of forest goods and services (Seidl et al. 2011).

Whilst researchers are analysing different management options, the extent to which they are being implemented in practice is generally limited. For example, in four regions in Germany, strategies for adapting forest management to climate change are in the early stages of development or simply supplement existing strategies relating to general risk reduction or to introduce more 'nature-orientated' forest management (Milad et al. 2013). Guariguata et al. (2012) found that forest managers across the tropics perceived that natural and planted forests are at risk from climate change but were ambivalent about the value of investing in adaptation measures, with climate-related threats to forests ranked below others such as clearing for commercial agriculture and unplanned logging.

Community-based management approaches are often argued to be the most successful approach for adaptation. An analysis of 38 community forestry organisations in British Columbia found that 45 % were researching adaptation and 32 % were integrating adaptation techniques into their work (Furness and Nelson 2012). Whilst these community forest managers appreciated support and advice from government for adaptation, balancing this advice with autonomy for communities to make their own decisions was considered challenging.

In a study of communities impacted by drought in the forest zone of Cameroon, Bele et al. (2013b) identified adaptive strategies such as community-created firebreaks to protect their forests and farms from forest fires, the culture of maize and other vegetables in dried swamps, diversifying income activities or changing food regimes. However, these coping strategies were considered to be incommensurate with the rate and magnitude of change being experienced and therefore no longer seen as useful. Some adaptive actions, whilst effective, were resource inefficient and potentially translate pressure from one sector to another or generated other secondary effects that made them undesirable.

3.2.2 Integrating adaptation and mitigation

In considering responses to climate change, forest managers will generally be looking for solutions that address both mitigation objectives and adaptation. To maintain or increase forest carbon stocks over the long term, the two are obviously inextricably linked (Innes et al. 2009). Whilst there are potentially strong synergies, Locatelli et al. (2011) identified potential trade-offs between actions to address mitigation and the provision of local ecosystem services and those for adaptation. They argued that mitigation projects can facilitate or hinder the adaptation of local people to climate change, whereas adaptation projects can affect ecosystems and their potential to sequester carbon.

Broadly, there has been little integration to date of mitigation and adaptation objectives in climate policy. For example, there is little connection between policies supporting the reducing emissions from deforestation and forest degradation plus (REDD+) initiatives and adaptation. Integrating adaptation into REDD+ can advance climate change mitigation goals and objectives for sustainable forest management (Long 2013). Kant and Wu (2012) considered that adaptation actions in tropical forests (protection against fire and disease, ensuring adequate regeneration and protecting against coastal impacts and desertification) will improve future forest resilience and have significant climate change mitigation value.

3.2.3 Sector-level adaptation

Analyses of climate change impacts and vulnerability at the sector level have been undertaken for some time (Lindner et al. 2002; Johnston and Williamson 2007; Joyce 2007). However, it has recently been argued (Wellstead et al. 2014) that these assessments, which focus on macro system-level variables and relationships, fail to account for the multi-level or polycentric nature of governance and the possibility that policy processes may result in the non-performance of critical tasks required for adaptation.

Joyce et al. (2009) considered that a toolbox of management options for the US National Forests would include the following: practices focused on reducing future climate change effects by building resistance and resilience into current ecosystems and on managing for change by enabling plants, animals and ecosystems to adapt to climate change. Sample et al. (2014) demonstrated the utility of this approach in a coniferous forest management unit in northwestern USA. It provided an effective means for guiding management decisions and an empirical basis for setting budgetary and management priorities. In general, more widespread implementation of already known practices that reduce the impact of existing stressors represents an important 'no regrets' strategy.

Johnston and Hesseln (2012) found that barriers to implementing adaptation across forest sector managers in Canada included inflexible tenure arrangements and regulatory environments which do not support innovation. Echoing calls for wider implementation of SFM as a key adaptation strategy (Innes et al. 2009), they argued that forest certification systems, participating in the Canadian model forest

programme, and adopting criteria and indicators of SFM can support sectoral level adaptation.

Decentralised management approaches are considered to be a more appropriate governance arrangement for forest management, but Rayner et al. (2013) argued that a decentralised forest policy sector in Canada has resulted in limitations where policy, such as adaptation, requires a coherent national response. Climate change adaptation has led to an expansion of departmental mandates that is not being addressed by better coordination of the available policy capacity. Relevant federal agencies are not well represented in information networks, and forest policy workers report lower levels of internal and external networking than workers in related policy subsectors.

Economic diversification can be a valuable strategy to improve resilience to climate-related shocks. This can take a range of forms: developing new industries or different types of forest-based industries based on different goods or services. For the timber sector, the value of diversification as a risk management strategy for communities is open to question. Ince et al. (2011) pointed out that the forest sector operates in an international market and is susceptible to changes in the structure of this market. In the US forest sector, globalization has accelerated structural change, favouring larger and more capital-intensive enterprises and altering historical patterns of resource use. They suggest that future markets for timber will be driven by developments in these larger scale enterprises and may not lead to expansion of opportunities for smaller scale forest enterprises because development of niche markets or customised products is likely to be pursued aggressively by larger globally oriented enterprises to develop branding, product identity and product value. How to best diversify for adaptation therefore remains an open question.

Consequently, whilst policies that support economic diversification will be important, this may involve diversification well beyond traditional sectors. For example, in areas where there is a high probability that forests will be lost in favour of other ecosystems, such as grasslands, managers should recognise early on that their efforts and resources may best be focused outside forests (Innes et al. 2009). These adjustments will involve taking into account the perceptions of climate risk by various stakeholders, including individuals, communities, governments, private institutions and organisations (Adger et al. 2007). Vulnerability assessments and adaptation measures also need to be developed in a framework that takes into account the vulnerabilities and actions in other sectors that are linked to the forest sector, such as food, energy, health and water (Sonwa et al. 2012).

3.3 New approaches to decision making

Climate change presents new challenges for forest managers. Change is likely to happen faster than traditional, empirical approaches can provide evidence to support changes in management. Uncertainties in a range of aspects of future climate may also not be reduced through investment in research. Given that management for activities such as timber production can no longer be based solely on empirically derived growth and yield trajectories and management plans must incorporate uncertainty and the increased probability of extreme events, what types of tools are available to support these approaches? This section presents key points from the literature on decision making under uncertainty, adaptive management and resilience as a guide to future decision making in forest management.

3.3.1 Decision making under uncertainty

The future conditions for forest managers are subject to a high degree of uncertainty, and the future prospects for reducing these large uncertainties are limited. There is uncertainty regarding the trajectory of future increases in atmospheric greenhouse gases, what kind of effects these might have on the climate system and the effects of climatic changes on ecological and social systems and their capacity to adapt (see Fig. 2) (Wilby and Dessai 2010).

Consequently, many forest managers consider that the future situation is too uncertain to support long-term and potentially costly decisions that may be difficult to reverse. Dessai and Hulme (2004) argued that uncertainty per se should not be a reason for inaction. However, the critical issue for managers is deciding the types of actions to take and the timing and conditions under which they should be taken (Ogden and Innes 2007a). A more reactive 'wait and see' approach (or 'purposeful procrastination') might be justified if uncertainty or costs are high relative to the expected impacts and risks, or if it is cheaper to implement interventions by waiting until after a significant disturbance (e.g. replanting an area with more fire- or drought-resistant tree species after a wildfire or drought-induced insect outbreak).

Effective adaptation requires setting clear objectives. Managers and policy makers need to decide whether they are trying to facilitate ecosystem adaptation through changing species composition or forest structure or trying to engineer resistance to change through proactive management strategies (Joyce et al. 2008). Establishing objectives often depends on the integration of the preferences of different stakeholders (Prato 2008), but changing social preferences presents another source of potential uncertainty.

Risk assessment and management provide a foundation for decision making in considering climate change in natural resource management. This approach provides both a qualitative and quantitative framework for evaluating climate change effects and adaptation options. Incorporating risk management approaches into forest management plans can provide

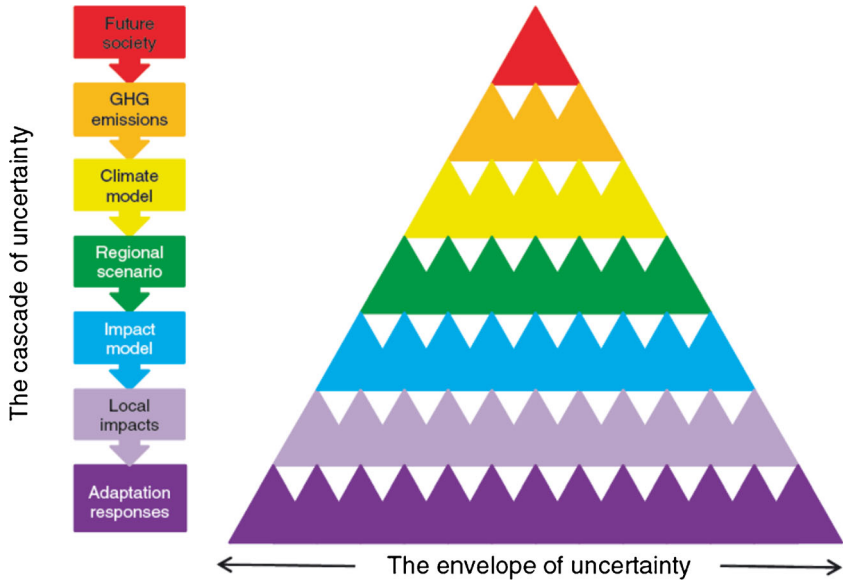

Fig. 2 The cascade of uncertainty (Wilby and Dessai 2010)

a basis for managers to continue to provide forest conditions that meet a range of important values (Day and Perez 2013).

However, risk approaches generally requiring assigning probabilities to future events. In a comprehensive review, Yousefpour et al. (2011) identified a growing body of research literature on decision making under uncertainty, much of which has focused on price uncertainty and variation in timber production but is extending to multiple forest management objectives and other types of risk. They argue that we are actually in a stochastic transition from one known stable (but variable) climate state to a new but largely unknown and likely more rapidly changing set of future conditions.

Decision makers themselves may also not be the rational actors assumed by these models, with their decisions taken according to quite different assumptions, preferences and beliefs (Ananda and Herath 2009; Couture and Reynaud 2008). Therefore, the communication approach will be important in determining whether the information is acted on. In a recent study, Yousefpour et al. (2014) considered that the speed with which decision makers will form firm beliefs about future climate depends on the divergence among climate trajectories, the speed of change and short-term climate variability. Using a Bayesian modelling approach, they found that if a large change in climate occurs, the value of investing in knowledge and taking an adaptive approach would be positive and higher than a non-adaptive approach. In communicating about uncertainty, it may be better to focus discussion on the varying time in the future when things will happen, rather than on whether they will happen at all (Lindner et al. 2014).

Increased investment in climate science and projections or species distribution modelling may not necessarily decrease uncertainty in climate projections or impacts. Climate models are best viewed as heuristic tools rather than as accurate forecasts of the future (Innes et al. 2009). Trajectories of change in many other drivers of forest management (social, political or economic) are also highly uncertain (Keskitalo 2008) and the effects of these on the projected performance of management can be the same order of magnitude, requiring an integrated social-ecological perspective to adaptation (Seidl and Lexer 2013).

In a more 'decision-centred' approach, plausible scenarios of the potential range of future conditions are required. These can be derived from climate models but do not need to be accurate and precise 'predictions' of future climate states (Wilby and Dessai 2010). To support this type of approach, research needs to focus on improved understanding of tree and ecosystem responses and identifying those aspects of climate to which different forest types are most sensitive.

Devising strategies that are able to meet management objectives under a range of future scenarios is likely to be the most robust approach, recognising that these strategies are unlikely to be optimal under all future conditions. In some cases, the effect of different scenarios on forest growth may not be that great and differences in the present value of different management options are relatively small. For example, Eriksson et al. (2011) found that there was limited benefit in attempting to optimise management plans in accordance with future temperature scenarios.

Integration of climate change science and adaptation in forest management planning is considered important for building resilience in forest social and ecological systems (Keskitalo 2011; D'Amato et al. 2011; Chmura et al. 2011; Parks and Bernier 2010; Lindner et al. 2014). Forest restoration is becoming a more prominent aspect of forest management in many parts of the world and restoration approaches will also need to integrate understanding of future climate change to be successful (Stanturf et al. 2014).

3.3.2 Adaptive management, resilience and decisions

Adaptive management provides a mechanism to move forward when faced with future uncertainty (Innes et al. 2009). It can be viewed as a systematic process for continually improving management policies and practices by monitoring and then learning from the outcomes of operational programmes as a basis for incorporating adaptation actions into forest management. Whilst many management initiatives purport to implement these principles, they often lack essential characteristics of the approach (Innes et al. 2009).

However, effective adaptation to changing climate cannot simply involve adaptive management as it is currently understood. The pace of climate change is not likely to allow for the use of management as a tool to learn about the system by implementing methodologies to test hypotheses concerning known uncertainties (Holling 1978). Future climatic conditions may result in system states and dynamics that have never previously existed (Stainforth et al. 2007), so observation of past experience may be a poor guide for future action. Management will need to be more 'forward-looking', considering the range of possible future conditions and planning actions that consider that full range.

How does this translate into the practical guidance forest managers are seeking on how to adapt their current practices and, if necessary, their goals (Blate et al. 2009)? Managers will need to consider trade-offs between different objectives under different conditions. For example, Seidl et al. (2011) showed that, to keep climate vulnerability in an Austrian forest low, Norway spruce will have to be replaced almost entirely by better adapted species. However, indicator weights that favoured timber production over C storage or biodiversity exerted a strong influence on the results. Wider social implications of imposing such drastic changes in forest landscapes will also deserve stronger consideration in decision making.

Ecosystem management will need to be reframed to accommodate the risks of a changing climate. Adaptive strategies, even without specific information on the future climate conditions of a target ecosystem, would enhance social and ecological resilience to address the uncertainties due to changing climate (Mori et al. 2013). These are likely to be more subject to change over the short to medium term, in response to more rapidly changing conditions.

Analysis of ecosystem resilience can provide a framework for these assessments. Resilience can be defined as 'the capacity of ecosystems to absorb disturbance and reorganise so as to retain essentially the same function, structure and feedbacks – to have the same identity' (Walker and Salt 2012). It is a function of the capacity of an ecosystem to resist change, the extent and pace of change and the ability of an ecosystem to reorganise following disturbance. The concept of resilience holds promise for informing future forest management, but Rist and Moen (2013) argue that its contributions are, so far, largely conceptual and offer more in terms of being a problem-framing approach than analytical or practical tools. There may also be trade-offs involved with focusing on resilience through retention of current species composition or using a more adaptation-oriented management approach after disturbances (Buma and Wessman 2013). Complexity theory and concepts can provide an appropriate framework for managing resilience (Messier et al. 2013).

Management decisions will ultimately depend on the costs and benefits of different options, but there are few examples of decision making frameworks that compare the costs of future impacts with the costs of different actions and the efficacy of those actions in reducing impacts. Ogden and Innes (2009) used a structured decision making process to identify and assess 24 adaptation options that managers considered important to achieve their regional goals and objectives of sustainable forest management in light of climate change. In the analysis of options for biodiversity conservation, Wintle et al. (2011) found that the amount of funding available for adaptation was a critical factor in deciding options aimed at minimising species extinctions in the mega-diverse fynbos biome of South Africa. When the available budget is small, fire management was the best strategy. If the budget is increased to an intermediate level, the marginal returns from more fire management were limited and the best strategy was added habitat protection. Above another budget threshold, increased investment should go into more fire management. By integrating ecological predictions in an economic decision framework, they found that making the choice of how much to invest is as important as determining what actions to take.

3.3.3 Adaptation as a social learning process

Whilst adaptation has been defined as 'adjustment in natural or human systems in response to actual or expected climatic stimuli or their effects' (Levina and Tirpak 2006), adaptation is essentially about meeting future human needs (Spittlehouse and Stewart 2003; Hahn and Knoke 2010). Consequently, it is inherently a social process. Forest landscapes are social-ecological systems that involve both nature and society (Innes et al. 2009), and resolving trade-offs between different management objectives to meet the different needs in society is an important element of sustainable forest management. As Kolström et al. (2011) pointed out, some proposed adaptation measures may change the balance between current objectives and stakeholder interests, and it will be important to consider the relative balance of different measures at the stand, management unit and landscape scales.

Those investigating adaptive management also recognise that it goes beyond the focus on scientific methods, statistical designs or analytical rigour favoured by its early proponents and that there is now an expectation of much greater stakeholder involvement, with the concept being renamed by some

as adaptive, collaborative management (Innes et al. 2009). SFM and adaptation are as much about those who inhabit, work in or utilise forests as it is about managing the forest ecosystems themselves (White et al. 2010; Pramova et al. 2012; Fischer et al. 2013).

The choice of adaptation options will thus likely be relatively complex, even in cases where information and policy have been developed, and communication measures for forest management have been well formulated. Making such choices may require considerable knowledge, competence and commitment for implementation at the local level (Keskitalo 2011). Effective adaptation will require much greater cooperation between stakeholders, more flexibility for management actions and commitment of time to develop the social license for action in the absence of conclusive evidence or understanding. This will require venues for sharing perspectives on the nature of the problem (Fig. 3).

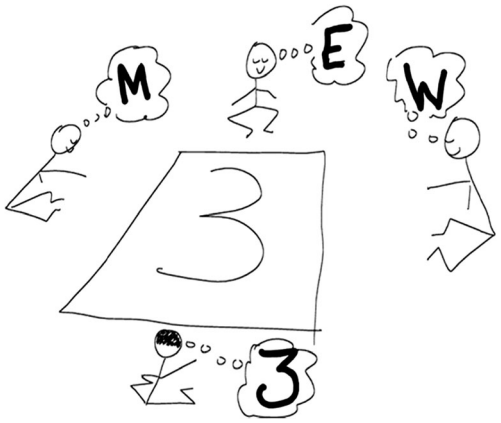

Fig. 3 Adaptation as a social learning process. There is a need to provide situations to share different viewpoints on the nature of the problem as a basis for developing shared solutions (image source: John Rowley, http://ch301.cm.utexas.edu/learn/)

3.3.4 Local and indigenous knowledge

The promotion of community-based forest management may increase local adaptive capacity by putting decisions in the hands of those people who first feel the effects of climate change (Gyampoh et al. 2009). In this context, local knowledge systems based on long-term observation and experience are likely to be of increasing importance in decision making. Adaptation strategies can benefit from combining scientific and indigenous knowledge, especially in developing countries (Gyampoh et al. 2009), with the translation of local forest knowledge into the language of formal forest science being considered an important step towards adaptation (Roberts et al. 2009). However, conservation and natural resource managers in government agencies have often discounted traditional local management systems (Scott 2005), although Spathelf et al. (2014) provided a useful approach for capturing local expert knowledge. Linking this type of knowledge with broader scientific understanding of ecosystem functioning and the global climate system will be a major challenge, requiring consideration of both technical and cultural issues (Caverley 2013), including intellectual property concerns of indigenous people (Lynch et al. 2010).

3.4 Policy arrangements for adaptation

Increasingly, many are arguing that effectively responding to climate change will require polycentric and multi-level governance arrangements (Peel et al. 2012). However, Nilsson et al. (2012) found that institutionalising of knowledge and knowledge exchange regarding climate change adaptation in Sweden was weak and that improved mechanisms are required for feedback from the local to the national level. Recent studies have described stronger relationships between scientific research and forest management to assess trade-offs and synergies, for participatory decision making and for shared learning (Blate et al. 2009; Littell et al. 2012; Klenk et al. 2011).

Many papers emphasised the need for greater flexibility in the policies, cultures and structures of forest management organisations (Brown 2009; von Detten and Faber 2013; Rayner et al. 2013). Because no single community or agency can prepare on their own for future impacts, inter-sectoral policy coordination will be required to ensure that policy developments in related policy sectors are not contradictory or counterproductive. Greater integration of information, knowledge and experience and collaborative projects involving scientists, practitioners and policy makers from multiple policy communities could increase focus on resilience, identify regions of large-scale vulnerability and provide a more rigorous framework for the analysis of vulnerability and adaptation actions (Thomalla et al. 2006).

There is also likely to be a greater need for cross-border implementation of different forest management options, requiring greater coordination between nation states and sub-national governments (Keenan 2012). Policy is the product of both 'top-down' and 'bottom-up' processes and these might sometimes be in conflict. Simply having 'good policy' in place is unlikely to be sufficient, as a great deal of what takes place at 'street level' is not determined by formal aims of central policy (Urwin and Jordan 2008). Having the right policies can send a strong political signal that adaptation needs to be considered seriously but flexibility in policy systems will be required to facilitate adaptive planning.

4 Discussion and conclusions

This broad survey of the literature indicated that, whilst there has been considerable development in research and thinking

about adaptation in forest management over the last 10 years, research is still strongly focused on assessment of future impacts, responses and vulnerability of species and ecosystems (and in some cases communities and forest industries) to climate change. There has been some movement from a static view of climate based on long-term averages to a more detailed understanding of the drivers of different climate systems and how these affect the factors of greatest influence on different forest ecosystems processes, such as variability and extremes in temperature or precipitation or fire disturbance. For example, Guan et al. (2012) demonstrated that quasi-periodic climate variation on an inter-annual (ENSO) to inter-decadal (PDO) time scale can significantly influence tree growth and should be taken into account when assessing the impact of climate changes on forest productivity.

Adaptation is, in essence, about making good decisions for the future, taking into account the implications of climate change. It involves recognising and understanding potential future climate impacts and planning and managing for their consequences, whilst also considering the broader social, economic or other environmental changes that may impact on us, individually or collectively. To effectively provide a role in mitigation, delivering associated ecosystem services and benefits in poverty reduction (Eliasch 2008) forest management will have to adapt to a changing and highly variable climate. In achieving this, the roles and responsibilities of different levels of government, the private sector and different parts of the community are still being defined.

The broader literature emphasises that adaptation is a continuous process, involving a process of 'adapting well' to continuously changing conditions (Tompkins et al. 2010). This requires organisational learning based on past experience, new knowledge and a comprehensive analysis of future options. This can take place through 'learning by doing' or through a process of search and planned modification of routines (Berkhout et al. 2006). However, interpreting climate signals is not easy for organisations, the evidence of change is ambiguous and the stimuli are not often experienced directly within the organisation. For example, many forest managers in Australia currently feel little need to change practices to adapt to climate change, given both weak policy signals and limited perceived immediate evidence of increasing climate impacts (Cockfield et al. 2011). To explain and predict adaptation to climate change, the combination of personal experience and beliefs must be considered (Blennow et al. 2012). 'Climate smart' forest management frameworks can provide an improved basis for managing forested landscapes and maintaining ecosystem health and vitality based on an understanding of landscape vulnerability to future climatic change (Fig. 4) (Nitschke and Innes 2008a).

Many are now asking, do we really need more research to start adapting forest management to climate change? Whilst adaptation is often considered 'knowledge deficit' problem—where scientists provide more information and forest managers will automatically make better decisions—the reality is that the way in which this information is presented and how it is interpreted and received, will play major roles in determining potential responses. Successful adaptation will require dissemination of knowledge of potential climate impacts and suitable adaptation measures to decision makers at both practice and policy levels (Kolström et al. 2011) but it needs to go well beyond that.

Adaptation is, above all, a social learning process. It requires an understanding of sense of place, a capacity for individuals and society to consider potential future changes and what they mean for their circumstances. Leaders in forest management organisations will need to support a greater diversity of inputs into decision making, avoid creating rigid organisational hierarchies that deter innovation, and be inclusive, open and questioning (Konkin and Hopkins 2009). They will need to create more opportunities for interaction between researchers, managers and the community and space for reflection on the implications and the outcomes of management actions and unplanned events. Researchers will need to develop new modes of communication, providing knowledge in forms that are appropriate to the management decision and suitable for digestion by a range of different audiences.

From this analysis, key gaps in knowledge for adaptation may not be improved climate scenarios or better understanding of the biophysical responses of individual tree species or forest ecosystems to future climate. Knowledge gaps lie more in understanding the social and community attitudes and values that drive forest management and the decision making processes of forest managers, in order to work out how 'climate intelligence' can be built in to these processes.

The impacts of changing climate will vary locally. Consequently, managers must be given the flexibility to respond in ways that meet their particular needs and capacity to choose

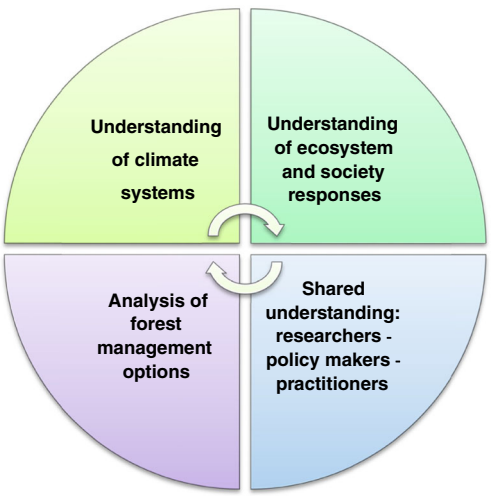

Fig. 4 Components of climate smart forest management (after Nitschke and Innes 2008a, b)

management options that are applicable to the local situation (Innes et al. 2009). This may not be consistent with rigid indicator-driven management assessment processes like forest certification. Whilst policy to support climate change mitigation is primarily a task for national governments and international agreements and processes, responsibility for supporting adaptation will fall more to sub-national and local governments, communities and the private sector. More active management will be required if specific values are to be maintained, particularly for forests in conservation reserves. This will require additional investment, but there has been little analysis to support the business case for investment in adaptation or to determine who should pay, particularly in developing countries.

We need to strengthen the relationship between climate science, forest research, forest managers and the community. Key challenges will include the setting of objectives for desired future conditions and accepting that we may not be able to maintain everything that forests have traditionally provided. It is important to discuss and agree on common goals in order to cope with, or benefit from, the challenges of future climates. Actively managing our forest ecosystems effectively and intelligently, using the best available knowledge and foresight capacity, can make those goals a reality.

Acknowledgments Thanks to Linda Joyce for her comments on an earlier draft of this paper, to a number of anonymous reviewers for their thoughtful suggestions and to many colleagues that I have discussed these ideas with over the past five years.

The Role of Indigenous Burning in Land Management

Robin Wall Kimmerer and Frank Kanawha Lake

ABSTRACT

This article highlights the findings of the literature on aboriginal fire from the human- and the land-centered disciplines, and suggests that the traditional knowledge of indigenous peoples be incorporated into plans for reintroducing fire to the nation's forests. Traditional knowledge represents the outcome of long experimentation with application of fire by indigenous people, which can inform contemporary policy discussions.

Keywords: biodiversity; fire; history; policy; traditional knowledge

Every landscape reflects the history and culture of the people who inhabit it. The worldview of a society is often written more truthfully on the land than in its documents. The current American landscape represents the historical legacy of one worldview superimposed on another, the colonial overlaying the indigenous. Nowhere is this history more apparent than in the attitudes toward fire, attitudes made manifest on the landscape.

Euro-Americans arrived in North America bearing their folk knowledge that held fire in forests to be destructive and hazardous to humans (Arno 1985; Lewis 1982). This view contrasted sharply with the traditional knowledge of the indigenous inhabitants, who embraced the benefits of burning and were skilled in application of fire technology.

Fire suppression began soon after colonization, and its effects followed the expansion of the frontier westward. Anthropogenic fire all but disappeared from eastern forests by the early 1700s and from the West by 1899 (Arno 1985). The consequences of suppression are written on the landscape today, creating what former Secretary of Interior Bruce Babbitt (1997) called "a crisis in forest health." Fire suppression was a "catastrophic disturbance for those ecosystems which had been influenced by anthropogenic fire throughout their development" (Packard 1993).

The results of fire suppression have been well documented for ecosystems throughout North America (e.g., Botkin 1990; Wilson 1992; Pyne 1995; Williams 2000a). Parklands were replaced by dense forests (Biswell 1989; Lewis 1993), prairies and savannas disappeared (Lewis 1993), and re-

generation patterns were dramatically altered. Fire suppression has promoted stand homogeneity and the associated problems of insects and disease, disrupting the age-class mosaic that was historically maintained by burning (Barrett 2000).

The loss of fire in the American landscape is inextricably linked with the history of federal Indian policy that removed tribal people and, therefore, indigenous land management. In the words of Williams (2000a),

> The basis for much of our forest health crisis nationwide lies in the almost complete cessation of burning by Indians in fire-adapted ecosystems. The crisis is commonly attributed to the advent of systematic fire suppression and the Smokey Bear mentality of the 20th century. To fully come to grips with our forest health crisis today, we must go back to much earlier land management decisions that ended thousands of years of Indian interactions with the land, especially through the use of fire.

Policymakers are struggling with the outcome of that history and trying to develop new management policy to restore forest health and biodiversity. The policy pendulum has now swung back from fire suppression to recognition that fire regimes are an important part of ecosystem health. However, the role of humans in a "natural" fire regime continues to be debated (Kilgore 1985).

National forest policy now calls for managers to recreate forests of the presettlement type. Babbitt (1997) proposed that fire be reintroduced for restoration of ecosystem health and productivity. If we are to manage forests with the intent of restoration of the presettlement condition, then it is imperative that we understand the role of indigenous practices in shaping the landscape (Kimmerer 2000).

Every ecosystem in North America has been affected in some way by a fire regime (Pyne 1982; Gruell 1985; Williams 2000a) manipulated by indigenous people. Much forest science, including ecological classifications of vegetation types, arose from observation of forests that were essentially in transition from conditions of indigenous fire management to post-colonial fire suppression. Our understanding of forest processes may thus be based on an anomalous, transitional landscape (Phillips 1985). "Humans have been a part of the ecosystem over the past ten centuries of major climatic change, so that all forests have developed under some kind of human influence. This influence must be accounted for as an important part of any study of forest structure and dynamics" (Russell 1997). Further, Anderson (1997) suggests that

> a full understanding of wild plant production will be achieved only through the development of a better rapprochement between the social, historical and biological sciences. It would require the sustained and cooperative efforts of scholars using both human- and land-centered avenues of research.

Extent of Indigenous Burning

In contrast to the romanticized view of native peoples living with minimal impact on unspoiled nature (Botkin 1990; Martinez 1998), the presettlement landscape was strongly influenced by indigenous land management to enhance productivity (Botkin 1992; Wilson 1992; Blackburn and Anderson 1993; Pyne 1995). The most powerful tool for landscape manipulation was fire. Fire was used by indigenous people throughout North America (Kilgore 1985; Williams 2000a), and its presence or absence strongly shaped the presettlement vegetation. For example, evidence suggests that the dominance of oak and chestnut in Appalachian forests was enhanced by vigorous resprouting after indigenous burning (Abrams 1986, 1992; Delcourt and Delcourt 1997). The extent of tallgrass prairie of the Midwest is thought to be largely a result of Indian fires (e.g., Axelrod 1985).

Western forests, often thought to be shaped primarily by wildfire, may be more the product of indigenous burning than previously thought. For example, the distribution and historical dominance of sugar pine cannot be explained by frequency of "natural" lightning ignition alone. Cultural data provide evidence that sugar pine stands were managed by tribal groups who took "ownership" of individual stands and applied fire to reduce encroachment by competing species (Schenk and Gifford 1952). Dated fire scars on sugar pine offer the best evidence of heightened aboriginal fire frequency in the Sierra Nevada (Lewis 1993), which altered the distribution and abundance of numerous species.

So ubiquitous was Indian burning that its absence also shaped forest composition. The coastal forests of the Pacific Northwest have a very low incidence of lightning fire. Williams (2000a) notes that coastal redwood forests were little affected by burning, although small clearings were made. He argues that fire was less prominent among peoples who relied primarily on marine resources for food and materials. However, a few miles inland even the coastal redwoods contained patches of prairie "too numerous to mention" which

> if left to themselves would doubtless soon have produced forest, but the Indians were accustomed to burn them annually so as to gather seeds. These prairies were of incalculable value to the Indians, not alone for their vegetable products, but for the game found upon them (Loud [1918] quoted in Lewis 1993).

Resource-rich patches in the old-growth coastal forests were created by indigenous manipulation of the fire return interval.

Goals of Indigenous Burning

Fires were intentionally ignited to fulfill a wide variety of purposes, from clearing village sites (Brown 2000) to long-distance signaling. Lewis (1993) documents more than 70 uses of fire, including treefelling, clearing travel corridors, fireproofing settlements, and hunting. Burning also was used to reduce pest populations, including rodents and biting insects, as well as for collecting edible insects such as Pandora moths and grasshoppers. Burning

in oak woodlands reduced the population levels of acorn weevils and yielded a more abundant acorn crop, which was easier to harvest after burning (McCarthy 1993). Riparian areas commonly were burned to attract game animals to the new grass and tree sprouts (Williams 2000a). Fire still is widely used in management of basketry plants, to provide a consistent crop of straight, slender shoots and roots (Ortiz 1993). From crop management to range management, fire was a ubiquitous tool.

Indigenous people used fire to modify the environment for their own survival. The most important outcome of fire use was the intentional creation of a mosaic of habitat patches that promoted food security by ensuring a diverse and productive landscape (Lewis 1985; Williams 2000a). Producing such a mosaic promoted stability in the food supply by creating multiple resource patches. Maintaining a diversity of habitats buffers the impact of natural fluctuation in a single food species and increases overall productivity. For example, fire was used to create prairies which would attract elk, deer, and other game. Indigenous people skillfully modified the fire regime to create a range of forest openings in many different stages of postfire succession, which enhanced the diversity and yield of game, berries, root crops, edible seeds, and medicinal plants. In contrast, fire was often used by the colonists with a different intent—uniformity, such as production of pastures, cropland, and plantations (Williams 2000a).

Philosophy

The policy of fire suppression in Western society arises from the myth that nature can be controlled. Ironically, trying to control nature through fire suppression has led to greater unpredictability. The indigenous worldview emphasizes the dual nature, creative and destructive, of all forces. Fire can be a force for good as it warms homes and stimulates grasses, but it can also be immensely destructive. The role of humans is not to control nature, but to maintain a balance between these opposing forces.

This balance is based on recognition of reciprocal relationships between human and nonhuman members of the ecological community. As coequals, humans are dependent on nonhumans, and the reverse is also true (Pierotti and Wildcat 2000). Human application of fire is part of that interdependence. The ethic of reciprocal responsibility underlies the indigenous use of fire, an adaptive symbiosis in which humans and nonhumans both benefit from burning. For example, indigenous people of the Northwest routinely burned grasslands and savannas to increase the yield of root crops, such as camas and other geophytes. The people realized a direct benefit from burning, and so did the plants, as the fire frequency and extent produced expansion in the patch size and population density of the geophyte species (Anderson 1997).

Meeting the responsibility for reciprocity among members of the ecosystem is understood to be simultaneously pragmatic and spiritual. Application of fire is viewed by many indigenous groups as a spiritual responsibility to the land, a tool that was given to people to fulfill the caregiving responsibilities for the land (Martinez 1998) and to promote world renewal (Krober and Gifford 1949). The Karuk people of northern California burn ritually in New Year ceremonies. Silas Whitman of the Nez Perce tribe states, "We burn because it is good for the land; fire brings more life." For example, the prairies of Walpole Island First Nation have been ritually burned since time immemorial by the Potawatomi, Ojibwe, and Ottawa peoples who accept this as their responsibility and name themselves the "keepers of the fire." The prairies of Walpole Island are renowned among ecologists for their species richness, which far exceeds the diversity where the indigenous fire regime has been interrupted.

Evidence

Sophisticated application of fire technology has been a major component of indigenous land management for millennia. The landscape encountered by colonists was largely shaped by indigenous burning, yet until recently, few people acknowledged that Indian fire use had an impact on the land (Pyne 1995; Williams 2000a). A forestry textbook published as recently as 1973 portrayed the view that "no habitual or systematic burning was carried out by the Indians" (Williams 2000a). This marginalization of traditional knowledge arose partly out of ignorance and prejudice, but also because of the fragmentary nature of the evidence (Williams 2000a). Accounts of aboriginal burning are found in notes, journals, and the oral tradition. These are qualitative, anecdotal sources that are not readily accepted by Western scientists whose training is usually limited to interpretation of quantitative data. Much traditional knowledge has been lost to time and forced assimilation, but much persists in the oral tradition and practices of contemporary native communities, who are only rarely consulted as equal partners in land management.

The correspondence between traditional ecological knowledge of fire response and later scientific evidence is very strong. Examination of traditional knowledge offers an opportunity for crosscultural verification of scientific hypotheses concerning fire management. There is an increasing body of evidence noted by Brown (2000) that validates the oral tradition, through data collected from historical documents, dendrochronology, charcoal profiles, archeological evidence, and statistical analysis of land survey records. Paleoecological data also support interpretation of widespread Indian burning and its effects on vegetation composition (e.g., Clark and Royall 1996; Delcourt and Delcourt 1997). However, it must be acknowledged that there are many pitfalls in the interpretation of such indirect evidence (Williams 2000a). The widespread significance of indigenous burning is by no means universally accepted. Kilgore (1985) summarizes the arguments critical of the importance of aboriginal burning, which focus primarily on issues of scale.

The main impediment to scientific acceptance of the wide impact of aboriginal burning arises from a lack of understanding of the cultural context in which it took place. For many peoples, manipulation of the landscape through

skillful application of fire was critical to cultural survival, and enhanced food productivity made agriculture unnecessary (Biswell 1989).The material culture of many tribal peoples simply could not have been sustained without extensive use of fire (Blackburn and Anderson 1993). In terms of energy efficiency, fire was the most potent land management tool available to indigenous people. Millennia of experimentation and detailed empirical observations led to a sophisticated application of fire technology. Coupled with a worldview that emphasizes the role of humans as active participants in nature, fire was integral to many cultures.

The Practice

A careful examination of the philosophy and practice of Indian burning reveals that it differs from a nonanthropogenic fire regime (i.e., wildfire) in five important respects: seasonality, frequency, extent, site, and outcome (Williams 2000a).

Seasonality of burning varied with the tribe and the ecosystem in question, but in general fire was applied at a carefully considered time that would minimize its destructive nature while harnessing its creative power. Numerous studies confirm that the timing of indigenous burns differs significantly from the seasonality of natural lightning ignitions (Barrett 1980; Barrett and Arno 1982; Lewis 1982; Arno 1985; Brown 2000; Williams 2000a). Lightning fires are most abundant in the late summer, but indigenous fires were set in seasons less conducive to wildfire. For example, in the boreal forests of northern Alberta, fire was applied in the early spring when the grass was dry but the soil was still moist and the surrounding forests were too wet to carry a fire. The small-scale, low-intensity burns created openings in the forest where regrowth was accelerated on the newly blackened earth, extending the growing season in this harsh environment by several weeks and attracting abundant game (Lewis 1982).

The season of burning also depended on the desired outcome. For example, people in the Southwest would burn the chaparral in the fall to increase forage for deer. The lower temperatures and increased soil moisture favored vigorous resprouting, which was beneficial in attracting deer in the winter. In contrast, if the intent was to clear land for tobacco cultivation, the chaparral was ignited in the spring, when a hotter burn would discourage resprouting and prepare a suitable seedbed. In the Great Plains, Indians rotated the seasonality of burning as a tool to influence seasonal movement of bison, in synchrony with their own semi-nomadic movements. In the mosaic of tallgrass prairie and aspen parkland, the prairie was burned in the fall, forcing bison into the parklands that the people inhabited during the winter. In spring, the parklands were burned, which stimulated movement of the bison out onto the open prairies (Lewis 1982). This sophisticated application of fire required extensive knowledge of the vegetation response, the life history of herbivores, and their interactions with predators.

Williams (2000a) reports an exception to the general pattern of burning in the spring or fall, when fire intensity would be reduced. In northern California and in the Willamette Valley of Oregon, Kalapuya people burned the grasslands in the summer, when fire might be expected to be more intense and potentially destructive. This unusual midsummer burn created a second flush of growth in the fall when the rains returned, a dual cropping system that maintained local herbivore populations. However, the intensity of the summer burns was quite low because of their high frequency, which reduced fuel accumulation. Appropriate season of burn was thus understood in interaction with fire frequency.

Frequency. Most wildfires are started by lightning strikes; however, scholars of aboriginal fire agree that anthropogenic fire far exceeded the frequency of natural lightning strikes. "Lightning in fire-adapted ecosystems does not usually cause fires. Lightning tends to strike … high rocky points, individual trees, or other places where no ignition occurs. Most snag fires are soon extinguished by the rain that usually accompanies lightning" (Williams 2000b). Indigenous people enhanced fire frequency not only with more ignitions but in creating fuel piles so that areas would burn that ordinarily might not carry a fire. Several studies of fire return intervals (Barrett 1980; Blackburn and Anderson 1993; Brown 2000; Williams 2000b) indicate that fire scars are much more abundant in areas of Indian habitation than in comparable regions not managed by indigenous people.

Ironically, trying to control nature through fire suppression has led to greater unpredictability.

The frequency of fire application generally was based on the management goal. Land was burned annually if the intent was to increase game by providing new grass forage. Berry patches were maintained by burning on a cycle of three to five years, depending on the ecology of the target species. A 10- to 12-year fire interval was typically observed around beaver ponds to maximize regeneration of aspen and willows to feed beaver (Lewis 1982; Williams 2000a). The result of altered fire frequency was to create a mosaic of successional patches, varying in species composition and age structure, which ensured a diversity of plant foods, medicines, game, and materials for the subsistence of the people.

Extent. Aboriginal burning also differs from wildfire in its extent. Most burns were of a modest scale, designed to maintain small successional patches. Large-scale burns could be viewed as maladaptive, disrupting the diverse mosaic, disrupting ecotones, and decreasing productivity and stability of the food supply (Lewis 1993). Extent of fires was controlled by careful timing, increased fire frequency and reduced fuel load, and the use of natural fire breaks. The mosaic of patches differing in successional age and flammability would itself limit the extent of fires.

Without doubt, fire control was not uniformly effective, just as we experience today, and some fires escaped, with unintended consequences. One notable exception to the general pattern of small-scale burning is the huge conflagrations traditionally set by peoples of the northern Great Plains. Prairie fires would extend for miles and were used to influence the distribution of buffalo. This large scale of burning reflects the very different ways of Plains peoples, whose food security arose not from a mosaic of diverse patches in a local area, but from maximizing productivity of a single species, the buffalo. A broad range of effects is seen, depending on the resource needs of the people and the flammability of their landscape.

Site. Indian fires also differ from lightning-ignited wildfires in the sites at which they occur. For example, riparian areas that might not burn without assistance were regularly ignited to improve waterfowl habitat and encourage growth of basketry materials and certain medicines. Locations of fires might reflect annual migrations along the elevational gradient, which enabled people to take advantage of seasonally available foods. By understanding differential burning conditions, Indians were able to restrict fires to certain areas, matching the fire regime to the ecological conditions and life history of the target species and thus enhancing productivity.

Application to Current Goals

Aboriginal use of fire to create and maintain a landscape mosaic is an ancient practice that can be a key to meeting contemporary land-use goals. Fire was used as a pragmatic tool to meet the goals of indigenous practitioners, to increase the yield and diversity of subsistence foods. These practical goals were also coupled to a spiritual responsibility to carefully use fire to multiply life. The "natural" fire regime was manipulated to produce a richly diverse mosaic of vegetation types differing in successional age and species composition.

The intent of contemporary forest management is no longer to support the subsistence economy of human beings but to enhance ecosystem health, productivity, and biodiversity. It is in this capacity that indigenous knowledge of fire is an invaluable resource for forest managers. The same indigenous strategy that was used to increase biodiversity and productivity for subsistence can also be used to enhance and maintain biodiversity for goals of ecosystem health.

For example, indigenous Kalapuya people of Oregon's Willamette Valley routinely burned savannas and meadows to increase the yield of food plants such as camas and tarweed (Williams 2000b). Other postfire species increased as well, among them the Kincaids Lupine, a legume that is vital to the life cycle of the Fenders blue butterfly (Schulz and Crone 1998). At least 24 species of butterflies once inhabited these meadows; since cessation of indigenous burning, seven have become extinct and six, including the Fenders blue, are listed as endangered species (Schulz and Crone 1998). Restoration of the indigenous fire regime and the mosaic it created can have significant impacts on biodiversity.

Restoration of indigenous-style burning is not a panacea for problems of fuel accumulation and structural changes that have accompanied a century of fire suppression, but it should be part of the strategy for restoration of forest health. Pyne (1995) states that

> to restore natural conditions without the Indians and the things they did, including burning, is to construct an artificial landscape that is historically and ecologically incomplete. The reason for reinstating fire is not to try and restore pre-Columbian vistas, but because we cannot sustain the landscape we value without it.

The suppression of traditional caregiving practices has contributed to the current state of forest health; resumption of human responsibility for fire can be part of the solution. Indigenous practice and philosophy offer us an alternative view of the "natural" fire regime, in which humans regain their role as "keepers of the fire" and the symbiotic relationship between humans, forests, and fire is reestablished for mutual benefit.

Abstract. Structural heterogeneity in forests of the Sierra Nevada was historically produced through variation in fire regimes and local environmental factors. The amount of heterogeneity that prescription burning can achieve might now be more limited owing to high fuel loads and increased fuel continuity. Topography, woody fuel loading, and vegetative composition were quantified in plots within replicated early and late season burn units. Two indices of fire severity were evaluated in the same plots after the burns. Scorch height ranged from 2.8 to 25.4 m in early season plots and 3.1 to 38.5 m in late season plots, whereas percentage of ground surface burned ranged from 24 to 96% in early season plots and from 47 to 100% in late season plots. Scorch height was greatest in areas with steeper slopes, higher basal area of live trees, high percentage of basal area composed of pine, and more small woody fuel. Percentage of area burned was greatest in areas with less bare ground and rock cover (more fuel continuity), steeper slopes, and units burned in the fall (lower fuel moisture). Thus topographic and biotic factors still contribute to the abundant heterogeneity in fire severity with prescribed burning, even under the current high fuel loading conditions. Burning areas with high fuel loads in early season when fuels are moister may lead to patterns of heterogeneity in fire effects that more closely approximate the expected patchiness of historical fires.

Additional keywords: fire ecology; landscape heterogeneity; prescribed fire; season of burning.

Introduction

Prior to European settlement and modern-day fire exclusion, vegetation in the mixed-conifer zone of the Sierra Nevada was likely a complex mosaic of early and late successional stages, ranging from montane chaparral to old-growth forest (Bonnicksen and Stone 1982; Chang 1996; Russell *et al*. 1998; Nagle and Taylor 2005). Patch size was typically very small, ranging from a fraction of a hectare to several hectares (Franklin and Fites-Kaufmann 1996). This within-stand heterogeneity is believed to have been produced by and maintained through spatial and temporal variation in fire regime (including severity, frequency, and size), as well as local environmental and topographic variability (Kilgore 1973; Agee 1993; Chang 1996; Skinner and Chang 1996; Taylor and Skinner 1998; Beaty and Taylor 2001).

Spatial heterogeneity is a vital component of forests, promoting a greater diversity of flora (Martin and Sapsis 1992; Halpern and Spies 1995) and fauna (Chang 1996). Gaps within the forest canopy allow shade-intolerant species such as ponderosa pine (*Pinus ponderosa* Laws.) and giant sequoia (*Sequoiadendron giganteum* [Lindley] Bucholtz) to become established (Harvey *et al*. 1980). Survival and rate of growth of newly germinating tree seedlings is often especially pronounced in areas that burn with the greatest intensity (Harvey and Shellhammer 1991; Stephenson *et al*. 1991; Stephenson 1994). However, fires cannot be uniformly intense over large spatial scales, or the ability of the forest to regenerate would be reduced. The matrix of mature forest surrounding gaps is vital for recruitment, because the majority of seeds are typically dispersed in relatively close proximity to the parent trees (Nathan *et al*. 2000). Once seedlings become established, growing in gaps may allow these young trees to escape mortality from subsequent fires. Deposition of litter and woody surface fuels is reduced in gaps due to lack of an overstory fuel source. By the time trees are large enough to produce enough ground fuel to carry fire, they are also more likely to be large enough to survive fire (Cooper 1960, 1961; Kilgore 1973; Keeley and Stephenson 2000).

Dramatic changes to forest structure and pattern have occurred in the Sierra Nevada mixed-conifer forest as a result of reduced fire frequency. In areas without a history of logging, the amount of forested area occupied by younger, early successional patches has declined and the amount of forested area occupied by dense intermediate-aged patches has increased (Bonnicksen and Stone 1982). Shade-tolerant tree species such as firs (*Abies* sp.) and incense cedar (*Calocedrus decurrens* [Torrey] Florin) have become more abundant at the expense of shade-intolerant species such as ponderosa pine and black oak (*Quercus kelloggii* Newb.), and the overall tree density is higher (Kilgore 1973; Vankat and Major 1978; Parsons and DeBenedetti 1979; Ansley and Battles 1998). In the absence of fire, forests may have become more structurally homogeneous (Bonnicksen and Stone 1980; Skinner 1995; Chappell and Agee 1996; Taylor 2000).

Another impact of the reduction in fire frequency in the mixed-conifer zone of the Sierra Nevada has been a substantial accumulation of surface fuels (Biswell *et al*. 1968; van Wagtendonk 1985) and greater fuel continuity (Miller and Urban 2000), both of which can increase the probability of large, high-intensity wildfires (van Wagtendonk 1985; Stephens 1998). Historically, frequent fires are believed to have resulted in low fuel loads and a patchy pattern of fire spread (Swetnam 1993). These fires burned predominantly at low-to-moderate intensity with patchy high intensity (Kilgore 1973; Stephenson *et al*. 1991; Stephenson 1999). Most overstory canopy trees survived in areas with lower-intensity fire, but groups of canopy trees were killed locally within a matrix of surviving trees in the higher-intensity areas (Stephenson 1999). This variability in fire behavior helped to maintain a patchy mosaic of vegetation and fuels. The size of high-severity patches produced when fire is reintroduced to the landscape may now be greater than it was historically (Keeley and Stephenson 2000).

The best means of reducing fuels and restoring a forest structure similar to the historical conditions is a source of debate (Bonnicksen and Stone 1985; Parsons *et al*. 1986; Stephenson 1999; Weatherspoon 2000). Bonnicksen and Stone (1985) have argued that prescription burning under the current fuel conditions could result in a more uniformly intense fire that is less likely to restore the desired landscape mosaic. This argument assumes that fuel loading and fuel continuity are the primary drivers of variability in fire severity in these forests and that both have become more homogeneous with fire exclusion. If other factors such as vegetation pattern, weather, topography, and ignition pattern also play an important role in generating variability in fire effects, prescribed fire alone may produce considerable forest heterogeneity, even under the current fuel conditions. Our understanding of patterns of landscape heterogeneity produced by prescribed fire and how this heterogeneity is affected by season of burning remains incomplete.

In the pre-Euro American Sierra Nevada, much of the area that burned did so during the dry late summer to early fall period (Caprio and Swetnam 1995). Most prescribed burning in Sequoia and Kings Canyon National Parks has, up to now, been done during the latter part of this same time period. However, because of poor air quality in the adjacent Central Valley, burning opportunities at this time of year are increasingly limited. As a result, only a fraction of the area necessary to maintain historical fire return intervals typically gets burned. Atmospheric conditions conducive to smoke dispersal are often more common during the spring to early summer period and expanding the burn window to include prescribed fire at this time of year allows more of the landscape to be treated.

Fuel moisture levels are typically higher in the spring and early summer than later in the season, which can strongly influence fire behavior and effects. Both the amount of heat generated and spread of fires is reduced at higher fuel moisture levels, owing to the energy required to vaporize water (DeBano *et al*. 1998; Nelson 2001). Computer models have shown fuel connectivity to be less at high fuel moisture levels (Miller and Urban 2000), and the depth of the forest floor fuel layer must be greater in order for combustion to propagate in moist duff (Miyanishi and Johnson 2002). Thus, early season burns in these mixed-conifer forests often consume less of the available fuel (Kauffman and Martin 1989; Knapp *et al*. 2005) and produce a patchier and less complete burn pattern (Knapp *et al*. 2005).

The purpose of the present study was to describe within-stand heterogeneity in fire severity resulting from early season and late season prescribed fire treatments, and to identify the relative importance of different topographic and biotic variables associated with this heterogeneity. Two components of fire severity were investigated: (1) scorch height; and (2) the percentage of the burnable ground surface that did burn.

Materials and methods

Study site description

Three early and three late season prescribed burn units were established, along with three control units, in an old-growth mixed-conifer forest within the watershed of the Marble Fork of the Kaweah River in Sequoia National Park. Each unit was 15–20 ha in size with irregular boundaries established along topographic features in accordance with National Park Service fire management concerns. The three control units were installed as part of another study and only the six burn units were used for the research reported in this paper. A map of the burn and control units is shown in Knapp *et al*. (2005).

Elevation in the study area ranged from 1900 to 2150 m above sea level and aspect was generally NW, although there was substantial micro-topographic variation. Tree species, in order of abundance, were white fir (*Abies concolor* [Gordon & Glend.] Lindley), sugar pine (*Pinus lambertiana*

Douglas), incense cedar, Shasta red fir (*A. magnifica* var. *shastensis* Lemmon), Jeffrey pine (*P. jeffreyi* Grev. & Balf.), ponderosa pine, mountain dogwood (*Cornus nuttallii* Audubon), and California black oak. The historical fire return interval in the study area was 27.4 years, but much of the study area had not burned since 1879 (A. C. Caprio and E. E. Knapp, unpublished data).

Pretreatment data collection

Ten 50 × 20 m (0.1 ha) plots were established within each of the six burn units (two treatments [early and late season burns] × three replicates [units] × 10 plots/unit = 60 plots total), in reference to a system of 36 permanent points on a 50-m grid. Plots were assigned randomly to 10 grid points and the direction of the plot was also random (one of four cardinal directions [0°, 90°, 180°, 270°]). Within each plot, diameter at breast height (dbh) was measured for all trees (dbh > 10 cm), and species and status (alive or dead) noted. Cover of herbaceous species, bare ground, and rock within the 0.1-ha plots was estimated by averaging the visual scores for twenty 1 × 1 m subplots systematically located within each plot. Cover was scored on the following scale: 1 = 0–1%; 2 = 2–10%; 3 = 11–25%; 4 = 26–50%; 5 = 51–75%; 6 = 76–100%. Cover scores were later converted back to a percentage, using the mean of each cover class range. Total herbaceous species cover was the sum of the cover of individual species.

Loading of woody fuels was estimated retrospectively using digital photographs taken of each plot from the midpoint of each 20-m side prior to the prescribed burns. Both small woody fuels (roughly including 1 h [<0.6 cm diameter], 10 h [0.6–2.54 cm diameter], and 100 h fuels [2.54–7.6 cm diameter]) and large woody fuels (1000 h [>7.6 cm diameter]) were visually scored (scale = 1–5, with 5 being the greatest amount of fuel) in all plots by seven different observers, and scores averaged. For an approximation of the actual fuel mass, the lowest small woody fuel score was similar to photo 1-PP-4 in a photo series depicting fuel loadings with different tree composition and size classes in the northern Sierra Nevada and southern Cascades (Blonski and Schramel 1981), whereas the highest small woody fuel score was similar to photo 2-MF-4. The large woody fuel scores approximated fuel mass values associated with photos 1-MF-4 to 5-MF-4 in the same photo series. Loading of litter and duff fuels could not be estimated from photographs, but both should be highly correlated with the basal area of trees within the plot.

Slope and aspect of each plot were calculated by overlaying the spatial coordinates of the nearest gridpoints with a 10-m-resolution digital elevation model in a geographic information system (GIS). Slope and aspect enabled an index of the potential total yearly heat load for each plot to be estimated, using equation 3 of McCune and Keon (2002). Potential total yearly heat load is proportional to the amount of direct incident solar radiation intercepted by a given aspect and slope, corrected for the fact that aspects with afternoon sun will have higher maximum temperatures than aspects with morning sun. Heating as a result of solar radiation will influence the amount of moisture contained within fuels (Byram and Jemison 1943), and variability in the potential heat load within the burn units may therefore be predictive of variability in fuel moisture at the same scale.

Prescribed burns

Early season burns were conducted on 20 and 27 June 2002, and late season burns were conducted on 28 September, 17 October, and 28 October 2001. Whereas the early season burns occurred approximately 6 weeks following the end of snow melt, the late season burns were preceded by over 4 months of mainly dry summer and early fall weather. Weather conditions and fuel moisture levels were very similar for burns within the same burning season treatment. One estimate of fuel moisture was made per unit immediately prior to ignition. Fuels were sampled widely outside of the plots in order to limit influence on fire behavior and effects resulting from disturbance of the fuel bed within the plots. Fuel moisture was significantly higher for the early season than the late season burns (Knapp *et al*. 2005). Average temperature, relative humidity, and maximum wind speed during the ignition period were 20°C, 52%, and 3 km h^{-1}, respectively, for the early season burns, and 15°C, 44%, and 3 km h^{-1}, respectively, for the late season burns. Using drip torches, strip head fires spaced ~10–15 m apart were ignited progressively from higher to lower elevations. With the exception of occasional single small trees that torched, fire was predominantly on the surface. Flame lengths were generally less than 1 m, except in areas with an abundance of large downed logs.

Post-treatment data collection

Scorch height, defined as the maximum height of complete needle kill, was measured on all trees within plots 2–9 months post burn, using a laser rangefinder. Scorch height often varied on different sides of a tree and was therefore measured at both the point of maximum height above ground and on the side of the tree opposite of where the maximum scorch height occurred. The two values were then averaged. Scorch height was not determined for trees that were completely scorched or trees with a base of live crown located above the scorching level. Percentage of the ground surface containing fuel that burned (hereafter referred to as 'percentage of area burned' for ease of explanation) was quantified for each plot as the average of visual scores within twenty 1 × 1 m subplots systematically located in each plot, to the nearest 10%. We felt that this was more accurate than making one visual estimate of percentage of area burned for the entire plot, because whether or not an area burned could often be determined only by close observation. Rocks were not considered in the visual estimates and the percentage of bare ground prior to the burns was subtracted from the field values; the percentage

of area burned variable was therefore the percentage of the area burned that contained fuel and potentially could have burned.

Percentage of area burned was evaluated during the first full growing season following completion of the prescribed burn in that unit. This was the earliest time at which the late season units could be entered owing to snow cover (snow began falling within days after completion of the burns). The early season burn units were evaluated the same way for consistency. More measurement error is likely associated with the early season than the late season percentage area burned estimates, owing to a heavy rainstorm in November 2002, which caused some soil erosion and made the boundaries between burned and unburned patches more difficult to distinguish.

Data analysis

Frequency histograms for scorch height and percentage of area burned were constructed to demonstrate the variation among plots in these two variables. Significance of differences between treatments was determined with one-way analyses of variance. Levene's test was performed on the residuals to determine if differences in the amount of among-plot variability existed. The Kolmogorov–Smirnoff goodness-of-fit test was used to evaluate the significance of differences in frequency histograms between treatments.

Mixed model analyses of variance (PROC MIXED; SAS Institute, Cary, NC, USA) were used to investigate factors most closely associated with scorch height and percentage of area burned. Slope, potential annual heat load, small woody fuel score, large woody fuel score, tree basal area, percentage of tree basal area composed of pine, herbaceous species cover, and bare ground or rock cover were fixed effects, whereas burn unit was random.

Slope affects flame length and rate of spread. Other variables that influence fire behavior directly, such as fuel moisture, fuel loading, and fuel bulk density, are more difficult to obtain accurate estimates of at the plot scale, but differences in these variables may have been captured by variables that were easier to measure. For example, potential heat load may be predictive of fuel moisture, because fuel moisture is expected to be lowest on SW-facing aspects and slopes perpendicular to the sun angle, where heat load is the greatest. Basal area of trees does not influence fire behavior directly because live trees in this system typically do not act as fuel, but basal area may be correlated with among-plot differences in fuel moisture, owing to the influence of shading by the canopy. Basal area also indirectly influences how much litter, duff, and small woody fuel is potentially deposited on the forest floor – the greater the tree volume, the more litter, duff, and small woody fuel production is expected. The percentage of basal area composed of pine may be an indicator of litter flammability because the lower bulk density of pine litter causes it to burn more readily than fir and other short-needled litter (Agee *et al*. 1978; van Wagtendonk *et al*. 1998). In addition, lower bulk density litter dries faster to the point where combustion is possible (Stephens 2001). The herbaceous species cover variable was possibly a predictor of fine-scale soil and fuel moisture differences because the presence of understory vegetation was generally highest in moister microsites. Most abundant herb species included bracken fern (*Pteridium aquilinum* [L.] Kuhn var. *pubescens* L. Underw.), hawkweed *Hieracium albiflorum* Hook., and violet draperia (*Draperia systyla* [A. Gray] Torrey), which in total comprised 56% of the herbaceous cover (E. E. Knapp, D. W. Schwilk, J. M. Kane and J. E. Keeley, unpublished data). The amount of bare ground and rock was a predictor of how much area lacked fuel and potentially provided quantification of the degree of fuel continuity.

The scorch height variable approximated a normal distribution and did not require transformation. The percentage of area burned variable was arcsine square root transformed prior to analysis to improve normality.

Results

Scorch height

Scorch height did not differ between burn season treatments (early = 11.1 m; late = 13.5 m; $F = 1.41$, $P = 0.240$), but was highly variable among plots, ranging from 2.8 to 25.4 m in the early season burns, and from 3.1 to 38.5 m in the late season burns (Table 1, Fig. 1). Analysis of variance conducted on the absolute value of the residuals (Levene's test) indicated that the amount of variability in scorch height generated by the burns also did not differ between the burn season treatments ($P = 0.181$). In addition, the scorch height frequency distributions for the two seasons (Fig. 1) were very similar (Kolmogorov–Smirnov test, $P = 0.995$).

Factors associated with variation in scorch height

When analyzed together in a mixed-model ANOVA, the variables most strongly associated with scorch height were slope, tree basal area, percentage of basal area composed of pine, and small woody fuel score, in order of significance (Table 2). Scorch height was greatest in plots on steeper slopes, plots containing more tree basal area, plots with a higher percentage of pine relative to short-needled species such as fir and incense cedar, and plots with abundant small woody fuel. The burn season variable approached significance ($P = 0.134$).

The large number of main effects made it impossible to analyze all possible two-way interactions without sacrificing most of the statistical power of the model. Therefore analysis of interactions was conducted in an exploratory manner, including only the two-way interactions among the four significant ($P < 0.05$) main effects in a separate mixed-model ANOVA. Of these, only slope × percentage of basal area composed of pine was significant ($P = 0.043$). When the non-significant interactions were removed, and the model

Table 1. Means and ranges for independent and dependent variables measured within early season and late season burn treatment units

Variable	Early season burn		Late season burn	
	Average	Range	Average	Range
Slope (degrees)	16.5	9.0–29.5	18.7	10.6–31.8
Heat load index[A]	0.99	0.84–1.07	0.93	0.71–1.07
Small woody fuel score (scale = 1 to 5)	3.09	1.79–4.38	2.75	1.31–4.19
Large woody fuel score (scale = 1 to 5)	2.24	1.10–3.79	2.14	1.24–4.57
Basal area (m^2/ha)	69.5	25.6–117.9	67.8	31.3–115.2
Pine basal area (%)	26.0	0–73.1	25.7	0–80.2
Herbaceous cover (%)	7.7	0–24.4	17.4	1.6–51.8
Bare ground/rock cover (%)	6.7	0–43.9	5.1	0–21.9
Scorch height (m)	11.1	2.8–25.4	13.5	3.1–38.5
Plot area burned (%)	70	15–96	88	48–100

[A]Calculated using formula #3 of McCune and Keon (2002).

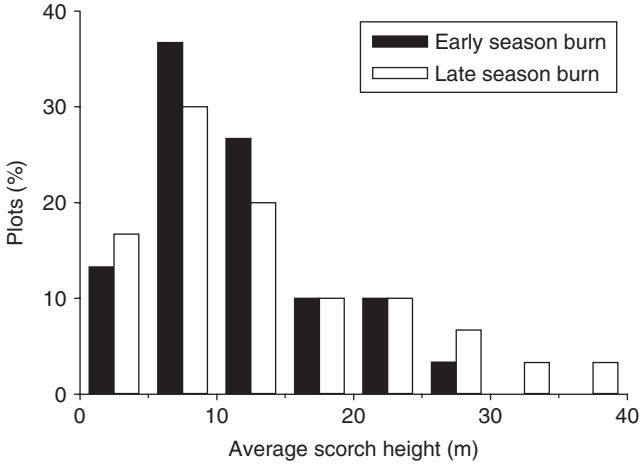

Fig. 1. Percentage of plots within different average scorch height (m) categories in both early season ($n = 30$) and late season ($n = 30$) prescribed burning treatments.

Table 2. Significance of fixed effects in a mixed-model analysis of variance of average scorch height for prescribed burns conducted in early and late season

The random effect (unit) was not significant ($P = 0.351$). Denominator degrees of freedom (d.d.f.) are based on Satterthwaite's approximation. n.d.f., numerator degrees of freedom

Fixed effect	n.d.f.	d.d.f.	*F*	*P*
Burn season	1	3.23	3.96	0.134
Slope	1	22	10.79	0.003
Head load	1	16.2	1.21	0.287
Small woody fuel score	1	48.5	4.82	0.033
Large woody fuel score	1	49	0.55	0.460
Basal area	1	46.8	7.82	0.008
Pine basal area (% of total)	1	47.8	7.16	0.010
Canopy closure	1	48.1	0.50	0.484
Herbaceous cover	1	20.4	0.28	0.606
Bare ground and rock cover	1	45.6	1.37	0.248

containing all main effects and the one significant interaction was run again, explanatory power, as expressed by Aikake's Information Criterion (AIC), was reduced relative to the model containing only the main effects. The mixed-model ANOVA including the slope × percentage of basal area composed of pine interaction is therefore not shown.

Percentage of area burned

The percentage of area burned varied substantially among plots, ranging from 15 to 96% in the early season burn units and from 47 to 100% in the late season burn units (Table 1, Fig. 2). Overall, significantly less area burned in the early season than in the late season (early season mean = 70%; late season mean = 88%; $F = 24.66$, $P < 0.001$). (The actual total plot area that burned was somewhat less because an average of 6% of the study area contained bare ground and rock prior to the burns, and this was factored out of the percentage of area burned estimates.) Variance in the percentage of area burned tended to be greater in the early season than the late season (Levine's test, $P = 0.080$). The difference in frequency distribution of percentage of area burned between seasons was strongly significant (Kolmogorov–Smirnov test, $P < 0.001$) (Fig. 2).

Factors associated with variation in percentage of area burned

When analyzed together in a mixed-model ANOVA, the variables most strongly associated with percentage of area burned were cover of bare ground and rock, burn season, and slope, in order of significance (Table 3). Percentage of area burned was greatest in plots containing less bare ground and rock, in plots burned in the fall, and in plots on steeper slopes. Percentage of basal area composed of pine and small woody fuel score approached significance ($P = 0.118$, $P = 0.097$, respectively), with a tendency for greater percentage of area burning in plots with a higher percentage of pine and in plots where loading of small woody fuels was high.

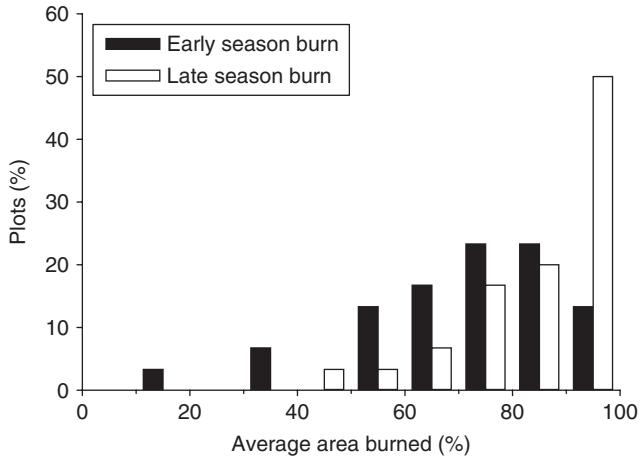

Fig. 2. Percentage of plots within different average percentage of area burned categories in both early season ($n = 30$) and late season ($n = 30$) prescribed burning treatments.

Table 3. Significance of fixed effects in a mixed-model analysis of variance of percentage of area burned for prescribed burns conducted in early and late season

The random effect (unit) was not significant ($P = 0.496$). Percentage of ground surface area burned was arcsine square root transformed prior to analysis. Denominator degrees of freedom are based on Satterthwaite's approximation

Fixed effect	n.d.f.	d.d.f.	*F*	*P*
Burn season	1	3.57	18.97	0.016
Slope	1	13.4	5.50	0.035
Head load	1	11.3	0.88	0.368
Small woody fuel score	1	49	2.66	0.110
Large woody fuel score	1	48.6	0.35	0.554
Basal area	1	47.6	0.12	0.735
Pine basal area (% of total)	1	48.6	2.38	0.129
Canopy closure	1	45.9	0.00	0.945
Herbaceous cover	1	17.3	0.01	0.924
Bare ground and rock cover	1	39.6	8.54	0.006

A separate exploratory mixed-model ANOVA was run to investigate possible two-way interactions among the three significant ($P < 0.05$) main effects. None of these interactions were found to be significant or add to the explanatory power of the model as expressed by AIC. The final model presented in Table 3 therefore includes only the main effects.

Discussion

The abundance of fuels that have accumulated in many forested areas has led to a concern that fire effects generated by prescription burning might now overwhelm mechanisms that historically generated heterogeneity in fire severity, leading to greater than desired landscape uniformity. Our results illustrate that substantial variation in two measures of fire severity – scorch height and percentage of area burned – can be produced by both early season and late season prescribed burns, even after over a century of fire suppression. Whereas several of the independent variables significant in the ANOVAs of scorch height were direct or indirect measures of fuel loading (small woody fuel score, tree basal area), other topographic and biotic factors also likely contributed to this heterogeneity. The importance of slope, the independent variable with the strongest significance, was expected because rate of fire spread increases with slope steepness (Agee 1993), and fireline intensity is higher when more fuel is consumed per unit time. In addition, hot air is more readily convectively lifted into tree crowns on slopes, contributing to greater scorching. Percentage basal area composed of pine was also important in explaining variation in scorch height, likely because fire in pine litter produces greater flame lengths than fire in the more compact litter of shorter-needled conifer species (Fonda *et al*. 1998). This relationship between proportional abundance of pines and height of crown scorching has been noted with wildfire as well (Weatherspoon and Skinner 1995).

Most of the independent variables significant in the ANOVA of percentage of area burned were more strongly related, either directly or indirectly, to fuel continuity rather than fuel loading. Less of the burnable area was burned in plots containing more bare ground and rock, presumably because these barriers can limit fire spread. Significance of burn season was likely largely the result of greater fuel moisture in the early season. Effective fuel continuity is less at higher fuel moisture levels (Miller and Urban 2000) because the likelihood that adjacent fuel particles will become heated to the point of combustion is reduced (Nelson 2001), limiting fire spread. Our finding of greater burn patchiness with prescribed fires conducted under higher fuel moisture conditions is consistent with other studies (e.g. Slocum *et al*. 2003).

The third significant independent variable, slope, was positively associated with the amount of area burned, presumably because fuels are exposed to greater convective and radiant heat on slopes, making preheating more effective (Rothermel 1972). The variables 'amount of small woody fuel' and 'percentage basal area composed of pine' both approached statistical significance and may have also influenced the percentage of area burned. Fuel continuity was expected to be greater in areas with more fine fuels and a higher proportion of long-needled conifers such as pine. Fire carries more readily in pine litter than in the litter of shorter-needled species, owing to lower bulk density of the pine litter (Agee *et al*. 1978; van Wagtendonk *et al*. 1998; Stephens *et al*. 2004). Miller and Urban (2000) reported that bulk density, in addition to fuel moisture, played a role in controlling area burned in fire spread models. High bulk density litter of short-needled conifer species dries more slowly to the point where combustion is possible after snows melt, potentially resulting in a shorter burning season (Stephens 2001). Agee *et al*. (1978) noted that pine fuels could be effectively reduced by burning

in the spring, summer, or fall, but white fir and other short-needled fuels required drier conditions in the summer and fall.

Other factors besides those included in the ANOVA models, such as weather and how fire was applied during the prescription burn, also likely contributed to the observed heterogeneity in fire severity. The number of igniters applying fire at one time, the horizontal distance between igniters, and the time between passes were variable and all can strongly influence fire severity. In addition, some breaks in ignition occurred when fire crews were preoccupied with burning snags or spot fires. Plots that burned during these times may have experienced reduced fire intensity (more backing fire, less heading fire). It was not possible to quantify these ignition factors at the plot scale, owing to operational constraints. Because weather conditions were mild and relatively consistent during all of the burns, variation in fire severity was probably less strongly influenced by weather than by ignition patterns. Still, variability in relative humidity and wind speed were likely sufficient to exert some influence on fire behavior. Although weather variables were recorded hourly during the burns, they were not included in the ANOVA models because it was difficult to determine exactly when each plot burned and to match weather conditions at that time. Another factor we did not quantify – proximity to water courses – has been shown to exert a strong influence on fire effects, presumably because of species composition and fuel moisture differences (Russell and McBride 2001; Skinner 2003). However, most water courses within the units in the present study were ephemeral and did not contain water at the time of the burns.

It is not known how the relative contribution of fuel loading-related and non-fuel loading-related factors for generating variation in fire severity compared to historical fires, but the role of non-fuel loading variables in generating heterogeneity under current conditions is perhaps under appreciated. The strong positive association between percentage of basal area composed of pine and scorch height (and to a lesser extent, percentage of area burned) suggests that some of the capacity of prescribed fires to generate a heterogeneous post-burn landscape might be jeopardized in the future by shifts in species composition away from pine. Whereas shade-tolerant species with less flammable and more compact litter have always been part of the mixed-conifer forest, they have become more abundant as a result of fire suppression and shade-intolerant species with more flammable litter, such as ponderosa pine and Jeffrey pine, have become less abundant. In addition, sugar pine is in decline, due in part to white pine blister rust, and may play a lesser role in forests of the future (van Mantgem *et al*. 2004). Loss of pines may be reducing the extent of the historical mosaic of long-needled and short-needled species.

Forest gap models parameterized with data from the Sierra Nevada predict that surface fire regimes should increase the fine-scale spatial heterogeneity in some components of forest structure, over that found in the absence of fire (Miller and Urban 1999). Of interest to resource managers is whether the heterogeneity produced by prescribed burns is comparable to the heterogeneity that was produced historically by natural fires. To modulate fire behavior and aid in control, prescribed fires are often ignited in strips and also conducted within a relatively narrow range of weather and fuel moisture conditions compared with historical fires. All potentially reduce heterogeneity in the burning pattern. However, the weather and fuel conditions under which prescribed fires are conducted may also be what maximize heterogeneity in burn patterns produced by other mechanisms. Model outputs of Miller and Urban (2000) indicate that connectivity of fuels influences fire spread under moderate weather conditions, but that this relationship diminishes under dry and windy conditions. Dry, windy conditions can lead to intense fire and uniform fire coverage over large areas, despite heterogeneity in the arrangement of fuels. In addition, fuel connectivity is a function of fuel moisture mainly at intermediate fuel moisture levels (Miller and Urban 2000). Model outputs of Miller and Urban (2000) predict that at low fuel moisture levels, much of the area will burn regardless of patterns of fuel connectivity. At high fuel moisture levels, little of the area burns. Both of the latter situations limit the amount of heterogeneity potentially produced by fire. Thus the heterogeneity in fire severity that results from conducting prescribed burns within a relatively narrow window of weather and fuel moisture conditions may to some extent compensate for the heterogeneity historically generated by variability in weather that natural fires burned under.

Heterogeneity in fire severity may play an important ecological role. Unburned or less severely burned patches provide refugia for plant and animal species and propagules for recolonizing more severely burned areas. Such patchiness can also slow erosion and increase infiltration of run-off (Martin and Sapsis 1992). Whereas both early and late season prescribed burns in the present study produced abundant heterogeneity in fire severity, patchiness in the percentage of area burned in the early season may be more similar to the patchiness of historical fires that typically burned under lower fuel moisture conditions but when fuel loading was not as high, or fuels as continuous. Even with the abundance of fuel in many forested areas today, variability in other factors may still be sufficient for prescribed fires conducted under moderate weather and fuel moisture conditions to produce a highly heterogeneous post-burn landscape.

Acknowledgements

We wish to thank Sequoia National Park Fire Management for conducting the prescribed burns, Nathan Stephenson for intellectual insights and his early involvement with the project, Tony Caprio for fire history information, Julie Yee and Jim Baldwin for statistical advice, Kyle Merriam for

assistance with GIS analyses, and members of the field crews (Anni Ala, Clara Arndt, Liz Ballenger, Tess Brennan, Lea Condon, Todd Erdody, Eric Fabio, Eric Groth, Shauna Hee, Jeffrey Kane, Dan Lieberman, Hanna Mershman, Katie Panichelle, Dorothy Wallace-Senft, Katie Vinzant, Kelly Wengronowitz and Upekala Wijayratne) for assistance with data collection. The paper benefited from comments by Teresa Brennan, Tony Caprio, Scott Ferrenberg, Kyle Merriam, Monique Rocca, Carl Skinner, Nathan Stephenson, Steven Schwarzbach, Phil van Mantgem, and two anonymous reviewers. This is contribution number 95 of the National Fire and Fire Surrogate Project (FFS-99S1), funded by the USA Joint Fire Science Program.

Fire suppression makes wildfires more severe and accentuates impacts of climate change and fuel accumulation

Fire suppression is the primary management response to wildfires in many areas globally. By removing less-extreme wildfires, this approach ensures that remaining wildfires burn under more extreme conditions. Here, we term this the "suppression bias" and use a simulation model to highlight how this bias fundamentally impacts wildfire activity, independent of fuel accumulation and climate change. We illustrate how attempting to suppress all wildfires necessarily means that fires will burn with more severe and less diverse ecological impacts, with burned area increasing at faster rates than expected from fuel accumulation or climate change. Over a human lifespan, the modeled impacts of the suppression bias exceed those from fuel accumulation or climate change alone, suggesting that suppression may exert a significant and underappreciated influence on patterns of fire globally. Managing wildfires to safely burn under low and moderate conditions is thus a critical tool to address the growing wildfire crisis.

Wildfires are becoming more destructive and deadly around the world[1–4]. The societal and ecological impacts of fires[5,6] are in our collective consciousness—from Australia's 2019–2020 megafires[7], to destructive wildfires in the Mediterranean[8], to beloved giant sequoias killed by fire in California[9]—prompting widespread calls to address the wildfire crisis[8,10–14]. We understand the broad drivers of increasing fire activity: changes in climate[1,15,16], vegetation and fuel accumulation[8,17,18], and ignition patterns[19]. However, humans also play a direct role in modifying fire activity across much of the globe by engaging with fires minutes to hours after ignition (i.e., initial attack[20,21]), and subsequent suppression of escaped fires[22–24]. While weather, fuels, topography, and ignitions determine how fires might burn, humans strongly shape this into when, where, and how fires do burn (Fig. 1).

Wildfires only burn if they are not extinguished through suppression. Thus, suppression is a "filter" that allows certain types of fire to pass through while removing other types of fire (Fig. 1b). In some locations (e.g., a remote wilderness area) this filter may be relatively porous, and many fires may burn with only minimal suppression[25]. In most landscapes, however, aggressive suppression of fire is a cultural expectation, and the suppression filter is much less permeable, with only the most extreme fires escaping (e.g., Maximum suppression in Fig. 1)[20,21]. Intentional fires (i.e., prescribed fires and cultural burning) are the only types of fires that do not pass through the suppression filter, as they are allowed to burn unimpeded if they are within prescription (Fig. 1a). Area that does not burn because it was "removed" through suppression, results in fuel accumulation and ultimately increases the likelihood and intensity of future fires[26,27] (Fig. 1a). This well-known consequence has been termed the "fire suppression paradox"[28,29]: by putting out a fire today, we make fires harder to put out in the future[26,30–32] (Table 1).

Suppressing wildfires also has an additional and poorly quantified consequence that we define as the "suppression bias":
