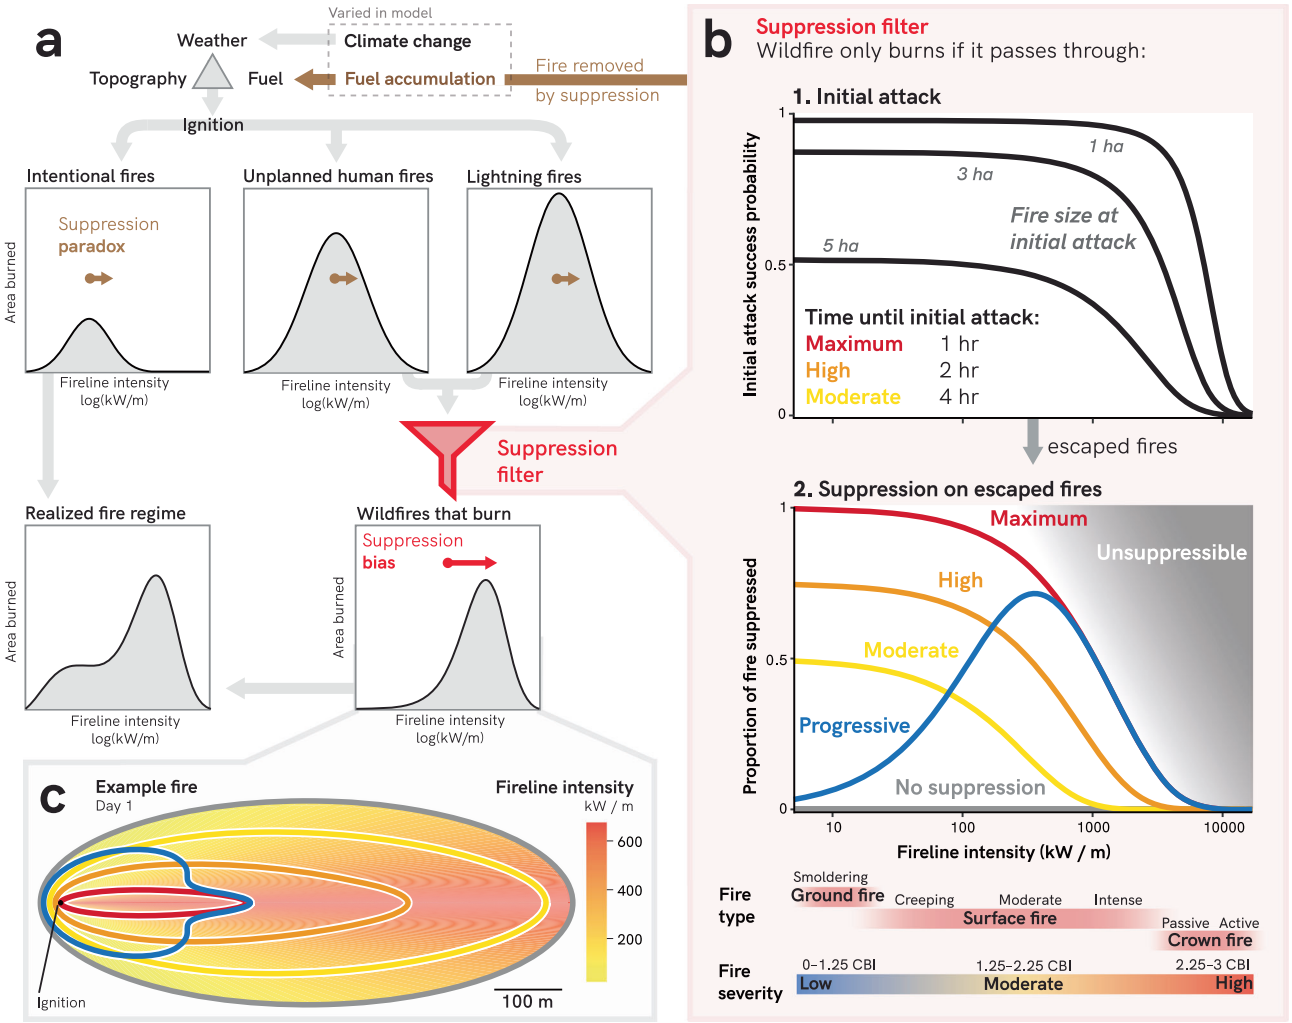

Fig. 1 | Conceptual diagram of how suppression influences fire. a Potential fire behavior depends on the fire triangle (topography, weather, fuel) and ignitions. Intentional ignitions (i.e., prescribed fires and cultural burning) do not pass through the suppression filter, as they are allowed to burn unimpeded if within prescription. Unplanned human ignitions and lightning ignitions only burn if they successfully pass through the "suppression filter." Fire "removed" by the suppression filter leads to fuel accumulation, influencing fires from all ignition types (suppression paradox, brown color). Wildfires that do burn are biased toward the fire that was not removed (suppression bias, red). These wildfires, together with intentional fires, form the realized fire regime with the suppression paradox and suppression bias inherently incorporated. **b** The suppression filter. 1) Initial attack success probability as a function of fireline intensity and fire size at initial attack (from Hirsch et al.[69]); 2) Proportion of escaped fire suppressed as a function of fire intensity. Suppression becomes increasingly impossible at high fire intensities. Colors depict the suppression scenarios used in the simulation. **c** Fire perimeters (viewed from overhead) after the first day of burning for an example ignition. Colors correspond to suppression scenarios shown in panel **b**. Fire intensity of the burned area is displayed with a color ramp.

Table 1 | Comparison of the fire suppression paradox and bias

Term	Definition	Mechanism	Impact	Time lag
Fire suppression paradox	By suppressing fire today, we increase fuel loads, making fires harder to suppress in the future	Fuel accumulation	Indirect	Future
Fire suppression bias	By suppressing some fire types more than others, the remainder reflects a biased representation of fire types	Differential suppression filter	Direct	Immediate

fire suppression extinguishes some types of fire (e.g., surface fire) more than others (e.g., crown fire), and thus skews the resulting fire activity toward those types less likely to be removed (Table 1). In contemporary fire management, which easily suppresses and removes low-intensity fire, this bias is inevitably toward higher-intensity burning occurring under extreme weather[20,21,33–35]. Thus, the fires which ecosystems, species, and people experience are skewed towards the most severe and destructive.

We define management approaches that suppress lower-intensity fire more heavily than higher-intensity fire as "regressive suppression," borrowing language from economics (e.g., a regressive tax rate decreases as taxable income increases) (Table 2). In some instances, however, management could contain and suppress relatively higher-intensity fire more heavily than lower-intensity fire, an approach we term "progressive suppression" (e.g., a progressive tax rate increases as taxable income increases) (Table 2). Both regressive and progressive suppression are subject to the same upper limit, above which fires are

Table 2 | How the type of suppression influences the resulting suppression bias

Type of suppression	Definition	Direction of suppression bias
Regressive suppression	Suppresses lower-intensity fire more heavily than higher-intensity fire	Toward higher-intensity fires, more extreme fires
Progressive suppression	Suppresses higher-intensity fire more heavily than lower-intensity fire	Toward lower-intensity fires, more moderate fires

simply too intense to suppress (Fig. 1b)[36]; however, within the domain where suppression is possible, regressive and progressive approaches can have profoundly different impacts (i.e., biases) on the way fires burn.

Although the fire suppression bias has been referenced tangentially in the literature[8,28,33,37–39], the emergent impacts of the suppression bias have not been assessed. This is largely due to the difficulty of isolating the impact of suppression with empirical data. Suppression is so ubiquitous that we have virtually no control landscapes where fire is completely unsuppressed; even in remote wilderness areas, some fires are still suppressed[40]. Furthermore, it is difficult to measure the magnitude of suppression efforts because even relatively direct proxies such as suppression cost are confounded by other factors, including terrain accessibility, human infrastructure at risk, and availability of suppression resources[41]. Finally, data on suppression efforts are generally only available for larger fires[42], obscuring the many ignitions that are quickly and easily suppressed during initial attack[20,21]. To overcome these constraints, we used a simulation approach to assess and quantify the magnitude of the fire suppression bias on fire behavior and ecological impacts, relative to the influence of climate change and fuel accumulation.

Our modeling framework simulates fundamental components of fires: weather and fuel moisture; ignitions; fire growth; fire suppression (through initial attack and containment of escaped fires); and ecological effects. To isolate the effect of fire suppression, we simulated thousands of fires with identical biophysical conditions, but which differed only in their suppression scenario, including three "regressive suppression" scenarios (Moderate, High, and Maximum; Fig. 1b), one "progressive suppression" scenario (Progressive; Fig. 1b), and a control scenario with no suppression. For each fire, we calculated the proportion burned at high severity, average fire severity, daily and total fire size, and the diversity of fire severity[43]. To compare the influence of suppression to that of climate change and fuel accumulation, we simulated fires across a range of plausible current and future fuel aridity (vapor pressure deficit; VPD) and fuel loading conditions in forest ecosystems in North America. These ranges represent a 240-year time period of modeled increases (e.g., increased VPD based on RCP 8.5 climate scenario[44]; fuel loading rates based on historical fuel modeling[45]).

Using this modeling framework, we show how the suppression bias directly influences fire activity and subsequent fire effects. Specifically, we asked: 1) How does fire suppression influence patterns of area burned, ecological impacts (i.e., fire severity), and the diversity of both factors over space and time? 2) How does the magnitude of this influence compare to that from climate change and fuel accumulation?

Results

Regressive fire suppression makes fires more severe

Across the simulated range of fuel aridity, regressive suppression scenarios (Moderate, High, and Maximum) increased the ecological impacts of wildfire, as reflected by higher fire severity metrics. We simulated fire severity by linking fire intensity to the Composite Burn Index (CBI), which runs from zero (unburned) to three (maximum fire severity), with values above 2.25 considered high-severity[46]. Under the Maximum fire suppression scenario, a greater proportion of each wildfire burned at high severity (Fig. 2a, b). On average, wildfires burning under the Maximum suppression scenario had over twice as high proportion that burned at high severity, compared to fires burning with no suppression. Across all fuel aridity simulations, Maximum suppression increased mean fire severity by an average of 0.21 CBI units, relative to fires with no suppression (Fig. 2c). This increase in fire severity is equivalent to the cumulative effects of 102 years of increased fuel aridity from climate change alone, under the no-suppression scenario (i.e., an increase in mean summer VPD of +0.85 kPa) (Fig. 2c inset). Similarly, across the simulated range of fuel loading values, Maximum suppression increased mean fire severity by an average of 0.22 CBI units, relative to control scenarios (Fig. 2d). This increase is equivalent to the effect of 102 years of additional fuel accumulation under no fire suppression (i.e., an increase in 100-h surface fuel loading of +3.7 Mg ha^{-1}) (Fig. 2d inset).

In contrast, Progressive suppression reduced the proportion of each wildfire that burned at high severity, for most levels of fuel aridity and fuel loading (Fig. 2a, b). Compared to fires burning with no suppression, wildfires burning under the Progressive suppression scenario had an average of 17% (across fuel aridity gradient) and 15% (across fuel loading gradient) less proportion that burned at high severity. Mean fire severity was also lower under the Progressive fire suppression scenario, across most of the simulated range of fuel aridity and loading, with an average reduction of 0.04 and 0.03 CBI units, respectively (Fig. 2c, d). Given modeled rates of fuel aridity and fuel loading change, these differences are equivalent to burning under scenarios of no suppression from 17 and 14 years in the past (i.e., changes of −0.15 kPa VPD and −0.49 Mg ha^{-1}), respectively (Fig. 2c, d insets).

Regressive fire suppression accentuates trends of increasing area burned

While increasing fuel aridity and fuel loading led to a rise in area burned for wildfires under all scenarios (i.e., suppression or not), fires under the regressive suppression scenarios displayed higher sensitivity to increasing fuel aridity and fuel loading (Fig. 3). Across the gradient of increasing fuel aridity, area burned under the Maximum suppression scenario increased by 5.0% per year, compared to only 1.8% per year for wildfires under the no-suppression scenario. Thus, across the 240-year range of increased fuel aridity, yearly burned area doubled nearly three times as fast under Maximum fire suppression, compared to scenarios without fire suppression (i.e., 14 vs. 39 years). This difference was even more marked under increasing fuel loading: area burned under the Maximum suppression scenario increased by 3.7% per year, compared to only 0.7% per year for wildfires that were not suppressed (Fig. 3). Thus, across the 240-year range of increased fuel loading, yearly burned area doubled over five times faster under Maximum suppression, compared to scenarios without fire suppression (i.e., 19 vs. 94 years). Fires simulated under the Progressive suppression scenario had the lowest sensitivity to increasing fuel aridity and fuel loading of any suppression strategy, including no suppression. Yearly burned area doubled every 44 years across the simulated increases in fuel aridity, and only every 133 years across the simulated gradient of fuel accumulation. Patterns were similar for area burned at high severity, with regressive scenarios leading to faster proportional increases in area burned and the Progressive scenario maintaining the slowest increase in area burned (Supplementary Fig. S1).

Regressive fire suppression decreases the diversity of fire effects

Relative to unsuppressed fires, regressive suppression decreased the diversity of fire effects (i.e., diversity of burn severity) at all levels of fuel aridity and fuel loading values (Fig. 4). In the Maximum

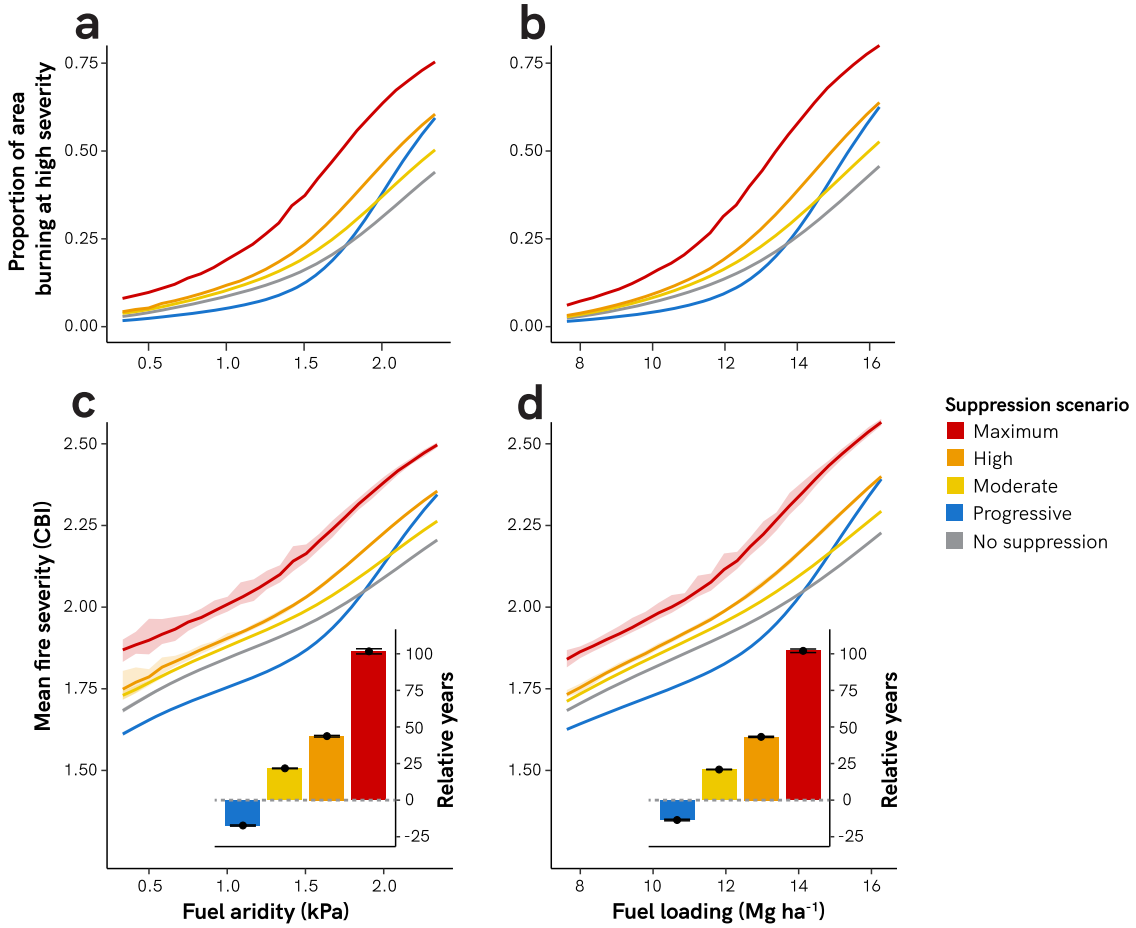

Fig. 2 | Effects of fire suppression on fire severity. Panels **a** and **b** show the proportion of high-severity fire (CBI > 2.25) across ranges of fuel aridity and fuel loading. Panels **c** and **d** show mean fire severity across ranges of fuel aridity and fuel loading. Insets show the average number of years of modeled climate change (vapor pressure deficit increase of 0.008 kPa yr^{-1}) or fuel accumulation (100-h fuel accumulation rate of 0.036 Mg ha^{-1} yr^{-1}) to yield the difference in fire severity between suppressed and unsuppressed fires. Variability across the 40 simulation replications is shown with 95% confidence intervals (too small to see for some) or error bars (insets on **c** and **d**). Fuel loading in panel **b** and **d** depicts 100-h surface fuel loading values. Simulations across the fuel aridity range were run at a constant 100-h surface fuel loading of 11.23 Mg ha^{-1}; simulations across the fuel loading range were run at constant mean fire season vapor pressure deficit of 1.17 kPa.

suppression scenario, 97–99% of fires were contained under 121 ha (300 ac) for all but the most extreme levels of fuel aridity and loading (Supplementary Fig. S2). Under the regressive fire suppression scenarios, a higher proportion of area burned came from a small proportion of extreme fires (Fig. 4c). For example, under the Maximum suppression scenario, 91% of the area burned came from the largest 1% of fires, compared to only 4% of the area burned that came from the largest 1% of fires under the scenario of no fire suppression. In contrast, under the Progressive fire suppression scenario, fires had the highest diversity of fire effects across the entire range of fuel aridity and fuel loading values, with especially pronounced increases in diversity under more extreme conditions. Progressive suppression also led to fires with the most even distribution of area burned across fires of any suppression scenario (Fig. 4c).

Discussion

We show with a simulation experiment how decades of regressive fire suppression have likely contributed to observed rates of increased burned area and high-severity area burned, independent of climate change and fuel accumulation. While some wildfires have always burned under extreme conditions and at high severity, the fire suppression bias magnifies the proportional representation of these fires by removing fires that would have burned with low or moderate severity (Supplementary Fig. S3). The result is akin to the over-prescription of antibiotics: in our attempt to eliminate all fires, we have only eliminated the less intense fires (that may best align with management objectives such as fuel reduction[47]) and instead selected for primarily the most extreme events (suppression bias) and created higher fuel loads and more "suppression-resistant" fires (suppression paradox). Through regressive fire suppression, we are effectively bringing a more severe future to the present—experiencing average fire severities that would not otherwise happen for a century. Our findings suggest that the abnormally high proportions of high-severity fire witnessed in many areas globally (e.g. refs. 48–51), is due, in part, to the influence of the suppression bias itself.

The suppression bias also has profound impacts on society and social perceptions of fire. By disproportionately removing fires with desirable impacts[47], regressive fire suppression ensures that most people interact with wildfires that burn during extreme events. This in turn makes it less likely for individuals to value the beneficial aspects of less-extreme fires, and less likely to support or desire active fire management[52], further exacerbating the suppression bias[10].

Though regressive suppression keeps many fires at small sizes (Supplementary Fig. S2) and reduces the absolute amount of burned area (relative to a world with no suppression), in the face of climate change and fuel accumulation, it counter-intuitively leads to a higher relative rate of increasing area burned over time. This is because regressive suppression amplifies the difference between the amount of fire that burns under less fire-conducive climates (e.g., in the recent past) and how much will burn despite heavy suppression under more

https://doi.org/10.1038/s41467-024-46702-0

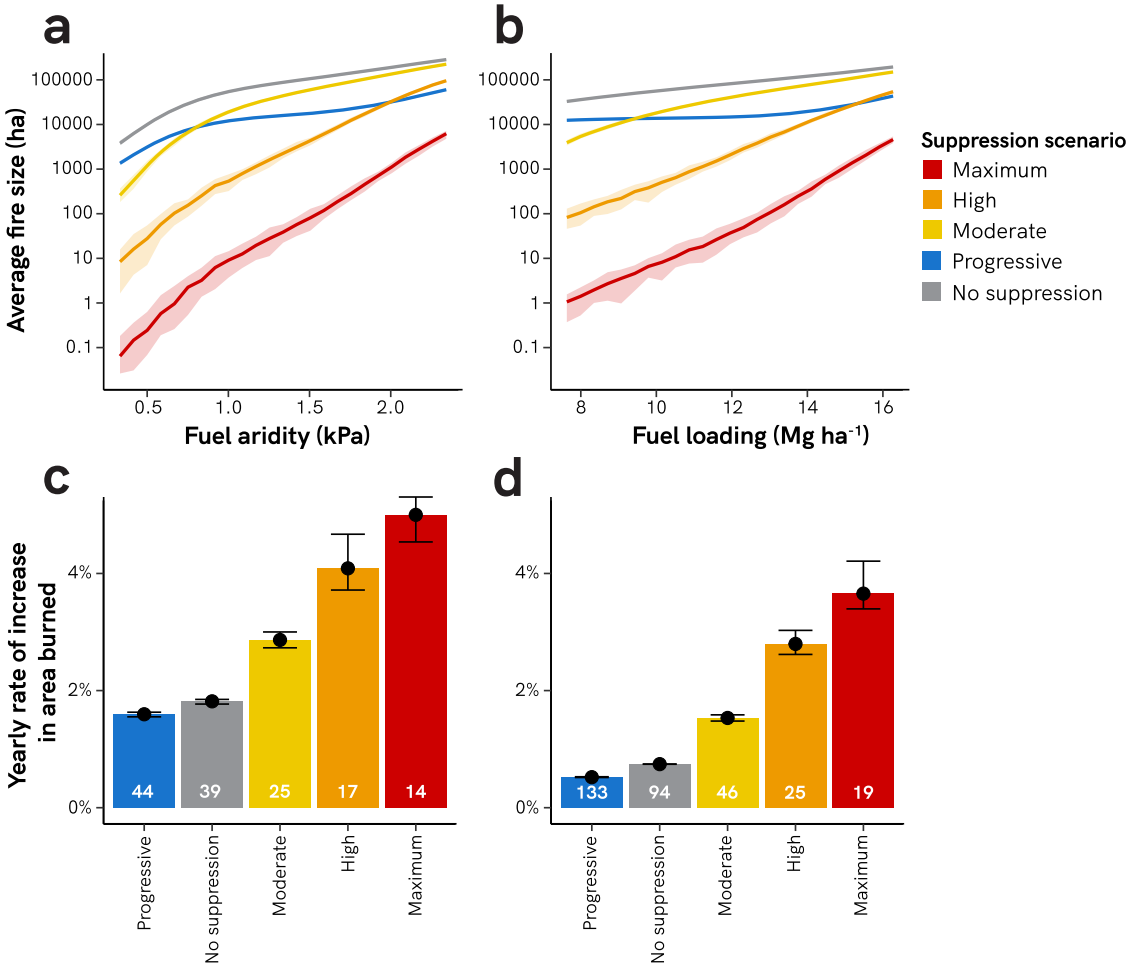

Fig. 3 | Effects of fire suppression on burned area increase. Panels **a** and **b** show trends in average fire size across ranges of fuel aridity and fuel loading. Fuel loading in panel **b** depicts 100-h surface fuel loading values. Yearly rates of increase in panels **c** and **d** are calculated with a yearly increase in fuel aridity of 0.008 kPa yr^{-1} or a yearly increase in fuel accumulation (100-h fuel accumulation rate) of 0.036 Mg ha^{-1} yr^{-1}, respectively. White numbers at the base of bars are the doubling time, in years, of burned area. Variability across the 40 simulation replications is shown with 95% confidence intervals (**a** and **b**; too small to see on some curves) or error bars (**c** and **d**). Simulations across the fuel aridity range were run at a constant 100-h surface fuel loading of 11.23 Mg ha^{-1}; simulations across the fuel loading range were run at constant mean fire season vapor pressure deficit of 1.17 kPa.

fire-conducive future climates. For example, across simulated climate change, area burned doubled nearly twice as quickly under regressive suppression, compared to not suppressing fires at all. Our work thus suggests that observed high rates of increasing area burned around the world (e.g. refs. 3,53) are at least partially driven by the suppression bias. People and societies are adapted to what they experience to be "normal," and deviations from this baseline require adaptation; by causing the baseline to shift at an even faster rate, regressive suppression further heightens the stress on societies responding to changing conditions[54,55].

The fire suppression bias also has fundamental effects on the longstanding ecological and evolutionary role of fire in terrestrial ecosystems[56]. Fire suppression not only reduces how often plants and animals are exposed to fire, which is detrimental to fire-dependent organisms[57], but it also guarantees that a greater proportion of these encounters are with high-intensity fire. By preferentially removing low-intensity fire through regressive suppression, we have likely shifted the selective pressures of natural selection, unintentionally favoring traits that confer resistance or resilience to high-intensity fire over traits supporting persistence through lower-intensity fire. Fire is also an important catalyst for community reorganization and adaptation in the face of changing environmental conditions such as global warming[58]. However, by reducing the prevalence of fire, suppression limits opportunities for reorganization; instead, ecosystems accumulate inertia from the current species composition and structure, which may not be well-aligned to future conditions[59–61]. Furthermore, because regressive suppression biases fire toward more severe conditions, with decreased seed and propagule availability and more stressful post-fire climatic environments, any reorganization that does occur is more likely to lead to state-shifts[61–64].

We demonstrate that progressive suppression leads to less extreme simulated fire behavior and effects. Indeed, empirical data from protected areas (which tend to have lower rates of suppression[65] and may represent the closest existing examples to progressive suppression) show lower fire severities[66,67] and a greater diversity of fire effects[43], consistent with our conclusions. In our simulations, fires under the Progressive suppression scenario had equivalent fire severity to unsuppressed fires burning under less fire-conducive conditions—in other words, effectively reversing the impacts of climate change or fuel accumulation by one to nearly two decades. Area burned under the Progressive suppression scenario also doubled much slower in response to climate change, compared to regressive suppression scenarios. A society living under progressive suppression would be less stressed by climate change, as their perceived "normal"

https://doi.org/10.1038/s41467-024-46702-0

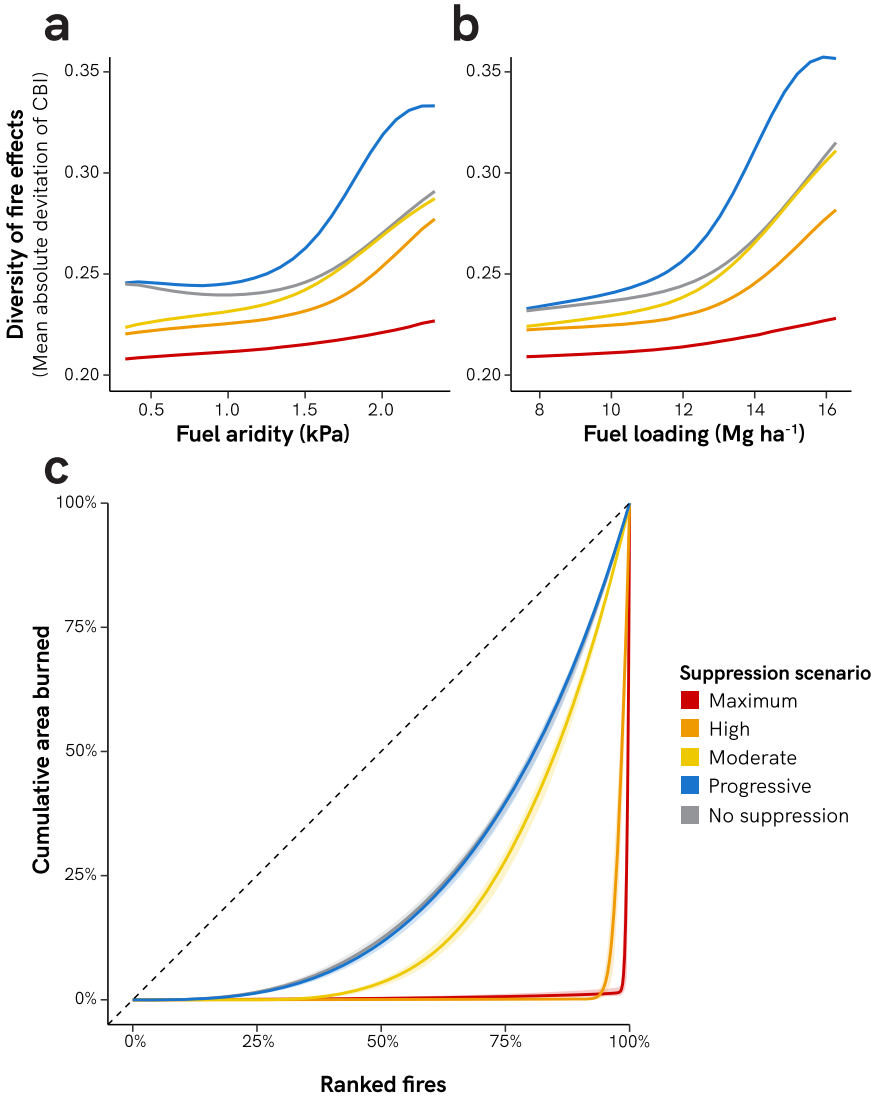

Fig. 4 | Effects of fire suppression on diversity of fire effects. Panels **a** and **b** show the effects of fire suppression on the diversity of fire effects across ranges of fuel aridity and fuel loading. Diversity of fire effects is calculated as the mean absolute deviation of fire severity (CBI) sensu Steel and colleagues[43]. Fuel loading in panel **b** depicts 100-h surface fuel loading values. Simulations across the fuel aridity range were run at a constant 100-h surface fuel loading of 11.23 Mg ha^{-1}; simulations across the fuel loading range were run at constant mean fire season vapor pressure deficit of 1.17 kPa. **c** Lorenz curves for each suppression scenario; fires are ranked by increasing area burned. Simulations run at mean seasonal vapor pressure deficit of 1.17 kPa and fuel loading of 11.23 Mg ha^{-1} (100-h fuel load). The dashed line represents hypothetical fire activity where the area burned is spread equally across all fire days. Variability across the 40 simulation replications is shown with 95% confidence intervals but which are too small to see for some curves.

conditions would change half as fast. By allowing more lower-intensity fire, progressive suppression could buy time, helping societies and ecosystems adapt to climate change[54].

Our simulations are grounded in fundamental physical aspects of fire behavior[68] and reveal important and underappreciated consequences of fire suppression; however, our model is not intended to predict fine-scale fire behavior. For example, we did not incorporate spatial variability in topography, wind direction, or fuel loading within any individual fire. Additionally, each modeled fire is unaffected by fires that have occurred in prior years (i.e., the model does not incorporate the effects of the fire suppression paradox; Table 1). This may make our results a conservative estimate of the total impact of regressive suppression, since landscapes under regressive suppression would accumulate fuel faster than those with no suppression, further heightening the difference in fire intensity.

While our model includes practical implementations of suppression[36,69], it does not incorporate dynamic resource allocation as the number of fires increase across a landscape. This means it does not explicitly account for scenarios where suppression resources are depleted from numerous fires burning simultaneously, such as during National Wildland Fire Preparedness Level 5 in the U.S.[41,70]. Consequently, the simulation may overestimate suppression effectiveness and underestimate suppressed fire sizes in these conditions. However, the model assumes near-complete ineffectiveness of suppression during extreme weather events when fire intensity is high (Fig. 1b), effectively incorporating resource scarcity. Regardless, in conditions when fire suppression is effective, our results show that it inherently biases resulting fire patterns.

Our model generates patterns of fire behavior that align with empirical data. For example, burned area patterns under Maximum suppression (e.g., nearly all fires contained before reaching 121 ha (300 ac); 1% of fires accounting for 91% of area burned) closely resemble long-term trends observed in the U.S. (97–99% of fires contained before reaching 121 ha (300 ac); 1% of fires accounting for 98% of area

burned[71]). Thus, our results reveal important general expectations of the impacts of fire suppression, relevant to any flammable location worldwide where suppression is used. Future empirical work can test these expected impacts across a variety of ecological and cultural settings.

Although safely allowing low- and moderate-intensity fire is essential for learning to co-exist with wildfire[72], implementing progressive suppression faces a range of challenges that span social-ecological systems[41]. Numerous land management agencies have ingrained cultures and policies that incentivize regressive fire suppression[8,10,33], and shifts in management may be hampered by a lack of trust and support from the public[73], in addition to the widespread public expectation that all wildfires should be suppressed[74]. Progressive suppression would let low-intensity fire spread relatively unencumbered, while more strongly suppressing higher-intensity fire −a management approach that may not always be practical, safe, or possible. Additionally, the operating space for progressive suppression (i.e., maintaining a gradient where higher-intensity fire is more heavily suppressed than lower-intensity fire) is increasingly constrained as conditions become more fire-conducive (Supplementary Fig. S4), and as more valued human resources are built in flammable environments[5]. Finally, while lower- and moderate-intensity fires can reduce the smoke-related health impacts of large, high-intensity wildfires[75], moving toward progressive suppression would likely increase the frequency of low-level smoke emissions, much like the increased use of prescribed fire[75,76]. As such, paradigm shifts in fire management would necessitate public health interventions at all levels: from individual behavioral strategies to public policies and community resources (e.g., facilitating the use of publicly available air-quality data, subsidizing or providing high efficiency particulate air [HEPA] air filters, and creating publicly accessible clean-air spaces)[4,77].

Even when and where progressive suppression is infeasible, our results show that less aggressive implementations of regressive suppression (e.g., moving from Maximum to Moderate suppression, analogous to calls for increased fire use[10]) can dramatically reduce the suppression bias. Adaptive management frameworks that facilitate risk-informed differences in management approaches (e.g., the PODs framework[78]) could likewise help lessen the impact of the suppression bias. For example, such fire management could implement regressive suppression approaches when necessary (e.g., near human infrastructure) and progressive or no suppression approaches when and where more feasible. Finally, intentional fires (i.e., prescribed fires and cultural burning; Fig. 1) also play an important role in tandem with progressive suppression[10,79,80]. While these practices support a range of values on their own[47], they also facilitate the implementation of progressive suppression strategies by introducing low-intensity fire and creating landscape heterogeneity.

We demonstrate that the suppression bias is a major driver of fire activity and ecological impacts. While the negative impacts of fuel accumulation are commonly recognized as an indirect consequence of fire suppression, integrating the impacts of the suppression bias would improve our understanding of fire-human relationships, and ongoing changes in fire activity. Part of the solution to coexisting with wildfire now and into the future requires developing and applying technologies and approaches that allow us to safely manage wildfires under moderate burning conditions. Arguably, this will be as effective as other needed interventions, such as mitigating global warming, minimizing unintentional human-related ignitions, and modifying forest structure to reduce fire severity when fires occur.

Methods

Our model simulates individual fire events independently, and it is not intended to represent a specific real-world landscape. All models are tradeoffs between fine-scale precision and large-scale generalizability[81], and we designed our simulation approach to be generalizable while incorporating fundamental physical aspects of fire behavior. We use a wide range of fuel loading and climate parameters, to both demonstrate the global applicability of our results and address the variability and uncertainty inherent in complex real-world environments[82] and demonstrate that the consequences of the suppression bias are not unique to a specific biophysical setting (i.e., a fire regime). The parameters and simulations described below are generally informed by variables and ranges of variability representing forest ecosystems in western North America. Full details are provided in the Supplementary Information (Supplementary Methods).

Simulating ignitions & fire spread

For each fire, we randomly chose an ignition day from a hypothetical 150-day fire season. Ignitions could smolder for up to three days, during which fire spread would occur if the daily fuel moisture was less than the moisture of extinction (25%). If fuel moisture never fell below 25% during this three-day period, the ignition was assumed to be extinguished naturally.

We assumed elliptical fire shape[83] and modeled daily fire growth based on Huygens' principle[84], which assumes that the growth of each point on the fire perimeter can be independently modeled as an expanding ellipse. The shape of this ellipse becomes longer and narrower at higher wind speeds[83] (Supplementary Fig. S5). We modeled daily heading-direction fire spread rate, using the rothermel function in the R package firebehavioR[85], which incorporates potential transitions to crown fire spread[86,87] (Supplementary Fig. S5). We converted the modeled heading-direction fire spread rates to elliptical expansion factors and distances at any angle from the ignition (Supplementary Methods). We calculated two metrics of fire intensity−fireline intensity and flame length−using equations from the rothermel function in the R package firebehavioR[85] and extended them to elliptical fireline intensity using equations of Catchpole and colleagues[88]. We estimated fire severity by linking flame length to estimated tree mortality from mixed-conifer ecosystems[89] and finally to Composite Burn Index (CBI), a measure of fire-caused vegetation mortality and soil organic matter consumption[46].

Simulating suppression

We tested several different suppression scenarios: three regressive suppression scenarios (Moderate, High, Maximum), one progressive suppression scenario (Progressive), and one control scenario (No suppression). We simulated suppression of fires with a two-step process: 1) initial attack, and 2) subsequent suppression of fires that escape initial attack[23,24]. To simulate initial attack success, we used a modeled relationship from Hirsch and colleagues[69] that estimates the probability of escape as a function of heading fireline intensity and fire size at the time of initial engagement. For regressive suppression scenarios, we stochastically simulated whether initial attack was successful (i.e., the fire was fully contained) using different times of initial engagement, and thus fire size (Moderate = 4 h; High = 2 h; Maximum = 1 h). For the progressive suppression scenario, we assumed ignitions were managed without any initial attack but with subsequent suppression. For fires where initial attack was not successful, we modeled subsequent suppression using suppression functions to relate fireline intensity to the expected proportion of fire suppressed (Fig. 1b). The Maximum suppression filter roughly equates to the maximum possible effectiveness of on-the-ground fire suppression efforts, where suppression becomes virtually impossible above a certain fireline intensity[36].

We calculated daily elliptical distance burned under each suppression scenario as the unsuppressed distance burned (with the assumption that fire actively spread for half of the day length) multiplied by the proportion of fire remaining after suppression. Points on the ellipse were considered permanently extinguished if the daily

distance burned was less than 5 m. Other points on the ellipse could continue burning, and a fire was not considered extinguished until points at all angles were extinguished or until after the 150th day of the fire season. Supplementary Fig. S6 shows the daily fire weather and progression of burning for an example ignition, across all suppression scenarios.

Fire behavior model inputs

For each ignition, we simulated daily fire weather: windspeed and temporally autocorrelated live and dead fuel moistures. We modeled daily windspeeds as arising from a Weibull distribution, with a single wind direction for each fire event. We simulated canopy fuel moisture as varying temporally across a sinusoidal seasonal trend. We also simulated daily live and dead surface fuel moisture (i.e., 1-, 10-, and 100-h fuel moisture, live woody and herbaceous fuel moisture) using a sinusoidal seasonal trend around a mean seasonal fuel aridity value, with random variation in amplitude and daily, temporally autocorrelated fluctuations. For a given ignition, we assumed a terrain slope of 40% (20.8°) and uniform and continuous fuel loading, meaning that simulated fires never experienced fuel breaks and would continue burning as long as weather conditions allowed for fire spread.

We ran simulations across ranges of mean fuel aridity and fuel loading to emulate changes in both time (i.e., climate change, fuel accumulation) and space (i.e., moving from one climatic region or forest type to another). Fuel aridity and fuel loading ranges spanned 240 years of modeled climate change or fuel accumulation in the Western U.S., respectively. To estimate a rate of yearly fuel aridity change under an RCP 8.5 climate change scenario, we used Ficklin & Novick's[44] projected median increase in summer vapor pressure deficit (VPD) of 0.72 kPa for the continental U.S. from the historical period (1979–2013; midpoint 1996) to the future period (2065–2099; midpoint 2082) to calculate a mean annual increase between midpoint years of 0.00837 kPa yr^{-1}. Because fire spread models are input with fuel moisture, we converted VPD to dead fuel moisture, using a statistical relationship parameterized with gridMET data[90] from across Western U.S. temperate conifer forests. To estimate plausible yearly increases in fuel loading, we estimated the slope of modeled dead wood carbon accumulation (i.e., the difference in fuel loads between suppressed and unsuppressed model scenarios) in the Western U.S. from 1980–2010 from Boisramé and colleagues[45]. We assumed that carbon made up 50% of total fuel weight and that 100-h fuels comprised 50% of all dead fuels (in keeping with ratios of Fuel Model 10 [91]), yielding a yearly 100-h fuel load increase of 0.036 Mg ha^{-1} yr^{-1}.

Simulation structure

We ran simulations where we varied either mean fuel aridity or fuel loading, while holding the other at constant mean values. A single simulation replicate involved 1000 ignitions, each of which had a unique, randomly simulated ignition day and timeseries of fuel moisture values and windspeeds (i.e., weather scenario). Using this ignition-day and weather scenario, we then simulated fire spread independently for either 1) all levels of fuel loading, while holding mean fire season fuel aridity constant (VPD of 1.17 kPa), or 2) all levels of mean fuel aridity, while holding fuel loading constant (100-h fuel loading of 11.23 Mg ha^{-1}). For each of these simulated fire-spread events, we also modeled all four scenarios of fire suppression (Maximum, High, Moderate, and Progressive) in addition to the no-suppression scenario. We then replicated a single simulation 40 times, for a total of 5 million simulated fires across each range of mean fuel aridity or fuel loading (1000 ignitions ×25 levels of fuel aridity or fuel loading ×5 levels of suppression ×40 replicates).

Summarizing the cumulative impacts of fire suppression

To assess the effect of fire suppression on patterns of fire severity, for each fire we calculated the proportion that burned at high severity (CBI values ≥ 2.25; sensu Parks & Abatzoglou[53]) and the weighted mean fire severity. For each simulation we calculated the required change in mean fuel aridity or fuel load for fires with no suppression to yield the same fire severity as suppressed fires. We divided this value by estimated yearly rates of change in mean fuel aridity and fuel loading, to evaluate how many years of climate change or fuel accumulation it would take for unsuppressed fires to burn at the same mean fire severity. To investigate how fire suppression affected patterns of burned area, we calculated the total area burned for each fire. For each simulation, we also calculated the average multiplicative yearly rate of increase (△) in burned area across the 240-year ranges of fuel aridity and fuel loading. We calculated the diversity of fire severity for each fire using the method detailed by Steel and colleagues[43], with CBI as the single input fire trait—which is equivalent to the mean absolute deviation of CBI values. We investigated how equally burned area was spread across fires by calculating Lorenz curves of area burned under each suppression scenario.

Within a replicate (i.e., 1000 ignitions × 25 fuel aridity or fuel loading levels), for each suppression scenario we calculated the mean values for parameters of interest, at each level of fuel aridity or fuel loading. We then calculated overall means across the 40 simulation replications and used 95% confidence intervals to display variability. We conducted all simulation and analysis in R[92].

Data availability

The source data generated in this study have been deposited in a public database[93] [https://doi.org/10.5281/zenodo.10729478].

Code availability

Effects of Fine Sediment Inputs from a Logging Road on Stream Insect Communities

David P. Kreutzweiser*, Scott S. Capell, and Kevin P. Good

Canadian Forest Service, Natural Resources Canada, 1219 Queen St. East, Sault Ste. Marie, ON P6A 2E5; 705-541-5648; dkreutzw@nrcan.gc.ca

Introduction/Objectives

One of the challenges in addressing forest sustainability objectives is scientifically determining the ecological implications of anthropogenic disturbances to the forest environment. Logging activity, and particularly the road construction associated with it, can result in degradation of aquatic habitats through fine sediment inputs to streams and siltation of stream beds. The biological consequences of sedimentation in streams can include perturbations to benthic insect communities resulting in declines in abundance and (or) changes in community structure. However, most studies that have examined the effects of fine sediments on stream insect communities have relied on small-scale manipulative approaches in artificial stream channels or flumes, on comparative studies between reference and sediment-impacted sites after the disturbance, or on comparisons along a gradient of sedimentation. These provide useful information on the potential for effects of sedimentation on stream insects, but may not be representative of real-world responses by benthic insects to fine sediment inputs because of limitations in scale and the lack of baseline or pre-disturbance community measures.

Effects of fine sediments on stream insects from logging activity have been reported from field monitoring studies, but the negative impacts on benthos may have been confounded by other catchment disturbances such as canopy modification or changes in nutrient flux. We conducted a stream manipulation study to examine effects of fine sediment inputs on stream insect communities, and focused on time trends over pre-disturbance and post-disturbance periods with comparisons to a nearby reference stream. This approach integrated the realism of a natural stream study with the experimental control of a manipulative study by including pre-sedimentation measurements to establish baseline trends, and by excluding other catchment disturbances. The objective was to determine the impacts on stream insect communities of fine sediment inputs at a magnitude that could occur from an active logging road.

Approach

A road crossing over a forest headwater stream was amended (gravel road surface upgraded, road-side ditches cleared) to induce fine sediment inputs to a stream reach. Sediment bed load in the study reach and at a nearby reference stream was quantified before and after the manipulation by extraction of fine sediments from core samples. Aquatic insect communities were sampled in spring and fall for 2 years before and 3 years after the sediment inputs, and compared to insect communities at the reference stream. Quantitative sampling was conducted with modified (increased size, 0.32 m^2) Suber-type samplers, n=10, over 120-m study reaches. Insect community structure was compared between the sediment site and the reference stream before and after the disturbance by multivariate ordination (nonmetric multidimensional scaling), multivariate analysis of similarity, and by time series analyses of univariate community metrics (repeated measures orthogonal polynomial coefficient analysis). Divergence in trends over time at the sediment and reference sites and (or) significant time X treatment interaction in the repeated measures analyses were considered evidence of treatment effects.

Buse, L.J. and A.H. Perera (comp.). 2003. Meeting emerging ecological, economic, and social challenges in the Great Lakes region: Popular summaries. Ont. Min. Nat. Resour, Ont. For. Res. Inst., Sault Ste. Marie, ON. For. Res. Inf. Pap. No. 155.

Results and Discussion

Fine sediment bed load at the manipulated site increased from a pre-disturbance average of about 800 g m^{-2} to over 5000 g m^{-2} that persisted for over 2 years. Fine sediment inputs were 97% inorganic and about 80% of the particles were in the coarse silt (40-63 μm) size range. This resulted in an average stream-bottom sediment coverage of 46.7%, compared to a fine sediment coverage of 14.5% in the reference stream by the end of the study period.

Despite these increases in fine sediment bed load at the manipulated site, only small changes in aquatic insect community structure could be detected. No obvious patterns to suggest sediment impacts and no significant differences in time trends between the sediment and reference sites were detected for total insect abundance or biomass. An examination of community structure by multivariate ordination (NMDS) demonstrated that over the 5-yr study period there were generally greater differences between sites than among years, but that these differences were as large or larger before the sediment inputs. This occurred despite the similarities between these paired sites in catchment size, stream widths, study reach lengths and orientation, forest composition, canopy structure and density, environmental influences (given the proximity of sites), and substrate characteristics. The distinct natural differences in community structure of these paired streams underscores the need for establishing baseline or pre-treatment conditions to which after-impact conditions can be compared in unreplicated, whole-stream experiments such as this one. A paired-stream comparison after the disturbance would have indicated distinct differences in aquatic insect community structure, suggesting a marked effect of sedimentation on benthic insects, but it is clear that distinct differences in community structure in these streams were present before the disturbance. The patterns in community structure over time illustrated by the ordination plots showed only subtle divergence in trends between sites after the disturbance.

Among the univariate metrics examining spring and fall communities at the sediment and reference sites (16 time series analyses in total), six gave evidence of a sediment impact on community structure. Of those, the clearest indications of an effect on community structure were small reductions in diversity and richness of spring communities (Figure 1). These were primarily the result of a decline in the proportion of spring shredders (insects feeding on leaf material) after the disturbance, accompanied by a significant increase in the percent Chironomidae (Figure 2). None of these community metrics gave evidence of a sediment impact on fall communities.

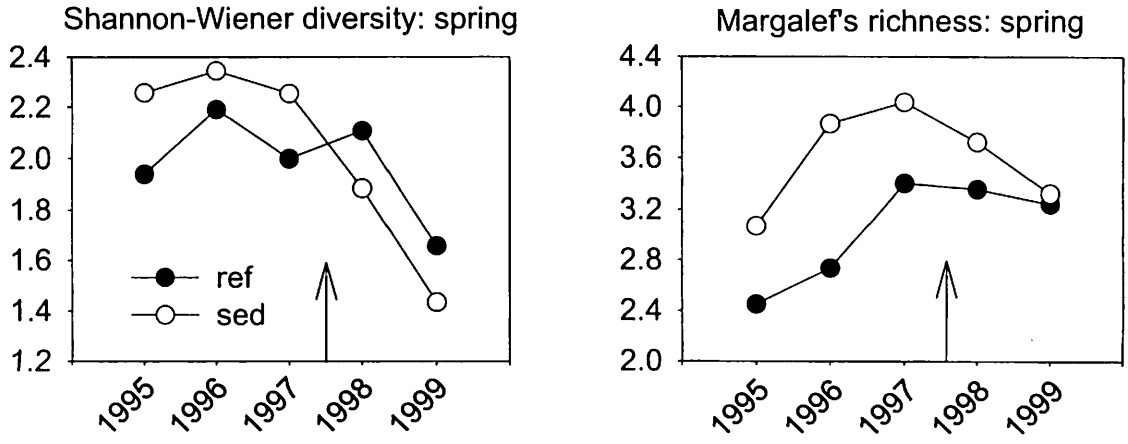

Figure 1. *Average insect diversity and richness indices based on spring samples. Arrows indicate sediment inputs.*

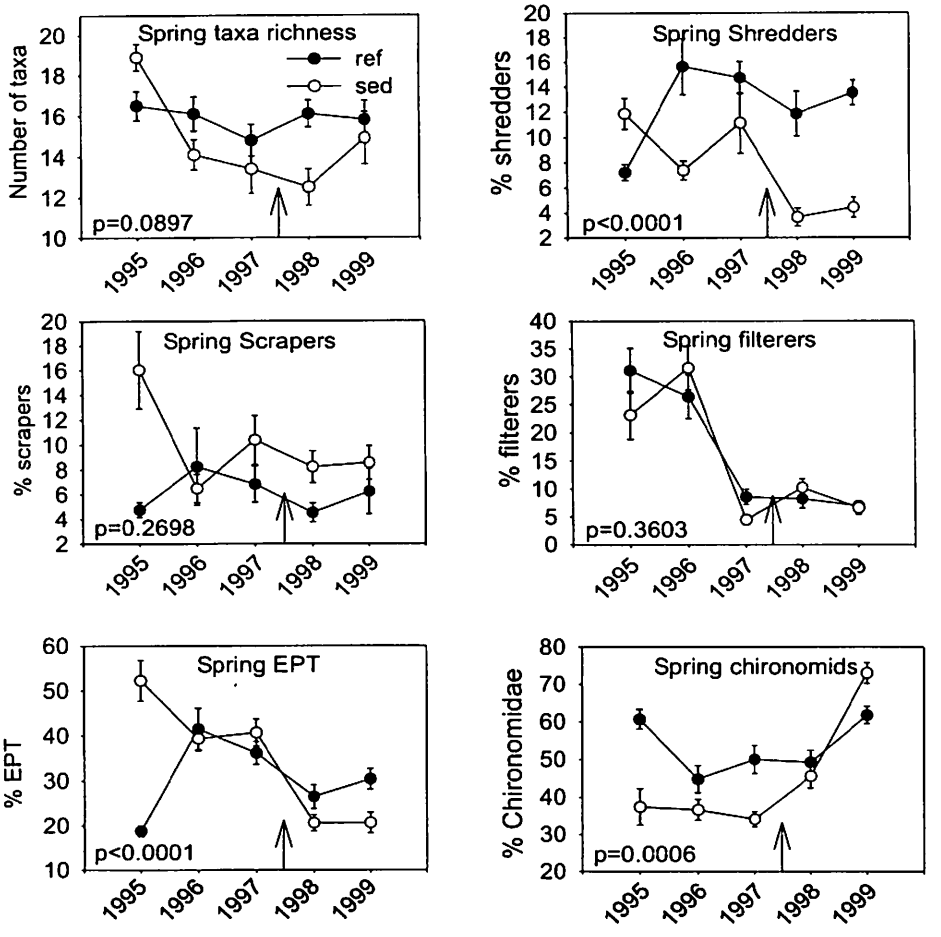

Figure 2. *Average insect community metrics in spring samples. Arrows indicate sediment inputs, p values are for time X treatment interaction terms.*

Conclusions

Despite large and sustained increases in fine sediment bed load (about 7-fold increase for 3 yr), only small changes in aquatic insect communities were detected. The insect community exhibited a high degree of resistance to fine sediment deposition of this magnitude. No effects on total insect abundance, biomass, or 10 of 16 community metric analyses were observed. A significant decline in the proportion of spring shredders (aquatic insects that feed on leaf material) may have resulted from reduced quality of food resources through siltation of benthic organic matter. An increase in the proportion of spring chironomids reflects their general tolerance of sediment-degraded habitats.

The large-scale experimental approach of this study integrated the realism of a whole-stream study with the experimental control of a manipulative study by including pre-sedimentation measurements and excluding other confounding catchment disturbances. In this regard, it may provide a more realistic measure of community-level effects on benthic insects of sedimentation at a magnitude that might be associated with logging activity, than most previous studies.

Notes

Effects of Post-Fire Salvage Logging on Cavity-Nesting Birds and Small Mammals in Southeastern Montana

WILLIAM J. KRONLAND[1] and MARCO RESTANI[2]

[1]Department of Biological Sciences, St. Cloud State University, St. Cloud, Minnesota 56301 USA
Current address: Center for Natural Lands Management, 215 West Ash Street, Fallbrook, California 92028 USA
[2]Department of Biological Sciences, St. Cloud State University, St. Cloud, Minnesota 56301 USA; corresponding author (email: restani@stcloudstate.edu)

Kronland, William J., and Marco Restani. 2011. Effects of post-fire salvage logging on cavity-nesting birds and small mammals in southeastern Montana. Canadian Field-Naturalist 125(4): 316-326.

We investigated how post-fire salvage logging of Ponderosa Pine (*Pinus ponderosa*) affected populations of cavity-nesting birds and small mammals in southeastern Montana in 2004 and 2005. We examined two salvage and two control plots with three point-count stations and one small mammal trap site randomly distributed across each plot. We used point counts and distance sampling methods to estimate density of cavity-nesting birds on each treatment. We also searched each plot for nests and used program MARK to construct a set of candidate models to investigate variations in nest survival related to treatment, year, and time. We used live traps arranged in webs centered on trapping sites and distance sampling methods to estimate small mammal density. Habitat characteristics were also quantified on each plot. Density of all cavity-nesting birds combined and of Hairy Woodpeckers (*Picoides villosus*) in particular were higher on the control than the salvage treatment. Density of large trees and abundance of active cavities were higher on the control treatment. Nest cavities on the salvage treatment were most often located in non-logged watersheds. Nest survival estimates were uniformly high, with only marginal variations attributed to treatment and year. Density of Deer Mice (*Peromyscus maniculatus*) was higher on the salvage than the control treatment, reflecting the amount of downed woody debris created during harvest.

Key Words: cavity-nesting birds, downed woody debris, forest management, nest survival, salvage logging, wildfire, Hairy Woodpecker, *Picoides villosus,* Deer Mouse, *Peromyscus maniculatus,* Custer National Forest, Montana.

The current fire regime within the Ponderosa Pine (*Pinus ponderosa*) forest type in western North America is thought to differ significantly from historical patterns and processes as a result of fire suppression, logging, and livestock grazing (Agee 1993; Arno and Allison-Bunnell 2002). The accumulation of woody fuels from decades of fire suppression is driving a shift from an historical regime of slow-burning ground fires to one that has a greater proportion of severe crown fires (Covington and Moore 1994; Allen et al. 2002). As a result, U.S. state and federal agencies are implementing the Healthy Forest Initiative and the Healthy Forest Restoration Act of 2003 to reduce fuels and the associated risk of severe wildfires and to address demand for commercial timber (Franklin et al. 2003). Federal policy promotes post-fire logging by exempting sales <100 ha from environmental review and allows operations to occur on lands otherwise unavailable for harvest (Federal Register 2003*). Ecologists are questioning the merit of salvage logging because of documented negative effects on soil, vegetation, and wildlife (McIver and Starr 2001; Beschta et al. 2004; Lindenmayer and Noss 2006; Hutto 2006). In addition, salvage logging may actually promote conditions suitable for severe wildfire and hinder forest regeneration (Donato et al. 2006; Greene et al. 2006).

Although burned forests are rare habitats at the landscape scale, spatial heterogeneity created by the patchy distribution of fire severities supports high biodiversity (Turner et al. 2003; Schmiegelow et al. 2006; Hutto 2006). Salvage logging homogenizes this forest structure and alters the post-fire wildlife community. Typically, large trees (>23 cm diameter at breast height [DBH]) favored by foraging and breeding cavity-nesting birds (Covert-Bratland et al. 2006; Pope et al. 2009) are harvested during salvage logging. Consequently, the abundance of cavity-nesting birds declines (Hutto 1995; McIver and Starr 2001; Kotliar et al. 2002) as they are replaced by ground- and shrub-nesting species (Morissette et al. 2002; Cahall and Hayes 2009; Castro et al. 2010). Size and distribution of burned tree stands that remain after salvage logging also shape composition of the cavity-nesting bird assemblage. For example, Black-backed Woodpeckers (*Picoides arcticus*) and American Three-toed Woodpeckers (*P. dorsalis*) require relatively large stands of burned trees, whereas Lewis's Woodpeckers (*Melanerpes lewis*) often occupy smaller stands typical of logged areas (Saab and Vierling 2001; Morissette et al. 2002; Hutto and Gallo 2006). In addition to spatial scale, temporal scale (measured as time since fire) affects the abundance of insect prey of primary and secondary cavity nesters and thus the composition of the post-fire bird assemblage (Saab et al. 2004; Smucker et al. 2005; Covert-Bratland et al. 2006; Hutto 2006).

Little is known about the effects of post-fire salvage logging on fauna other than cavity-nesting birds (McIver and Starr 2001; but see Converse et al. 2006). Salvage logging may increase the amount of downed woody debris (Donato et al. 2006), which provides

small mammals with additional habitat for reproduction, foraging, and predator avoidance (Harmon et al. 1986). The accumulation of downed woody debris following wildfire correlates with the rate of recolonization and an increase in the diversity of small mammals (Carey and Johnson 1995; Fisher and Wilkinson 2005; Converse et al. 2006). In contrast, removal of downed woody debris following salvage of trees damaged by a tornado was correlated with a decrease in the abundance of small mammals (Loeb 1999).

A stand-replacement fire of moderate to high intensity that was ignited by lightning occurred over 26 527 hectares of Ponderosa Pine in southeastern Montana in 2002. The U.S. Forest Service implemented a management plan in summer 2003 to reduce the risk of fire by salvage logging all standing dead trees >25 cm DBH on 485 ha. Literature reviews (McIver and Starr 2001; Kotliar et al. 2002) urged more research into the effects of post-fire salvage logging, so we took the opportunity to compare the density of cavity-nesting birds and the density of small mammals on salvage-logged and control plots. We also estimated breeding success of cavity-nesting birds, because most studies investigating the effects of logging have not measured this important parameter (Sallabanks et al. 2000; Kotliar et al. 2002; but see Saab et al. 2011).

Nest abundance and foraging activity of cavity-nesting birds after fire has been shown to be positively correlated with the size and density of standing snags (Haggard and Gaines 2001; Nappi et al. 2003). Therefore, we predicted that salvage logging would lead to a significant decrease in the number of active nest sites and a significant decrease in the overall abundance of cavity-nesting species. We expected that the volume of downed woody debris would be greater on logged areas (Donato et al. 2006), and we predicted that the density of small mammals would be greater on salvage plots.

Methods

Study area

The study area is located in a Ponderosa Pine forest approximately 40 km southeast of Ekalaka, Montana, U.S.A., in the Long Pines unit of the Custer National Forest (45°38'N, 104°11'W). The study site (1320 ha) is part of a larger forested area (28 368 ha) intermixed with pine savannah, native grassland (*Achnatherum* spp., *Bouteloua* spp., *Carex* spp., and *Pseudoroegneria* spp.), and woody draws. The area consists of hills and rocky buttes (elevation 1000–1200 m) surrounded by lower elevation sagebrush shrubland (*Artemisia* spp.), native grassland, and cultivated hayfields. Mean annual temperature in 2004 and 2005 (January through September) was 7°C and 10°C, respectively, with mean precipitation of 20 cm and 42 cm, respectively (National Oceanic and Atmospheric Administration 2005*). All surface water was ephemeral except for cattle tanks and a few small reservoirs. The area was managed for multiple use, including recreation, grazing, and timber harvest.

We were limited in our study design by management activities and fire behavior. The U.S. Forest Service selected salvage sites based on the presence of pre-existing roads and merchantable timber rather than by randomization, a problem common to wildlife forest management studies (Marzluff et al. 2000; Sallabanks et al. 2000). Distribution and size of patches of burned forest also limited the number and interspersion of independent replicates we were able to consider. Other studies that examined effects of salvage logging faced similar design limitations (Saab and Dudley 1998; Hutto and Gallo 2006). Consistency in the results of multiple independent examinations of salvage logging could overcome lack of power associated with individual efforts. We therefore saw value in conducting this study despite the limitations in randomization, sample size, and interspersion.

We examined the response of the vertebrate community to a reduction in fuels on two salvage-logged and two control plots in 2004 and 2005 (two and three years post-fire; Figure 1). We used Geographic Information Systems (GIS) timber data to select control sites with burn severity and commercial timber value similar to pre-logged salvage sites, distributing two control and two salvage plots (45 to 50 ha), each representing continuous patches of salvaged and non-salvaged forested habitat, to improve experimental design (Hurlbert 1984; Underwood 1997). The salvage areas were mechanically logged in summer 2003. All trees >25 cm DBH with an intact bole and <50% live green crown cover were removed. Trembling Aspen (*Populus tremuloides*) and Green Ash (*Fraxinus pennsylvanica*) were not harvested, and a no-cut buffer of 15.2 m was placed on either side of ephemeral streams to maintain watershed quality.

We used the Minnesota Department of Natural Resources Sample Generator Extension v. 1.1 for ArcView 3.0 to randomly place three point-count stations and one small mammal trap site per plot, positioning point-count stations ≥250 m apart in order to reduce the likelihood of double counting individual cavity-nesting birds (Hutto et al. 1986) (Figure 1). Small mammal trap sites were placed ≥500 m apart, also to maintain sample independence, and all points were positioned ≥50 m from treatment boundaries to avoid collecting data beyond treatment boundaries.

Bird sampling

We conducted 10-minute surveys of cavity-nesting birds from each point-count station from mid-April to 1 July. Point counts were conducted from sunrise to 0900 following standard protocols (Hutto et al. 1986), and an estimated distance of detection was assigned at 10-m intervals from the observer to each bird (Buckland et al. 2001). We excluded from analyses all fly-overs or birds detected >100 m from the observer.

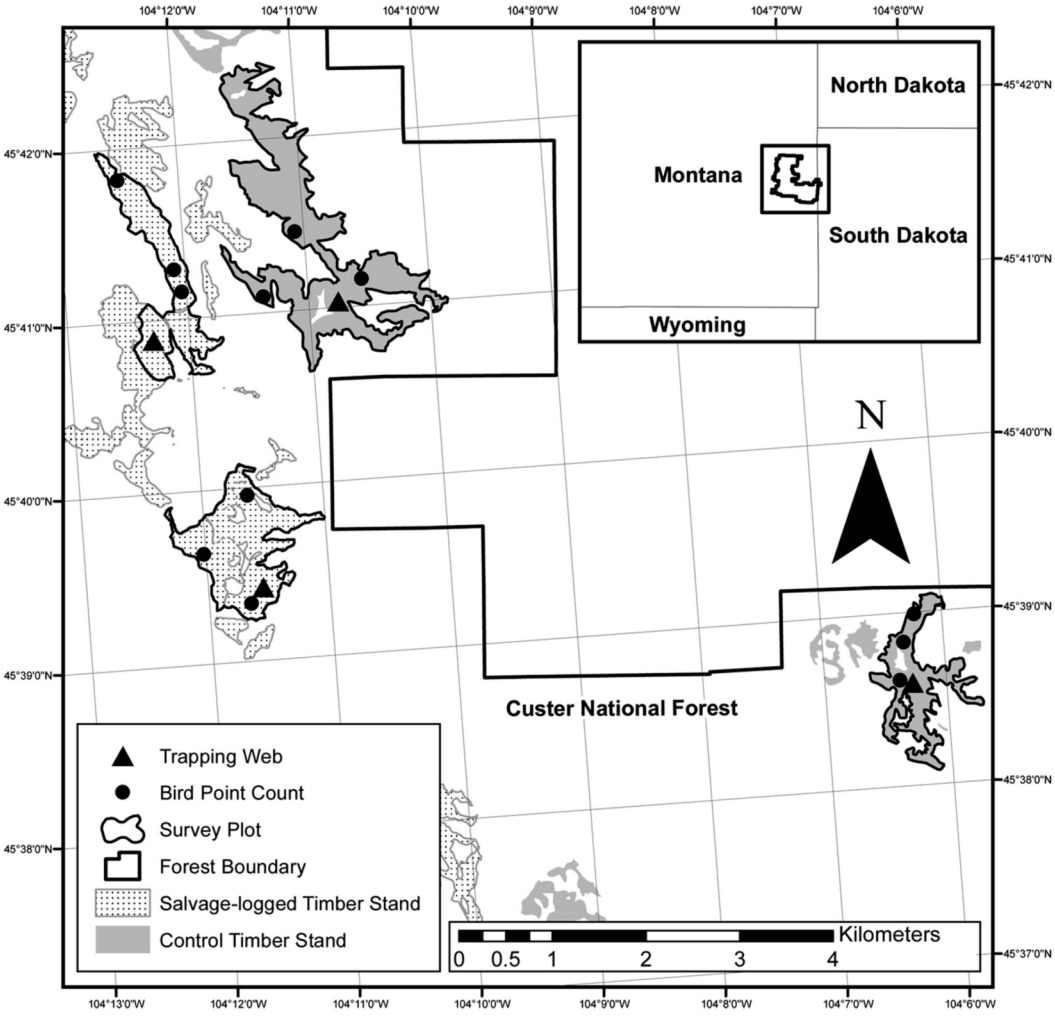

FIGURE 1. Plots and survey points sampled on salvage-logged and control treatments, Custer National Forest, Montana, 2004 and 2005.

Nest searches were conducted from mid-April through 1 July 2004 and 2005. We visited each plot every one to two days and located nests by observing adult behavior and systematically searching for cavities. Target species included Northern Flicker (*Colaptes auratus*), Red-headed Woodpecker (*Melanerpes erythrocephalus*), Hairy Woodpecker (*P. villosus*), Eastern Bluebird (*Sialia sialis*), Mountain Bluebird (*S. currucoides*), and European Starling (*Sturnus vulgaris*). We recorded the location of active nests with a Garmin E-trex Global Positioning System (GPS) receiver and flagged a bearing tree no closer than 30 m away.

We visited each cavity every three days for up to 30 minutes, or until the status of the nest (active or inactive) could be determined by observing adults or nestlings inside the cavity (Martin and Geupel 1993; Kronland 2007). We estimated nest stage according to courtship displays, duration of adult visits to the nest (courtship and egg laying vs. incubation), food deliveries, and nestling vocalizations. We monitored active cavities from the time of location to the completion of the nesting effort. We determined that a nest had failed if predation or usurpation was observed, or if the nest stage was known and inactivity occurred before the estimated fledge date (Martin and Geupel 1993; Kronland 2007). We considered a nest successful if fledglings were observed <20 m from the cavity, or if the fledge date was known and the cavity did not show signs of predation (e.g., enlarged cavity entrance or feathers at base of tree).

Small mammal sampling

We used trapping webs (one for each area) and distance sampling methods to estimate density based

on likelihood of detection rather than area trapped (Anderson et al. 1983). Each web consisted of 12 traplines radiating from a central point at 30° intervals (Jett and Nichols 1987). Trap stations consisted of two Sherman style live traps (8 cm × 8 cm × 25 cm) placed every 20 m along a trapline (l = 130 m) using 100-m tapes, starting 10 m from the center, for 168 traps per web. We covered exposed traps with aluminum flashing, rocks, or bark to provide shade, and we baited all traps with peanut butter. We trapped each web over four consecutive nights in August 2004 and 2005 in random order. Traps were checked daily beginning at sunrise and baited after each check. We applied a uniquely numbered ear tag to each individual (No. 1005-1 Monel, National Band and Tag Company, Newport, Kentucky, USA) and examined capture histories to determine if new animals were being detected at the innermost ring on the final night of trapping. We also examined data *post hoc* to ensure that movement of individuals across trap stations within trapping webs did not occur (Buckland et al. 2001).

We identified the species and sex of each captured animal. We measured tail, body, ear, and hind foot to the nearest mm with a stainless steel 30-cm ruler, and we weighed individuals to the nearest 1 g with a 100-g spring scale. Numerous Deer Mice (*Peromyscus maniculatus*) were captured in 2004 (n = 761) and 2005 (n = 869). We aged Deer Mice as juvenile or adult based on mass after examining the distribution of 20 to 30 individuals aged by pelage in the field (Pearson et al. 2003). We recorded ear tag number and trap location (trapline and ring) within the web before releasing animals at the trap site.

Habitat sampling

We measured habitat characteristics, such as size and density of burned trees, because of their known influence on the distribution and abundance of cavity-nesting birds (Hutto 1995; Murphy and Lehnhausen 1998; Nappi et al. 2003; Smucker et al. 2005). We recorded habitat features on plots of 11.3 m radius at the random point-count locations used to sample cavity-nesting birds in 2005 (Figure 1). Three subplots were arranged 120° from each other and 30 m from a central subplot centered on point-count locations, for a total of four subplots (Martin et al. 1997). Bearing of the first subplot from each point-count location was chosen semi-randomly in the field by multiplying the time in seconds by 6.

We measured DBH of all trees >7.5 cm DBH on each subplot, and we also recorded species and status (alive or dead). We categorized each subplot (1 = least decayed, 7 = most decayed) according to crown condition, bark retention (%), and the severity of the burn (%) (Nappi et al. 2003). In 2005, we also arranged four subplots around each nest tree found on the two replicates per treatment, and we conducted the same habitat measurements to describe these nest sites (salvage: n = 22; control: n = 27). For each nest tree, we recorded species, DBH, crown condition, bark retention (%), and the severity of the burn (%). Nest trees were often used by multiple pairs in a single season, and we considered measurements taken at these sites as independent samples when representing different species. We measured each nest site and nest tree only once if it was reused by the same species (Hutto and Gallo 2006).

Small mammal abundance has been positively correlated with the amount of downed woody debris (Carey and Johnson 1995). We therefore measured downed woody debris on subplots centered on each random point count used to survey cavity-nesting birds (Figure 1). We recorded downed woody debris lying at an angle of less than 45° with the ground that intersected a plane 1.8 m high and extended 11.3 m from the subplot center in a random direction (Brown and Roussopoulos 1974). Mean kg of downed woody debris per ha per point was calculated following methods described in Brown and Roussopoulos (1974).

Statistical analyses

We considered mean number of detections per point across years as an index of individual species abundance between treatments. We used distance sampling methods to estimate density (individuals per ha) of all cavity-nesting birds per treatment because we lacked sufficient observations to fit detection curves to species-specific data. Concern about independence of errors associated with sampling points within replicates over multiple occasions led us to pool data across visits and within replicates. We binned observations into five distance categories (0-20 m, 21-40 m, 41-60 m, 61-80 m, 81-100 m,) and used program DISTANCE 6.0 to fit global detection curves to salvage-logged and control treatment datasets (Buckland et al. 2001; Thomas et al. 2005*). We considered the full combination of uniform, half-normal, and hazard rate key functions with cosine, simple-polynomial, and Hermite-polynomial expansion terms, and we removed models with poor fit according to shape of the detection curve (shape criterion) and χ^2 goodness-of-fit tests (Buckland et al. 2001).

We used Program MARK (White and Burnham 1999*) and methods described by Dinsmore et al. (2002) to estimate nest survival (S). We first constructed a set of candidate models that included the full combination of underlying treatment-, year-, and time-varying effects on S. We then ranked models according to difference in Akaike's Information Criterion for small samples (ΔAIC_c), removed models that contained virtually no Akaike weight ($w_i < 0.01$) and failed to estimate parameters, and calculated a weighted-average survival estimate ($\hat{\bar{S}}$) across the remaining models (Burnham and Anderson 2002). We ended nest observation while some nests were still active, so we used only nests with complete histories (i.e., fledged or failed) to estimate reproductive success (n = 39). Nest survival estimates represent the period of mid-April through 1 July and were calculated for all cavity-

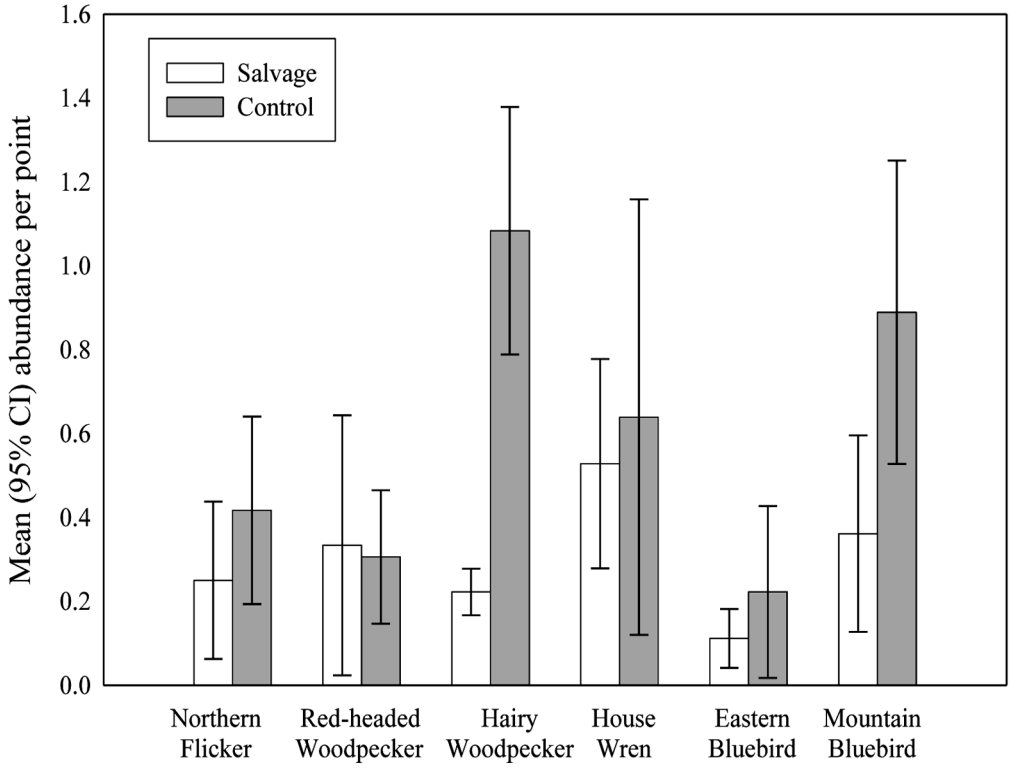

FIGURE 2. Mean (95% CI) abundance of selected cavity-nesting species per point count (pooled across years) on salvage-logged and control treatments, Custer National Forest, Montana, 2004 and 2005.

nesting species combined because sample sizes for individual species were small. We accounted for variation in size of nest-search plots by dividing the number of nests located by plot size to estimate density of active cavity nests (number of nests ha^{-1}).

We used program DISTANCE 6.0 to estimate small mammal density (individuals per ha) from initial captures by fitting detection curves to the full combination of uniform and cosine key functions combined with cosine, simple-polynomial, and Hermite-polynomial expansion terms (Buckland et al. 2001; Thomas et al. 2005*). We did not consider the hazard-rate or negative-exponential key functions because these models have been shown to overestimate density (D) and perform poorly with trapping-web data (Parmenter et al. 2003). We removed models with poor fit according to shape of the detection curve (shape criterion) and χ^2 goodness-of-fit test (Buckland et al. 2001), ranked remaining models based on difference in Akaike's Information Criterion (ΔAIC), assigned Akaike weights, and calculated weighted-average estimates of density ($\hat{D}$) across models (Burnham and Anderson 2002). Variance and 95% confidence intervals were calculated using formulas described in Buckland et al. (2001) and Burnham and Anderson (2002). Data were pooled across sampling occasions at each trapping web, and reported estimates represent the mean density of small mammals across sites within each treatment.

We used nested MANOVA to compare habitat characteristics between treatments at point-count locations (salvage: $n = 6$; control: $n = 6$) and nest sites (salvage: $n = 22$; control: $n = 27$). Variables included mean density of large trees, mean density of small trees, mean crown condition, the mean percentage of bark remaining on the tree bole, and the mean percentage of the tree that had been burned (severity). We also used nested MANOVA to examine difference in mean DBH, the crown condition, the bark remaining (%), and the severity of the burn (%) of individual nest trees on each treatment.

Results

Birds

We recorded the highest mean number of detections per point across years for Hairy Woodpecker ($\bar{x} = 0.65$, SE = 0.21), Mountain Bluebird ($\bar{x} = 0.63$, SE = 0.18), and House Wren (*Troglodytes aedon*) ($\bar{x} = 0.58$, SE = 0.2), followed by Northern Flicker ($\bar{x} = 0.33$, SE = 0.1), Red-headed Woodpecker ($\bar{x} = 0.32$, SE = 0.12), and Eastern Bluebird ($\bar{x} = 0.17$, SE = 0.08).

TABLE 1. Akaike's Information Criterion (AIC_c) ranking, Akaike weight (w_i), number of parameters estimated (K), and log likelihood (−2log(L)) of candidate models examining treatment (g), year (y), and constant (.) effects on nest survival.

Model	AIC_c	ΔAIC_c	w_i	K	−2log(L)
S(g)	137.8717	0	0.4114	2	133.8546
S(.)	138.2474	0.3757	0.3409	1	136.2417
S(y)	140.1623	2.2906	0.1309	2	136.1452
S(g*y)	140.3893	2.5176	0.1168	4	132.3322

White-breasted Nuthatch (*Sitta carolinensis*), American Kestrel (*Falco sparverius*), and Red-breasted Nuthatch (*S. canadensis*) were rarely detected during point counts (mean detections per point <0.1). No cavity-nesting species was found exclusively on either treatment, but mean abundance per point was greater on the control than the salvage treatment for Hairy Woodpecker (i.e., non-overlapping 95% CI, Figure 2).

The uniform key function with cosine expansion term was the only model that fit cavity-nesting bird data according to shape of detection curves and χ^2 goodness-of-fit tests (control: $\chi^2 = 5.7$, df = 3, $P = 0.13$; salvage: $\chi^2 = 0.1$, df = 1, $P = 0.75$). Estimated density of cavity-nesting birds was greater in 2005 ($\hat{D} = 3.83$; 95% CI – 3.5 to 4.11) than 2004 ($\hat{D} = 2.05$; 95% CI – 1.61 to 2.49) on the control treatment, and did not differ between years on the salvage treatment (2004: $\hat{D} = 1.39$; 95% CI – 0.98 to 1.59; 2005: $\hat{D} = 2.33$; 95% CI – 1.5 to 2.72). Density of cavity-nesting birds across both years was greater on the control ($\hat{D} = 2.94$; 95% CI – 2.7 to 3.15) than the salvage ($\hat{D} = 1.86$; 95% CI – 1.24 to 2.17) treatment.

We located 36 nest cavities on the control treatment (2004: $n = 17$; 2005: $n = 19$), representing 48 nest attempts (1.3 attempts per cavity), and 29 nest cavities on the salvage treatment (2004: $n = 15$; 2005: $n = 14$), representing 43 nest attempts (1.5 attempts per cavity). Red-headed Woodpeckers accounted for 34% of located cavities, and were the only species that had higher nest density on the salvage than the control treatment (0.20 nests/ha versus 0.12 nests/ha, respectively, $n = 31$). Other cavity nesters included Hairy Woodpecker (salvage: 0.07 nest/ha; control: 0.14 nests/ha; $n = 20$), Mountain Bluebird (salvage: 0.05 nests/ha; control: 0.11 nest/ha; $n = 15$), Northern Flicker (salvage: 0.06 nests/ha; control: 0.07 nests/ha; $n = 12$), Eastern Bluebird (salvage: 0.03 nests/ha; control: 0.05 nests/ha; $n = 8$), and European Starling (salvage: 0.02 nests/ha; control: 0.03 nests/ha; $n = 5$). Hairy Woodpeckers were known, through direct observation, to have constructed 32% ($n = 21$) of the located nest cavities. Excavator was uncertain for 52% ($n = 34$) of cavities, Red-headed Woodpeckers produced 11% ($n = 7$) of cavities, and 5% ($n = 3$) of cavities were created naturally.

We compared eight candidate models of nest survival, and four models received some support (Table 1). Weighted-average estimates of S between treatments and across years were high (salvage: $\ddot{\hat{S}} = 0.96$, SE = 0.01 (2004), $\hat{S} = 0.97$, SE = 0.01 (2005); control: = 0.98, SE = 0.01 (2004), $\hat{S} = 0.98$, SE = 0.01 (2005)) and strongly overlapped, indicating that differences in nest survival between treatments were negligible. Eight of 19 nest attempts with known histories failed on the salvage treatment, compared to 9 of 20 attempts on the control treatment. Red-headed Woodpeckers were responsible for 11 nest failures (65%) by depredating or usurping nests. House Wrens were observed filling 2 Mountain Bluebird cavities with twigs, and the cause of 5 nest failures remained unknown.

Small mammals

We captured 1630 Deer Mice and 64 Meadow Voles (*Microtus pennsylvanicus*) in 2004 and 2005. Other species that accounted for <1% of captures included Hispid Pocket Mouse (*Chaetodipus hispidus*), Thirteen-lined Ground Squirrel (*Spermophilus tridecemlineatus*), Olive-backed Pocket Mouse (*Perognathus fasciatus*), Western Harvest Mouse (*Reithrodontomys megalotis*), Bushy-tailed Woodrat (*Neotoma cinerea*), White-footed Mouse (*P. leucopus*), and Eastern Cottontail (*Sylvilagus floridanus*).

We estimated density of Deer Mice only, because other species did not comprise a large enough sample to use distance-based models. We derived yearly estimates of density because excessive lumping of detections between 70 m and 110 m in the pooled dataset prevented us from fitting a detection curve. Models consisting of the uniform and half-normal key functions with cosine adjustment had strong support across treatments and years (Table 2). Density of Deer Mice was greater on salvage-logged (2004: $\hat{D} = 24.2$, 95% CI – 18.9 to 30.9; 2005: $\hat{D} = 21.5$, 95% CI – 15.4 to 30.0) than control areas (2004: $\hat{D} = 6.5$, 95% CI – 3.3 to 12.6; 2005: $\hat{D} = 5.8$, 95% CI – 3.5 to 9.5). We categorized Deer Mice weighing ≤17 g as juveniles, based on mass of a subset of individuals that were aged by pelage. The mean ratio of juveniles to adults captured per trapping web was 1:1.3 on salvage-logged and 1:0.8 on control sites.

Habitat

Large trees (>23 cm DBH) were less abundant on salvage-logged ($\bar{x} = 6.64$ trees ha^{-1}, SE = 2.62) than control sites ($\bar{x} = 53.1$ trees ha^{-1}, SE = 8.64), as determined by habitat measurements at point-count locations (Table 3). Microsites surrounding nest trees on

the control treatment also had greater mean density of trees >23 cm DBH (salvage: $\bar{x}$ = 26.45 trees ha^{-1}, SE = 4.97; control: $\bar{x}$ = 62.27 trees ha^{-1}, SE = 3.64) and more bark remaining on the tree bole (salvage: $\bar{x}$ = 5.17, SE = 0.29; control: $\bar{x}$ = 1.95, SE = 0.08) than salvage-logged sites (Table 3).

Nest trees on the salvage had more deteriorated crowns (salvage: $\bar{x}$ = 5.00, SE = 2.37; control: $\bar{x}$ = 2.85, SE = 1.85) and less bark remained on the tree bole (salvage: $\bar{x}$ = 3.86, SE = 2.34; control: $\bar{x}$ = 2.63, SE = 1.62) than nest trees on the control plots (Table 3). Nest attempts on the salvage were most often (61%; n = 15) located in non-logged stands of green Ponderosa Pine, Trembling Aspen, or Green Ash. Only 7% (n = 2) of nest attempts in control areas occurred in those trees.

Mean volume of downed woody debris was greater on the salvage ($\bar{x}$ = 1964 kg/ha, 95% CI – 822 to 3160) than the control treatments ($\bar{x}$ = 460 kg/ha, 95% CI – 189 to 731). Mean number of downed woody debris pieces on the salvage treatment was 5.7 per replicate with a mean volume of 89 cm^3. Mean number of pieces of downed woody debris on the control treatment was 1.9 per replicate with a mean volume of 122 cm^3.

Discussion

Our results were consistent with the growing body of evidence demonstrating that post-fire salvage logging has significant negative effects on cavity-nesting birds, at least two to three years following a wildfire (Hutto 1995; Saab and Dudley 1998; Smucker et al. 2005; Hutto and Gallo 2006). Density of cavity-nesting birds was lower on the salvage than the control treatment. Moreover, few potential nest sites existed on the salvage treatment and occupied cavities were most often located in riparian buffer strips or in stands of green trees and hardwoods not subject to harvest. In contrast, abundance of Deer Mice was greater on salvage-logged than on control plots, and was closely associated with the high amount of downed woody debris on the salvage treatments.

Dense stands of trees >23 cm DBH were also more common on the control than the salvage treatment. The stands provided potential foraging opportunities for primary cavity nesters, such as Hairy Woodpeckers, probably because large trees contain high densities of beetle larvae (Cerambycidae and Buprestidae) (Mannan et al. 1980; Nappi et al. 2003; Hanson and North 2008). Cavity nesters, particularly Hairy Woodpeckers, were infrequently detected during point counts in areas dominated by small trees. At least 18% of the excavations produced by Hairy Woodpeckers were used by other cavity nesters, and the paucity of Hairy Woodpeckers in salvage-logged areas probably had a negative effect on secondary cavity nesters. For example, both Mountain Bluebirds and House Wrens nested less often in the salvage-logged than the control areas. Post-fire logging therefore had both direct and indirect negative effects on the cavity-nesting assemblage.

TABLE 2. Akaike's Information Criterion (AIC_c) ranking, Akaike weight (w_i), number of parameters estimated (K), log likelihood (−2log(L)), and results of χ^2 goodness-of-fit test for candidate models used to estimate population density of Deer Mice on salvage-logged and control treatments, 2004 and 2005.

Treatment	Year	Model	AIC	ΔAIC	w_i	K	−2log(L)	χ^2	df	P
Salvage	2005	Half-normal + cosine	2155.73	0	0.70	4	−1073.87	2.12	2	0.35

The distribution and abundance of breeding habitat that remained after salvage logging differed between treatments and affected nest site use. Stands of high tree density on salvage treatments existed only in non-harvested areas. Non-logged areas represented approximately 15% of the total area on salvage treatments, yet they contained 71% of nest cavities. In contrast, most nest cavities on the control were in habitats that would have been logged (e.g., stands of large dead Ponderosa Pine). Trembling Aspen and Green Ash accounted for only 6% of nest attempts on the control while representing 40% of attempts on the salvage. If Trembling Aspen and Green Ash had been preferred breeding habitat, the number of nest attempts in these habitats would probably have been similar between treatments. Regardless of treatment, cavity nesters were found most often in areas with high densities of large trees, habitat features considered important legacies in burned forests (Franklin et al. 2000; Hutto 2006).

Post-fire salvage logging did not reduce reproductive success of cavity-nesting birds on our study area in southeastern Montana, despite negative effects on bird abundance. To our knowledge, only three other studies have reported reproductive information while investigating effects of post-fire logging on cavity-nesting birds. One study found no effect and two studies found reduced reproductive success, but only for Hairy and Lewis's woodpeckers (reviewed by McIver and Starr 2001; Saab et al. 2011). The small number of existing studies on post-fire effects reflects the general pattern reported by Sallabanks et al. (2000), where only 13% of studies investigating effects of silviculture on birds collected demographic data. Clearly, data on reproductive success and survival remain a research priority (Kotliar et al. 2002).

Density of Deer Mice was greater on salvage than control plots. This reflected the four-fold difference in volume of downed woody debris across treatments. Mechanical removal of trees during logging led to an incidental and rapid accumulation of downed branches, debris used by small mammals for breeding, foraging, and predator avoidance (Harmon et al. 1986; Ucitel et al. 2003). Dead trees on the control remained standing two to three years post-fire and had not yet replaced downed woody debris consumed during the fire. Debris on the control would be expected to continue to accumulate as trees deteriorated (Tinker and Knight 2001; Russell et al. 2006), whereas the amount of debris on the salvage treatment had probably reached its maximum because most standing dead trees had been harvested.

Although Deer Mice responded favorably to the accumulation of downed woody debris on the salvage treatment, density of small mammals may not reflect habitat quality if dominant individuals exclude subordinates from the best habitats (Van Horne 1983; Rodenhouse et al. 1997). Adult Deer Mice defend territories against non-reproducing juveniles (Long and Mont-

TABLE 3. Results of Multivariate Analysis of Variance (MANOVA) tests comparing habitat characteristics at point-count locations in salvage-logged and control plots and at nest sites on salvage-logged and control plots, and comparing nest-tree characteristics on salvage-logged and control treatments, Custer National Forest, Montana, 2004 and 2005.

	Point counts salvage: $n = 6$; control: $n = 6$			Nest sites salvage: $n = 22$; control: $n = 27$			Nest trees salvage: $n = 22$; control: $n = 27$		
Habitat characteristic	F	df	P	F	df	P	F	df	P
Trees 10–23 cm DBH ha^{-1}	0.003	1,8	0.958	1.576	1,45	0.216	NA	NA	NA
Trees >23 cm DBH ha^{-1}	22.519	1,8	0.001	38.761	1,45	<0.001	NA	NA	NA
$\bar{x}$ tree DBH (cm)	NA	NA	NA	NA	NA	NA	3.267	1,45	0.077
Crown condition [a]	0.096	1,8	0.764	3.111	1,45	0.085	12.434	1,45	0.001
Bark retention [b]	0.183	1,8	0.68	163.139	1,45	<0.001	5.28	1,45	0.026
Burn severity [c]	0.019	1,8	0.894	0.748	1,45	0.392	2.987	1,45	0.091

[a] Relative amount of twigs, branches, and limbs on tree crown (1 = intact crown, 7 = broken top).
[b] Percentage of bark remaining on tree bole (1 = 100%, 7 = no bark).
[c] Percentage of tree burned (1 = unburned, 7 = completely burned).

gomerie 2006), so a large juvenile to adult ratio would indicate low-quality habitat. However, adults were more abundant than juveniles on the salvage treatment where densities of Deer Mice were highest. This supports the conclusion that density reflects high-quality habitat. Information regarding individual reproductive status (not recorded in this study) might have provided further insight into habitat quality between treatments for Deer Mouse.

Despite temporarily benefiting Deer Mice populations, the rapid accumulation of downed woody debris may have increased the short-term risk of wildfire because woody ground debris is a primary determinant of fire behavior (Donato et al. 2006). One of the goals of salvage logging is to reduce the probability of large wildfires, and failure to achieve fire management objectives is particularly important in southeastern Montana because of the historically high frequency of wildfires (Brown and Hull Sieg 1996). The risk of future fire could be reduced by creating heterogeneous landscapes of logged and non-logged areas, where woody debris would accumulate and deteriorate at different rates, thus creating fuel breaks. Retaining some intact stands of large trees (>23 cm DBH) could also mitigate the negative effects of salvage logging on cavity nesters.

Current federal and state guidelines recommend retaining 6 to 10 dead trees per hectare (Hutto 2006). However, salvage prescriptions that retain a specific number of trees per hectare or uniformly remove a specific size class of tree (e.g., >25 cm DBH) accelerate post-fire succession and create homogeneous landscapes unsuitable for many cavity-nesting birds (Hutto 1995; Kotliar et al. 2002; Hutto 2006; Schmiegelow et al. 2006). Conserving intact stands of large trees would create heterogeneous landscapes that resemble natural post-fire conditions and harbor many of the legacies deemed important in such landscapes (Franklin et al. 2000). Although further investigation is needed to determine the size and distribution of burned tree stands that should be retained, conditions resulting from salvage logging in this study provided lower quality habitat than unlogged areas.

Acknowledgements

We thank T. Whitford for initiating and supporting the study. B. Haase contributed field assistance in 2005, and the Sioux Ranger District provided housing during field seasons. S. Carson and A. Messer provided small mammal traps and helped with species identification. Trapping and marking of small mammals was approved by the Institutional Animal Care and Use Committee at St. Cloud State University, in cooperation with Montana Fish, Wildlife and Parks. J. Arriagada and L. Onyiah commented on the draft manuscript, and J. Marzluff provided advice on experimental design and data analysis. We thank D. Nagorsen and an anonymous reviewer for helpful comments on the final version. Funding was provided by the U.S. Forest Service, Custer National Forest (Agreement No. 04-PA-11010803-008) and St. Cloud State University.

Abstract

1. In response to mounting wildfire risks, land managers across the country will need to dramatically increase proactive wildfire management (e.g. fuel and forest health treatments). While human communities vary widely in their vulnerability to the impacts of fire, these discrepancies have rarely informed prioritizations for wildfire mitigation treatments. The ecological values and ecosystem services provided by forests have also typically been secondary considerations.
2. To identify locations across the conterminous US where proactive wildfire management is likely to be effective at reducing wildfire severity and to yield co-benefits for vulnerable communities and ecological values, we developed a set of spatial models that estimated wildfire mitigation potential (based on wildfire hazard and biophysical forest conditions) and either included or excluded information on vulnerable human communities, ecological values and ecosystem services. We then compared areas with high wildfire mitigation potential alone to refined 'focal areas' that overlaid social and ecological considerations to quantify the potential benefits of targeted wildfire mitigation treatments.
3. Inclusion of social and ecological considerations substantially increased representation of vulnerable communities and ecological values in focal areas relative to the model that considered wildfire alone. For instance, restoration in these refined focal areas would cover 28% greater imperilled species richness, 45% greater water importance and 26% more families falling below the poverty line.
4. By examining overlap between our refined focal areas and U.S. Forest Service top ranked firesheds (a prominent existing wildfire prioritization scheme), we show that our analysis can help to target wildfire mitigation efforts within firesheds to areas with particularly high social vulnerability and/or ecological value, providing an important compliment to a prioritization scheme based largely on risk to structures.
5. Our results highlight the importance of considering ecological and social factors when implementing wildfire mitigation treatments and provide actionable guidance for integrating these considerations into existing prioritizations.

1 | BACKGROUND

Forest fire activity has been on the rise due to fire suppression, changing climatic conditions, exclusion of indigenous burning, human-caused ignitions and tree mortality caused by the compounding stressors of climate change, pests and disease (Balch et al., 2017; Hessburg et al., 2021; Parks & Abatzoglou, 2020). Simultaneously, conversion of forested areas to development has expanded the wildland-urban interface (WUI), enhancing the threat of fire to human infrastructure, lives and livelihoods (Balch et al., 2017; Mietkiewicz et al., 2020; Radeloff et al., 2018).

Increased wildfire activity has the potential to impact not only human communities, but also critical ecological values and ecosystem services. While fire is indeed a natural component of a healthy landscape, an increasing number of wildfires are growing to atypical sizes with larger areas burning at high severity (Parks & Abatzoglou, 2020). These 'megafires' can alter or impede post-fire recruitment and ecosystem recovery, even in systems well-adapted to natural fire regimes (Brown & Johnstone, 2012; Davis et al., 2018). A reduction in fire severity could better enable ecosystem recovery, especially as warmer and drier conditions complicate tree regeneration (Davis et al., 2023).

Fuel treatments, including prescribed fire and mechanical thinning, can reduce fire severity with the potential to support biodiversity, habitat quality and vegetation diversity (Hessburg et al., 2021; Jones et al., 2022; Stephens et al., 2024). They have also been shown to decrease the overall cost of future wildfire response, reduce the likelihood of structure loss or risk to firefighters, and maintain beneficial ecosystem services (Bayham et al., 2022). As a result, fuel treatments have been the dominant method of mitigating wildfire risk. For instance, the Biden Administration has committed $1.5 billion to reducing wildfire risk, including safeguarding communities, via proactive wildfire management such as fuel treatments on both federal and non-federal lands (The White House, 2022a, 2022b; U.S. Department of the Interior, 2022). Likewise, the U.S. Forest Service (USFS) 'Confronting the Wildfire Crisis' strategy commits to an 'all-lands' approach to treating up to 8.1-million ha (20-million acres) of national forest (NF) lands and 12.1-million ha (30-million acres) of other federal, state, tribal and private lands over the next 10 years with the goal of protecting human communities and improving forest health and resilience (U.S. Department of Agriculture, 2022; USFS, 2023).

Our goal with this analysis was to identify places where the proactive application of fuel and forest health treatments (hereafter 'restoration', but see Stephens et al., 2020) is likely to be effective in reducing wildfire risk while also directing restoration efforts towards socially vulnerable communities and areas of particularly high ecological value. Typically, restoration is directed towards areas biophysically prone to wildfire and where risk to structures is relatively high (i.e. the WUI); however, research has shown that this approach does not always distribute resources to the communities with the greatest need. In some instances, these resources have even disproportionately gone to more affluent communities at a direct cost to more vulnerable communities (Evans et al., 2007; Morton, 2003; Poudyal et al., 2012; Program for Watershed and Community Health, 2003).

Indeed, communities considered 'socially vulnerable' are less likely to receive or engage in restoration efforts, even when they are at a high wildfire risk (Gaither et al., 2011; Ojerio, 2008; Ojerio et al., 2011; Poudyal et al., 2012). Social vulnerability describes "the ability of individuals and communities to plan for, respond to, and recover from natural disasters" (Ojerio et al., 2011, p.29). The concept centres on a lack of (or limited) access to political power, representation, physical and intellectual resources, social capital, physical health or ability, and infrastructure and is often measured as an integration of contributing factors (Cutter et al., 2003; Cutter & Finch, 2000). For example, in the context of wildfire, prevalence of respiratory conditions including chronic obstructive pulmonary disease (COPD) and asthma are highly relevant due to potential smoke exposure. Likewise, income level reflects the ability to pay for restoration efforts (e.g. brush removal) or to recover from loss of property or livelihood. Discrepancies in social vulnerability necessitate the development of more equitable risk mitigation measures.

The ecological value of forest ecosystems and the services they provide to human communities are also frequently left out of restoration prioritizations. For example, the capacity of forests to support habitat and connectivity (Thompson et al., 2021) as well as provide clean drinking water and carbon storage (Thom & Seidl, 2016; Vukomanovic & Steelman, 2019) can be threatened by wildfire and should be considered in restoration prioritizations (Chamberlain & Jones, 2023). Moving forward, it will be necessary to focus restoration efforts on locations with the greatest restoration efficacy and broader social and ecological co-benefits (Gaither et al., 2011; Poudyal et al., 2012; Wigtil et al., 2016).

To date, restoration prioritizations, such as the USFS Fireshed Registry (Ager et al., 2021), have largely centred on risk to infrastructure, particularly in the WUI. Our research was thus motivated by the need for an intentional shift towards more equitable restoration priorities. Specifically, our research objective was to identify places where restoration is likely to be effective in both reducing subsequent fire severity and in safeguarding socially vulnerable communities as well as important ecological values and services. We developed a tool that highlights the potential co-benefits of restoration for vulnerable communities and ecosystems and that can be used to further refine existing prioritizations (e.g. firesheds)

25758314, 2025, 1, Downloaded from https://besjournals.onlinelibrary.wiley.com/doi/10.1002/pan3.10733, Wiley Online Library on [16/02/2025]. following an 'all-lands' approach across the conterminous U.S. (CONUS). We then compared a spatial prioritization that included only 'wildfire mitigation potential' (i.e. the potential for restoration to effectively mitigate future wildfire behaviour) with a model that integrated wildfire mitigation potential with social and ecological considerations. This allowed us to quantify the potential benefits of targeted restoration efforts for vulnerable communities and ecosystems. Rather than attempting to highlight exact locations where fire management activities should occur, our intent was to identify landscapes that can serve as starting points for consideration when the USFS or other land management agencies are determining which areas to target for restoration. Once landscapes have been identified, collaboration with local communities, tribes, and stakeholders will be necessary to guide the design and implementation of these projects on the ground.

2 | METHODS

To achieve our research objective, we developed two composite indices (Burgass et al., 2017; Greco et al., 2019; Wiréhn et al., 2015; see Appendix S1) describing (i) the potential to reduce future wildfire severity (hereafter, the 'wildfire mitigation potential index' or WMPI) and (ii) social vulnerability of communities and ecological values and services that are potentially at risk from wildfire (hereafter, the 'social-eco index' or SEI). The WMPI was derived from existing spatial indicators describing forest condition and wildfire hazard potential. To derive the SEI, we developed and combined three sub-indices, each describing a distinct category of factors potentially at risk from wildfire (social vulnerability, ecological value, ecosystem services; Figure 1) and each composed of a unique set of social or ecological indicators. We then overlaid the WMPI and SEI to identify areas for restoration that achieve multiple objectives (Figure 1). Spatial data used to derive each of these indicators are described below.

The method of combining indicators to derive a particular index (or sub-index) varied between models, drawing on the most appropriate approach for a particular index type. Most of the indices described below were derived as the weighted linear sum of the underlying indicator values such that

$$y_i = \sum_{j=1}^{J} x_{ij} w_j \quad (1)$$

where y_i is the value of the index at location i, x_{ij} is the (standardized) value of indicator j at location i, and w_j is the weight applied to indicator j. We utilized a recently developed method for deriving indicator weights, w_j, such that each indicator had a predefined influence on the resulting index value, y_i while accounting for correlations among indicators (Becker et al., 2017; Paruolo et al., 2013; Suraci, Farwell, et al., 2023; see also Appendix). Analyses were conducted in R (v4.2.1), ArcGIS Pro (v3.0.0) and Google Earth Engine (GEE; Gorelick et al., 2017) via the Earth Engine Python application programming interface. Final model layers (indices and sub-indices) were resampled to 90-m resolution in GEE.

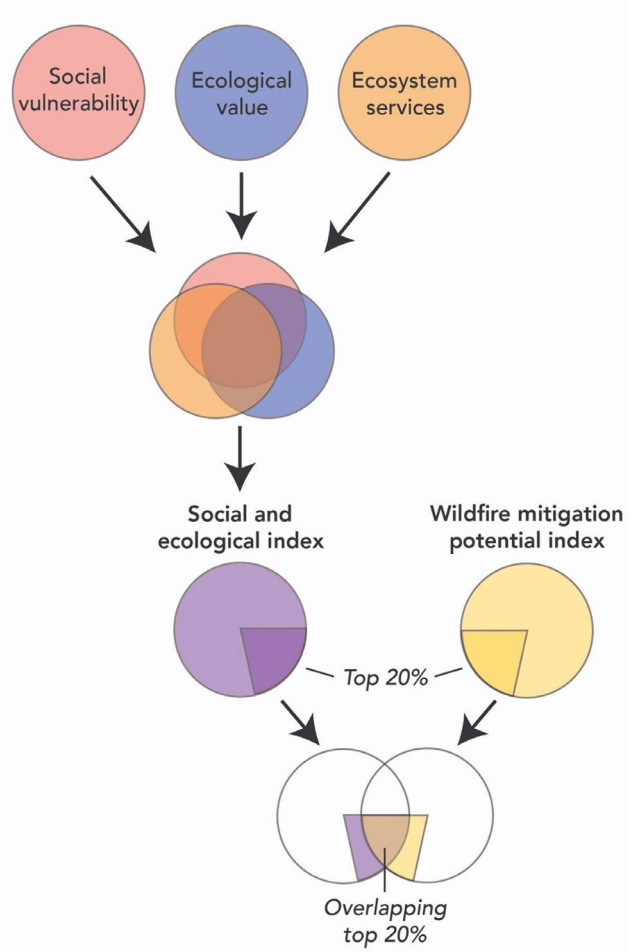

FIGURE 1 Workflow for identifying areas where restoration has the potential to both reduce subsequent fire severity and to safeguard vulnerable communities and important ecological values and services. Spatial sub-indices defining social vulnerability, ecological value and ecosystem services were combined into a 'social and ecological index'. Pixels of this index and a separately derived 'wildfire mitigation potential index' were thresholded to identify areas falling in the top 20% for each index within each U.S. Forest Service administrative region (USFS regions shown in Figure 2). Locations where the top 20% of both indices overlapped were identified as targets, or 'focal areas', for restoration.

2.1 | Wildfire mitigation potential index

The WMPI integrates forest conditions and wildfire hazard potential to suggest where restoration may be most effective from a biophysical perspective and may therefore moderate future wildfire behaviour. Specifically, we included the following datasets in this index (see also Appendix S1):

25783814, 2025, 1, Downloaded from https://besjournals.onlinelibrary.wiley.com/doi/10.1002/pan3.10733, Wiley Online Library on [16/02/2025]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

- *Wildfire hazard potential* (*WHP*) quantifies the relative potential that a wildfire will occur at a given location and that the fire will be difficult to control through standard suppression techniques (Dillon et al., 2015; Scott et al., 2020).
- *Percent low-severity fire* (*PLS*) estimates the historical proportion of low-severity fire relative to mixed- and high-severity fires prior to European settlement (LANDFIRE, 2020).
- *Vegetation departure* (*VDep*) depicts the degree to which present-day vegetation is different from historical conditions prior to European settlement (LANDFIRE, 2020).

We included WHP to ensure that our model focused on areas most likely to experience difficult-to-control wildfire. We included VDep to capture locations where human actions have drawn forests far from the conditions historically maintained by natural dynamics. For example, widespread fire suppression has led to substantial changes in forest composition, structure and fuel accumulation in many contexts (Hagmann et al., 2021). Lastly, we included PLS because high VDep cannot independently discern where restoration may be most beneficial. High VDep may occur in locations such as tree plantations in moist climates (e.g. the southeastern U.S.) where vegetation departures are substantial but where restoration is not known to reduce fire severity. Accordingly, areas that historically experienced high degrees of low-severity fire (high PLS) are elevated in our index. These locations tend to experience arid conditions conducive to frequent burning and have historically not had high accumulations of fuel, but fire suppression has interrupted that dynamic (e.g. ponderosa pine or oak woodlands in the western U.S.). Ample evidence points to the efficacy of restoration in moderating fire behaviour in such contexts (e.g. Jones et al., 2022), whereas there is limited evidence that restoration is effective in forest types that historically experienced less low-severity fire and more mixed or high-severity fire (Halofsky et al., 2018; Schoennagel et al., 2004).

We derived the WMPI as the weighted linear sum (see above) of WHP, VDep and PLS, with each layer rescaled to 0–100. We used the optimization procedure described in Appendix S1 to identify the set of weights that lead to relative influence of 2:1:1 for WHP, VDep and PLS, respectively, on the final index values (i.e. WHP was twice as influential as VDep and PLS in determining the index result for a given pixel). We chose this set of relative influence values to ensure that our index highlighted areas with relatively high probability of actually experiencing a wildfire.

2.2 | Social and ecological index

The SEI was derived by combining three separate sub-indices, each describing a set of characteristics or values that may be threatened *if an uncharacteristic wildfire were to occur* and was designed to be agnostic to the actual likelihood of wildfire in a given location. It is important to note that these sub-indices do not necessarily quantify the expected loss of a given value *to* wildfire (e.g. amount of forest carbon or degree of connectivity potentially lost to fire), but rather are meant to highlight locations where these values are high and where restoration may jointly protect these values and yield substantial co-benefits as a result.

2.2.1 | Social vulnerability sub-index

The social vulnerability sub-index identifies places where communities may be particularly impacted by, or least able to recover from, wildfire due to factors such as income, prevalence of health issues, or other demographic characteristics. We focused on census tracts as the spatial unit of analysis given data availability and the common usage of census tract-level data in deriving similar indices (e.g. Davies et al., 2018). We reviewed indicators across 14 existing indices of social vulnerability and selected indicators most salient to wildfire (see Appendix S1). The final set of indicators encompassed nine themes (Table 1). All indicators, with the exception of median household income, were provided as a percentage of the census tract population or an otherwise regionally adjusted value to reduce potential bias associated with regional variation.

These 22 indicators were combined in a principal components analysis (PCA) using the 'factoextra' package in R to reduce the dimensionality of the indicator set and account for correlation among them. Any missing indicator values at individual census tracts (3% of the total dataset) were imputed using a regularized iterative PCA algorithm in the R package 'missMDA' (see Appendix S1). PCA scores for all census tracts with imputed values were then predicted from the original PCA run only on complete records.

We used the inverse of the first principal component (PC1) as our metric of social vulnerability (i.e. social vulnerability $= -1 \times$ PC1). Our intent with the PCA was not to explain as much variance as possible (PC1 explained 27.6% of variance across all indicators), but rather to reduce the dimensionality of a large set of indicators. In our view, the inverse of PC1 serves this purpose well in that all social indicators vary with our social vulnerability metric in an intuitive direction. For instance poverty, unemployment and minority status all increase with our vulnerability index while income level, broadband access and voter turnout all decrease (see Figure S1.1). Incorporating PC2 into the index would indeed have explained more of the overall variation in the set of social indicators, but the PC2 axis did not map clearly onto social vulnerability (see Appendix S1). We acknowledge the limitations associated with PCA, namely its assumption that linearity can be established between variables. However, given our primary goals of reducing data dimensionality and deriving a continuous metric of social vulnerability, PCA remained the most readily interpretable approach in this context and is consistent with similar analyses (e.g. Wigtil et al., 2016). We calculated social vulnerability values for each census tract, and tracts were then rasterized at a 90-m resolution for subsequent analysis.

25783814, 2025, 1, Downloaded from https://besjournals.onlinelibrary.wiley.com/doi/10.1002/pan3.10733, Wiley Online Library on [16/02/2025]. TABLE 1 The 22 indicators of social vulnerability in the context of wildfire used to represent the social vulnerability sub-index, organized by theme.

Theme	Dataset
Education level	% of the total population (25+ years old) without a high school diploma[a]
Employment status	% of the civilian labour force (16+ years old) currently unemployed[a]
Health status and access to care	Prevalence (%) of COPD[b]
	Prevalence (%) of asthma[b]
	% of the total population with a disability[b]
	% of the total population without health insurance[b]
	Number of ICU beds available per 100k people[c]
Living situation	% of housing units that are mobile homes[a]
	% of crowded housing (i.e. housing units with more than one occupant per room)[a]
	% of households with children under 18 that are headed by a single parent[a]
	% of the total population living within institutionalized group quarters[a]
	% of the total population living in nursing and skilled nursing facilities[d]
Income	% of families whose income is below the poverty line[a]
	Median household income[a]
Cost of living	Median gross rent as a percentage of income[a]
Demographics	% of the total population (5+ years old) that speaks limited English[a]
	% of the total population with minority status[a]
Community engagement	Voter turnout in the 2020 presidential election (as a percentage of the total population over 18)[e]
Quality of life	% of households with a broadband subscription[a]
	% of households with phone service[a]
	% of households without complete plumbing[a]
	% of housing units without a vehicle[a]

2.2.2 | Ecological value sub-index

The ecological value sub-index estimates the potential for a location to contribute to important ecological processes such as supporting biodiversity, connectivity and climate adaptation. The set of indicators included the following (see also Appendix S1):

- *Climate accessibility* estimates the degree to which the local climate conditions currently experienced by a species will be accessible in the future (by the year 2055; higher climate accessibility = greater ability of species to adapt to climate change via movement). This metric is effectively the inverse of climate velocity (Hamann et al., 2015).
- *Imperilled species richness* estimates the number of species of conservation concern likely to occur in a given area (NatureServe, 2020).
- *Vertebrate species richness* estimates the number of terrestrial, non-volant species likely to occur in a given area (Conservation Science Partners, 2021).
- *Ecological intactness* estimates the degree to which a given location remains in a natural state (i.e. little to no influence from contemporary human land use changes; Parrish et al., 2003; Suraci, Farwell, et al., 2023).
- *Ecological connectivity* estimates the ability of a given location to support the natural movement of organisms through processes such as dispersal, migration and gene flow and to provide linkages between areas of high quality habitat (Dickson et al., 2017; Suraci, Littlefield, et al., 2023).
- *Vegetation diversity* describes the diversity of plant communities, defined here as groups of 'plant community types (associations) that tend to co-occur within landscapes with similar ecological processes, substrates, and/or environmental gradients' (Comer et al., 2003).

The above indicators were standardized (*z*-score transformation), resampled to a common resolution (90-m) and combined using the weighted linear sum method described above. We applied the set of weights such that each indicator had equal influence in the resulting sub-index (see Appendix S1).

2.2.3 | Ecosystem services sub-index

The ecosystem services sub-index captured two key ecosystem services that forests provide – (1) the provisioning of clean drinking water and (2) carbon storage. This sub-index identifies areas where wildfire may negatively impact the capacity of forests to provide these services. While recognizing that forests provide many ecosystem services beyond those discussed here (e.g. recreational value), we focused on water supply and carbon sequestration because they are (i) readily quantifiable at the national scale and (ii) largely non-redundant with the values in the ecological value sub-index. As noted above, these indicators are not intended to capture the actual loss of carbon or drinking water to fire, but rather to focus attention on locations where these values are relatively high (see also Appendix S1):

- *Total forest carbon* estimates current (circa 2018) carbon storage as tons of carbon per pixel across forests in CONUS (USFS Forest Inventory & Analysis, 2022; Wilson et al., 2018).

25758314, 2025, 1, Downloaded from https://besjournals.onlinelibrary.wiley.com/doi/10.1002/pan3.10733, Wiley Online Library on [16/02/2025]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

- *Relative importance to surface drinking water* quantifies a watershed's ability to provide clean drinking water to human communities (National Forests to Faucets v2.0—Mack et al., 2022).

The ecosystem services sub-index was derived by standardizing (*z*-score transformation) the indicator layers, resampling them to 90 m and calculating a weighted linear sum using the set of weights that yielded equal influence of the two indicators.

2.2.4 | Deriving the social-eco index

Finally, we combined each of the three sub-indices (social vulnerability, ecological value and ecosystem services) into the SEI using the same weighted linear sum approach described above. We acknowledge that our approach of applying the social vulnerability metric across entire census tracts will result in some uninhabited areas being considered socially vulnerable. However, there is a trade-off between generalizing social vulnerability to uninhabited areas and focusing instead on mapped developed areas, which risks inadvertently overlooking some of the most socially vulnerable rural and isolated communities. Given this, we maintained our census tract-wide social vulnerability values when combining these three sub-indices. We recognize this would lead to some areas (specifically those with higher ecological values and ecosystem services) being elevated in the SEI, despite a relatively limited number of people affected. However, the communities that could be affected in or near those areas are among the most underserved in risk reduction investments (Morgan et al., 2024; Ojerio et al., 2011), and thus we deem this trade-off warranted.

We standardized the three sub-indices (*z*-score transformation) and derived weights such that each sub-index had equal influence on the resulting index values. While our goal here was to ensure equal influence of each sub-index, there is inherent subjectivity in selecting any particular weighting scheme for combining metrics into a composite index. Accordingly, we emphasize the exploratory nature of this analysis and the potential for similar analyses to produce varying results depending on researcher or practitioner priorities and variable weights assigned, which we find to be a valuable opportunity for future research.

2.3 | Combining the wildfire mitigation potential and social-eco indices

To identify target landscapes for management considerations across CONUS, we smoothed each index by taking the mean within a 405 ha (1000 acre) moving window. This smoothing process retained the original data resolution but removed spatial artefacts or anomalies (e.g. single high-value pixels surrounded by those of lower value), thus identifying contiguous areas of similarly high value for a given index. We chose 405 ha to ensure that our smoothing would be done at a scale substantially smaller than what typically constitutes a project planning area (on the order of 10,000 ha; Ager et al., 2021). To avoid targeting areas where active management is administratively constrained, we masked out of the smoothed rasters designated Wilderness and Wild and Scenic Rivers (both categories of GAP 1 protected area within which natural disturbances are allowed to occur; USGS, 2020).

For each smoothed index (WMPI and SEI), we then identified areas with pixel values in the top 20% of index values within each USFS region (Figure 1). Finally, we identified contiguous groups of pixels falling within the top 20% of both the WMPI and SEI within a given USFS region and drew polygons around these areas (Figure 2). These polygons containing the overlapping top 20% of WMPI and SEI values (hereafter, 'focal areas') were considered as potential targets for restoration given the co-benefits they represent. We chose the 20% cut-off as a conservative decision rule meant to focus attention on the lands with greatest potential for co-benefits. To remove potential artefacts and polygons too small to be of relevance to management, we filtered the focal areas to only those greater than 405 ha.

2.4 | Identifying coincidence and complementarity between focal areas and alternative management targets

To assess the complementarity between prioritizations focused solely on biophysical wildfire risk or structural impacts and our alternative that *also* integrates social and ecological considerations, we then compared our focal areas to (1) areas within the top 20% of the WMPI (identified based on biophysical wildfire risk) and (2) the USFS' top 10 firesheds within each USFS region (identified based on wildfire ignitions on NF land, restoration feasibility, and risk to structures; Ager et al., 2021). Given that our indices followed an 'all-lands' approach and were scaled relative to values within each USFS region, we selected the 'all-lands' top 10 firesheds ranked relative to all firesheds within each region for use in our comparisons.

The CONUS-wide mean value for each indicator that contributed to the three sub-indices of the SEI (e.g. prevalence of COPD, ecological connectivity) was extracted within the following domains: (1) areas within the top 20% of the WMPI, (2) all focal areas (i.e. where the top 20% of both the WMPI and SEI overlap), (3) USFS top 10 firesheds in each region, and (4) all areas in which focal areas and the USFS top 10 firesheds overlap. These values were then used to compute the percent change in each indicator value when (1) refining targets from the top 20% of the WMPI down to focal areas alone and (2) refining targets from all USFS top 10 firesheds per region down to only locations in which those firesheds overlap with our focal areas.

3 | RESULTS

The top 20% of values within the WMPI for each USFS region encompassed 106.2 million ha. Retaining areas within the top 20% of

25758314, 2025, 1, Downloaded from https://besjournals.onlinelibrary.wiley.com/doi/10.1002/pan3.10733, Wiley Online Library on [16/02/2025]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

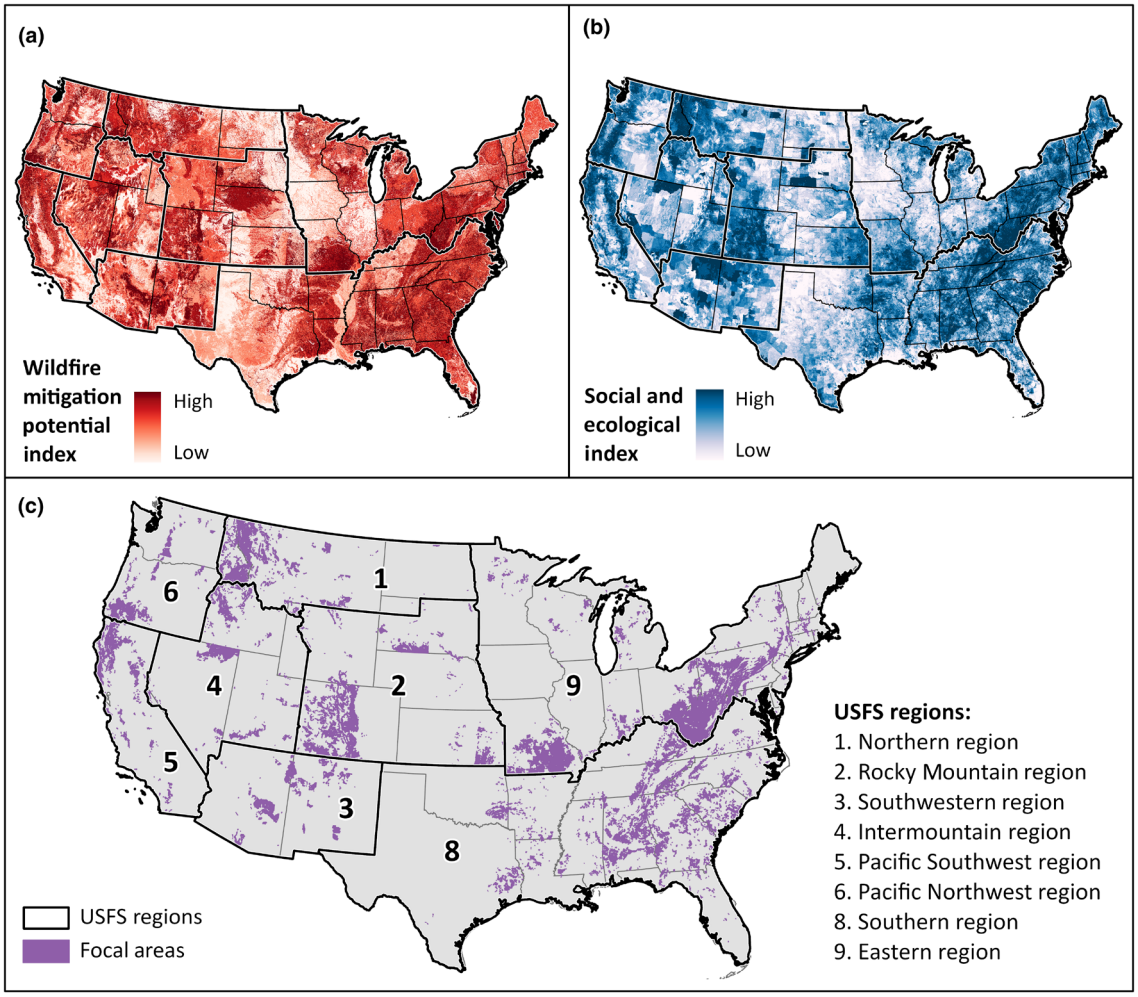

FIGURE 2 CONUS-wide distribution of (a) the WMPI, (b) the SEI, and (c) focal areas (areas of overlap between the top 20% of WMPI values and top 20% of SEI values). Both indices were scaled relative to values within each USFS region (regions indicated by bold black lines and listed according to region ID).

both the WMPI and SEI (i.e. focal areas) reduced this land area by more than half, to 41.9 million ha. These focal areas are locations where restoration is likely to be effective in both reducing the severity of future wildfires and safeguarding vulnerable communities and important ecological values and were generally concentrated along the Appalachian Mountains, Ozarks, Rocky Mountains and the Pacific Coastal Ranges (Figure 2). The Eastern Region contained the largest amount of land within focal areas (14.2-million ha; 8.3% of total region area), and the smallest amount was found in the Pacific Northwest Region (2.0-million ha; 4.7% of total region area; Table 2).

The addition of the SEI in identifying focal areas substantially increased representation of ecological values, ecosystem services and social vulnerability. Relative to conducting restoration within areas defined only by high values (top 20% per region) of the WMPI, prioritizing focal areas would target restoration to locations with, on average, 28% greater imperilled species richness and 45% greater drinking water importance and would increase the representation of families falling below the poverty line and populations with COPD by 26% and 14%, respectively (Figure 3a).

There is a high degree of complementarity between our focal areas and the top 10 firesheds within each USFS region, with 33.6% (2.9-million ha) of the top 10 firesheds overlapping focal areas (Figure 4). If the USFS were to target restoration on the 2.9-million ha in which firesheds and focal areas coincide, they would capture more climate resilient and intact landscapes that provide greater connectivity for wildlife and that also support greater overall species richness than firesheds do on average (Figure 3b). Likewise, these areas of overlap present opportunities to preserve 14% more clean drinking water and 39% greater forest carbon as well as reach nearly 50% more families below the poverty line and 42% more individuals with COPD. The region around Boise, Idaho, provides a localized example of the complementarity between areas prioritized by USFS firesheds and the focal areas developed here, refining the overall footprint of firesheds to focus on locations that are particularly high for both wildfire mitigation potential and social and ecological considerations (Figure 5, see Section 4 for more details). Additional case studies for Denver, Colorado and Charleston, West Virginia are presented in Appendix S2.

TABLE 2 Total area of identified focal areas (in millions of hectares) within each USFS region across CONUS. Focal area is also expressed as a percentage of total region area.

Region name[a]	Region area	Focal area
Northern	64.7	4.3 (6.6%)
Rocky Mountain	105.3	6.1 (5.8%)
Southwestern	61.0	2.5 (4.1%)
Intermountain	72.6	2.9 (4.0%)
Pacific Southwest	42.3	2.5 (5.9%)
Pacific Northwest	42.5	2.0 (4.7%)
Southern	220.7	7.4 (3.4%)
Eastern	171.5	14.2 (8.3%)

[a]Regions correspond to those shown in Figure 2c.

4 | DISCUSSION

The mounting threat of uncharacteristic wildfire and its inequitable impacts necessitate swift and strategic action from land managers as they identify restoration priorities. Here we have integrated critical social and ecological considerations and developed an index that is complementary to existing prioritizations based on potential structural loss, a combination that is essential to better understand where and when communities and resources are likely to be impacted by wildfire. Our results suggest that focusing on biophysical components of wildfire risk alone may not account for some of the important ecological values and services and vulnerable human communities that would be compromised if a wildfire were to occur. By integrating our focal areas with existing prioritizations, managers

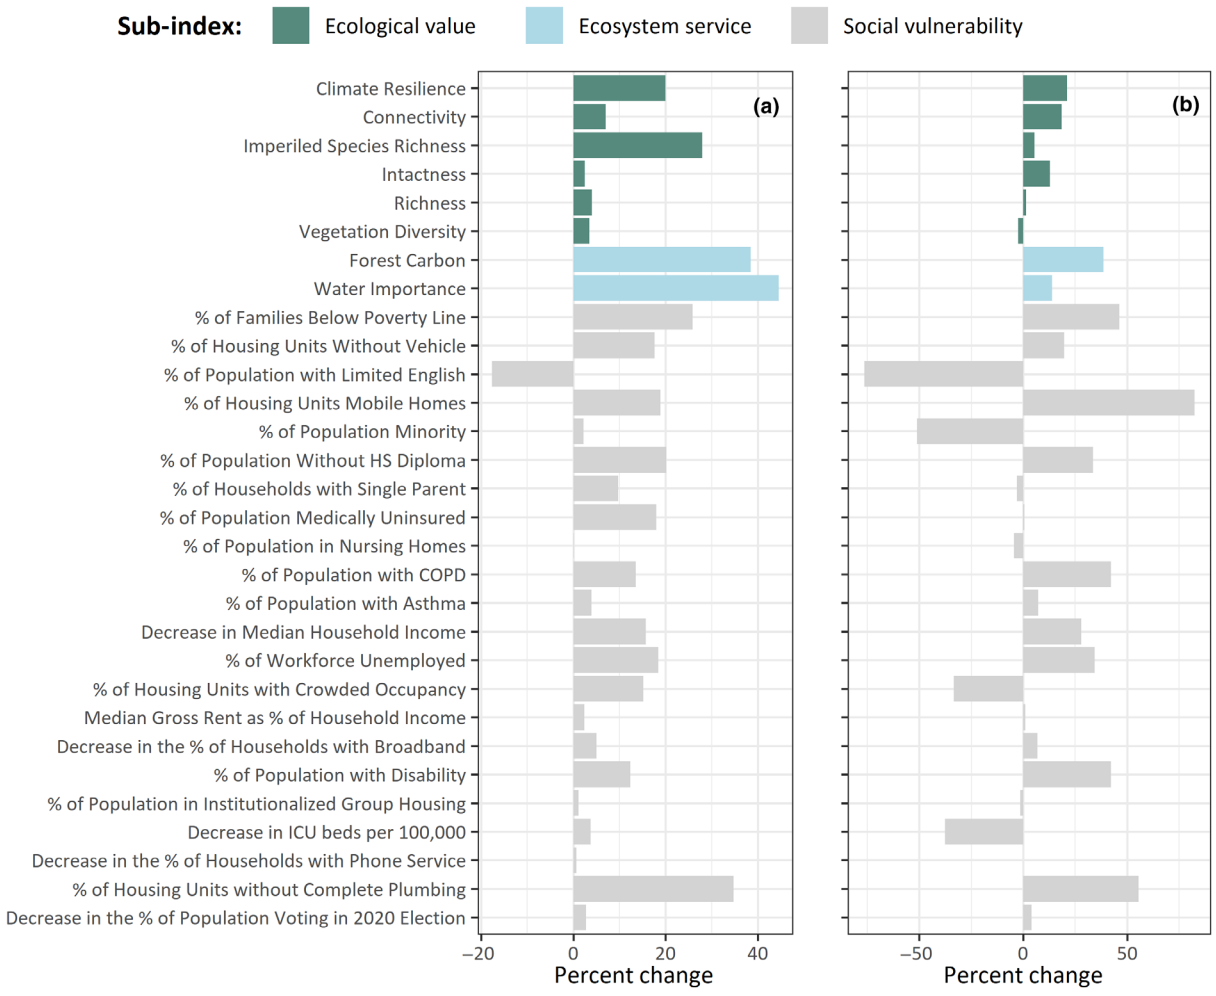

FIGURE 3 The percent change in all ecological value (green), ecosystem service (blue) and social vulnerability (grey) indicators that contributed to the SEI within target areas when (a) refining the target areas from the top 20% of the WMPI down to focal areas alone (i.e. where the top 20% of both the WMPI and SEI overlap) and (b) refining the target areas from USFS top ten firesheds per region to only areas of overlap between those firesheds and focal areas. Five indicators were quantified such that a decrease in their value indicates greater representation of social vulnerability: Median household income (USD), % of households with broadband, % of households with phone service, % of population participating in voting and the number of ICU beds per 100,000 people. These indicators have been represented as the percent change in the *decrease* of their values. See Appendix S2 for tables of values.

25783314, 2025, 1, Downloaded from https://besjournals.onlinelibrary.wiley.com/doi/10.1002/pan3.10733, Wiley Online Library on [16/02/2025]. FIGURE 4 USFS top 10 firesheds (green) for each USFS region overlaid with all focal areas (purple), which were identified as the locations in which the top 20% of the WMPI coincided with the top 20% of the SEI. Areas of overlap between firesheds and focal areas are indicated in yellow.

can strategically focus their efforts in areas with the greatest co-benefits across all of these factors.

The region around Boise, Idaho, demonstrates some of the distinct opportunities to capture greater overall social and ecological values through a strategic refinement of USFS management targets. Wildfires in this region have the potential to threaten human communities as well as nearby highly intact, connected and climate resilient landscapes, including Boise NF. Boise NF also contains some of the most important watersheds in all of Idaho for the provisioning of clean drinking water, making it essential to many of the human and ecological communities found here. The areas of overlap between the top ranked firesheds and our focal areas in this region (a total of 236,900 ha) capture some of the highest values within both indices and could help focus restoration that would maximize combined benefits to human communities and ecological systems (Figure 5). This strategic management will be necessary given the wide range of costs associated with fuel treatments and land managers' limitations in restoration funding (Hunter & Taylor, 2022).

In a time of increasingly frequent, large and destructive wildfires and mounting ecological crises, understanding which locations are at the nexus of these diverse priorities will be essential to efficiently deploy a finite amount of funding and resources for restoration. This is particularly salient given that wildfire is a nationwide issue, with the greatest number of wildfires occurring in the southeastern U.S. and the largest in terms of burn area occurring in the west (Mitchell et al., 2014; Schoennagel et al., 2017; U.S. Environmental Protection Agency, 2022). This issue also extends beyond the U.S. (e.g. Australia's bushfires (Deb et al., 2020), Canada's Northwest Territory fires and record-breaking 2023 season (Kochtubajda et al., 2019; Kolden et al., 2024), and a dramatic increase in wildfire across the Amazon in Brazil (Kolden et al., 2024)), thus this analysis can inform a more integrated approach to prioritizing wildfire restoration efforts worldwide as governments work to fight a global increase in extreme wildfire (United Nations Environment Programme, 2022). The all-lands approach employed here paired with the balanced consideration of social, ecological, and wildfire-based metrics will ensure a more even distribution of priority landscapes identified across the whole of CONUS, rather than emphasizing any single region and could serve as a transferable model for similar analyses elsewhere.

Although previous research has integrated a variety of social, ecological and/or wildfire-relevant biophysical metrics in identifying priority areas for restoration (e.g. Ager et al., 2015; Baskent et al., 2020; Davies et al., 2018; D'Evelyn et al., 2022; Peeler et al., 2023; Wigtil et al., 2016), none integrated all three at once as we have done here. Giving these important ecological values and services and vulnerable communities ample consideration is necessary given their dependence on healthy, functioning forests. For example, forest conversion in fire-prone landscapes could alter biodiversity and habitat connectivity (Sitters & Di Stefano, 2020; Thompson et al., 2021) and affect vegetation diversity (Forrestel

25783814, 2025, 1, Downloaded from https://besjournals.onlinelibrary.wiley.com/doi/10.1002/pan3.10733, Wiley Online Library on [16/02/2025]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

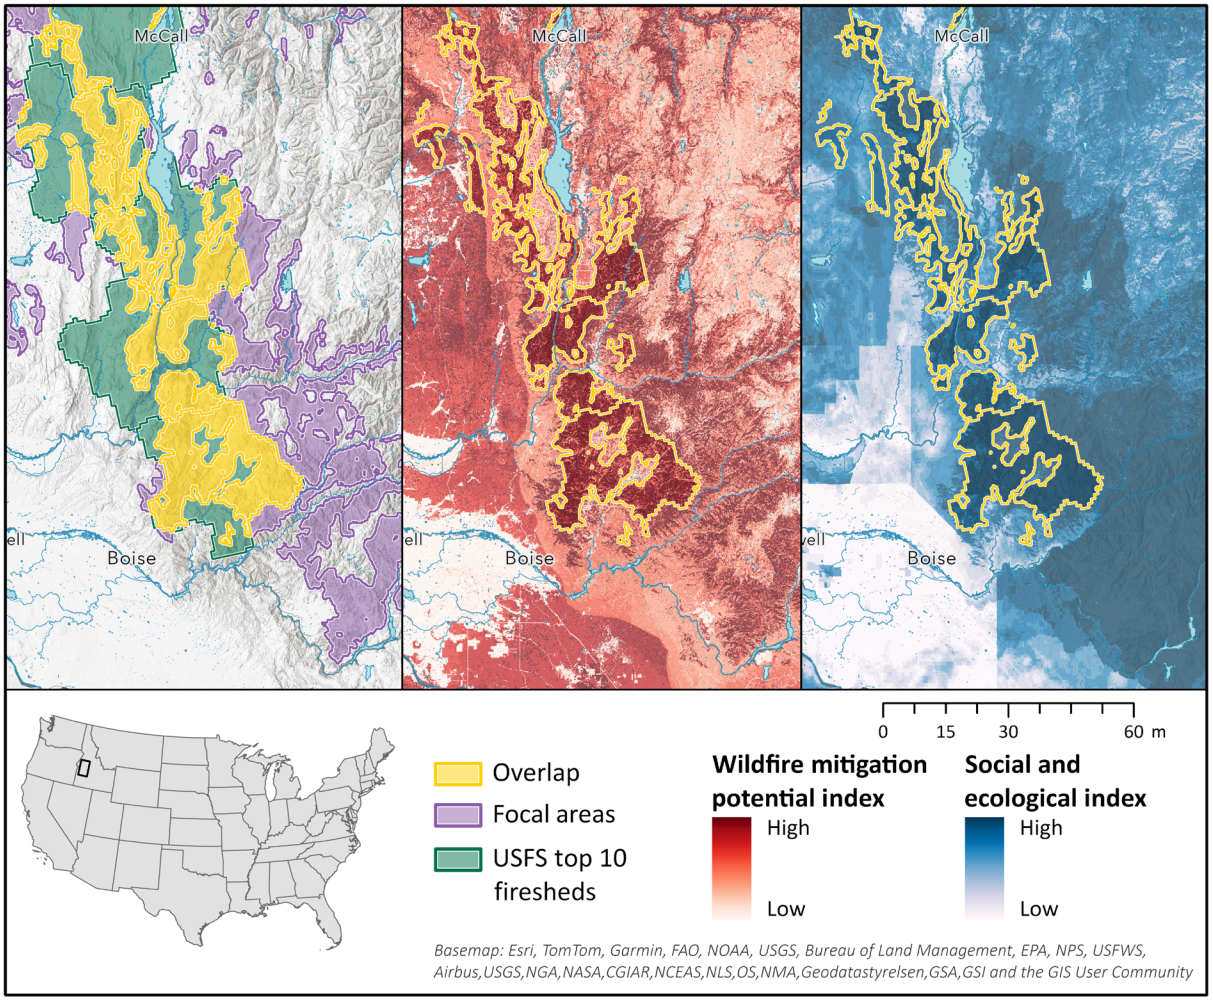

FIGURE 5 The overlapping area (236,900 ha) between a portion of the USFS top 10 firesheds and our focal areas (left) near Boise, Idaho, and the WMPI (centre) and SEI values (right) that are contained within those overlapping polygons.

et al., 2011; Keeley et al., 2003). By integrating social and ecological values and ecosystem services into our prioritization, we were able to increase the representation of families below the poverty line by 26%, imperilled species richness by 28%, climate resilient landscapes by 20%, and clean water provisioning by 45% when compared to areas identified by the WMPI alone. We also increased the representation of populations with COPD and asthma by 14% and 4%, respectively, which is critical given a positive association between exposure to wildfire smoke and aggravation of these respiratory conditions (Cascio, 2018; D'Evelyn et al., 2022).

The overall representation of social vulnerability, ecological values and ecosystem services increased, on average, by 10%, 11%, and 42%, respectively, compared to prioritizations based on wildfire mitigation potential alone. The focal areas identified here could therefore serve as a complement to similar analyses, including that of Peeler et al. (2023) examining hotspots of wildfire-caused carbon loss and risk to human communities across USFS firesheds, to ensure even greater gains for human and ecological communities alike. An examination of our results alongside those of Peeler et al. (2023), Wigtil et al. (2016), and other similar studies underscores how the spatial distribution of landscape priorities can shift based on researcher or practitioner priorities and that these priorities must be thoughtfully identified and results interpreted with caution.

We used the best available CONUS-scale datasets, drawing on USFS and other federally derived datasets where available (e.g. WHP, PLS, VDep, Census Bureau data) and employed established methods for combining these datasets into a set of composite indices (Suraci, Farwell, et al., 2023). However, all spatial datasets are subject to uncertainties, which are inherently propagated into our indices. These datasets serve as approximations that should be interpreted with caution at finer scales. We also note that the datasets used here had variable native resolutions (90-m to 2-km), or in the case of social vulnerability, were based on data summarized at the level of census tracts. We therefore anticipate that our results will be most relevant for landscape-level prioritizations, rather than localized decision-making. We have accounted for this consideration in part by smoothing and filtering our focal areas to 405 ha. Given this, we suggest that the focal areas identified here can best serve as starting points to direct attention to landscapes that may provide substantial co-benefits if managed to reduce wildfire risk.

More detailed, on-the-ground investigations of proposed focal areas, as well as collaboration with local communities, tribes and stakeholders, would be necessary in making any final determination about where to apply treatments. These collaborations, especially an integration of Indigenous Knowledge and Western science, could help scientists and practitioners garner valuable historical context for land management practices in a given area while gathering localized details that can inform fine-scale decision-making (Ray et al., 2012).

When incorporating these results into community level decisions, it will be essential to carefully consider the complex and varied relationships between different communities and the role of fire on the landscape, as well as the historical dynamics of power surrounding decision-making regarding dominant land management practices (Bourke et al., 2020; Christianson et al., 2022). Great care and respect should be given to understanding and elevating Indigenous fire stewardship practices that have historically been excluded from post-colonization land management practices (Bourke et al., 2020; Hoffman et al., 2022; Peeler et al., 2023), as well as the social and cultural dynamics within a community (e.g. livelihood, income level, upbringing) that may influence how individuals perceive or respond to wildfire risk (Hamilton et al., 2019; McFarlane et al., 2011). The interplay of these dynamics must be thoughtfully addressed in the process of identifying wildfire treatment areas, particularly through identifying and bridging 'collaboration gaps' to establish more coordinated, collaborative, supportive and incentivized wildfire restoration efforts moving forward through an interweaving of Indigenous Knowledge and Western science (Charnley et al., 2020; Eisenberg et al., 2024; Hamilton et al., 2021).

In practice, these efforts could include participatory mapping initiatives or multi-criteria analyses and planning activities that engage communities and reveal local priorities. Such efforts could also improve researchers' and land managers' understanding of finer-scale interactions between wildfire risk and community-defined social and ecological values (Gamboa et al., 2023; McBride et al., 2017). McBride et al. (2017) highlight how participatory mapping can facilitate more effective communication and integration of Indigenous Knowledge and Western science in forest management by compiling information in a Geographic Information Systems (GIS) interface and thus can provide a roadmap for similar applications. Another approach could centre on establishing collaborative organizations composed of members representing community groups, government agencies and non-profits at local, regional and/or national levels. These collaboratives can then coordinate and scale large-scale analyses and guidance to local-scale needs and existing social and political infrastructure within a community (Edgeley & Paveglio, 2024; Huayhuaca et al., 2023). For example, the USFS Collaborative Forest Landscape Restoration Program (CFLRP) was established in 2009 with the goal of encouraging collaborative, science-based forest ecosystem restoration on USFS lands by integrating local, national and private stakeholders and resources (Schultz et al., 2012). Through the CFLRP, communities can apply for funding and the opportunity to work collaboratively with USFS land managers to implement community-led landscape-scale restoration projects. This program has helped to bridge information gaps between community members and federal agency staff and has served as a valuable incubator and model for a collaborative, multi-scale approach to land management (Schultz et al., 2012; Urgenson et al., 2017). The proposed National Old Growth Amendment is another example of how a national direction for adaptive management can be used to develop local solutions through close collaboration with Tribes and other governmental and non-governmental stakeholders, particularly through the development of an *Adaptive Strategy for Old-Growth Forest Conservation* for each national forest to ensure locally appropriate management and monitoring (U.S. Forest Service, 2024).

Lastly, we acknowledge that while we identify the ecological values, ecosystem services and socially vulnerable communities that could be protected by or benefit from restoration, we cannot say that high-severity fire will diminish any of the indicators contributing to these sub-indices. Further analysis is necessary to deepen our understanding of how much of these indicators may in fact be lost in the absence of restoration if a wildfire were to occur (Peeler et al., 2023). Regardless, the ecological, social, and biophysical aspects of wildfire risk are highly interconnected. For example, wildfire can impact biodiversity, which could result in carbon loss that may affect ecosystem services that can determine human community health. As we increasingly recognize these dynamics, we must begin to reflect them in our restoration prioritizations.

5 | CONCLUSION

The focal areas we have identified can inform a strategic shift or refinement of current management prioritizations, including the USFS' top ranked firesheds approach. Based on an average treatment cost per hectare of just over $3700 ($1500/acre; Hunter & Taylor, 2022), the $1.5 billion pledged by the Biden Administration could support fewer than 405,000 ha (1 million acres) of restoration activities, requiring tough decisions about which areas to prioritize. To begin these decision-making conversations, we have provided the model results, sub-indices comprising the SEI, and a set of focal area polygons summarized to areas within and immediately adjacent to USFS lands in a web application for viewing at https://csp-inc.github.io/pew-usfs-app/. While the analysis described here followed an 'all-lands' approach across CONUS, the results provided in the web application are intended to specifically inform USFS management and thus were limited to the extent of NFs and their intersecting firesheds. Irrespective of analysis extent, we can ensure the USFS and other land managers secure the maximum possible co-benefits while working within budgetary constraints by focusing restoration on areas with the greatest identified wildfire mitigation potential while also considering social and ecological values within and around their existing fireshed framework. Safeguarding these values now will be essential to ensure their resilience in an uncertain future.

AUTHOR CONTRIBUTIONS

Justin P. Suraci, Blake S. Busse and Brett G. Dickson conceived the ideas. Caitlin E. Littlefield, L. Mae Lacey, Justin P. Suraci, Blake S. Busse and Brett G. Dickson designed the methodology. Justin P. Suraci, L. Mae Lacey and Caitlin E. Littlefield collected and analysed the data; L. Mae Lacey led the writing of the manuscript. All authors contributed critically to the drafts and gave final approval for publication.

ACKNOWLEDGEMENTS

We thank The Pew Charitable Trusts for supporting this project, and in particular, wish to acknowledge Jon Fisher and John Seebach for their contributions in conceiving of and refining this work. We are also grateful to the U.S. Forest Service for valuable guidance on our selection of indicator layers for each index and sub-index. We would also like to thank Travis Belote and one anonymous reviewer for their valuable feedback on this methodology.

CONFLICT OF INTEREST STATEMENT

None of the authors have a conflict of interest to declare.

DATA AVAILABILITY STATEMENT

All data supporting this analysis are publicly available, and all analysis outputs are available at https://doi.org/10.6084/m9.figshare.c.7430305.v2.

Edited by William H. Schlesinger, Duke University, Durham, NC, and approved January 22, 2018 (received for review November 16, 2017)

Strategies to mitigate carbon dioxide emissions through forestry activities have been proposed, but ecosystem process-based integration of climate change, enhanced CO_2, disturbance from fire, and management actions at regional scales are extremely limited. Here, we examine the relative merits of afforestation, reforestation, management changes, and harvest residue bioenergy use in the Pacific Northwest. This region represents some of the highest carbon density forests in the world, which can store carbon in trees for 800 y or more. Oregon's net ecosystem carbon balance (NECB) was equivalent to 72% of total emissions in 2011–2015. By 2100, simulations show increased net carbon uptake with little change in wildfires. Reforestation, afforestation, lengthened harvest cycles on private lands, and restricting harvest on public lands increase NECB 56% by 2100, with the latter two actions contributing the most. Resultant cobenefits included water availability and biodiversity, primarily from increased forest area, age, and species diversity. Converting 127,000 ha of irrigated grass crops to native forests could decrease irrigation demand by 233 billion $m^3 \cdot y^{-1}$. Utilizing harvest residues for bioenergy production instead of leaving them in forests to decompose increased emissions in the short-term (50 y), reducing mitigation effectiveness. Increasing forest carbon on public lands reduced emissions compared with storage in wood products because the residence time is more than twice that of wood products. Hence, temperate forests with high carbon densities and lower vulnerability to mortality have substantial potential for reducing forest sector emissions. Our analysis framework provides a template for assessments in other temperate regions.

forests | carbon balance | greenhouse gas emissions | climate mitigation

Strategies to mitigate carbon dioxide emissions through forestry activities have been proposed, but regional assessments to determine feasibility, timeliness, and effectiveness are limited and rarely account for the interactive effects of future climate, atmospheric CO_2 enrichment, nitrogen deposition, disturbance from wildfires, and management actions on forest processes. We examine the net effect of all of these factors and a suite of mitigation strategies at fine resolution (4-km grid). Proven strategies immediately available to mitigate carbon emissions from forest activities include the following: (*i*) reforestation (growing forests where they recently existed), (*ii*) afforestation (growing forests where they did not recently exist), (*iii*) increasing carbon density of existing forests, and (*iv*) reducing emissions from deforestation and degradation (1). Other proposed strategies include wood bioenergy production (2–4), bioenergy combined with carbon capture and storage (BECCS), and increasing wood product use in buildings. However, examples of commercial-scale BECCS are still scarce, and sustainability of wood sources remains controversial because of forgone ecosystem carbon storage and low environmental cobenefits (5, 6). Carbon stored in buildings generally outlives its usefulness or is replaced within decades (7) rather than the centuries possible in forests, and the factors influencing product substitution have yet to be fully explored (8). Our analysis of mitigation strategies focuses on the first four strategies, as well as bioenergy production, utilizing harvest residues only and without carbon capture and storage.

The appropriateness and effectiveness of mitigation strategies within regions vary depending on the current forest sink, competition with land-use and watershed protection, and environmental conditions affecting forest sustainability and resilience. Few process-based regional studies have quantified strategies that could actually be implemented, are low-risk, and do not depend on developing technologies. Our previous studies focused on regional modeling of the effects of forest thinning on net ecosystem carbon balance (NECB) and net emissions, as well as improving modeled drought sensitivity (9, 10), while this study focuses mainly on strategies to enhance forest carbon.

Our study region is Oregon in the Pacific Northwest, where coastal and montane forests have high biomass and carbon sequestration potential. They represent coastal forests from northern California to southeast Alaska, where trees live 800 y or more and biomass can exceed that of tropical forests (11) (Fig. S1). The semiarid ecoregions consist of woodlands that experience frequent fires (12). Land-use history is a major determinant of forest carbon balance. Harvest was the dominant cause of tree mortality (2003–2012) and accounted for fivefold as much mortality as that from fire and beetles combined (13). Forest land ownership is predominantly public (64%), and 76% of the biomass harvested is on private lands.

Significance

Regional quantification of feasibility and effectiveness of forest strategies to mitigate climate change should integrate observations and mechanistic ecosystem process models with future climate, CO_2, disturbances from fire, and management. Here, we demonstrate this approach in a high biomass region, and found that reforestation, afforestation, lengthened harvest cycles on private lands, and restricting harvest on public lands increased net ecosystem carbon balance by 56% by 2100, with the latter two actions contributing the most. Forest sector emissions tracked with our life cycle assessment model decreased by 17%, partially meeting emissions reduction goals. Harvest residue bioenergy use did not reduce short-term emissions. Cobenefits include increased water availability and biodiversity of forest species. Our improved analysis framework can be used in other temperate regions.

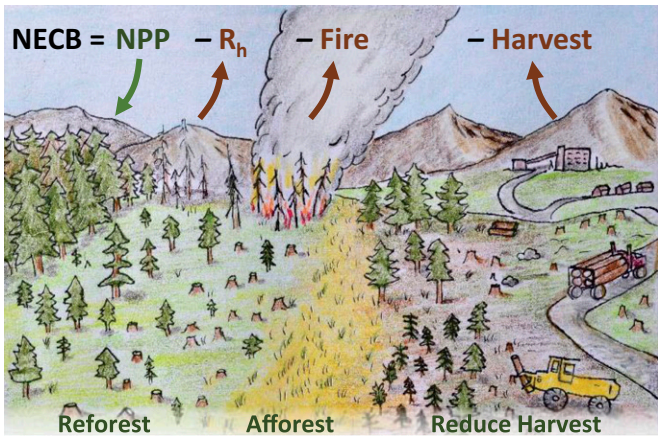

Fig. 1. Approach to assessing effects of mitigation strategies on forest carbon and forest sector emissions. NECB is productivity (NPP) minus Rh and losses from fire and harvest (red arrows). Harvest emissions include those associated with wood products and bioenergy.

Many US states, including Oregon (14), plan to reduce their greenhouse gas (GHG) emissions in accordance with the Paris Agreement. We evaluated strategies to address this question: How much carbon can the region's forests realistically remove from the atmosphere in the future, and which forest carbon strategies can reduce regional emissions by 2025, 2050, and 2100? We propose an integrated approach that combines observations with models and a life cycle assessment (LCA) to evaluate current and future effects of mitigation actions on forest carbon and forest sector emissions in temperate regions (Fig. 1). We estimated the recent carbon budget of Oregon's forests, and simulated the potential to increase the forest sink and decrease forest sector emissions under current and future climate conditions. We provide recommendations for regional assessments of mitigation strategies.

Results

Carbon stocks and fluxes are summarized for the observation cycles of 2001–2005, 2006–2010, and 2011–2015 (Table 1 and Tables S1 and S2). In 2011–2015, state-level forest carbon stocks totaled 3,036 Tg C (3 billion metric tons), with the coastal and montane ecoregions accounting for 57% of the live tree carbon (Tables S1 and S2). Net ecosystem production [NEP; net primary production (NPP) minus heterotrophic respiration (Rh)] averaged 28 teragrams carbon per year (Tg C y^{-1}) over all three periods. Fire emissions were unusually high at 8.69 million metric tons carbon dioxide equivalent ($tCO_2e\ y^{-1}$, i.e., 2.37 Tg C y^{-1}) in 2001–2005 due to the historic Biscuit Fire, but decreased to 3.56 million $tCO_2e\ y^{-1}$ (0.97 Tg C y^{-1}) in 2011–2015 (Table S4). Note that 1 million tCO_2e equals 3.667 Tg C.

Our LCA showed that in 2001–2005, Oregon's net wood product emissions were 32.61 million tCO_2e (Table S3), and 3.7-fold wildfire emissions in the period that included the record fire year (15) (Fig. 2). In 2011–2015, net wood product emissions were 34.45 million tCO_2e and almost 10-fold fire emissions, mostly due to lower fire emissions. The net wood product emissions are higher than fire emissions despite carbon benefits of storage in wood products and substitution for more fossil fuel-intensive products. Hence, combining fire and net wood product emissions, the forest sector emissions averaged 40 million $tCO_2e\ y^{-1}$ and accounted for about 39% of total emissions across all sectors (Fig. 2 and Table S4). NECB was calculated from NEP minus losses from fire emissions and harvest (Fig. 1). State NECB was equivalent to 60% and 70% of total emissions for 2001–2005 and 2011–2015, respectively (Fig. 2, Table 1, and Table S4). Fire emissions were only between 4% and 8% of total emissions from all sources (2011–2015 and 2001–2004, respectively). Oregon's forests play a larger role in meeting its GHG targets than US forests have in meeting the nation's targets (16, 17).

Historical disturbance regimes were simulated using stand age and disturbance history from remote sensing products. Comparisons of Community Land Model (CLM4.5) output with Forest Inventory and Analysis (FIA) aboveground tree biomass (>6,000 plots) were within 1 SD of the ecoregion means (Fig. S2). CLM4.5 estimates of cumulative burn area and emissions from 1990 to 2014 were 14% and 25% less than observed, respectively. The discrepancy was mostly due to the model missing an anomalously large fire in 2002 (Fig. S3*A*). When excluded, modeled versus observed fire emissions were in good agreement ($r^2 = 0.62$; Fig. S3*B*). A sensitivity test of a 14% underestimate of burn area did not affect our final results because predicted emissions would increase almost equally for business as usual (BAU) management and our scenarios, resulting in no proportional change in NECB. However, the ratio of harvest to fire emissions would be lower.

Projections show that under future climate, atmospheric carbon dioxide, and BAU management, an increase in net carbon uptake due to CO_2 fertilization and climate in the mesic ecoregions far outweighs losses from fire and drought in the semiarid ecoregions. There was not an increasing trend in fire. Carbon stocks increased by 2% and 7% and NEP increased by 12% and 40% by 2050 and 2100, respectively.

We evaluated emission reduction strategies in the forest sector: protecting existing forest carbon, lengthening harvest cycles, reforestation, afforestation, and bioenergy production with product substitution. The largest potential increase in forest carbon is in the mesic Coast Range and West Cascade ecoregions. These forests are buffered by the ocean, have high soil water-holding capacity, low risk of wildfire [fire intervals average 260–400 y (18)], long carbon residence time, and potential for high carbon density. They can attain biomass up to 520 Mg C ha^{-1} (12). Although Oregon has several protected areas, they account for only 9–15% of the total forest area, so we expect it may be feasible to add carbon-protected lands with cobenefits of water protection and biodiversity.

Reforestation of recently forested areas include those areas impacted by fire and beetles. Our simulations to 2100 assume regrowth of the same species and incorporate future fire responses to climate and cyclical beetle outbreaks [70–80 y (13)]. Reforestation has the potential to increase stocks by 315 Tg C by 2100, reducing forest sector net emissions by 5% by 2100 relative to BAU management (Fig. 3). The East and West Cascades ecoregions had the highest reforestation potential, accounting for 90% of the increase (Table S5).

Afforestation of old fields within forest boundaries and nonfood/nonforage grass crops, hereafter referred to as "grass crops," had to meet minimum conditions for tree growth, and crop grid cells had to be partially forested (*SI Methods* and Table S6). These crops are not grazed or used for animal feed. Competing land uses may decrease the actual amount of area that can be afforested. We calculated the amount of irrigated grass crops (127,000 ha) that could be converted to forest, assuming success of carbon offset programs (19). By 2100, afforestation increased stocks by

Average annual values for each period, including uncertainty (95% confidence interval) in Tg C y^{-1} (multiply by 3.667 to get million tCO_2e).

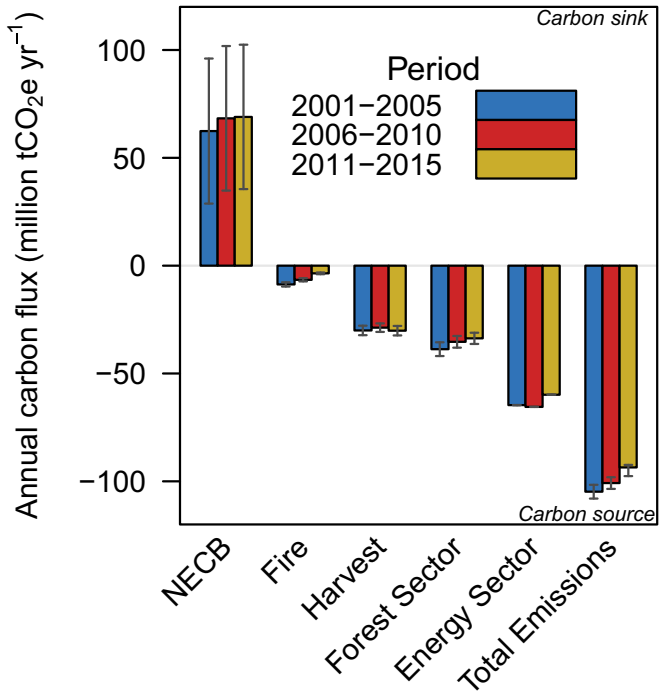

Fig. 2. Oregon's forest carbon sink and emissions from forest and energy sectors. Harvest emissions are computed by LCA. Fire and harvest emissions sum to forest sector emissions. Energy sector emissions are from the Oregon Global Warming Commission (14), minus forest-related emissions. Error bars are 95% confidence intervals (Monte Carlo analysis).

94 Tg C and cumulative NECB by 14 Tg C, and afforestation reduced forest sector GHG emissions by 1.3–1.4% in 2025, 2050, and 2100 (Fig. 3).

We quantified cobenefits of afforestation of irrigated grass crops on water availability based on data from hydrology and agricultural simulations of future grass crop area and related irrigation demand (20). Afforestation of 127,000 ha of grass cropland with Douglas fir could decrease irrigation demand by 222 and 233 billion $m^3 \cdot y^{-1}$ by 2050 and 2100, respectively. An independent estimate from measured precipitation and evapotranspiration (ET) at our mature Douglas fir and grass crop flux sites in the Willamette Valley shows the ET/precipitation fraction averaged 33% and 52%, respectively, and water balance (precipitation minus ET) averaged 910 $mm \cdot y^{-1}$ and 516 $mm \cdot y^{-1}$. Under current climate conditions, the observations suggest an increase in annual water availability of 260 billion $m^3 \cdot y^{-1}$ if 127,000 ha of the irrigated grass crops were converted to forest.

Harvest cycles in the mesic and montane forests have declined from over 120 y to 45 y despite the fact that these trees can live 500–1,000 y and net primary productivity peaks at 80–125 y (21). If harvest cycles were lengthened to 80 y on private lands and harvested area was reduced 50% on public lands, state-level stocks would increase by 17% to a total of ~3,600 Tg C and NECB would increase 2–3 Tg C y^{-1} by 2100. The lengthened harvest cycles reduced harvest by 2 Tg C y^{-1}, which contributed to higher NECB. Leakage (more harvest elsewhere) is difficult to quantify and could counter these carbon gains. However, because harvest on federal lands was reduced significantly since 1992 (NW Forest Plan), leakage has probably already occurred.

The four strategies together increased NECB by 64%, 82%, and 56% by 2025, 2050, and 2100, respectively. This reduced forest sector net emissions by 11%, 10%, and 17% over the same periods (Fig. 3). By 2050, potential increases in NECB were largest in the Coast Range (Table S5), East Cascades, and Klamath Mountains, accounting for 19%, 25%, and 42% of the total increase, whereas by 2100, they were most evident in the West Cascades, East Cascades, and Klamath Mountains.

We examined the potential for using existing harvest residue for electricity generation, where burning the harvest residue for energy emits carbon immediately (3) versus the BAU practice of leaving residues in forests to slowly decompose. Assuming half of forest residues from harvest practices could be used to replace natural gas or coal in distributed facilities across the state, they would provide an average supply of 0.75–1 Tg C y^{-1} to the year 2100 in the reduced harvest and BAU scenarios, respectively. Compared with BAU harvest practices, where residues are left to decompose, proposed bioenergy production would increase cumulative net emissions by up to 45 Tg C by 2100. Even at 50% use, residue collection and transport are not likely to be economically viable, given the distances (>200 km) to Oregon's facilities.

Discussion

Earth system models have the potential to bring terrestrial observations related to climate, vulnerability, impacts, adaptation,

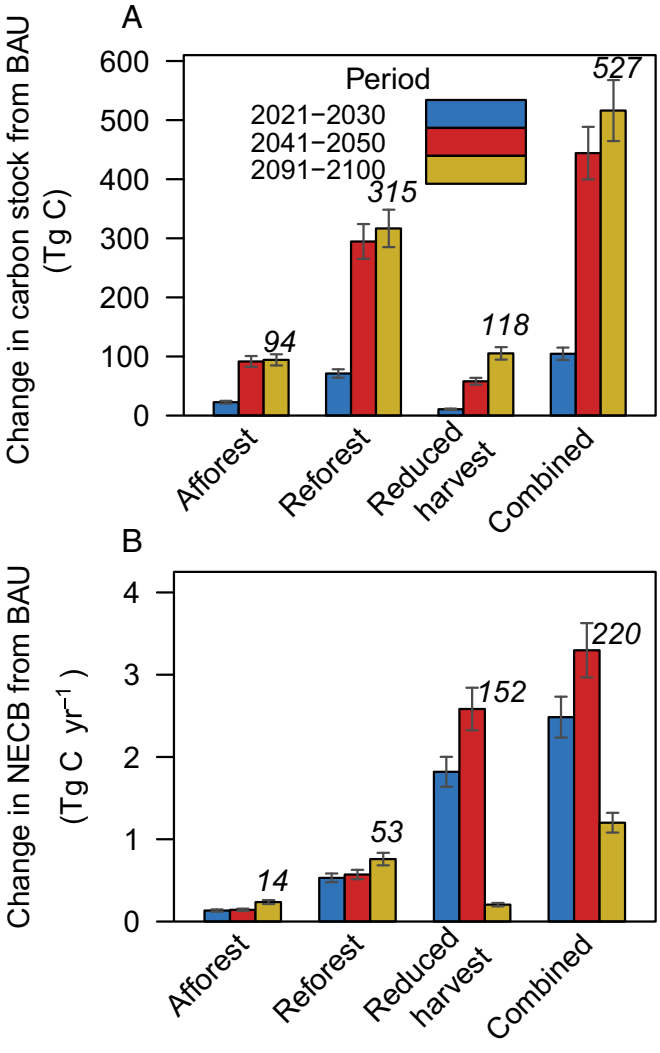

Fig. 3. Future change in carbon stocks and NECB with mitigation strategies relative to BAU management. The decadal average change in forest carbon stocks (*A*) and NECB relative to BAU (*B*) are shown. Italicized numbers over bars indicate mean forest carbon stocks in 2091–2100 (*A*) and cumulative change in NECB for 2015–2100 (*B*). Error bars are ±10%.

and mitigation into a common framework, melding biophysical with social components (22). We developed a framework to examine a suite of mitigation actions to increase forest carbon sequestration and reduce forest sector emissions under current and future environmental conditions.

Harvest-related emissions had a large impact on recent forest NECB, reducing it by an average of 34% from 2001 to 2015. By comparison, fire emissions were relatively small and reduced NECB by 12% in the Biscuit Fire year, but only reduced NECB 5–9% from 2006 to 2015. Thus, altered forest management has the potential to enhance the forest carbon balance and reduce emissions.

Future NEP increased because enhancement from atmospheric carbon dioxide outweighed the losses from fire. Lengthened harvest cycles on private lands to 80 y and restricting harvest to 50% of current rates on public lands increased NECB the most by 2100, accounting for 90% of total emissions reduction (Fig. 3 and Tables S5 and S6). Reduced harvest led to NECB increasing earlier than the other strategies (by 2050), suggesting this could be a priority for implementation.

Our afforestation estimates may be too conservative by limiting them to nonforest areas within current forest boundaries and 127,000 ha of irrigated grass cropland. There was a net loss of 367,000 ha of forest area in Oregon and Washington combined from 2001 to 2006 (23), and less than 1% of native habitat remains in the Willamette Valley due to urbanization and agriculture (24). Perhaps more of this area could be afforested.

The spatial variation in the potential for each mitigation option to improve carbon stocks and fluxes shows that the reforestation potential is highest in the Cascade Mountains, where fire and insects occur (Fig. 4). The potential to reduce harvest on public land is highest in the Cascade Mountains, and that to lengthen harvest cycles on private lands is highest in the Coast Range.

Although western Oregon is mesic with little expected change in precipitation, the afforestation cobenefits of increased water availability will be important. Urban demand for water is projected to increase, but agricultural irrigation will continue to consume much more water than urban use (25). Converting 127,000 ha of irrigated grass crops to native forests appears to be a win–win strategy, returning some of the area to forest land, providing habitat and connectivity for forest species, and easing irrigation demand. Because the afforested grass crop represents only 11% of the available grass cropland (1.18 million ha), it is not likely to result in leakage or indirect land use change. The two forest strategies combined are likely to be important contributors to water security.

Cobenefits with biodiversity were not assessed in our study. However, a recent study showed that in the mesic forests, cobenefits with biodiversity of forest species are largest on lands with harvest cycles longer than 80 y, and thus would be most pronounced on private lands (26). We selected 80 y for the harvest cycle mitigation strategy because productivity peaks at 80–125 y in this region, which coincides with the point at which cobenefits with wildlife habitat are substantial.

Habitat loss and climate change are the two greatest threats to biodiversity. Afforestation of areas that are currently grass crops would likely improve the habitat of forest species (27), as about 90% of the forests in these areas were replaced by agriculture. About 45 mammal species are at risk because of range contraction (28). Forests are more efficient at dissipating heat than grass and crop lands, and forest cover gains lead to net surface cooling in all regions south of about 45° latitude in North American and Europe (29). The cooler conditions can buffer climate-sensitive bird populations from approaching their thermal limits and provide more food and nest sites (30). Thus, the mitigation strategies of afforestation, protecting forests on public lands and lengthening harvest cycles to 80–125 y, would likely benefit forest-dependent species.

Oregon has a legislated mandate to reduce emissions, and is considering an offsets program that limits use of offsets to 8% of

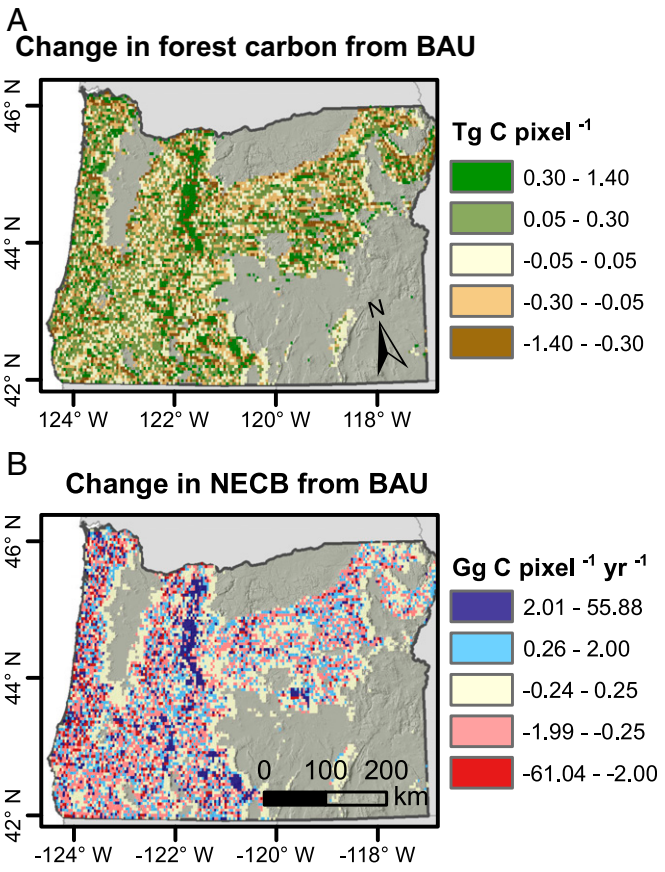

Fig. 4. Spatial patterns of forest carbon stocks and NECB by 2091–2100. The decadal average changes in forest carbon stocks (*A*) and NECB (*B*) due to afforestation, reforestation, protected areas, and lengthened harvest cycles relative to continued BAU forest management (red is increase in NECB) are shown.

the total emissions reduction to ensure that regulated entities substantially reduce their own emissions, similar to California's program (19). An offset becomes a net emissions reduction by increasing the forest carbon sink (NECB). If only 8% of the GHG reduction is allowed for forest offsets, the limits for forest offsets would be 2.1 and 8.4 million metric tCO_2e of total emissions by 2025 and 2050, respectively (Table S6). The combination of afforestation, reforestation, and reduced harvest would provide 13 million metric tCO_2e emissions reductions, and any one of the strategies or a portion of each could be applied. Thus, additionality beyond what would happen without the program is possible.

State-level reporting of GHG emissions includes the agriculture sector, but does not appear to include forest sector emissions, except for industrial fuel (i.e., utility fuel in Table S3) and, potentially, fire emissions. Harvest-related emissions should be quantified, as they are much larger than fire emissions in the western United States. Full accounting of forest sector emissions is necessary to meet climate mitigation goals.

Increased long-term storage in buildings and via product substitution has been suggested as a potential climate mitigation option. Pacific temperate forests can store carbon for many hundreds of years, which is much longer than is expected for buildings that are generally assumed to outlive their usefulness or be replaced within several decades (7). By 2035, about 75% of buildings in the United States will be replaced or renovated, based on new construction, demolition, and renovation trends (31, 32). Recent analysis suggests substitution benefits of using wood versus more fossil fuel-intensive materials have been overestimated by at

least an order of magnitude (33). Our LCA accounts for losses in product substitution stores (PSSs) associated with building life span, and thus are considerably lower than when no losses are assumed (4, 34). While product substitution reduces the overall forest sector emissions, it cannot offset the losses incurred by frequent harvest and losses associated with product transportation, manufacturing, use, disposal, and decay. Methods for calculating substitution benefits should be improved in other regional assessments.

Wood bioenergy production is interpreted as being carbon-neutral by assuming that trees regrow to replace those that burned. However, this does not account for reduced forest carbon stocks that took decades to centuries to sequester, degraded productive capacity, emissions from transportation and the production process, and biogenic/direct emissions at the facility (35). Increased harvest through proposed thinning practices in the region has been shown to elevate emissions for decades to centuries regardless of product end use (36). It is therefore unlikely that increased wood bioenergy production in this region would decrease overall forest sector emissions.

Conclusions

GHG reduction must happen quickly to avoid surpassing a 2 °C increase in temperature since preindustrial times. Alterations in forest management can contribute to increasing the land sink and decreasing emissions by keeping carbon in high biomass forests, extending harvest cycles, reforestation, and afforestation. Forests are carbon-ready and do not require new technologies or infrastructure for immediate mitigation of climate change. Growing forests for bioenergy production competes with forest carbon sequestration and does not reduce emissions in the next decades (10). BECCS requires new technology, and few locations have sufficient geological storage for CO_2 at power facilities with high-productivity forests nearby. Accurate accounting of forest carbon in trees and soils, NECB, and historic harvest rates, combined with transparent quantification of emissions from the wood product process, can ensure realistic reductions in forest sector emissions.

As states and regions take a larger role in implementing climate mitigation steps, robust forest sector assessments are urgently needed. Our integrated approach of combining observations, an LCA, and high-resolution process modeling (4-km grid vs. typical 200-km grid) of a suite of potential mitigation actions and their effects on forest carbon sequestration and emissions under changing climate and CO_2 provides an analysis framework that can be applied in other temperate regions.

Materials and Methods

Current Stocks and Fluxes. We quantified recent forest carbon stocks and fluxes using a combination of observations from FIA; Landsat products on forest type, land cover, and fire risk; 200 intensive plots in Oregon (37); and a wood decomposition database. Tree biomass was calculated from species-specific allometric equations and ecoregion-specific wood density. We estimated ecosystem carbon stocks, NEP (photosynthesis minus respiration), and NECB (NEP minus losses due to fire or harvest) using a mass-balance approach (36, 38) (Table 1 and *SI Materials and Methods*). Fire emissions were computed from the Monitoring Trends in Burn Severity database, biomass data, and region-specific combustion factors (15, 39) (*SI Materials and Methods*).

Future Projections and Model Description. Carbon stocks and NEP were quantified to the years 2025, 2050, and 2100 using CLM4.5 with physiological parameters for 10 major forest species, initial forest biomass (36), and future climate and atmospheric carbon dioxide as input (Institut Pierre Simon Laplace climate system model downscaled to 4 km × 4 km, representative concentration pathway 8.5). CLM4.5 uses 3-h climate data, ecophysiological characteristics, site physical characteristics, and site history to estimate the daily fluxes of carbon, nitrogen, and water between the atmosphere, plant state variables, and litter and soil state variables. Model components are biogeophysics, hydrological cycle, and biogeochemistry. This model version does not include a dynamic vegetation model to simulate resilience and establishment following disturbance. However, the effect of regeneration lags on forest carbon is not particularly strong for the long disturbance intervals in this study (40). Our plant functional type (PFT) parameterization for 10 major forest species rather than one significantly improves carbon modeling in the region (41).

Forest Management and Land Use Change Scenarios. Harvest cycles, reforestation, and afforestation were simulated to the year 2100. Carbon stocks and NEP were predicted for the current harvest cycle of 45 y compared with simulations extending it to 80 y. Reforestation potential was simulated over areas that recently suffered mortality from harvest, fire, and 12 species of beetles (13). We assumed the same vegetation regrew to the maximum potential, which is expected with the combination of natural regeneration and planting that commonly occurs after these events. Future BAU harvest files were constructed using current harvest rates, where county-specific average harvest and the actual amounts per ownership were used to guide grid cell selection. This resulted in the majority of harvest occurring on private land (70%) and in the mesic ecoregions. Beetle outbreaks were implemented using a modified mortality rate of the lodgepole pine PFT with 0.1% y^{-1} biomass mortality by 2100.

For afforestation potential, we identified areas that are within forest boundaries that are not currently forest and areas that are currently grass crops. We assumed no competition with conversion of irrigated grass crops to urban growth, given Oregon's land use laws for developing within urban growth boundaries. A separate study suggested that, on average, about 17% of all irrigated agricultural crops in the Willamette Valley could be converted to urban area under future climate; however, because 20% of total cropland is grass seed, it suggests little competition with urban growth (25).

Landsat observations (12,500 scenes) were processed to map changes in land cover from 1984 to 2012. Land cover types were separated with an unsupervised K-means clustering approach. Land cover classes were assigned to an existing forest type map (42). The CropScape Cropland Data Layer (CDL 2015, https://nassgeodata.gmu.edu/CropScape/) was used to distinguish nonforage grass crops from other grasses. For afforestation, we selected grass cropland with a minimum soil water-holding capacity of 150 mm and minimum precipitation of 500 mm that can support trees (43).

Afforestation Cobenefits. Modeled irrigation demand of grass seed crops under future climate conditions was previously conducted with hydrology and agricultural models, where ET is a function of climate, crop type, crop growth state, and soil-holding capacity (20) (Table S7). The simulations produced total land area, ET, and irrigation demand for each cover type. Current grass seed crop irrigation in the Willamette Valley is 413 billion $m^3 \cdot y^{-1}$ for 238,679 ha and is projected to be 412 and 405 billion m^3 in 2050 and 2100 (20) (Table S7). We used annual output from the simulations to estimate irrigation demand per unit area of grass seed crops (1.73, 1.75, and 1.84 million $m^3 \cdot ha^{-1}$ in 2015, 2050, and 2100, respectively), and applied it to the mapped irrigated crop area that met conditions necessary to support forests (Table S7).

LCA. Decomposition of wood through the product cycle was computed using an LCA (8, 10). Carbon emissions to the atmosphere from harvest were calculated annually over the time frame of the analysis (2001–2015). The net carbon emissions equal NECB plus total harvest minus wood lost during manufacturing and wood decomposed over time from product use. Wood industry fossil fuel emissions were computed for harvest, transportation, and manufacturing processes. Carbon credit was calculated for wood product storage, substitution, and internal mill recycling of wood losses for bioenergy.

Products were divided into sawtimber, pulpwood, and wood and paper products using published coefficients (44). Long-term and short-term products were assumed to decay at 2% and 10% per year, respectively (45). For product substitution, we focused on manufacturing for long-term structures (building life span >30 y). Because it is not clear when product substitution started in the Pacific Northwest, we evaluated it starting in 1970 since use of concrete and steel for housing was uncommon before 1965. The displacement value for product substitution was assumed to be 2.1 Mg fossil C/Mg C wood use in long-term structures (46), and although it likely fluctuates over time, we assumed it was constant. We accounted for losses in product substitution associated with building replacement (33) using a loss rate of 2% per year (33), but ignored leakage related to fossil C use by other sectors, which may result in more substitution benefit than will actually occur.

The general assumption for modern buildings, including cross-laminate timber, is they will outlive their usefulness and be replaced in about 30 y (7). By 2035, ~75% of buildings in the United States will be replaced or renovated, based on new construction, demolition, and renovation trends, resulting in threefold as many buildings as there are now [2005 baseline (31, 32)]. The loss of

the PSS is therefore PSS multiplied by the proportion of buildings lost per year (2% per year).

To compare the NECB equivalence to emissions, we calculated forest sector and energy sector emissions separately. Energy sector emissions ["in-boundary" state-quantified emissions by the Oregon Global Warming Commission (14)] include those from transportation, residential and commercial buildings, industry, and agriculture. The forest sector emissions are cradle-to-grave annual carbon emissions from harvest and product emissions, transportation, and utility fuels (Table S3). Forest sector utility fuels were subtracted from energy sector emissions to avoid double counting.

Uncertainty Estimates. For the observation-based analysis, Monte Carlo simulations were used to conduct an uncertainty analysis with the mean and SDs for NPP and Rh calculated using several approaches (36) (*SI Materials and Methods*). Uncertainty in NECB was calculated as the combined uncertainty of NEP, fire emissions (10%), harvest emissions (7%), and land cover estimates (10%) using the propagation of error approach. Uncertainty in CLM4.5 model simulations and LCA were quantified by combining the uncertainty in the observations used to evaluate the model, the uncertainty in input datasets (e.g., remote sensing), and the uncertainty in the LCA coefficients (41).

Model input data for physiological parameters and model evaluation data on stocks and fluxes are available online (37).

ACKNOWLEDGMENTS. We thank Dr. Thomas Hilker (deceased) for producing the grass data layer, and Carley Lowe for Fig. 1. Strategic reserves in Oregon's forests for biodiversity, water, and carbon to mitigate and adapt to climate change

Beverly E. Law[1]*, Logan T. Berner[2], David J. Mildrexler[3], Ralph O. Bloemers[4] and William J. Ripple[1,2,5]

[1]Department of Forest Ecosystems and Society, Oregon State University, Corvallis, OR, United States, [2]EcoSpatial Services L.L.C., Flagstaff, AZ, United States, [3]Eastern Oregon Legacy Lands, Joseph, OR, United States, [4]Green Oregon Alliance, Portland, OR, United States, [5]Conservation Biology Institute, Corvallis, OR, United States

Creating strategic forest reserves is essential for stemming the loss of biodiversity and contributing to climate mitigation and adaptation. Meeting preservation targets of 30% protection by 2030, and 50% by 2050 would lead to greater protection of animal taxa and tree species habitat, carbon stocks and accumulation, and forests that are important sources of drinking water. Here, we develop a regional framework to specifically identify at a fine resolution (30 m) high priority forestlands for preservation in Oregon, USA. We include a resilience metric that represents connectivity and topographic diversity, and identify areas within each ecoregion that are ranked high priority for carbon, biodiversity, resilience and drinking water. Oregon has less than 10% of its forestlands protected at the highest levels, yet its temperate forests are among those with the highest carbon densities in the world. Reserves for surface drinking water sources and forest habitat for birds, mammals, amphibians, and reptiles could increase to 50–70% protection at the highest levels by 2050. Protected aboveground biomass carbon could triple to 635 teragrams of carbon by 2050. The ownership of the high preservation priority lands for carbon and biodiversity is primarily federal (67% by 2050) followed by private (28% by 2050), with much less in the other ownerships. Forest reserves could be established on federal lands through executive action, regulation and rule-making, while private landowners could be incentivized to store more carbon, limit harvest in certain areas and transfer ownership to land trusts. Protecting mature and old forests on federal lands fulfills an urgent need for protection and provides a low-cost way to simultaneously meet national and international goals. This study provides a flexible, dynamic framework for identifying areas that are high priority to protect for climate mitigation and adaptation at regional and sub-regional scales.

KEYWORDS

forests, carbon, biodiversity, drinking water, resilience, climate mitigation, adaptation

Introduction

Immediate and effective action is essential to address accelerated warming, water shortages and biodiversity losses, which includes animals, plants, and ecosystems (Pörtner et al., 2021). Biodiversity loss, degradation and transformation of ecosystems are already worse than predicted due to past global warming and will continue to escalate with increased warming (IPCC, 2022). Safeguarding biodiversity and ecosystem services depend on effective "conservation of about 30–50% of Earth's land, freshwater and ocean areas, including currently near-natural ecosystems" (IPCC, 2022).

In the conterminous United States, only 6.1% of forestland is protected at the highest level, with 0.2% in strict nature reserves to protect biodiversity, 4.8% in wilderness areas, and 1.1% in National Parks (Nelson et al., 2020). Some of the responsibility for immediate action to halt biodiversity loss, protect human drinking water supplies, and mitigate climate change rests upon the states and requires cross-jurisdictional coordination across complex multi-ownership boundaries.

Over the western US, we previously prioritized forest areas for protection based on their carbon densities and biodiversity of animal taxa and tree species (Law et al., 2021). The study suggests the Pacific Northwest has a large amount of forest area that should be high priority for protection by 2030 and 2050. Yet, Oregon has the lowest percentage (10%) of its forest area permanently protected in the eleven western US states. This shortfall called for a closer examination of available ecological data and policy considerations.

Oregon is positioned to take significant actions to meet the protection targets, as it has more than 12 million hectares of forestland, with some of the highest carbon densities in the world (Hudiburg et al., 2009; Law et al., 2018). Oregon relies on mountain watersheds and rivers for a large portion of the drinking water supply. Identifying important areas for conservation at the local scale may require finer spatial data than our western US study (Law et al., 2021), and consideration of different facets of biodiversity, from species richness to the importance of species with small ranges (Pollock et al., 2017), and consideration of all land ownerships to formulate appropriate policy actions. Here, we refined our regional framework to identify forest areas within Oregon for permanent protections that, if preserved, would stem further biodiversity loss, protect drinking water supplies at their sources, prevent carbon dioxide emissions from forest conversion, and safeguard natural carbon stocks and accumulation. We focus on the following questions:

(1) How much of Oregon's land and forestland is currently protected by ecoregion?
(2) Which forestlands could be strategically preserved under 30 × 30 and 50 × 50 within each ecoregion based on forest carbon, biodiversity and/or climate resilience?
(3) Who owns the high preservation priority forestlands?
(4) How would reaching 30 × 30 or 50 × 50 affect protection of species habitat, current forest carbon stocks and surface drinking water sources?
(5) What are potential social and cultural effects of preservation actions and how could policies address this?

Here we used fine resolution datasets (30 m), and expanded our analysis from using species richness as a biodiversity metric to include a priority class based on landscape characteristics such as connectivity and topographic diversity as a resilience metric (Carroll et al., 2018). Stable land characteristics that increase diversity and resilience are not likely to change with climate change (Lawler et al., 2013). We applied the priority ranking within each ecoregion to address the importance of distributing protections across the diversity of ecoregions (Dinerstein et al., 2017; Law et al., 2021).

Our study demonstrated that Oregon has high carbon density forests that also have high biodiversity and connectivity for species movement. When these characteristics were prioritized within each ecoregion, it identified sufficient forestland to meet both the 30% protection by 2030 and 50% by 2050 targets that are important nationally and internationally. Our study did not consider the effects of livestock grazing, but this topic was recently investigated in Oregon and across the American West (Ripple et al., 2022).

Materials and methods

Study region

The study region is Oregon, USA, with a total land area of about 25.06 Mha, of which 12.45 Mha (∼49.7%) is forested (**Figure 1**). Oregon has strong climatic gradients from the Pacific coast to the inland high desert, and multiple mountain ranges that have their own climatic gradients associated with aspect and elevation. Because of this variation, we chose to identify areas with relative potential for protection within each ecoregion. Oregon has nine Environmental Protection Agency (EPA) level 3 ecoregions (Omernik and Griffith, 2014) ranging from temperate mesic forests in the Coast Range and West Cascades ecoregions to semi-arid East Cascades and high biodiversity forests of the Klamath Mountains to interior mixed-conifer forests of the Blue Mountains. Ecoregions are defined by seasonal temperature, precipitation, soil properties, and vegetation types. Three of the eleven ecoregions have little to no forest, including the Columbia Plateau, Northern Basin and Range, and Snake River Plain. Soils range from the high nitrogen and high soil water holding capacity of the Coast Range ecoregion to volcanic soils in the semi-arid East Cascades,

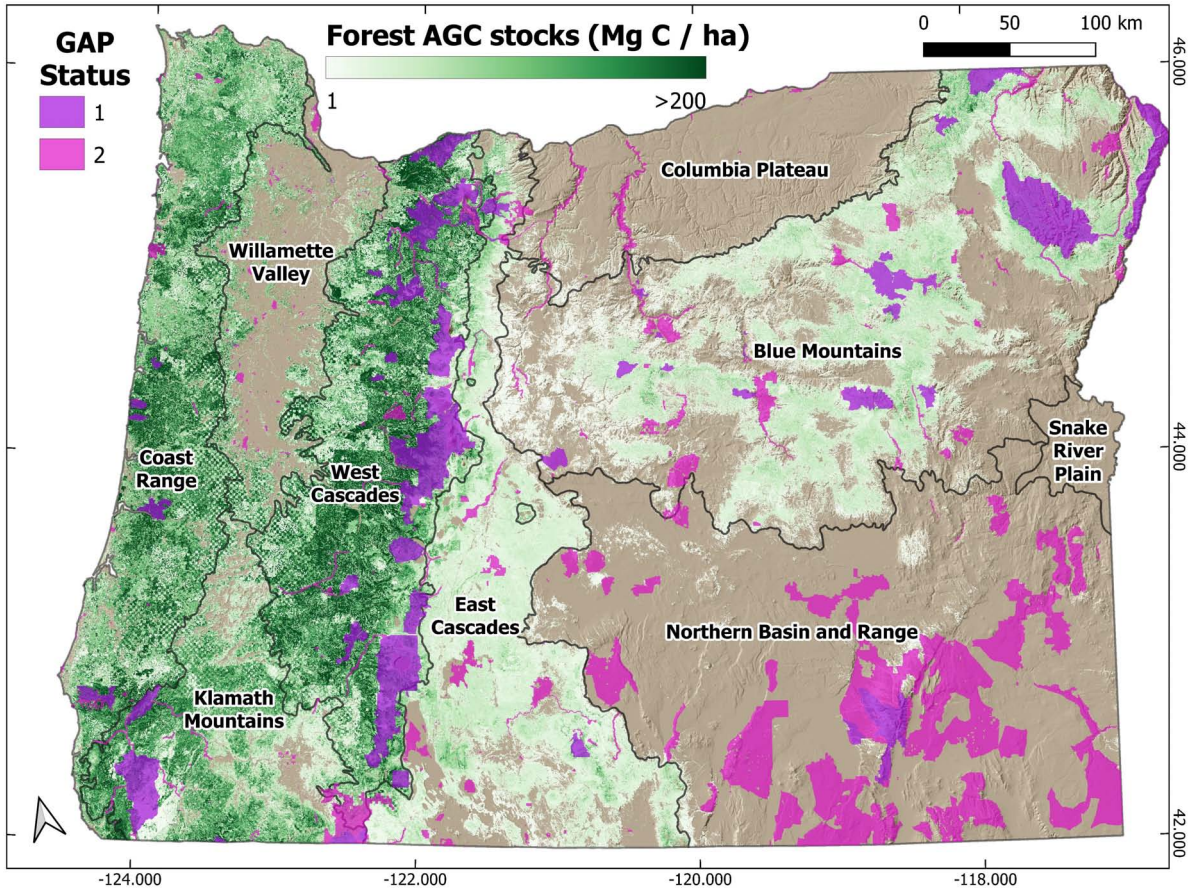

FIGURE 1
Current protected lands and forest aboveground carbon stocks across Oregon. Protected lands depicted here are assigned GAP Analysis Project (GAP) Status 1 or 2 by the Protected Areas Database of the United States (PAD-US v. 2.1) (USGS GAP, 2020) and include both forestlands and non-forestlands. These statuses characterize areas with permanent protection from anthropogenic conversion of natural land cover. Forest aboveground carbon stocks (Mg C ha^{-1}) in 2017 were spatially modeled from inventory measurements, satellite remote sensing, and environmental data (Landscape Ecology Modeling Mapping and Analysis (Lemma) Team, 2020).

affecting productivity. The study region provides a range of conditions that might be expected at much larger scales.

The forests in the region experienced intensive harvesting across public and private lands from the early 1900s through the late 1980s. Implementation of the Northwest Forest Plan (NWFP) in the wetter western portion of Oregon, Washington, and Northern California to protect sensitive aquatic and terrestrial species and habitat in old-growth forests resulted in an 82% decrease in timber harvest on public forestlands. These protections also benefited other ecosystem services like watershed protection (Frissell, 2013) and increased forest carbon accumulation on public lands. Prior to implementation of the NWFP, both public and private forests were about equal net carbon sources (Turner et al., 2011). Between 1990 and 2007, net carbon accumulation on public lands, even after accounting for fires and harvest, was 8 times that on private lands where intensive harvest of young tree plantations continued (Turner et al., 2011; Law et al., 2022). This demonstrates how forest carbon increases when harvest on public lands is limited for biodiversity and water protection. In the drier eastern forests, a set of rules were adopted around the same time to protect sensitive species, older trees and aquatic life, but these rules were rolled back by the US Forest Servic (2021).

Data processing

We analyzed the current extent, future opportunities, and benefits of forest preservation across Oregon using existing spatial datasets related to live tree aboveground carbon stocks, biodiversity, climate resilience, disturbance, and other factors. These spatial datasets were mapped at 30 m to 90 m spatial resolution and thus well suited to inform local to regional forest management decisions (Hansen et al., 2013; USGS GAP, 2018). Therefore, we conducted our spatial analysis at moderately high (30 m) spatial resolution using a common grid in an Albers

Equal Area projection. We analyzed and visualized data using the open-source software R (version 4.0) (R Core Team, 2021) with the libraries *terra* (Hijmans, 2022), *raster* (Hijmans, 2019), *sf* (Pebesma, 2018), *data.table* (Dowle and Srinivasan, 2021), and *ggplot2* (Wickham, 2016). We created the maps using open-source software QGIS (v3.20; R Core Team, 2021).

Current and additional protection to meet targets

We determined the current extent of protected lands across Oregon using the Protected Areas Database of the United States (PAD-US version 2.1) that is the official national inventory of protected areas. The PAD-US is a geospatial database created by the United States Geological Survey (USGS) GAP Analysis Project (GAP) that includes information on the spatial extent and protective status of public and private lands across the nation (USGS GAP, 2020). Protective status is characterized by GAP status codes that describe management intent to preserve biodiversity following guidelines from the International Union for the Conservation of Nature (IUCN). The highest protective statuses are GAP 1 and 2, which are for lands that have management plans to maintain the natural state of ecosystems and include permanent protection from human activities that cause land cover conversion. GAP 1 typically aligns with IUCN Categories Ia, Ib, and II, whereas GAP 2 aligns with IUCN Categories III through VI. We clipped the PAD-US shapefile to the boundaries of Oregon and then gridded the GAP status codes at 30 m resolution. Lands can have multiple GAP status codes when under multiple forms of management, in which case we used the lowest GAP status code. We then computed the total land and forest area with permanent protection (GAP 1 or 2) in each ecoregion, as well as how much additional area would be required to protect 30 and 50% of total land and forest area in each ecoregion.

Prioritizing forest protection using preservation targets

To strategically meet the 30 × 30 and 50 × 50 preservation targets in each of Oregon's ecoregions, we jointly and singularly prioritized forestlands for protection using carbon, biodiversity, and climate resilience metrics (*sensu* Law et al., 2021). For each prioritization metric, we computed the percentile rank (0–100%) of every grid cell compared to all other grid cells in the ecoregion. We then computed each grid cell's overall forest preservation priority rank by reranking the sum of its live tree aboveground carbon stocks, biodiversity, and climate resilience ranks. We identified the highest ranked currently unprotected forestlands that could be strategically protected (GAP 1 or 2) to meet each preservation target with the prioritization metrics.

For the carbon priority ranking, we focused on live tree aboveground carbon stocks (AGC). Tree AGC stocks in Oregon's forests typically account for 41 to 55% of total ecosystem carbon and are a focus for climate change mitigation because of their sensitivity to forest management activities. Tree AGC stocks have been mapped across Oregon's forestlands for the year 2017 using forest inventory, satellite, and environmental datasets (Landscape Ecology Modeling Mapping and Analysis (Lemma) Team, 2020). Specifically, tree AGC stocks were mapped for all live trees ≥2.5 cm diameter at breast height that occurred in areas that had or could potentially have at least 10% tree cover (Landscape Ecology Modeling Mapping and Analysis (Lemma) Team, 2020). To account for impacts of recent stand-replacing disturbances (e.g., wildfires, logging), we identified areas where forest loss occurred from 2017 to 2020 using the most recently available Global Forest Change dataset derived from 30 m resolution Landsat satellite data (Hansen et al., 2013). We set tree AGC stocks to zero in any grid cell where forest loss was observed during this period, and assumed the disturbances did not cause a permanent transition to non-forest.

For the biodiversity priority ranking, we used terrestrial vertebrate species (hereafter animal) richness by taxa and tree species richness. Current potential habitat distribution of 1,718 animal species was mapped by the USGS at 30 m resolution across the contiguous U.S. using geospatial predictors (USGS GAP, 2018). This included potential habitat for amphibian, bird, mammal, and reptile species found in the region. These habitat maps do not include stopover habitats for migratory species. Furthermore, we characterized the current potential habitat distribution of 89 tree species across Oregon based on the presence or absence of live tree basal area mapped statewide at 30 m resolution using forest inventory, satellite, and environmental datasets (Landscape Ecology Modeling Mapping and Analysis (Lemma) Team, 2020). For each species that occurred in Oregon, we masked out habitat on non-forestlands, which resulted in our analysis including 544 animal species and 89 tree species. We then estimated species richness for each taxon by counting the number of species with habitat in each forested grid cell. For each grid cell, we (1) derived an animal priority rank based on the ranked sum of the four animal taxa ranks and then (2) derived the biodiversity rank by reranking the sum of the animal and tree priority rank.

For the climate resilience ranking, we used a metric of terrestrial landscape resilience that incorporated geophysical and topo-climatic diversity and landscape permeability (Buttrick et al., 2015). Landscape resilience refers to the capacity of a landscape or ecoregion to maintain biological diversity and ecological function despite climate change. As the climate continues to warm, biodiversity and ecological function are more likely to be maintained in landscapes that are topographically complex and permeable to movement of animals and plants. Complex topography provides corridors

and microsites where species can move in response to climate change while a landscape free of barriers (i.e., highly permeable) allows species to take advantage of different microclimates. We used the terrestrial landscape resilience dataset (90 m resolution) produced for the Pacific Northwest USA by The Nature Conservancy (Buttrick et al., 2015). The topo-climatic diversity metric incorporated a heat-load index computed from a digital elevation model and topographic index as a metric of relative variation in water availability. Permeability is a measure of the hardness of barriers, connectedness of natural cover, and arrangement of land uses. More details are in Buttrick et al. (2015).

To select areas with the highest priority for preservation that could meet the 30 × 30 and 50 × 50 targets, forestlands within each ecoregion were ranked by carbon, biodiversity, and/or climate resilience metrics. We used pixel by pixel prioritization ranking rather than neighborhood average for adding spatial structure to the prioritization. The highest ranked forests were then combined with areas currently protected at GAP 1 or 2 until each preservation target was reached. We then assessed who owns these high-preservation priority forestlands, as well as potential effects of increased forest preservation for carbon, biodiversity, and drinking water.

Ownership of high preservation priority forests

Forestland ownership across the state was assessed using the Oregon Department of Forestry (ODF) data representing forest ownership conditions in 2015. The ownership classes in this spatial dataset include Federal, Tribal, State, Local, Private, and Industrial. We examined current ownership of forestlands, as well as ownership of forestlands that we identified as high priority for preservation.

Assessing effects of forest preservation on carbon, biodiversity, and water

We assessed current protection of forest carbon, biodiversity, and surface drinking water across Oregon, as well as potential protection of these ecosystem services if each preservation target was met. To help Oregon's public water systems and communities, the Department of Environmental Quality identified and mapped public surface drinking water source areas across the state, including rivers, streams and lakes (Oregon Department of Environmental Quality [DEQ], 2019). We used these data in our analysis. First, we quantified the amount of tree AGC stocks, animal and tree species' habitat, and surface drinking water source areas that are currently protected (GAP 1 or 2) across forestlands in Oregon. Next, we quantified potential protection of these ecosystem services if the 30 × 30 and 50 × 50 preservation targets were met. We focused particularly on forestlands that could be jointly prioritized for preservation using carbon, biodiversity, and climate resilience metrics. Given the importance of protecting the habitat that sustains threatened and endangered (T&E) species, we summarized current and potential habitat protection for animal species that are currently listed by Oregon and/or the federal government. A list of current T&E species is maintained by the Oregon Department of Fish and Wildlife (2021). We excluded from analysis (1) T&E fish, sea turtles, shore birds, and marine mammals; (2) animal species with only distinct population segments listed as T&E [e.g., Pacific marten (*Martes caurina*)]; and (3) the streaked horned lark (*Eremophila alpestris strigata*) because habitat data were not available.

Results

Current protected forests

Oregon has 12.45 Mha of forestland of which 1.23 Mha is protected at GAP 1 or 2 levels, less than 10% of the forested area (**Figure 1** and **Table 1**). The largest protected forest area is in the mesic West Cascades (0.55 Mha) followed by the Blue Mountains in eastern Oregon (0.32 Mha) and Klamath Mountains in southwestern Oregon (0.13 Mha). Oregon's portion of the Coast Range with its heavily forested temperate rainforests is primarily in industrial ownership and managed as tree plantations and, therefore, it holds the smallest portion of forestland that is permanently protected (3%, 0.06 Mha). When the Washington to California portions of the Coast Range are included, it increases to 10%. Similarly, the full Blue Mountains ecoregion that extends into southeast Washington has 10% of its forestland permanently protected (0.48 Mha) (Law et al., 2021).

High priority areas for preservation of carbon and/or biodiversity

The forest preservation rankings for carbon and/or biodiversity at GAP 1 or 2 status levels are widely distributed across the forested ecoregions (**Figures 2B,C**; **Supplementary Figures 1–6**). However, the climate resilience rank highlights large areas within the ecoregions with larger landscape features that are important for resilience (**Figure 2D**), such as the topography of mountain ranges in southwest Oregon, the Coast Range, Cascades, and Blue Mountains in the northeast.

To reach 30% protection in each forested ecoregion by 2030, an additional 2.5 Mha (20.1% of forest area) would need to be protected in less than 10 years (**Table 1**). To reach the 50% target, a total of 5 Mha (40.1%) would need to be protected by 2050, most of which is in the Blue Mountains, followed by East and West Cascades and the Coast Range (**Figure 3**).

TABLE 1 Current extent of all forestlands, protected forestlands, and additional forestlands needed to meet preservation targets for each ecoregion in Oregon.

								Additions needed to meet preservation targets							
								All lands				Forest			
	All lands	Protected lands		All forest		Protected forest		30% target		50% target		30% target		50% target

Forestlands are considered currently protected if GAP 1 or 2 (IUCN categories Ia-VI).

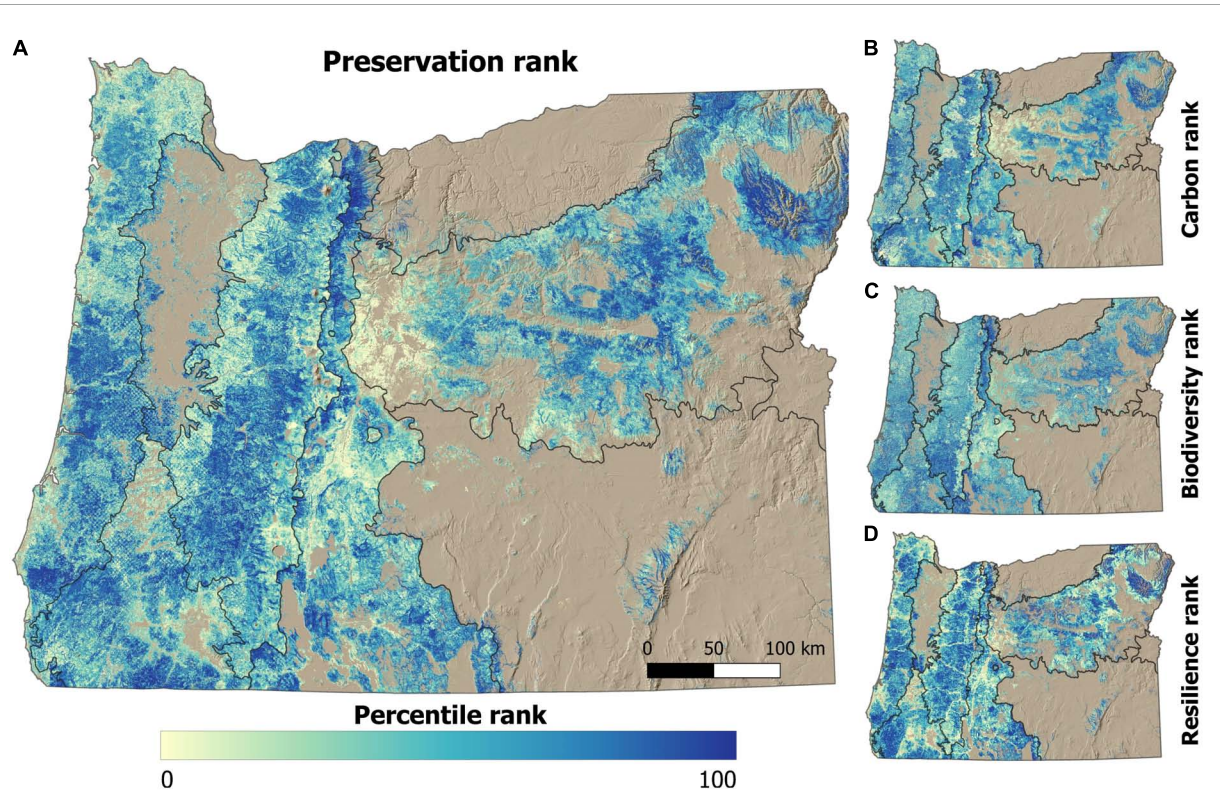

FIGURE 2
Oregon forest preservation, carbon, biodiversity, and climate resilience priority rankings. **(A)** Forest preservation priority ranks were derived from **(B)** carbon, **(C)** biodiversity, and **(D)** climate resilience priority ranks within each ecoregion. Forest carbon ranks were based on tree aboveground carbon stocks (AGC) stocks. Forest biodiversity ranks incorporate species richness of amphibians, birds, mammals, reptiles, and trees. Climate resilience priority ranks incorporated topoclimatic diversity and landscape connectivity.

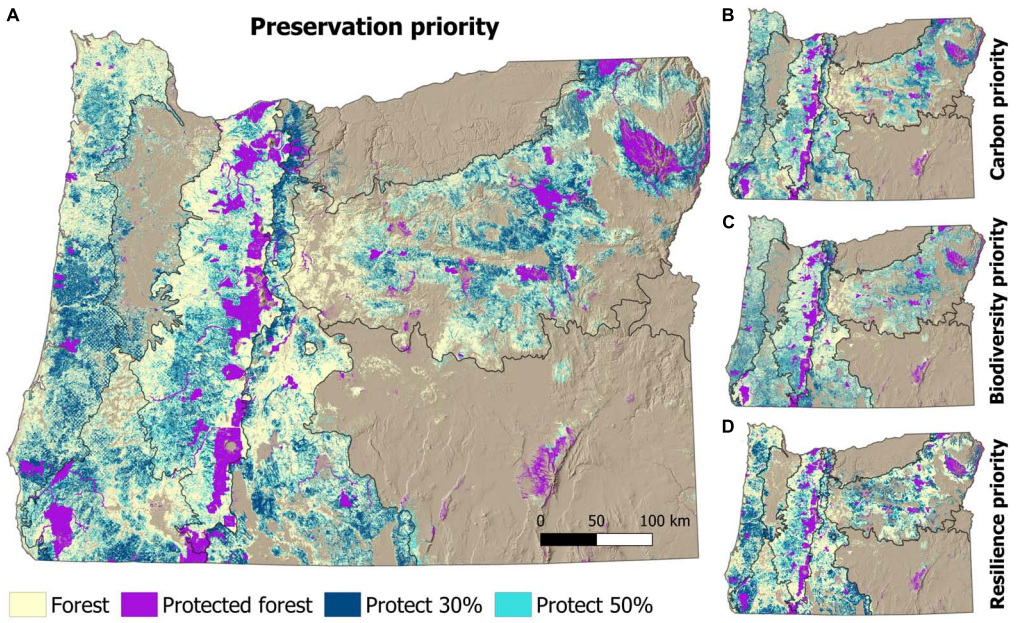

FIGURE 3
Forestlands prioritized to meet preservation targets across Oregon. Preservation targets include protecting 30 and 50% of each ecoregion's forestlands. To identify preservation targets, the current extent of forest protection was determined for each ecoregion and then the highest ranked unprotected forestlands were sequentially added to the protected area network until each preservation target was met. **(A)** Forest preservation priority targets are shown, as are the **(B)** carbon, **(C)** biodiversity, and **(D)** climate resilience priority targets.

We chose four areas for closer examination as examples of potential co-benefits and synergies with existing public lands (**Figure 4**).

The Coast Range ecoregion stretches along the coasts of Washington, Oregon, and northern California. The low elevation mountains (~1000 m) generally have deep soils with high soil water holding capacity and frequent fog that keeps vapor pressure deficits relatively low, resulting in a longer period of photosynthesis. The Coast Range contains two of the tallest conifer species in the world–Coast Douglas-fir (*Pseudotsuga menziesii var. menziesii*) and Sitka spruce (*Picea sitchensis*). These cool, temperate, moist forests can achieve higher biomass carbon density than tropical forests (Law et al., 2018). It is also the most intensively logged ecoregion. Within the areas we identified as high priority for both carbon and biodiversity are the Devil's Staircase Wilderness and the 32,375 ha Elliott State Research Forest (**Figure 4**). Both areas have a large portion of mature and old forests. Together, the ESRF reserves in Conservation Research Watersheds and adjacent Devil's Staircase Wilderness Area represent 26,404 ha of protected reserve (3.8% of Coast Range forestland), the largest in the Oregon Coast Range. The Devil's Staircase Wilderness was designated in 2019, and could be expanded to a larger area with connectivity corridors on BLM and State forestlands. The 83,000-acre Elliott State Forest was established as Oregon's first state forest in 1930. By 2020, half of it had been clearcut and planted. In 2020, the Elliott State Research Forest (ESRF) was established following an attempt to privatize the area for industrial management. The Research Forest has strong public support for conservation values including protection of mature and older forests, and threatened and endangered species (northern spotted owl, marbled murrelet, and Oregon Coast coho). Approximately 61% of the Elliott is identified as a reserve to meet state conservation goals, including 13,759 contiguous hectares, and another 5,870 ha of reserves located in harvest areas "protecting older trees and critical species habitat" (Oregon Division of State Lands, 2021; College of Forestry, 2022). To meet IUCN rules and national goals, at least 75% of the ESRF needs to be protected as strict reserves (IUCN, 2013).

The Klamath Mountains ecoregion is very diverse in climate, topography and plant and animal species. This area extends from southwestern Oregon into northern California where high priority forestlands provide connectivity between several large protected Wilderness Areas (Law et al., 2021). The most diverse forest flora in western North America (Whittaker, 1960) is found here, with more than 3,500 plant species, partly due to its steep climatic and topo-edaphic gradients. Plant communities range from temperate rain forests to moist inland forests, oak forests and savannas, and high elevation forests. The Kalmiopsis and Wild Rogue Wilderness Areas are in the Klamath Mountains, and each one presents potential for expansion (**Figure 4**). The Kalmiopsis was designated an Area of Global Botanical Significance by the IUCN, one of only seven in the United States. The area experienced the large Biscuit Fire

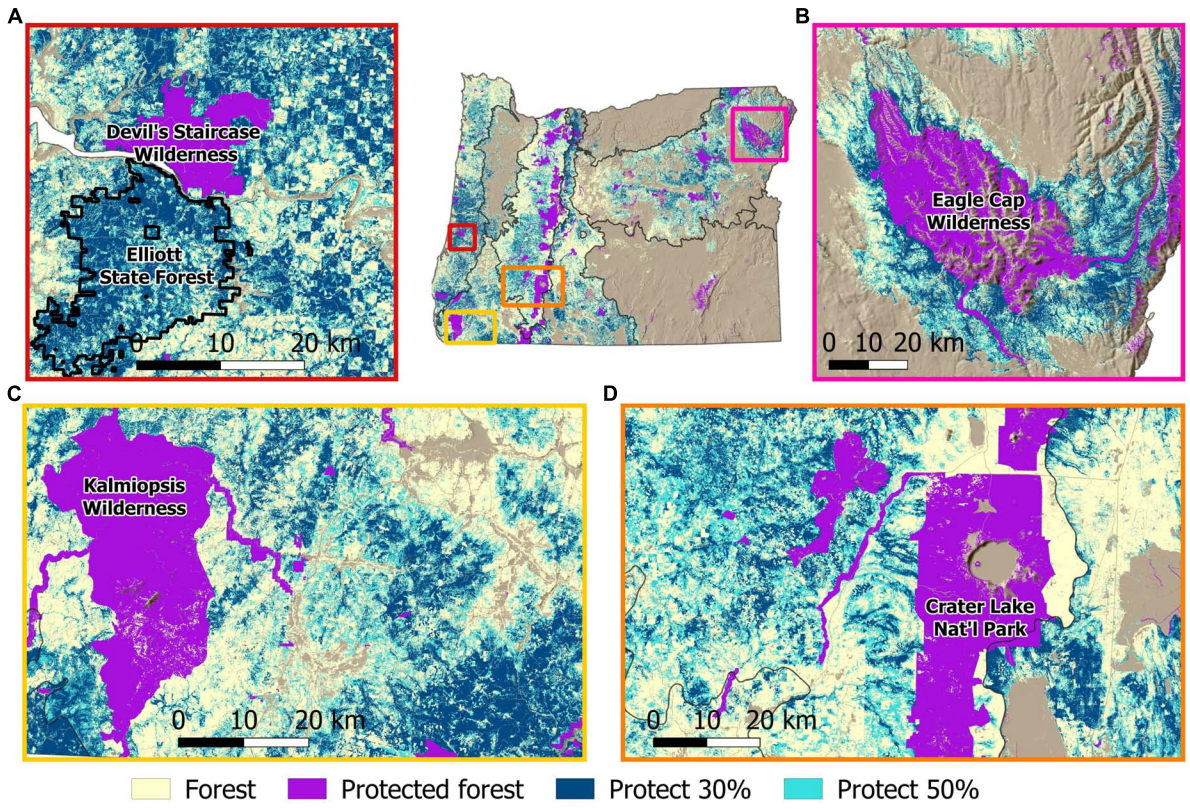

FIGURE 4
Close-up examples of forestlands prioritized to meet preservation targets in Oregon. Examples include forestlands around the **(A)** Devil's Staircase Wilderness and Elliot State Forest in the Coast Range, **(B)** Eagle Cap Wilderness in the Blue Mountains, **(C)** Kalmiopsis Wilderness in the Klamath Mountains, and **(D)** Crater Lake National Park in the Cascade Mountains. In these examples, forestlands were jointly prioritized using carbon, biodiversity, and climate resilience metrics.

in 2002, but has been slowly recovering its carbon stocks as conifer regeneration continued and woody biomass increased in the 10 years after the fire (Donato et al., 2015). The proposed Wild Rogue Wilderness would protect the Zane Grey Roadless Area, the largest forested BLM roadless area in southern Oregon and northern California.

The West Cascades ecoregion has a moist temperate climate that supports high productivity coniferous forests that are also intensively managed for logging. High-elevation forests along the Cascades Crest have received more protection including Crater Lake National Park, Oregon's only National Park (Figure 4). Crater Lake and surrounding forestlands include significant expansion opportunities of its protected area boundaries to include multiple rivers and elevating the protection of species (GAP 1 or 2) to become part of the strategic reserves system. The Crater Lake Wilderness Proposal would designate 219,744 hectares (2,197 km^2) of intact roadless forestlands as Wilderness on National Forest and National Park lands in a conservation area.

The Blue Mountains ecoregion contains a complex of mountain ranges interspersed with valleys stretching from the Cascades in the west to the Rocky Mountains in the east. This is the largest ecoregion in Oregon and has the largest Wilderness area in the state. The area supports diverse and abundant native fish and wildlife populations and has a significant portion of the region's remaining road-free wildlands. The forest types have fire-adaptive traits related to the wildfire regimes in this ecoregion, with ponderosa pine dominated forests in the south and a greater mix of dry, moist and cold forest types in the north due to receiving more moisture through the Columbia River Gorge. The Eagle Cap Wilderness (Figure 4) is surrounded by roadless areas and presents expansion opportunities that would help secure connectivity in a crucial wildlife corridor with large Wilderness areas in the Rocky Mountains.

Land ownership of high priority areas

In 2015, Oregon forestlands were primarily owned by the federal government (59%), private entities (31%), and industry (7%), whereas little was owned by state, local, or tribal governments (0–3%; Table 2). However, forest ownership widely varied among ecoregions. The federal government

owned 66–77% of forestlands in the Blue Mountains, East and West Cascades, and Northern Basin, with these four ecoregions together accounting for 80% of federal forestlands statewide. Conversely, private or industrial owners held 57–92% of forestlands in the Coast Range, Columbia Plateau, Snake River Plain, and Willamette Valley, though these ecoregions together made up only 35% of private and industrial forestlands statewide because, with the exception of the Coast Range, these ecoregions are minimally forested. In terms of total forest area, private ownership was concentrated in the Blue Mountains and Coast Range, which respectively, accounted for 30 and 20% of private forestlands statewide. Similarly, industrial ownership was concentrated in the Coast Range and West Cascades, which respectively, accounted for 46 and 36% of all industrial forestlands statewide. The notable checkerboard pattern of forest carbon stocks and preservation priorities in the Coast Range (**Figures 1–3**) reflects differences in forest management between public and private ownership.

The ownership of the high preservation priority forestlands for carbon and biodiversity is primarily federal (72% by 2030, 67% by 2050) followed by private (20% by 2030 and 25% by 2050), with much less in the other ownerships (**Figure 5**). The additional federal lands needed to meet the high preservation priority targets adds up to 1.75 Mha by 2030 and 3.3 Mha by 2050 (**Table 1** and **Figure 5**). Prioritizing biodiversity increases the percentages on private lands (**Figure 5**, right frame).

There are large differences among ecoregions in the ownership of high priority forestlands (**Figure 6**). For example, 80 to >90% of high priority forestlands are federally owned in the Cascade, Klamath, and Blue Mountains, whereas about 80% are privately owned in the Willamette Valley. In ecoregions with very little forestlands (Willamette Valley, Snake River, and Columbia Plateau), most high priority areas are privately owned. The highest population density is in the Willamette Valley and the other two ecoregions are drier. In the Coast Range, 60% of high priority forestlands are on federal lands, and 15% are on Tribally owned lands, the highest in the State.

Forest habitat, carbon, and drinking water if protected

Meeting the forest preservation targets would substantially increase protection of tree carbon stocks, animal and tree species' habitat, and surface drinking water source areas. Tree AGC stocks in all of Oregon's forests is 905 Tg C (**Table 3**). Currently, only 12% of Oregon's tree AGC stocks (104 Tg C) are in protected areas, mostly in the West Cascades (65 Tg C), followed by the Blue Mountains (13.5 Tg C) and Coast Range (10.9 Tg C). If the 30 and 50% forest preservation targets were met, then protected tree AGC stocks would total 405 and 635 Tg C (**Table 3**). The West Cascades and Coast Range would account for about 60% of the additional protected carbon stocks.

For most of the considered animal taxa and tree species, only a small percentage of their forest habitat is currently protected. Merely 6 and 14% of animal and tree species have at least 30% of their forest habitat currently protected. Moreover, the median percentage of forest habitat currently protected ranges from 8 to 12% among amphibian, bird, mammal, and reptile species and is 10% among tree species (**Figure 7A**). If the 30 and 50% forest preservation targets were met, then the median amount of forest habitat protected would be 27–42 and 45–63% among animal taxa, respectively, and reach 41 and 67% among tree species (**Figure 7B**).

Meeting these forest preservation targets would substantially increase forest habitat protection for threatened and endangered (T&E) species and other species of interest (**Table 4**). For example, only 8% of marbled murrelet (*Brachyramphus marmoratus*) and spotted owl (*Strix occidentalis*) forest habitat is currently protected, yet 36–44% would be protected if the 30% forest preservation target was met. Similarly, forest habitat protection for Canada lynx (*Lynx canadensis*) would increase from 12 to 40%, while it would increase from 34 to 55% for wolverines (*Gulo gulo*). Important non-T&E species such as wolves (*Canis lupus*) and beavers (*Castor canadensis*) would see forest habitat protection increase from 35 to 59% and from 10 to 40%, respectively, if this preservation target was met. These wolf and beaver habitat targets would help fulfill a recent proposal for rewilding the American West (Ripple et al., 2022). The additional habitat that could be protected by 2030 and 2050 increases dramatically for most of these species when forestlands are jointly prioritized based on carbon, biodiversity and climate resilience, which includes connectivity for animal movement.

Forestlands account for 78% (4.14 Mha) of the 5.3 Mha of surface drinking water source areas across Oregon, yet only 9% (0.37 Mha) of these forestlands are currently protected at GAP 1 or 2 levels (**Table 5**). This would increase to 27% by 2030 and 48% by 2050 if the high priority areas for carbon, biodiversity and resilience are protected (GAP 1 or 2). Most of the currently protected surface water source areas and the areas suitable for potential increases in protection are in the West Cascades, though protection of surface water sources areas would also increase notably in the Blue Mountains, Klamath Mountains, and Coast Range (**Figure 8**).

Discussion

Regional considerations for protecting carbon, biodiversity, and water

The IPCC AR6 (2022) states that "maintaining the resilience of biodiversity and ecosystem services at a global scale depends on effective and equitable conservation of approximately 30–50% of Earth's land, freshwater and ocean

TABLE 2 Current forestland ownership and management within each ecoregion and overall for Oregon.

Ecoregion	Ownership land management					
	Federal	State	Tribal	Local	Private	Industrial
Blue Mountains	2.26 (66%)	0.02 (1%)	0.02 (0%)	0.00 (0%)	1.14 (33%)	0.00 (0%)

areas, including currently near-natural ecosystems." This acknowledges the multiple lines of evidence that maintaining ecological integrity of biodiversity is essential for addressing climate change effectively.

Accordingly, our analysis prioritizes areas within ecoregions to ensure biodiversity losses are reduced, or even enhanced in some areas through natural recovery of species and reintroductions, across the range of ecosystems. This approach also benefits carbon for climate mitigation, protects water availability and increases other ecosystem services.

A global application of the ecoregion approach found that temperate broadleaf, mixed, and conifer forests could achieve

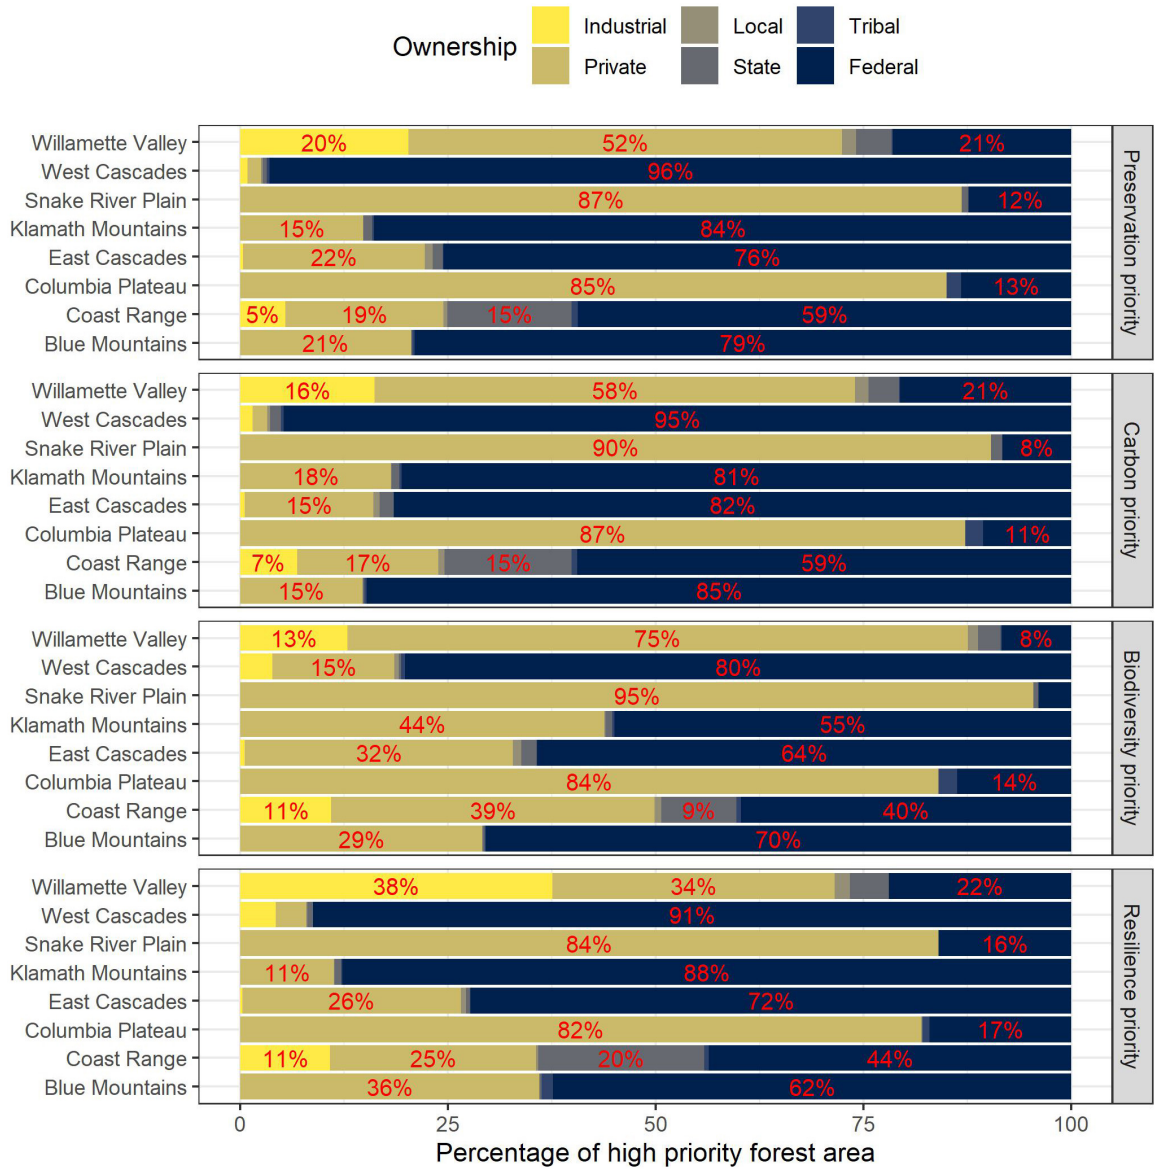

FIGURE 6
Land ownership of high priority forest areas to protect to reach 30% preservation for each ecoregion in Oregon. Ownership is summarized for each preservation priority **(rows)**. Land ownership data from Oregon Department of Forestry (2015).

protection of half of the global forest area, and the majority of the ecoregions are categorized as "imperiled" or "could recover" (Dinerstein et al., 2017). This emphasizes the need for protection.

Here, we found that the current 1.3 Mha protected as GAP 1 or GAP 2 status would increase to 2.5 Mha by 2030 and 5 Mha by 2050 to meet the preservation targets. Federal lands account for the majority of the protected area needed, which would provide more permanence. Protecting high carbon priority forests from timber harvest (GAP 1) is critical to dampen the accelerating anthropogenic carbon dioxide emissions.

Mitigation strategies need to explicitly protect existing old-growth forests, and allow mature secondary forests to regrow to their carbon capacity. For climate mitigation using natural climate solutions, effectiveness is based on the time that a unit of biomass carbon is resident in a forest ecosystem stock and thus kept out of the atmosphere (Körner, 2017; Mackey et al., 2020). Oregon's wet coastal forests have among the highest carbon residence times of any forests in the western USA (Berner et al., 2017). The large and old trees dominate forest carbon in temperate and tropical forests, and can maintain large carbon stocks and accumulation for centuries (Luyssaert et al., 2008; Hudiburg et al., 2009).

TABLE 3 Current tree aboveground carbon (AGC) stocks in each ecoregion's forests, protected forests, and forests that would be protected by meeting preservation targets using joint prioritization.

	All forest	Unprotected forest		Protected forest		Forestland preservation target			
						30% protection		50% protection	
Ecoregion	Tg C	Tg C	%	Tg C	%	Tg C	%	Tg C	%
Blue Mountains	110.8	97.2	88	13.5	12	53.0	48	79.1	71
West Cascades	323.6	258.6	80	65	20	125.7	39	220.7	68
Coast Range	240.3	229.4	95	10.9	5	117.9	49	171.9	72
Columbia Plateau	1.5	1.5	94	0.1	6	0.9	58	1.2	79
East Cascades	73.8	69.4	94	4.4	6	35.8	48	50.1	68

N. Basin and Range*	1.7	1.3	75	0.4	25	–	–	1.0	60
Snake River Plain	< 0.1	< 0.1	99	< 0.1	1	< 0.1	36	< 0.1	56
Willamette Valley	40.3	39.7	98	0.7	2	20.7	51	30	75
Oregon	904.9	800.5	88	104.4	12	405.1	45	634.8	70

*32% of forestlands in the Northern Basin and Range ecoregion are currently protected, thus summaries of tree AGC stock protection were not computed for the 30% forest preservation target. Each category includes tree AGC stocks in teragrams (10^{12} g or million metric tons) of carbon and as the percentage of the ecoregion's total tree AGC stocks. Tree AGC stocks protected by meeting each preservation target include the stocks in current protected forests. Tree AGC stocks are considered currently protected if they occur on forestlands as GAP 1 or 2 status.

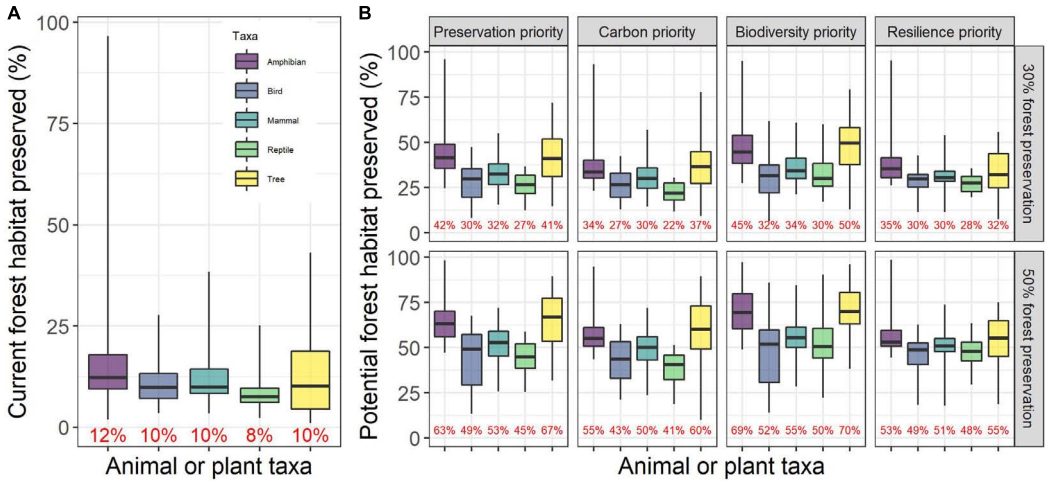

FIGURE 7
Current and potential protection of animal taxa and tree species forest habitat across Oregon. The percentage of each species' forest habitat that **(A)** is currently protected and **(B)** would be protected by meeting preservation targets based on each priority. The median percentage of current and potential protected species habitat is provided for each taxon (red text). Boxplots depict medians (intra-box lines), 25th–75th percentiles (box edges), and 5th to 95th percentiles (whiskers). Animal and tree species habitat data were from the USGS GAP (2018) and Landscape Ecology Modeling Mapping and Analysis (Lemma) Team (2020), respectively.

Oregon inventory data show that stand ages reach beyond 1,000 years, and public lands have far more stands older than 200 years than private lands do (Hudiburg et al., 2009). Mean and maximum live biomass are also higher on public lands. The maximum mean trend of biomass within each ecoregion occurred by the age of 300 years in the Coast Range to 430 years in the West Cascades and 600+years in the Klamath Mountains, and biomass continued to increase beyond these ages (Hudiburg et al., 2009). Ecoregions with the highest ecosystem carbon density in vegetation and soils are the Coast Range, West Cascades, and Klamath Mountains (330, 318 and 316 Mg C ha^{-1}, respectively), with 55% of it in live tree carbon (180, 175, 173 Mg C ha^{-1}) (Law et al., 2018). Oregon's forest carbon stocks could almost double in the absence of disturbance (Hudiburg et al., 2009). These trends are influenced by harvest intensities, particularly in the Coast Range where the temperate rainforests have so little forestland protected, yet they are among the highest carbon dense forests in the world (**Table 1**).

TABLE 4 Current and potential habitat protection for animal species listed as threatened (T) or endangered (E) by the state of Oregon.

Common name	Scientific name	State (Federal) status	Forest habitat (km^2)	Forest habitat protected (%)		
				Current	30% protected	50% protected
Oregon spotted frog	*Rana pretiosa*	T	507	17	42	65
Marbled murrelet	*Brachyramphus marmoratus*	E (T)	14,913	8	44	65
Northern spotted owl	*Strix occidentalis caurina*	T (T)	39,379	8	36	59
Canada lynx	*Lynx canadensis*	T	16,211	12	40	62
Kit fox	*Vulpes macrotis*	T	295	25	26	32
Washington ground squirrel	*Urocitellus washingtoni*	E	1	4	27	41
Wolverine	*Gulo gulo*	T	791	34	55	71

Several of these species are also listed by the federal government. Each species includes the amount of forest habitat that is currently protected (GAP 1 or 2), as well as how much would be protected by reaching the 30 and 50% preservation targets when jointly prioritizing forestlands based on carbon, biodiversity, and climate resilience metrics. Information on listing status was from the Oregon Department of Fish and Wildlife as revised October 2021.

TABLE 5 Surface drinking water source areas for public water systems in each ecoregion's forests, protected forests, and forests that would be protected by meeting preservation targets using joint prioritization.

Ecoregion	All lands	All forest		Protected forest		Preservation target			
						30% protection		50% protection

Oregon	5.30	4.14	78	0.37	9	1.11	27	2.00	48

Joint prioritization was based on forest carbon, biodiversity, and climate resilience metrics. Surface drinking water source areas are considered currently protected if they occur on forestlands as GAP 1 or 2 status. Surface drinking water source areas were mapped by the Oregon Department of Environmental Quality (DEQ) (updated 2019).

Although we did not simulate changes in forest carbon and accumulation under future climate, our previous studies showed that preserving 50% of high priority forests by 2050 would triple the amount of carbon accumulation compared to current levels over the western United States (Law et al., 2021), accounting for projected climate effects including CO_2 enhancement of photosynthesis constrained by nitrogen and carbon losses from forest fires. Because we prioritized relatively high carbon density within each forested ecoregion in our current study, the carbon accumulation is probably lower than if priorities were only in the ecoregions with the highest net accumulation (average of 1.4 compared to 4 to 8 Mg C ha^{-1} yr^{-1}; Law et al., 2013).

A global study assumed an average accumulation rate of 0.14 MgC ha^{-1} yr^{-1} for boreal and temperate forests over the next decades (Griscom et al., 2017). Our estimate for natural forest management in Oregon is almost ten times the global value. We also found that limiting harvest to half of current levels on public lands and doubling harvest cycles to 80 years on private lands was three times more effective as a land use strategy than replanting and reforestation after cutting within current forest boundaries in Oregon (Law et al., 2018). The global study presents different results, highlighting the need for consistent approaches for national, regional and state-level analysis to refine estimates of forest carbon benefits.

There is concern that protecting areas that are vulnerable to increased drought and fire will be ineffective, however, species diversity, and threatened and endangered species still need habitat, refugia and connectivity with other protected areas. Wildfires tend to be patchy, and a majority of trees survive low to mixed-severity fires (Halofsky et al., 2011) that can be critical habitat, and burned forests still retain the vast majority of their carbon (Hudiburg et al., 2009; Law et al., 2018). When very few populations of a given species exist, the potential to recolonize areas with strong site fidelity is needed.

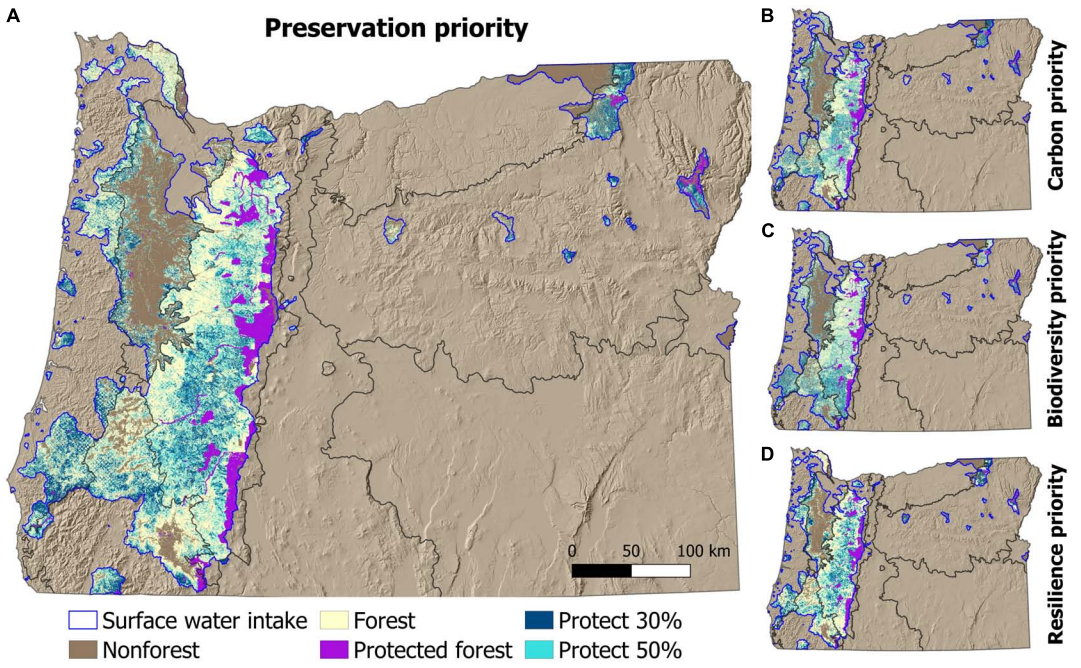

FIGURE 8
Current and potential protection of surface drinking water source areas in forestlands across Oregon. Potential protection is shown for the **(A)** forest preservation priority targets, as well as for **(B)** carbon, **(C)** biodiversity, and **(D)** climate resilience priority targets. Surface drinking water source area data were from the Oregon Department of Environmental Quality (Oregon Department of Environmental Quality [DEQ], 2019).

The conservation of habitat suitability is necessary even if it is currently unoccupied by those populations (Merkle et al., 2022). Moreover, transboundary assessment of priority areas for preservation and connectivity is essential, as well as collaborative development of implementation plans that transcend political boundaries (Noss et al., 2012; Law et al., 2021).

Across the western U.S., federal forestlands are the dominant source of clean drinking water, and private forestlands are the most likely to experience land use change and impacts on water supplies (Liu et al., 2021). In western Oregon, where human population is concentrated and projected to continue growing rapidly, communities depend on drinking water from both private and federal forestlands. While there is concern about the impacts of wildfire on drinking water sources, forestlands tend to be adapted to these periodic disturbances and recover with minimal interventions. However, repeated harvesting, road networks and application of pesticides can expose aquatic systems to chronic stressors that continuously reduce water quantity and degrade water quality (e.g., soil erosion, sediment load, higher stream temperature) (Rieman et al., 2003; Karr et al., 2004).

As warming increases, mountain snowpack is expected to melt earlier in spring, which reduces drinking water supplies (Evan and Eisenman, 2021). The Cascade Mountains are expected to be among the most vulnerable mountain ranges because of their mild climate where even small temperature increases will result in precipitation falling as rain rather than snow, further reducing snowpack accumulation and increasing melt. This ecoregion is the largest area currently protecting forest drinking water sources at GAP 1 or 2 status and it is critical for additional preservation area for protection of habitat, biodiversity, and carbon. Protecting clean drinking water sources from extractions (mining, logging) is cost effective and essential, as loss of forest cover or conversion to plantations has been shown to reduce water supplies by up to 50% as compared to mature forests (Segura et al., 2020). Logging is still occurring in Oregon watersheds that feed surface water and replenish groundwater sources of drinking water.

In the drier Klamath and Blue Mountains ecoregions, dependence of water supplies on sufficient accumulated winter snowpack is amplified due to less rainfall. The mountains serve as crucial water collection sources for these areas. Mountains receive far more moisture than the lower elevation valleys and canyons that they eventually supply with water. As snow melts, it recharges soil water to support ecosystems through seasonally dry summers. The slow transfer of water sustains water supplies and maintains summer stream flows that in turn support high levels of biodiversity in aquatic and riparian systems. Mountain water is also of major importance to agriculture. In these seasonally dry forests, protecting forested watersheds will be crucial to the long-term water security of the region.

Older forests in Oregon's watersheds exhibit greater water retention and improved late summer stream flows compared to managed plantations (Segura et al., 2020). Intact forests also tend to harbor more large and old trees, bolstering carbon stores and biodiversity services that large trees provide (Lutz et al., 2018; Plumtre et al., 2021). As warming increases, protecting the integrity of these intact forested watersheds would help sustain valuable ecosystem services, including a clean, reliable supply of water. Oregon's largest protected area, the Eagle Cap Wilderness, demonstrates the tremendous value of a largely protected forested mountain range for providing a reliable source of clean water to the ecosystems and communities of northeast Oregon.

Some ecoregions will see declines and even biome shifts as warming continues, but this is somewhat counteracted by the positive effect of atmospheric CO_2 on photosynthesis and lengthened growing seasons in the wetter ecoregions. The effects of increasing atmospheric CO_2 will continue in spite of reaching greenhouse gas reduction targets because surface temperatures will not immediately return to previous levels and may persist for a millennium or more (Solomon et al., 2009). While strategic forest reserves for climate mitigation and adaptation by plants and animals may face near-term challenges, the urgency and benefits of protecting landscapes for community and ecosystem values is nonetheless very high as the world moves to transition away from fossil fuel pollution.

The diversity of ecoregions and forest communities within Oregon also suggests that systems will respond differently to warming across the region. Even within forest types, individual species have unique adaptations and vulnerability thresholds. In Oregon's Coast Range, conversion of diverse conifer systems to Douglas-fir plantations has increased vulnerability to Swiss Needle Cast disease (Shaw et al., 2021), and climatic change may further exacerbate this vulnerability (Mildrexler et al., 2019). Moreover, young industrial plantations show a higher incidence of high severity fires, almost twice as many as on public lands (Levine et al., 2022). In other ecosystems, disturbance-induced shifts may facilitate changes in species composition, including shifts toward communities better adapted to changing climatic conditions. Taken as a whole, Oregon's exceptional ecosystem diversity will help buffer its forests against large-scale shifts in ecosystems.

Improving measurement, reporting and verification

To initiate strategic reserves, consistent guidelines, definitions, and accounting rules need to be established. Similar to international requirements for monitoring, reporting and verification (MRV; Ellis and Moarif, 2015), there is a need to upgrade our measurement systems as recommended in national and international reports (e.g., Law et al., 2008; Ciais et al., 2014). Consistent, current metrics will help refine locations for reserves, establish baseline conditions, and monitor changes in plant and animal species, forest carbon and other metrics of condition. Updated metrics will also ensure reliability in protection agreements.

An executive order issued by President Biden in 2022 recognized the importance of mature and old-growth forests in limiting climate change and makes their conservation a national policy.[1] The land management agencies are tasked with defining mature and old. Carbon per unit area ground (carbon density) is an essential climate variable for mitigation, and can be used to distinguish mature from young forests. Carbon density is computed from tree diameter and height and can be used to identify the inflection point at which the increase following stand-replacing disturbance begins to slow for a tree community within ecoregion. In addition, tree diameter and height are useful to infer site fertility and could be used to scale forest carbon potential in different environments. When assessing the mitigation potential of forests in a region, we must consider that carbon density and removal rates are strongly variable with edaphoclimatic conditions, even within the same forest type. Young forests have low carbon density compared to mature and old (Hudiburg et al., 2009). Age alone is not a good metric because it is not measured well in most regions or is approximated from tree diameter. Furthermore, age is a good indicator of the time since the last stand-replacing disturbance only in early successional stands with pioneer tree species. In late-successional stands with shade-tolerant trees (i.e., long suppression phases), maximum tree age is not necessarily related to disturbance. Long-term repeated measurements of ecosystems across the landscape/ecoregion provide a much more precise picture of carbon dynamics, like the repeated direct measurements of diameter and height in federal inventories (Forest Inventory and Analysis [FIA], 2014). In addition, these measurements are used to produce a metric of structural diversity that is important for biodiversity.

Coordination among federal, state and international programs are needed for consistency of repeated measurements, reporting, and verification. To inform strategic assessments and decision making, spatial datasets must represent environmental conditions consistently across the country at moderate to high spatial resolution (30–250 m) and must be updated at least every 5-year (e.g., for the federally mandated National Climate Assessment produced every 4 years), and include:

- Processed inventory data that use height and dbh in improved algorithms for estimating aboveground biomass carbon.

1 https://www.federalregister.gov/documents/2022/04/27/2022-09138/strengthening-the-nations-forests-communities-and-local-economies

- More frequent maps of forest area, forest type, forest carbon stocks, forest age (young, mature, and old) and spatial estimates of uncertainty for each product.
- Consistent and repeated measurements of plant and animal species richness and habitat quality in a measurement system that is co-located or coincides with the forest inventory, and data reporting to a central database.
- Habitat connectivity data products.
- Ecosystem model projections of future forest carbon dynamics and vulnerabilities to drought, fire, and insects under various climate scenarios (transition model projection from research oriented to operational oriented analysis).

Socioeconomic and policy challenges and solutions

To some extent, forest management priorities on national forests have changed from timber harvest and maximizing wood production to conservation and adaptation to climate change (USDA Forest Service, 2022). These changes are well aligned with strategic forest reserves that can serve as focal areas of ecological integrity and genetic diversity that benefit adjacent areas (Greater Protected Areas). As our western US and Oregon analyses show, achieving protected area targets is a practical goal and does not require all federal forestlands. Many areas will remain outside protected areas, but these forests will experience long-term benefits from increased proximity to protected landscapes.

Forest ownership by public real estate investment trusts (REITs) and timber investment management organizations (TIMOs) have the goal of maximizing return on investment. In Canada and the United States, 60% of the timberland area owned by the top ten entities was in REITs in 2015. Over the past 40 years, as much as 304,000 hectares of Oregon's non-industrial forest ownership has transferred to forest industries by buyouts and mergers, now dominated by a few industrial owners in each county (Willer, 2021). As of 2020, at least 40% of private forest lands are owned by investment companies as public or private REITs whose forestland portfolio is managed by TIMOs. The industry consists of investors or owners and corporate management that serves them, and it often subcontracts harvest, transport, reforestation and pesticide chemical application. Forest operations are compartmentalized. While REITs and TIMOs seek to monetize the value of timber harvest, they also have been involved in projects that monetize ecosystem services, carbon sequestration, and, in some cases, a land use change from forestry to development. Integrated forest companies own forestland and mills and they, on the other hand, depend on a consistent, predictable supply of wood. They view limits on harvest for ecosystem values as an encumbrance that impacts the bottom line. REITs, TIMOs and integrated forest product companies own the bulk of private forests in Oregon, but there are approximately 1.49 million hectares of family owned non-industrial forests that are enjoyed for privacy, wildlife, scenic values, water and, to a far lesser extent, harvest.

Currently, there is little incentive to manage private forestlands for ecosystem resilience to climate change impacts, biodiversity or carbon storage, and industrial management has resulted in significant losses of habitat and biodiversity and carbon stocks, and degraded water systems. Oregon's private forests laws have lagged behind those in California and Washington for decades, and recent changes adopted in 2022 focus primarily on changes for threatened and endangered fish species, not climate mitigation, terrestrial biodiversity or drinking water supplies.

Land trusts have played a role in protecting Oregon's private forestlands, yet their coverage area is growing but not yet substantial. With significant funding, land trusts could play a greater and important role in securing high-priority private forest lands from development and harvest. Land trusts typically use conservation easements to protect key private lands from extractive management and to protect certain values in perpetuity. This analysis provides a framework to spatially examine the value of private forestlands and prioritize efforts for the greatest climate mitigation and biodiversity protection benefits.

To sustainably achieve climate and conservation goals, projects must not lead to more emissions from deforestation and forest degradation (Nolan et al., 2021). To do so and be included in meeting preservation targets, lands should be protected at GAP 1 or GAP 2 status (IUCN 1a to VI). Roadless areas that are not currently inventoried should be inventoried to determine if they qualify.

Projects have to demonstrate permanence of protected forest carbon, and account for leakage and additionality. Regular assessment of permanence, leakage and additionality is essential for forest offsets programs to ensure there is not over-crediting (Anderegg et al., 2020). Moreover, carbon accounting among projects is needed to understand their contributions to meeting climate goals. Permanence can be addressed by requiring a portion of the credits (e.g., 20%) be set aside as a buffer in case natural disturbances occur in the project area (wildfire, beetle kill; Anderson et al., 2017). Leakage means that protecting one area of forest could result in cutting elsewhere, even in another country, and currently there is no international program to track it. Leakage could be addressed by assuming leakage exists and providing only partial credit for projects. Although a regulatory pathway is the typical approach to constraining what qualifies for meeting the intended goal with a minimum of unintended consequences, the requirement of additionality can hinder success in protecting private and indigenous forestlands. Additionality means one has to demonstrate that the climate benefits of preserving forests would not have occurred without the project. An option is to have science-based verification of proposed projects before they are approved, and if a proposed

project cannot protect the whole area, then provide partial credit for the areas that are most likely to be protected with permanence. Accounting and incentives could be applied to ensure the protection targets are met at local to national scales. Offsets are just one of a number of ways (and not the best way from a climate mitigation perspective) in which forest ecosystem carbon removals from the atmosphere and accumulated carbon stocks can be used, accounted for, and forest stewards rewarded.

Conclusion

The most important action Oregon can take to mitigate climate change, reduce biodiversity losses, and protect watersheds for drinking water is to set aside existing forests. Reforestation or afforestation can be done too, but it takes decades for young trees to mature into net carbon sinks. Planting young trees will not result in much additional storage within the time forest carbon stocks need to increase in order to contribute to emission reduction and global warming targets.

The approach developed by Law et al. (2021) demonstrated the value of coupling forest carbon and biodiversity metrics into a spatially continuous prioritization framework that can be applied across large, diverse forested regions. Here, we improved the approach by adding a resilience metric that represents connectivity and topographic diversity, and used finer resolution (30 m) and more recent data to better resolve within-state variability in carbon, drinking water sources, and biodiversity and resilience metrics. An ecoregion-based approach along with resilience-based metrics will ensure species and habitat are protected and connected so that species can move to areas where they can survive and thrive as climate change intensifies.

The analysis identifies the potential for a well distributed forest reserve network within Oregon that captures unique ecological facets by ecoregion to achieve targets for protecting 30% of forests by 2030 and 50% by 2050. Protecting forest carbon, watersheds, and biodiversity are universally important priorities regionally, nationally and globally, and our framework could be applied in other regions for mitigation and adaptation to climate change.

Data availability statement

The datasets presented in this study can be found in online repositories. The names of the repository/repositories and accession number(s) can be found below: The forest prioritization dataset generated for this study will be publicly archived with PANGAEA (https://www.pangaea.de/). Further, the following existing dataset were analyzed for this study. Forest structure and composition data were from the Landscape Ecology Modeling Mapping and Analysis (Lemma) Team (https://lemma.forestry.oregonstate.edu/data). Forest disturbance data were from University of Maryland's Global Forest Change dataset (https://earthengine.google.com/). Protected Area data were from the United States Geological Survey GAP Analysis program (https://doi.org/10.5066/P92QM3NT), as were species habitat maps (https://doi.org/10.5066/F7V122T2). Forest land management data were from the Oregon Department of Forestry (https://spatialdata.oregonexplorer.info/). Surface drinking water source data were from the Oregon Department of Environmental Quality (https://www.oregon.gov/deq/wq/programs/Pages/DWP-Maps.aspx).

Author contributions

BL: conceptualization the project. BL and LB: investigation and writing – original draft preparation. LB: data analysis and visualization. BL, LB, DM, WR, and RB: writing – review and editing. All authors have read and agreed to the published version of the manuscript.

Funding

RB was supported by the Oregon Community Foundation.

Acknowledgments

The authors thank Mary Wood and Doug Quirk from U Oregon and Polly Buotte from UC-Berkeley for reviewing an early draft.

Conflict of interest

The authors declare that the research was conducted in the absence of any commercial or financial relationships that could be construed as a potential conflict of interest.

Abstract

Indigenous communities in the Pacific West of North America have long depended on fire to steward their environments, and they are increasingly asserting the importance of cultural burning to achieve goals for ecological and social restoration. We synthesized literature regarding objectives and effects of cultural burning in this region within an ecosystem services framework. Much scholarly literature focuses on why various species harvested from burned areas were important historically, while tribes and recent research increasingly stress the benefits of contemporary cultural burning for a wide range of ecological and cultural benefits. These tribal values generally align with broader ecological restoration objectives, although Indigenous practitioners espouse holistic views on the benefits of burning rather than focusing narrowly on fuel reduction and wildfire mitigation. While government agencies are motivated to treat more and larger areas to reduce fire risk (expanding pace and scale), tribal practitioners have tended to burn comparatively small areas at one time, and cumulatively due to various constraints. However, they would like to burn more widely and frequently to promote resilience to wildfire and drought; conserve biocultural diversity, maintain traditional knowledge and spiritual values; and provide material goods such as foods, medicines, and fiber materials. Much of the experimental research on the effects of cultural burning has been conducted as graduate research and has tended to look at single burns (sometimes agency prescribed burns or wildfires rather than tribally-led cultural burns) for short periods in very limited contexts. Such studies have found that treatments often promote desirable plant qualities, including reduced incidence of pests and structural qualities that facilitate weaving and other crafts. However, effects on understory plant diversity, wildlife, fruit production, parasites, and other key aspects of resource quality have been more difficult to evaluate due to complex interactions and scale considerations. Expanding long-term tribal collaboratives, including designating cultural management areas with

frequent burning, would help to understand the potential to achieve ecocultural restoration objectives.

Keywords: ecosystem services, Indigenous stewardship, cultural burning, fire ecology, forest management, socioeconomic values, prescribed burning, wildland fire, American Indians

1. Introduction

Indigenous communities in the Pacific West of North America have long depended on fire to steward their environments (Boyd, 1999; Turner, 1999; Anderson, 2009; Lightfoot and Parrish, 2009; Anderson, 2018). Indigenous communities in this region have expressed their interest in reasserting their traditional fire stewardship practices (Goode *et al.*, 2018; Clark *et al.*, 2021). Federal and state agencies have sought to increase their engagement with tribes and other Indigenous organizations to support restoration, including collaboratives such as the Western Klamath Restoration Partnership (Kelly *et al.*, 2019). Consequently, there is heightened interest in how Indigenous approaches to burning can integrate with broader ecosystem restoration policies and investments.

1.1. Calls for increased use of fire

Scientists and land managers have increasingly called for greater use of fire, including both prescribed and naturally-ignited fires, to expand the "pace and scale" of restoration and promote resilience of social-ecological systems (Kolden, 2019; McWethy *et al.*, 2019; Spies *et al.*, 2019). These calls have become stronger as uncharacteristically large and severe wildfires have become more common (Miller and Safford, 2012; Miller *et al.*, 2012; Reilly *et al.*, 2017), and disruptive to ecological and social values, including public health (O'Dell *et al.*, 2019) and cultural resources (Welch, 2012). National forests in this region have initiated the process of revising their land management plans to expand the role of intentional fire (Spies *et al.*, 2019), while the

State of California has committed to sweeping new initiatives (Forest Management Task Force, 2021) that include support for tribal cultural burning. However, significant policy obstacles, including liability concerns and air quality regulations, may hinder these efforts (Clark *et al.*, 2021).

1.2. Intent and scope of this review

In this paper we review and synthesize publications about Indigenous use of fire in the Pacific West in the present-day United States to explain its importance to tribal communities, its utility in advancing social and ecological well-being now and in the future, and key implications for research and management. Our review concentrates on the forested regions of Northern California and southern Oregon, which is a center stage for Indigenous burning, including being the place where the Indigenous Peoples Burning Network (http://www.conservationgateway.org/ConservationPractices/FireLandscapes/Pages/IPBN.aspx) was founded. However, we also reference studies from the wider region of Western North America that are associated with frequent fire regimes.

We considered a variety of sources, including previously published review articles and synthesis reports, publications derived from social science research including interviews and ethnographies, articles and theses that report findings from monitoring/observational studies, as well as recent reports produced by and for tribal entities that have a policy orientation (Sloan and Hostler, 2014; Goode *et al.*, 2018; Tribe, 2019; Clark *et al.*, 2021). Older academic publications often focus on historical practices and intentions described by cultural practitioners to non-Indigenous researchers (e.g., Stewart 2002), while more recent documents help to understand contemporary needs and constraints often as part of tribal collaborative efforts. Our approach complements a recent review of Indigenous fire management across the globe whose scope was

limited to articles published in peer-reviewed journals since 2000 to reflect contemporary knowledge (Nikolakis and Roberts, 2020). Older literature and tribal reports can highlight objectives that are pertinent to our region, but which may not be well-represented in recent peer-reviewed articles.

We begin by briefly summarizing debates over the past importance of Indigenous burning and the implications for addressing contemporary challenges. Next, we consider how an ecosystem services framework can help to identify important benefits of cultural burning, while also acknowledging how such classification could also misrepresent more holistic tribal perspectives. We then consider implications for management and research. Throughout the paper, we include figures that illustrate examples of contemporary Indigenous burning and their associated targets.

1.3. Evolving debates over the past influence of Indigenous burning

After modern land management institutions in the U.S. were established over a century ago, some land managers decried Indigenous burning, then derided by some as "Paiute forestry", as harmful to forests (Harley, 1918; Greeley, 2000). Early U.S. Government records include derogatory references to "old superstitious Indians" (Crouse, 1902), "renegades" (Harley, 1918), and the "hand of the incendiary" with "selfish and malicious motives" (Lake, 2007) (p. 273). Over the past century, academics have debated the importance of Indigenous burning versus climate on fire regimes. Whitlock and Knox (2002) provided a review for the Pacific Northwest that considered paleoecological evidence over thousands of years and historical accounts and which highlighted the extensive influences in the Willamette Valley of Oregon. Focusing on ethnoecology research in the same region, Boyd (1999) highlighted regional features associated with fire use, including huckleberry patches, ponderosa pine forests, oak woodlands, and prairies. Other scientists have contended that the influence of Indigenous burning in the Pacific

West was confined to localized areas around settlements (Vale, 2002). These claims have been challenged by researchers who have found evidence that changes in fire regimes coincide with interruption of Indigenous practices (Fry and Stephens, 2006; Skinner *et al.*, 2009; Taylor *et al.*, 2016; Metlen *et al.*, 2018). They have also been challenged by other researchers who have engaged directly with Indigenous communities to document their use of fire (Anderson, 2009; Lake, 2013; Anderson, 2018). Recent research using paleoecological reconstruction and landscape modeling found that Indigenous burning shaped the environment, including promoting oaks, over large areas around meadow sites in the southern Sierra Nevada (Klimaszewski-Patterson and Mensing, 2020).

Debates over the influence of Indigenous burning have occurred in other regions of North America, leading some scientists to note how conventional paleoecology approaches may fail to recognize the influence of Indigenous burning. For example, Oswald *et al.* (2020b) recently synthesized paleoecological research and historical documents and concluded that "Native people did not use fire to shape New England's landscape" (Oswald *et al.*, 2020a) and that fire was not an appropriate management tool in that region. That work generated several responses that explained why the effects of Indigenous burning may be difficult to resolve at landscape scales and why it is important to carefully consider such evidence and Indigenous knowledge (Abrams and Nowacki, 2020; Leonard *et al.*, 2020; Roos, 2020).

Recent studies in other regions, many of which have involved partnerships with Tribes, have also documented legacies of Indigenous burning. In a study in the Northern Great Plans that involved the Blackfeet Nation, Roos *et al.* (2018) concluded that small groups of Indigenous bison hunters were using fire in response to favorable climate conditions, thereby enhancing climate impacts in ways that might be difficult to distinguish from Indigenous burning. A study in the high plateaus

of Utah using archaeological data and modeling found that fire activity was more strongly correlated with ancient Indigenous farming-foraging systems than the climate factors that dominate more recent wildfire activity (Carter *et al.*, 2021). In the Jemez Mountains of the Southwest, a recent study by Roos *et al.* (2021), which involved several tribes in the region, documented the ecological influence of patchy Indigenous burning and wood collection around an ancestral Jemez community. This work added to research by Liebmann *et al.* (2016), who provided fine-grained evidence of the impacts of Spanish colonization on Native Jemez populations and the indirect changes on fire regimes and forest regeneration. These recent studies contrast with older ecological research in the Southwest that discounted Indigenous influence on fire regimes and instead emphasized the influence of lightning (Allen, 2002).

This evolving science demonstrates the importance of engaging with tribes to interpret records and understand implications of research. In many of the more recent publications that were informed by collaborations with Indigenous peoples, researchers have noted that methods need to be sensitive to the finer-scale, more subtle signatures of Indigenous burning (Lake, 2013; Roos *et al.*, 2019). We return to research issues later in this paper, while turning our focus to understanding how and why Indigenous burning can help confront present and future social and ecological challenges.

1.4. Definition and objectives of cultural burning

Cultural burning has been recently defined by Clark *et al.* (2021) as the "purposeful use of fire by a cultural group (e.g., family unit, Tribe, clan/moiety, society) for a variety of purposes and outcomes" (p. 3). Other terms such as Indigenous fire management (Nikolakis and Roberts, 2020), Indigenous burning, and Indigenous stewardship encompass cultural burning. Practitioners note that cultural burns are generally preceded by extensive site preparation and

148 followed by monitoring and additional cultural practices as part of a land stewardship tradition.
149 Agency-led prescribed burns may be informed by cultural practitioners to achieve cultural
150 objectives (Fig. 1). However, cultural burners contend that typical agency-led prescribed burns
151 tend to be more focused on reducing fuels and avoiding canopy mortality, while relying more on
152 climatological metrics, constructed fire lines, and suppression technology (Marks-Block and
153 Tripp, 2021).

154

Figure 1: A prescribed burn project led by a crew from Greenville Rancheria, with guidance from elders, to promote beargrass (*Xerophyllum tenax*) near Canyon Dam on the Plumas National Forest. Photo by Reina Rogers.

155 Scholars have previously catalogued the many objectives of cultural burning. Williams (1994)
156 condensed 70 different reasons for Indigenous burning documented by Lewis (1973) into 11
157 categories (Table 1). A recent review of international burning across temperate and tropical
158 biomes around the work identified 18 categories of objectives (Trauernicht et al., 2015) (Table
159 1). Recent reviews from chaparral ecosystems in California (Anderson and Rosenthal, 2015;
160 Anderson and Keeley, 2018) identify particular organisms that were targeted in Indigenous
161 burning, while then explaining how those practices support social engagement and ecosystem-
162 level functions.

163 *1.5. Present-day priorities*

164 Priorities for cultural burning have shifted in response to the present-day challenges facing tribal
165 communities. A recent article reported that tribes in British Columbia had goals of strengthening
166 cultural connection and well-being, restoring the health of the land, and respecting traditional
167 laws (Nikolakis *et al.*, 2020). Another recent review from British Columbia (Lewis *et al.*, 2018)
168 found that cultural burning continues to follow traditional rationales, but that debris control and
169 hazard abatement have become more predominant while foodstuff amelioration has become less
170 predominant. Recent reports in California directed toward policy change (Goode *et al.*, 2018;
171 Clark *et al.*, 2021) focus on present-day needs and intentions that emphasize social values
172 including the right to burn and cultural integrity, as well as material benefits and community
173 safety. Such forward-looking approaches are an expression of tribal adaptive capacity and self-
174 determination (Mauer, 2020).

2. Ecosystem services frameworks

2.1. Millenium Ecosystem Assessment framework and revisions

Ecosystem services are commonly defined as benefits that ecosystems provide to people, or more precisely as those *functions* of ecosystems that benefit humans (Kremen, 2005). Scholars have noted that humans have to make some investment (for example, harvest and processing) to convert the services into actual benefits (Willot *et al.*, 2019). The United Nations' Millennium Ecosystem Assessment (MEA) featured a function-based typology that included "provisioning", "regulating", and "cultural" services that directly affect people, as well as the "supporting services" that maintain the system (Patterson, 2014). Scholars have tried to update these frameworks to avoid problems such as double counting by not using a supporting services category (Willot *et al.*, 2019). Despite these issues, ES frameworks like the MEA are increasingly structuring agency land management planning, including revision of national forest plans in the U.S. (Armatas *et al.*, 2018), as well as international vulnerability assessments of forest and communities (Paudyal *et al.*, 2015; Long and Steel, 2020). Consequently, an ecosystem services framework may be useful in relating values important to tribes to these institutional processes. In Table 1, we crosswalk these categories to ones previously suggested in reviews of Indigenous burning with different spatial scopes, while acknowledging that objectives often relate to multiple kinds of services.

2.2. Services for ecosystems and other modifications to better reflect Indigenous worldviews

While applying an ecosystem services framework, we recognize that its utilitarian emphasis may conflict with worldviews commonly held by Indigenous people. Applications of the framework often emphasize services that are amenable to economic valuation (Binder *et al.*, 2017); however, for many cultural ecosystem services, quantification and monetization may be difficult or objectionable (Fish *et al.*, 2016). Indigenous communities often maintain more holistic,

reciprocity-based philosophies, which reflect a deontological, or duty-based, framework (Whyte, 2018). This philosophy of stewardship has been described as "reciprocal restoration" (Kimmerer, 2011), a "caretaker responsibility" (Deur, 2009), and "human services for ecosystems" (Lake, 2021). Members of Indigenous communities have emphasized both benefits and a sense of duty as motivations for cultural burning (Deur and Turner, 2005; Strass, 2010). Many Indigenous practitioners view cultural burning as fulfilling their stewardship responsibilities to the land, while suggesting that such practices will in turn benefit the people who depend on those ecosystems (Kimmerer and Lake, 2001). Therefore, frameworks that emphasize measurable goods and ends may reinforce consumerism and fail to appreciate the importance of maintaining proper ways of living and the well-being of whole systems to Indigenous peoples.

Researchers have proposed alternative frameworks for examining cultural services, especially to better integrate Indigenous perspectives (Fish *et al.*, 2016; Mucioki *et al.*, in press). The MEA and other frameworks apply the term "cultural ecosystem services" only to *non-material* benefits, including aesthetic, spiritual and existence values, in contrast with more tangible services (Fish *et al.*, 2016). However, associating cultural services only with intangible benefits is awkward because material provisions are so critical to maintaining Indigenous cultures. In response, Fish *et al.* (2016) (p. 212) instead defined cultural services as "contributions ecosystems make to human well-being in terms of the identities they help frame, the experiences they help enable and the capabilities they help equip."

2.3. Non-material cultural services

Non-material cultural services are one of the least studied dimensions of Indigenous fire stewardship, but they are particularly important in explaining why Indigenous people assert the need to conduct burning themselves. We discuss several examples of non-material cultural

222 services, while noting that these benefits intersect synergistically with each other and with the
223 physical effects that also support tribal cultures.

224 *2.3.1. Maintenance of lifeways*

225 After living in fire-prone landscapes for millennia, many tribes across the Pacific West have
226 become culturally dependent on fires to obtain benefits from their ecosystems. They developed
227 practices to modify fire regimes that responded to climate and other environmental factors
228 (Anderson, 2005; Eriksen and Hankins, 2014; Lake, 2021). These relationships vary across and
229 among tribes and at different levels of organization, including individuals, families, clans/groups,
230 and villages/towns. Differences among practices are associated with gender, specialized trades
231 (e.g., basketweaver, hunter, food gatherer, regalia maker), and cultural roles (e.g. ceremonial
232 leader, defender of sacred areas) (Lake, 2021). Some uses of fire reported from historical
233 literature (e.g. smoke signaling, felling trees, driving game, economic warfare) have been
234 displaced by adoption of alternative technologies and other social changes. As discussed further
235 under provisioning services, to yield good returns on their investments of labor, Indigenous
236 practitioners target areas that are accessible and expected to be productive (Long *et al.*, 2016).
237 Burning remains important for clearing areas and enhancing resource quality in ways that make
238 it sufficiently worthwhile to invest time in tending and harvest (Anderson, 2018; Long and Lake,
239 2018). Accounts from more than a century ago noted the lack of fire and effects of non-
240 Indigenous forest practices were reducing opportunities for traditional harvest (Editor, 1916;
241 Thompson, 1916).

242 *2.3.2. Transmission of knowledge*

243 Indigenous knowledge is derived from observations of the environment, ecological processes and
244 species life histories and interactions; it is also taught continually as members engage in ritual,

subsistence, and other domestic activities that provide opportunities for intergenerational exchange (Huffman, 2013). When environmental conditions deteriorate in ways that no longer support traditional lifeways, the associated knowledge and social structures are likely to erode (Willette *et al.*, 2016; Norgaard *et al.*, 2017; Long and Lake, 2018). Cultural burns are a mechanism for reversing this erosion, as they draw in members from many tribal communities who share their knowledge of using fire and tending resources while reaffirming shared obligations. Such burns are conducted to create more open and safer areas that facilitate access by elders and youth (Anderson and Rosenthal, 2015). Burning and associated stewardship practices maintain culturally important traditions including intergenerational learning and place-making (LeCompte-Mastenbrook, 2016; Norgaard, 2019).

2.3.3. Ceremonies and spiritual well-being

Cultural use of fire is important for sustaining Indigenous spiritual values, including fulfilling obligations in Tribal belief systems and practices (Eriksen and Hankins, 2014). For example, among the Southern Paiute, "oral history states that the Creator charged them with balancing the land, which is sentient and considered a close relative, at different points in time", and fire is one of the tools they are expected to use to maintain that balance (Spoon et al., 2015). Cultural burns are featured in ceremonies (Kimmerer and Lake, 2001), and they are typically conducted with offerings of ceremonial plants like tobacco (*Nicotiana* spp.), wild celery (*Lomatium* spp.) and sage (*Salvia* spp. and *Artemisia* spp.) and sharing of songs. Many Indigenous practitioners consider fire to be "medicine" for both humans and the land, and traditional medicine persons have a key role in using fire (Norgaard, 2019; Wynecoop *et al.*, 2019; Lake, 2021). Some individuals received special training and acquired knowledge of fire, winds, and responses of dead and living plants to fire. Stewart (2002) described such a chosen individual among the

Karuk Tribe as a "formulist": "When setting a fire, the fire setter said formula (made incantations?) for a big fire, yet one which would do no harm…. Then the formulist blows in all four directions to keep the fire from spreading. The formulist is a fire setter who knows the proper medicine" (p. 277). Today such individuals become recognized as cultural burning specialists and serve in roles comparable to a "burn boss" in agency-led prescribed burns.

Areas that have been used to manage wildfires are often located in places of ceremonial and spiritual importance. For example, fire lookout towers were placed upon sacred peaks, which are often used for making medicines and are associated with weather and fires (Norgaard, 2019), and culturally important plants and sites are located along trails and ridges that have been co-opted for agency wildfire management, chiefly suppression (Fig. 2). These places are culturally significant for many reasons, including having long been sites for gathering ceremonial and medicinal plants and instructing youth in the use of fire, as explained by Karuk Tribal member Charlie Thom: "When they [US Forest Service] first come to this country, they start putting lookouts all over…[Mountain peaks named]…I can't make Indian Doctors without [named Mountain peak]…that we go up there, [via] Indian trail, not other trail, but Indians" (Karuk Tribe and Cultural Solutions, 1999a) (p. 13). Failure to recognize the cultural significance of locations being used for wildfire control could reinforce negative impacts to tribal cultures.

Figure 2: Historical tribal trail (upper right) along a ridge, which was maintained using bulldozers as a fire line within the Red-Salmon Complex, August 2020, Klamath National Forest, near Forks of Salmon, California, USA. Photo by Frank Lake, USDA Forest Service.

2.3.4. Sense of place especially at gathering sites

Indigenous tending and gathering often occurs in places that have enduring organisms and cultural associations. Low-intensity fire regimes help ensure the survival of many legacy, "specimen", or "elder" trees that maintain a sense of place and community well-being (Figs. 3, 4, and 5). For many tribes in the Sierra Nevada and Klamath mountains, sugar pine (*Pinus lambertiana)* groves were managed as tribal family-owned resource sites: "the places where the sugar pines grow are owned by individuals. When it is time to gather the cones, each owner invites his family and friends to come with him, and then, when the cones are gathered, they are divided equally among the relatives and guests" (Schenck and Gifford, 1952)*(p. 378)*. Many open old-growth hardwood forests and woodlands support rare wildlife and distinctive architectures, including broad crowns and low branches (Fig. 4) (Long *et al.*, 2016). Fire suppression has aided conifer encroachment in these areas, resulting in development of narrow-

301 crowned trees with high branches that are less conducive for harvesting nuts (Fig. 5). These
302 examples illustrate the difficulty in segregating cultural services from provisioning services.

303

304 Figure 3: An elder sugar pine (*Pinus lambertiana*) provides special cultural values including sense of
305 place in addition to producing edible seeds. Photo by Frank Lake, USDA Forest Service.

Figure 4: This elder canyon live oak tree (*Quercus chrysolepis*) has a distinctive, low-branching architecture growing within an area of Indigenous use that likely moderated fire regimes and facilitated its endurance. Photo by Michael Hentz, Mid Klamath Watershed Council.

Figure 5: An elder tanoak (*Notholithocarpus densiflorus*) tree at a cultural heritage site in the Western Klamath Restoration Project area, where lack of fire and stand densification have accumulated surface fuels and resulted in a loss of lower tree limbs, both of which limit opportunities for gathering. Photo by Kenny Sauve, Karuk Tribe.

2.4. Material cultural-provisioning services

2.4.1. Plants and fungi used for foods, medicines, and materials

Provision of material benefits, often summarized as foods, medicines, and fibers, remain central objectives of Indigenous burning. Several species of hardwood trees, including tanoak, California black oak (*Quercus kelloggii)*, and giant chinquapin (*Chrysolepis chrysophylla*) and some conifers such as sugar pine are associated with low-moderate fire regimes and yield staple foods for tribes throughout the region (Bowcutt, 2013; Long et al., 2018a). Many tribes rely upon cultural burning to stimulate production of berry-producing shrubs, including huckle-blue-bilberries (*Vaccinium* spp.); geophytes, also known as “root crops” or “Indian potatoes” that

propagate from underground storage organs that are edible; and many seed-producing forbs and grasses (Anderson, 1997; Anderson and Rowney, 1999). Many foods, such as roots and berries, are also regarded as medicines (Lynn *et al.*, 2013) and have prominent roles in ceremonies and celebrations of the annual return of "first foods" (Long *et al.*, 2018b). Mushrooms are another tribal resource that may be promoted by cultural burning (Anderson and Lake, 2013). Some fungi including morels and cap mushrooms commonly produce fruiting bodies following disturbances that include fire, although only a few species appear to depend more exclusively on fire (Pilz *et al.*, 2004; Larson *et al.*, 2016). Declines in many of these species have been attributed to fire exclusion, lack of tribal cultivation, and associated growth of competing vegetation (Anderson and Rowney, 1999).

Tribes have long utilized wood for a variety of purposes, including fuel for heating and material for construction. Large trees, especially redwood (*Sequoia sempervirens*), have long been important for constructing structures, furnishings, and canoes (Thompson, 1916; Huntsinger *et al.*, 1994). Frequent, low-intensity Indigenous burning may have promoted development and retention of old-growth redwood (Stephens and Fry, 2005) and therefore, promoted the supply of large logs needed to support tribal traditions. Access to such logs has made traditional canoes available for ceremonies and jumpstarted economic enterprises such as the Yurok Tribe's recently established redwood canoe tours.

Many plants utilized for weaving materials have traditionally been cultivated through burning and associated horticultural practices (Anderson, 1999, 2005; Lake and Long, 2014). Several kinds of plants have been the subjects of recent collaborative research on burning, including beargrass (*Xerophyllum tenax*) (Shebitz *et al.*, 2009b; Hummel *et al.*, 2012; Hart-Fredeluces *et al.*, 2021), sandbar willow (*Salix exigua*) (Lake, 2007; Ross *et al.*, 2008), and hazel (Marks-

347 Block *et al.*, 2019). Thompson (1916) described how Yurok people "take the greatest care of the
348 hazel nut flats" (p. 29) using fire to stimulate nut production and the vast quantities of young
349 shoots needed for baskets.

350 *2.4.2. Harvest of animals*

351 Cultural burning has long been used to facilitate harvest of wild animals, including large and
352 small animals used for meat, tools, regalia, and other material uses (Long and Lake, 2018).
353 While diets in many communities have shown a reduction in the harvest of wild game (Kuhnlein
354 and Receveur, 1996; Norgaard, 2005), burning to promote game animals remains an objective in
355 tribal plans (Karuk Tribe, 2019). Burns were used both to facilitate hunting and to encourage
356 important forage plants, including bracken fern (*Pteridium aquilinum*) relished by deer in
357 prairies of the Olympic peninsula (Norton, 1979). Burning has also been important for harvest of
358 small animals such as insects; for example, Anderson (1996) noted accounts of burning to
359 harvest grasshoppers. A recent collaborative investigation with Northern Paiute Tribes indicated
360 that bark charring encouraged egg deposition of the pandora moth (*Coloradia pandora*), the
361 larvae of which remain a desired traditional food resource (Slaton *et al.*, 2019). Burning was also
362 important in maintaining accessibility for fishing, "Fishing in small streams possible formerly;
363 now completely choked out by brush" (Stewart, 2002) (p. 282).

364 *2.4.3. Multiple dimensions of material productivity*

365 While material uses are considered more straightforward to observe and quantify than other
366 services, measuring provisioning services associated with cultural burning can be very complex.
367 Many products, including traditional foods, medicines, and regalia, may be passed down, traded
368 or gifted rather than sold in markets; often, only finished products such as baskets are priced
369 rather than the component materials harvested from the forest (Marks-Block *et al.*, 2019).

370 Furthermore, wild-harvested products are valued based upon multi-dimensional, non-
371 standardized qualities that resist simple evaluation based upon quantity. For example, several
372 studies have tried to quantify the criteria used by Indigenous basketweavers, who prize the long,
373 pliable and defect-free shoots or leaves that grow after burns (Lake, 2007; Hummel *et al.*, 2015;
374 Marks-Block *et al.*, 2019). While fruit size is not a common measurement in ecological studies,
375 some practitioners suggest that burning could enhance the size of berries. For example, a cultural
376 facilitator, Wally Morgan (Gitxsan) said, "this place was recently burned, that's why the berries
377 are so juicy and the size of marbles" (Armstrong and Anderson, 2020). In a field study,
378 Wynecoop et al. (2019) reported observing large huckleberries in burned plots. These examples
379 illustrate why commonly measured metrics, such as plant canopy cover and frequency, may not
380 capture the many benefits of cultural burning.

381 *2.4.4. Non-substitutable effects of fire on provisional services*

382 While many of the species mentioned previously can also be promoted by non-fire disturbances,
383 fire is considered both an efficient tool and one that is not well-substituted. For example, smoke
384 can enhance germination of plants such as tobacco and beargrass (Preston and Baldwin, 1999;
385 Shebitz *et al.*, 2009a). Tobacco is a featured product of cultural burning in both historical
386 literature and contemporary projects (Harrington, 1932; Boyd, 1999; Baldy, 2013; Tushingham
387 *et al.*, 2013; Aldern and Goode, 2014). In the Klamath region, tobacco has been sowed into burns
388 by individual cultivators, as described by Lucy Thompson over a century ago (1916). As
389 discussed further below, burning also has distinctive effects in regulating insect pests that reduce
390 quality of forest foods and materials.

2.4.5. Managing fire frequency to enhance provisioning services

Indigenous practitioners have long managed the intensity, frequency, and spatial arrangement of fires to promote provisioning services. Indigenous peoples in the region have long considered how fire severity influences mushroom production and the relationships between fungi and host shrubs and trees of cultural importance (Anderson and Lake, 2013). Native Americans in southwest Oregon sometimes burned hazel shrubs at low intensity to "scorch" and "roast" the nuts on the bush as they were harvested (Pullen, 1996). Many roots crops and basketry plants, including those mentioned above and deergrass (*Muhlenbergia rigens*), were burned frequently (1 to 15 years, but often less than 5 years) to cultivate desired forms and to maintain their abundance in openings (Anderson, 1996). Recent burning is critical for maintaining the supply for weavers (Anderson, 1996). As one elder explained, "you find out the places that burned the year before, because that means next year there will be many good materials waiting for you" (Baldy, 2013). Similarly, groves of nut trees were also burned regularly to clear debris and make it easier to collect and separate good acorns from infertile or infested ones (Lake, 2019). Sierra mountain misery (*Chamaebatia foliolosa*) forms dense foliage that impedes acorn harvest (Anderson, 2005), and experimental research has shown the burning can temporarily reduce its abundance (Kauffman and Martin, 1985). Frequent burning to foster open understory forest conditions and grasslands facilitates the gathering of roots and bulbs (Anderson, 2005; Anderson and Lake, 2016). In a study of multiple prescribed burns in Washington State (Orr, 2014), camas (*Camassia quamash*), an important root crop, was more abundant in recently burned areas while strawberry (*Fragaria virginiana*) was more abundant in less recent burns. In response to such complex temporal dynamics, practitioners vary the timing of burns in forests and account for overstory tree cover to promote desired products. Hazel (*Corylus cornuta var. californica*) yields high quality basketry materials after recent burns under closed canopy conditions (Marks-Block

et al., 2019), but hazel nut production requires more exposure to sun and longer time between fires. In addition to the frequency of burning, the seasonality of burning controls the quantity and quality of hazel shoots for weaving (Marks-Block *et al.*, 2021).

2.5. Regulating and supporting services

We combine both regulatory and supporting services since they are difficult to distinguish and they involve ecological processes such pollination, hydrology, and soil development. While anthropologists have long documented how tribes burned to promote species that afforded material and cultural benefits, the effects of cultural burning on ecosystem functions are not as well documented. One reason is that these broad-scale climate factors are likely to overwhelm the effects of small-scale cultural burns. Reflecting this challenge, the review by Anderson (2018) begins by detailing how Indigenous people have used fire to promote individual species, but ends by considering the likely effects of burning on biodiversity, water, and fire regimes at a landscape scale. Some of these effects on ecological processes have also been suggested by field experiments and/or modeling of prescribed burns and wildfires as proxies for cultural burns.

2.5.1. Species biodiversity

Indigenous practitioners emphasize the importance of supporting the wide variety of species (including plants, animals, and fungi, and often described as "relations") that are connected through complex food webs and interconnected life cycles (Anderson and Lake, 2013; Long *et al.*, 2016). Consistent with that perspective, Bowman and Legge (2016) asserted that restoration of degraded ecosystems needs to focus on the influence of fire management on food webs and biodiversity. Such expansive views contrast with management systems that focus heavily on conserving or mitigating impacts to rare and threatened species (Long *et al.*, 2020).

Burning can enhance localized diversity, especially compared to areas that have been encroached by trees due to fire suppression. For example, Livingston *et al.* (2016) reported more understory species in sites within oak woodlands that had been treated with fire than in encroached sites. Studies of fall cultural burns in chaparral and oak woodlands reported greater abundance and diversity of herpetofauna and small mammals (Hankins, 2009; Hankins, 2013). Another study in blue oak (*Quercus douglasii*) woodland found an increase in native plant species cover, but not in an isolated valley oak (*Quercus lobata*) woodland surrounded by agricultural fields (Hankins, 2015).

Cultural burning practices may target relatively common resources to enhance their quality rather than to simply make them more abundant. They may focus on single species that dominate patches, including sedge *(Carex* spp.) beds, oatgrass (*Danthonia* spp.) meadows, and sandbar willow thickets (Fig. 6). Frequent burning may favor certain plant groups that have fire resistant and resilient traits, such as annual forbs, open bunchgrasses, and rhizomatous and resprouting perennials (Kerns and Day, 2018). Maintenance of fire regimes can also help some vegetation communities to resist invasion by non-native species, including Scotch broom (*Cytisus scoparius*), that can displace native plants (Hamman *et al.*, 2011).

Figure 6: A US Forest Service burner and Yurok tribal member (right), uses a propane torch to burn at sandbar willow at Tishunick, a Karuk village near Orleans, CA, with guidance from a Karuk/Yurok cultural adviser, Laverne Glaze. Photo by Frank Lake, USDA Forest Service.

2.5.2. Ecosystem biodiversity

Cultural burning may augment the diversity of communities within a landscape (Anderson, 2018), particularly at a finer grain than occurs under wildfires (Bowman and Legge, 2016). Recent field studies of wildfires are finding evidence that a diversity of fire characteristics, or "pyrodiversity" supports plant and pollinator diversity by sustaining a wide variety of successional communities and associated nesting habitats (Ponisio *et al.*, 2016). However, field studies of wildfires with varying severities may not account for the diversity associated with frequent, predominantly low-severity cultural burning. In the Pacific Northwest, cultural burning over time can enhance landscape diversity by maintaining rare species associated with open habitats such as prairies (Fig. 7), including western lily (*Lilium occidentale*) (Long *et al.*, 2018b), Howell's triteleia (*Triteleia howellii*) (Douglas and Penny, 2004) and certain butterflies

(Hamman *et al.*, 2011). Frequent fires are important for curbing the encroachment of conifers (Engber *et al.*, 2011) and shrubs into open, herbaceous-dominated or savanna communities. For example, one historical account described such conditions within an area in modern day Mendocino County in northern California (which was recently burned in the enormous August Complex of 2020) "Lassik burned a hell-of-a-lot. [Tribal] Informant said country was kept burned off completely—almost a prairie…. Did not harm oak trees. Kept brush from getting too thick or higher…Indians complain about modern [Government fire] restrictions." (Stewart, 2002) (p. 282). In the Yurok country, Thompson (1916) observed that "our Legends tell when they arrived in Klamath River country, that there were thousands of acres of prairie lands and with all the burning they could do the country has been growing up to timber more and more." (p. 31). Skinner (1995) also attributed the loss of forest openings in the Klamath mountains to fire exclusion, while Lake (2007, 2013) described the landscape as the product of tribally-mediated cultural fire regimes. Tribes today have highlighted the impacts of losing these open grasslands and associated biodiversity (Anderson, 2009; Sloan and Hostler, 2014; Karuk Tribe, 2019). Some initiatives, such as the prescribed burning program in Redwood National Park, reflect these concerns, with research suggesting that the savanna areas of the Little Bald Hills are the legacy of fire stewardship by the Tolowa people (Varner *et al.*, 2012).

Figure 7: Prescribed burn conducted by the Confederated Tribes of Grande Ronde at Champoeg Prairie to curb invasive plants and facilitate future harvest of camas, yampa, tarweed, and other culturally important plants. Photo by Andy Neill, Institute for Applied Ecology.

2.5.3. Pollination

Indigenous traditional knowledge and teachings often relate the interconnectedness between host plants, pollinators, and tribal uses (Charnley and Hummel, 2011; Hill *et al.*, 2019; Underwood, 2020). Many pollinators, including hummingbirds, bees, and butterflies, depend upon resources found in recent fires, including plant flowers, exposed mineral soil patches, and dead wood that serves as nesting burrows. Fire diversity in forests managed with intentional fire can buffer pollinator communities against the scarcity of floral resources during droughts (Ponisio *et al.*, 2016). Declines in several rare butterfly species have been linked to the combination of long-

497 term declines in fire, loss of prairie habitat, and reductions in Indigenous stewardship such as
498 tending of camas, which is an important nectar source (Schultz *et al.*, 2011). The California
499 tortoiseshell butterfly (*Nymphalis californica*) and ceanothus silk moth (*Hyalophora euryalus*)
500 are examples of two culturally important pollinator species that may benefit from cultural
501 burning of shrub areas (Anderson and Keeley, 2018). Some of the field studies of prescribed
502 burns in butterfly habitat have revealed challenges in minimizing potential short-term negative
503 impacts of prescribed burns while restoring the benefits of fire-maintained habitats (Trudeau,
504 1996; Schultz *et al.*, 2011). Such findings point to the value of understanding how to use fires of
505 different intensities and scales to promote multiple objectives.

506 *2.5.4. Regulating pests and diseases*

507 Indigenous people have long used fires to reduce the incidence of pests that degrade nut foods,
508 basketry materials, and berry-producing shrubs (Anderson, 2005; Anderson and Rosenthal,
509 2015). This objective is prominent in early discussion of Indigenous burning in the region
510 (Editor, 1916; Harley, 1918). These pests include filbertweevils (*Curculio* spp.) and filbertworms
511 (*Cydia latiferreana*) in acorns, hazel, chinquapin, and other nuts (Anderson, 2005; Bowcutt,
512 2013; Halpern, 2016). Recent research has illustrated how burning can modulate insect levels in
513 contemporary tanoak groves (Halpern, 2016). Indigenous burners have also asserted that burning
514 can reduce mistletoe (*Phoradendron* spp.) infestations through smoke fumigation (Anderson,
515 2018), and some studies have shown such effects on dwarf mistletoe (*Arceuthobium* ssp.) in
516 pines (Zimmerman and Laven, 1987; Harrington and Hawksworth, 1990). Research has also
517 indicated that burning sandbar willow can reduce insects that render stems unsuitable for
518 weaving (Lake, 2007). Although most of these examples refer to harvested species, pest control
519 was related to general forest health. For example, one individual reported in 1933 that the

520 "smoke kept the bugs down and kept the country healthy" (Stewart, 2002) (p. 283). In a more
521 recent example, Earl Scrub Albury (a Karuk elder) explained that when fir trees were weeping
522 pitch, that indicated a need to burn to rejuvenate the area (Lake, 2007). The introduced Sudden
523 Oak Death pathogen (*Phytophthora ramorum*) has impacted fire-prone coastal forests, including
524 many hardwoods of special cultural importance to tribes. Recent research has suggested that
525 intense wildfires can reduce the incidence of that introduced disease, but with costs to healthy
526 forests and other values (He *et al.*, 2021). Researchers have begun to investigate how tribal
527 stewardship practices including prescribed burning and silviculture to promote large hardwoods
528 may reduce spread of the disease and resulting tanoak mortality (Cobb *et al.*, 2017).

529 *2.5.5. Soil health*

530 Similar to other Indigenous cultures around the world, the relationships among fires, soils,
531 plants, and fungi are recognized by tribes of the Pacific West region (Sillitoe, 1998). The
532 combination of burning with other horticultural practices can increase organic matter, promote
533 soil fertility and aeration, facilitate nutrient cycling, maintain mycorrhizae networks, and
534 generate biochar (a product of incomplete combustion of coarse woody material) (Norton, 1979;
535 Anderson and Rowney, 1999; Anderson and Lake, 2013; Anderson and Lake, 2016). Burning
536 can stimulate growth of various species that support nitrogen-fixation including deerbrush
537 (*Ceanothus* spp.) and lupines (*Lupinus* spp.) (Story, 1974; Anderson and Keeley, 2018). Such
538 plants are often important food sources for rare butterflies (Trudeau, 1996; Goergen and
539 Chambers, 2009; Schultz *et al.*, 2011). Biochar can enhance soil quality in ways that promote
540 plant growth (Lehmann *et al.*, 2006) and consumption of biochar by animals can improve their
541 health (Schmidt *et al.*, 2019). Authors Ron Goode and Frank Lake note that Indigenous

practitioners incorporate charred material into the soil to enhance plant growth and have long observed that animals also use it to rid themselves of parasites.

2.5.6. Enhanced hydrology

Cultural burning has been practiced to reduce vegetation density and increase water availability. Tribes have recognized that burning can increase water levels in springs and meadows that favor many culturally important plants (Anderson and Rosenthal, 2015). Historical research documented an example of this intention on the Trinity River, "He [Indian informant circa 1933] told me that they [Indians] were sure that the burning made the springs run better" (Stewart, 2002) (p. 283). Such hydrologic effects of prescribed burning received attention by pioneering fire researcher Harold Biswell (1999). Research has documented increased water flows in a forested montane watershed that has been managed with extensive use of wildland fire (Boisramé *et al.*, 2019). Furthermore, Indigenous burners indicated that smoke would benefit salmon and other fish by reducing summer water temperatures (Karuk Tribe, 2019). A recent study reported that wildfire smoke had such beneficial effects in the Klamath River valley (David *et al.*, 2018).

2.5.7. Wildfire regulation

A recent global review found that intentional burning to protect resources by preventing high-intensity, destructive fires was common in both ethnographic studies (49%) and all studies (36%) in their analysis (Trauernicht et al., 2015). Within the past century in the Pacific West region, tribal members reported setting fires to inhibit spread of wildfires. For example, Johnny Bennett (Karuk, Forks of Salmon, 1977) said "when the lightning hit they [old Indians] never put it out, push them [fires] back, [Indians] make a fire line, let them go back up the mountain. Take sticks out there, burn up against it" (Karuk Tribe and Cultural Solutions, 1999b) (p. 25). Indigenous

565 burning was conducted to maintain open conditions around villages, harvesting sites, and
566 processing sites, and other favored areas, and to facilitate travel along ridges, riparian areas, and
567 trails between those locations (Boyd, 1999; Lake *et al.*, 2018; Lake and Christianson, 2019) (Fig.
568 2). In the western Sierra Nevada foothills, such dispersed but spatially extensive burning by
569 different tribal communities cultivated a mosaic of fuel conditions that would curtail large
570 wildfires (Anderson and Rosenthal, 2015; Spoon *et al.*, 2015; Anderson and Keeley, 2018),
571 Furthermore, intensive fuelwood gathering, plant pruning and cleaning of areas used for
572 gathering acorn and other resources would have reduced fuel amounts and continuity.

573 Researchers have used modeling and understanding of these spatial patterns to demonstrate that
574 Indigenous burning was a major influence on fire regimes in areas such as the southern Sierra
575 Nevada (Klimaszewski-Patterson *et al.*, 2018). Fire ecology modeling has suggested that
576 reducing fuels within relatively small portions of a landscape, such as 10-20% of a landscape per
577 decade, can greatly moderate extreme fire outcomes in parts of our region (Finney *et al.*, 2007;
578 Collins *et al.*, 2013). Finney *et al.* (2007) suggested that those effects would be achieved with
579 some areas repeatedly treated and others left untreated, that patch size was generally not a key
580 driver of outcomes, and that strategic placement would result in greater benefits. Analysis of
581 historical photography had indicated that high heterogeneity, including areas of very open forests
582 and low fuel continuity, promoted landscape resilience to severe fire (Lydersen and Collins,
583 2018). These findings suggest how widespread application of cultural burning would be
584 consistent with wildfire mitigation efforts.

585 Many tribal resources including homes and infrastructure; ancestral villages, camps, petroglyphs,
586 and sacred sites; and populations of plants used for a range of traditional purposes can be
587 damaged by high-severity fire through both direct consumption and impacts from high heating

588 (Ryan *et al.*, 2012). However, high-severity burn patches were also essential to promoting tribal
589 values, as they often become dominated by shrubs such as hazel, manzanita (*Arctostaphylos*
590 spp.), deerbrush (*Ceanothus* spp.), and gooseberry (*Ribes* spp.) that provide food for wildlife and
591 Indigenous people (Anderson, 2018).

592 Tribal practitioners emphasize that their treatments are not intended to stop fires with stark fuel
593 breaks, but rather to facilitate control of fires and to moderate their intensity and severity.
594 Treatments along ridgelines and in wildlife-urban interface areas have been designed to temper
595 fires while supporting other values, including production of acorns (Harling and Tripp, 2014).
596 This approach is relevant to the wildland fire management strategies of developing Potentially
597 Operational Delineation Units (PODs), which are bounded by linear control features, such as
598 trails (Fig. 8), within which fires can be managed (Wei *et al.*, 2019).

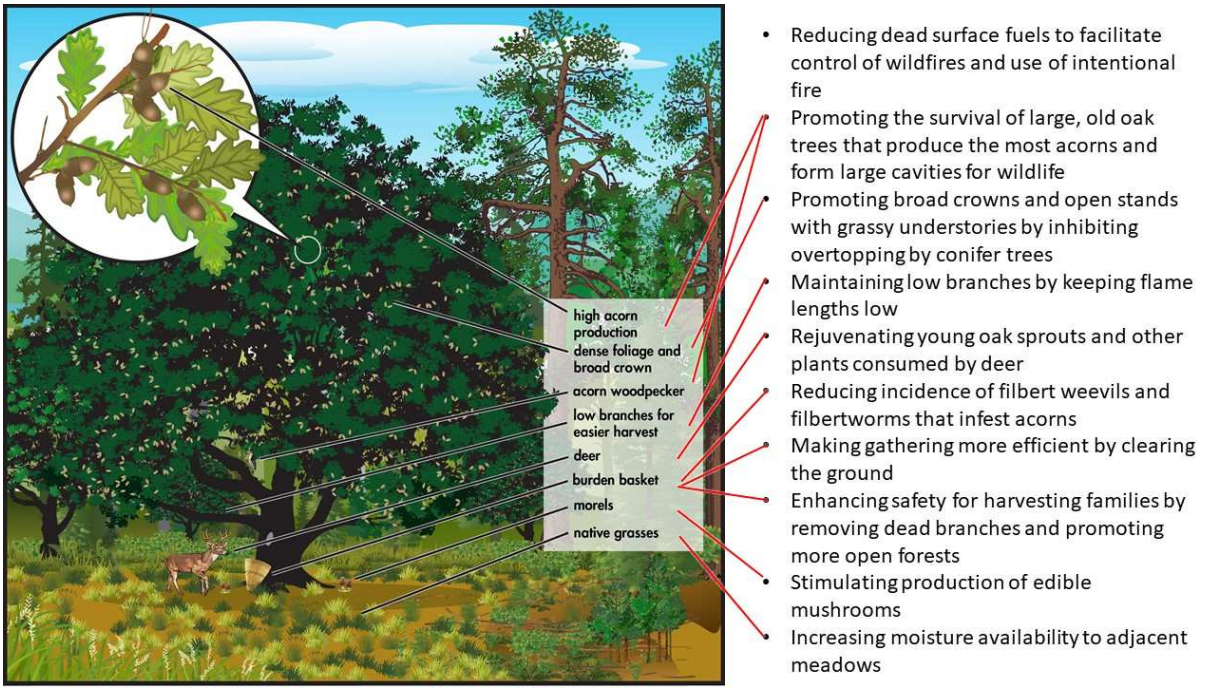
3. Implications for management and research



3.1. Recognizing the many ecological and social benefits of cultural burning

Indigenous communities have repeatedly championed the importance of burning as a means of restoring ecosystems and revitalizing their cultures (Anderson, 2009; Sloan and Hostler, 2014; Goode *et al.*, 2018; Karuk Tribe, 2019; Clark *et al.*, 2021). A goal of restoring reference fire regimes, including Indigenous influence, is guiding prescribed burning programs (Thornburgh *et al.*, 2000) and remains a topic of great importance for research (Varner and Jules, 2017). The

610 ecosystem services framework may help to highlight the many positive aspects of fire in ways
611 that can advance burgeoning forest restoration initiatives. Practitioners contrast their holistic
612 approach with strategies that focus on reducing fuels and wildfire impacts. Cultural burning is
613 intended to reduce fuels and rejuvenate and reconfigure shrubs and other understory plants, but
614 not to eliminate them. Indigenous practitioners acknowledge both the benefits and risks
615 associated with vegetation. Despite the salience of cultural burning to tribal communities and to
616 broader restoration outcomes, recent strategy documents paid little attention to the subject. For
617 example, the National Cohesive Wildland Fire Management Strategy does not specifically
618 address tribal interests in using fire (Wildland Fire Leadership Council, 2014). Related academic
619 works proposing strategies to promote more resilient socioecological systems (Abrams *et al.*,
620 2015; Schoennagel *et al.*, 2017) similarly do not discuss Indigenous fire stewardship. These
621 omissions may in part reflect an ingrained emphasis on combating the negative, destructive
622 aspects of wildfires, in contrast to more holistic tribal frameworks.

623 *3.1.1. Holistic understanding of overlapping benefits for social-ecological well-being*
624 Indigenous burners use fire with multiple, overlapping benefits in mind (Anderson and Keeley,
625 2018). For example, burning hazel underneath a canopy of hardwood trees may reduce nuisance
626 diseases and pests, generate stems used for basketry or tools, stimulate flowering for pollinators,
627 enhance nut quality and abundance, enhance browse and forage for game animals, increase
628 hunting efficiency, and reduce risks of severe fire (Marks-Block *et al.*, 2019). Tribal practitioners
629 tune the tending and burning regimes to promote a desired mix of benefits. For example, the
630 Karuk Tribe has prioritized treatments to reduce fuels and threats of wildfire in community areas,
631 while promoting hazel sticks and retaining mature yew and dogwood (Diver, 2016; Karuk Tribe,
632 2019). Within California black oak groves, cultural burning similarly has a multiplicity of effects

633 that promote conditions that support tribal harvest and many other ecosystem services (Fig. 9)
634 (Long *et al.*, 2016). Species like Pacific fisher (*Pekania pennanti*), California condor
635 (*Gymnogyps californianus*), and pileated woodpecker (*Dryocopus pileatus*) are valued in terms
636 of material uses of their fur or feathers, their supporting roles (e.g., predation, cavity excavation),
637 and their roles in stories and ceremonies (Jordan, 2015; Long and Lake, 2018; Karuk Tribe,
638 2019). These multiple benefits cross ecosystem service categories and make it more challenging
639 to evaluate the cumulative benefits of treatments because they involve many effects at different
640 scales. Furthermore, categorizing services may obscure the conjoined nature of socio-ecological
641 values. Previous scholars have noted that culture, ecology and place are inextricably woven
642 together (Berkes, 2012), which complicates efforts to understand changes in community systems
643 (Tremblay *et al.*, 2020).

644

645 Figure 9: Relationships between various objectives of cultural burning and conditions desired by tribes
646 for black oak ecosystems.

In the Klamath region, community-based research has revealed how suppression of cultural burning and other Indigenous stewardship practices led to declines in diet and social well-being (Norgaard, 2019). Understanding how to use fire to restore culturally important resources helps young people to understand both the ecology of their homelands, and their own place within their communities (Norgaard *et al.*, 2017; Norgaard, 2019). Such approaches could shift Indigenous practitioners from being considered "outlaws" or malicious arsonists and turn them into "valued food service employees" (Sowerwine *et al.*, 2019). Such reframing moves the discussion about the need for cultural burning beyond narrow evaluations of ecological conditions and into a broader examination of socio-ecological well-being.

Indigenous peoples also burn to stimulate growth of various plants with medicinal values, although research on this topic is likely to be limited by concerns over protecting sensitive information regarding their use and location. An example of a medicinal plant appearing following a recent early spring cultural burn is Pacific sanicle (*Sanicula crassicaulis*) (Fig. 10). Researchers have reported on its historical use to treat snakebite (Barrett and Gifford, 1933), its use as food by Indigenous people (Anderson and Keeley, 2018), and its value for bees (Wray and Elle, 2017). The plant's ability to store energy in its taproot, intolerance of shade, and association with oak savannas are all traits that explain why it would respond favorably to cultural burning. Indeed, conservationists have identified a decline in Indigenous stewardship as one of the threats to a rare relative in Canada, snakeroot sanicle (*Sanicula arctopoides*) (Zevit and Fairbarns, 2010). Therefore, this plant represents just one of many opportunities to better appreciate the multifaceted effects of cultural burning.

3.1.2. Promoting diverse fire mosaics

Indigenous practitioners seek to cultivate a diversity of conditions within a patchy arrangement to ensure that surrounding lands maintain sustainable supplies for current and future needs. These arrangements consider ecological variation across large landscapes; for example, in the Klamath region, tribes cultivated huckleberries, bilberries, tanoaks, and black oaks in lower and mid-elevation forests, while relying on blueberries and acorns in more intermixed shrub-dominated patches following higher severity fire at higher elevations (Pullen, 1996). When staggered across watersheds, elevation ranges, and time, treatments promote food production,

679 facilitate harvest, and enhance food security in the face of drought, wildfire, and other
680 disturbances.

681 A strategy that emphasizes cultural burning may contrast with ones that favor treating large areas
682 in ambitious individual projects that require lengthy environmental reviews (or wildfires
683 managed for resource objectives that are not governed by such reviews). It reflects the "small is
684 beautiful" concept, which holds that small groups working locally can achieve better
685 conservation outcomes than large corporate entities (Schumacher, 1985). This concept has been
686 widely incorporated into natural resources management (Lovell *et al.*, 2002). In addition to
687 relying on smaller treatments, a strategy geared toward cultural burning would also require
688 retreating sites more frequently than national forest managers in the Pacific West region have
689 typically achieved (Kolden, 2019; North *et al.*, 2021). In California, despite calls to rely on
690 greater use of fire, there are few examples of restored fire regimes in frequent fire vegetation
691 types outside of a few areas that have experienced managed wildfires for resource objectives
692 (North *et al.*, 2021). However, current tribal plans such as one advanced by the Western Klamath
693 Restoration Partnership emphasize the role of cultural burning, along with greater use of
694 managed wildfires, in protecting communities from the detrimental effects of uncharacteristically
695 large and severe wildfires (Harling and Tripp, 2014). The intent is not to exclude fire from the
696 landscape but to moderate wildfires so they will not damage vast areas and harm communities.

697 *3.2. Addressing challenges between Indigenous objectives and government agency objectives*
698 There appears to be strong alignment between the benefits of cultural burning and agency
699 restoration strategies, but there are some challenges in implementing both and in making them
700 mutually supportive.

3.2.1. Addressing policy constraints on cultural burning

Constraints on prescribed burning, such as air quality regulations and liability concerns, also have constrained cultural burning by Indigenous practitioners (Clark *et al.*, 2021). Other constraints on restoration treatments include concerns for rare wildlife, including spotted owls (*Strix occidentalis*) and Pacific fisher, which have been translated into requirements to maintain higher levels of forest canopy cover than were historically widespread (Lydersen *et al.*, 2019) and to avoid burning during especially sensitive denning, nesting, and breeding periods in the spring (Thompson and Purcell, 2016). Traditional burning was generally a fall or late winter activity, and tribes have sometimes expressed concerns that burning outside of those traditional seasons could be harmful to wildlife (Halpern, 2016). However, contemporary practitioners may desire flexibility to use fire to advance restoration objectives through an adaptive process.

3.2.2. Recognizing that thinning complements, but does not substitute for, cultural burning

Forest management intended to support tribal values has in many cases relied more on thinning than burning (LeCompte-Mastenbrook, 2016). Researchers have found that both tree cutting and fire will likely benefit both biodiversity conservation and fire management in current mixed conifer forests (Abella and Springer, 2015). However, field studies have found larger effects on plant communities from moderate- to high-severity fires than from low-severity prescribed burning (Kerns and Day, 2018), or from canopy thinning treatments followed by prescribed burns. Such responses are especially likely in forests that are highly departed from historical fire regimes—they may require greater and different forms of disturbance to reset their trajectories. However, even where thinning is effective in increasing light, nutrients, and water to understory plants, it may not accomplish other objectives such as pest reduction and desirable growth forms. Moreover, practitioners have reported contexts in which some traditional plants, such as

huckleberry and western redcedar (*Thuja plicata*), are favored by fire but not by mechanical thinning (Wynecoop *et al.*, 2019).

3.2.3. Avoiding negative effects

Prescribed burning has potential for negative effects, and some of those risks could also apply to cultural burning. However, the likelihood of negative outcomes may be greatly reduced due to practices adhered to by cultural practitioners. Any kind of wildland fire has potential to result in other unintended and undesirable effects including escape, consumption of snag habitats, undesired mortality of large trees, and nuisance levels of smoke (Ryan *et al.*, 2013). In general, however, cultural burns may have lower potential for such effects than other kinds of fire for several reasons. First, individual cultural burns are often intended to result in small, patchy, low-moderate severity burns. Second, cultural burning is often practiced as an intergenerational endeavor with both young people and elders. Burning and tending are often planned to enhance safety for family gatherings. When burners purposefully limit their operations to relatively traditional technologies, they have incentives to avoid conducting risky burns. Cultural practitioners tend their burns closely, with attention to effects on understory plants, wildlife, community health, and protecting legacy resources. The small, patchy scale of cultural burning is likely to inhibit the delivery of large quantities of smoke to large populations, especially as compared to wildfires (Long *et al.*, 2018c). Furthermore, the preparation that precedes cultural burns reduces the likelihood that a fire escape or an infestation of invasive plants will occur.

Despite such precautions, reintroduction of indigenous burning may be complicated in areas that have undergone transformations resulting from Euro-American colonization, including invasion by non-native species and increases in accidental ignitions. In such systems, such as chaparral in southern California, some managers and ecologists are concerned that burning too frequently

could negatively impact native vegetation (Keeley and McGinnis, 2007). In an extreme example, a study in Washington state found that five decades of annual burning resulting from artillery fire transformed the dominant vegetation in a prairie from native fescue to non-native grasses; in contrast, prescribed burning on a 3-5 year rotation for two decades reduced cover of most non-native species while inhibiting conifer encroachment on oaks (Tveten and Fonda, 1999). Potential for increases in non-native species following prescribed burning has been reported from a variety of vegetation types in the region, including chaparral and grasslands (Safford and Harrison, 2008), ponderosa pine forest (Keeley and McGinnis, 2007; Kerns and Day, 2018), and riparian areas (Hankins, 2013), although results often vary greatly. The potential for undesirable increases in non-native species is often associated with the existing level of non-natives within or adjacent to the treatment areas. Research in Arizona forests showed that burning in an area with high levels of cheatgrass promoted the invasive, while burning in a native-dominated site did not (McGlone *et al.*, 2012). Hankins, an Indigenous practitioner and scholar, observed a similar dynamic when comparing outcomes following burning in two oak-grasslands sites in the north-central Sacramento Valley (Hankins, 2015). He speculated that reintroducing cultural burning over time could help to gradually restore the native composition.

3.2.4. Explaining the relevance of services

Different categories of services may be associated with different challenges and opportunities for advancing cultural burning. Many of the benefits of cultural burning may be devalued within market-based frameworks; however, the value of some provisioning services can often be more easily quantified in other economic frameworks. For example, researchers have estimated the volume of materials needed to produce products such as baskets that command high prices (Anderson, 2018; Marks-Block *et al.*, 2021). Furthermore, provisioning services may be afforded

special leverage where the federal government recognizes off-reservation tribal rights to gather, fish, and hunt, especially in Washington and Oregon (Bernholz and Weiner, 2008). Because the ability to exercise such rights depends on the availability of resources of suitable quality and quantity, those legal levers could support cultural burning. On the other hand, the effects of burning on provisioning services may be difficult to measure easily since resource quality of root crops, acorns, and shoots may be best evaluated upon harvest by tribal gatherers (Hummel *et al.*, 2015).

Regulating and supporting systems including wildfire protection, water availability, pollination, food webs, biodiversity, carbon sequestration, and soil tilth, have all been a focus of management and research (Nikolakis and Roberts, 2020). However, quantifying such services can be challenging because of the broad spatial and temporal scales needed to understand them. Burning affects a tremendously wide variety of species and their interactions, including not only biomass removal and more complex effects on air, soil, water, food webs, and parasitic and symbiotic associations. This complexity poses substantial challenges in selecting metrics and scales for evaluation. Cultural services are even more challenging to integrate into institutional processes since they tend to be non-quantified, non-fungible, less openly discussed, and yet more contested. For example, court decisions have often denied protection to tribal sacred sites on public lands (Carpenter, 2004). A resistance to explicit co-management lands under current legal interpretations may impede the ability of Indigenous groups to steward specific places on public lands. The concepts of cultural services and services for ecosystems elucidate why Indigenous people want to directly apply fire themselves.

An ecosystem services framework can help to integrate Indigenous perspectives more fully within planning frameworks (Armatas *et al.*, 2018). Such approaches depart from past efforts

that often focused on tribal concerns for archaeological sites (Long *et al.*, 2020). Recognizing the interconnections between ecological and social services can help to identify opportunities to unravel persistent effects of colonialism (Long and Lake, 2018).

3.3. Addressing limitations of paleoecological research

As noted in the introduction, ecologists have explained that methods used to reconstruct environmental histories, including sampling of charcoal deposits in lakes and fire scars on trees, may have poor ability to detect Indigenous influences (Klimaszewski-Patterson *et al.*, 2018; Abrams and Nowacki, 2020). This methodological challenge is acute in areas where fires would be naturally frequent in the absence of human influence (Roos *et al.*, 2019). Tree rings can sometimes help to distinguish wildfires from Indigenous burning based upon time of year, but even they are likely to underrepresent light Indigenous burning (Whitlock *et al.*, 2004). However, analysis of tree-ring records can also be modified to be more sensitive to patchy burning (Roos *et al.*, 2019). Roos *et al.* (2018) explain that Indigenous burning may have either enhanced or buffered climate impacts on fire regimes at different scales, and it is difficult to separate those influences without considering multiple types of evidence. Responding to the exclusion of Indigenous values and knowledge in this field, researchers have called for more transdisciplinary efforts including collaborations with Indigenous experts to interpret paleoecological evidence and to inform contemporary forest management (Lake, 2013; Lightfoot *et al.*, 2013; Leonard *et al.*, 2020).

3.4. Addressing shortcomings of controlled experiments

Many experimental research studies on cultural burning have been set up as relatively short-term investigations, often as part of graduate studies, with limited resources to obtain environmental clearances needed for treatments. While many projects have been conducted in partnership with

816 tribal practitioners (Shebitz, 2006; Lake, 2007; Shebitz *et al.*, 2008; Hankins, 2013; Halpern,
817 2016), they may not have recreated traditional burning regimes due to such external constraints.
818 For example, Halpern (2016) noted that practitioners wanted to study fall burning, but she had to
819 examine spring burns to comply with federal and state prescribed burning regulations. Similarly,
820 environmental review requirements initially constrained Lake (2007) to study relatively small
821 burns using propane torches to evaluate effects of burning on willow shoots (Fig. 6). He later
822 was able to study a larger prescribed burn, which he found to be more effective in controlling
823 insect pests. Meanwhile, a tribal-Forest Service collaborative research study (Wynecoop *et al.*,
824 2019) considered how burning treatments could benefit culturally important plants by comparing
825 areas burned in a wildfire, treated with a combination of mechanical thinning and prescribed fire,
826 or not having been treated within 10 years. While these studies advance our knowledge, they
827 reveal a lack of studies that explicitly incorporate cultural burning practices.

828 The complexity associated with scale and potential shadow effects of treatment are some of the
829 challenges in delineating "treatment" and "control" units. Studies of single burns are not likely to
830 be representative of cultural burning regimes for several reasons. First, the strong influence of
831 precipitation on plant growth makes the effects of burning more difficult to resolve (Hankins,
832 2015). Second, single burns in long-unburned areas may be more intense than would be typical
833 for cultural burns. For example, a recent study of ceramic sherds in an ancient village site in
834 northern New Mexico found that a that a large prescribed burn during mild October weather, but
835 following 119 years of fire exclusion, burned more intensively than any fires in the previous 900
836 years (Roos *et al.*, 2020). Third, fire effects are likely to change as cultural burning is
837 reintroduced, because consumption rates, fuels, and vegetation composition change with

repeated burning (Levine *et al.*, 2020). Establishment of long-term studies could address many of these shortcomings.

3.5. Establishing long-term collaborative studies

Indigenous peoples are rightfully concerned about potential for traditional ecological knowledge to be extracted and used by non-Indigenous contractors or scientists in ways that do not directly advance tribal stewardship and sovereignty (Klenk *et al.*, 2017). Some collaboratives, such as the Western Klamath Restoration Partnership, have enjoyed success in fostering tribal engagement (Kelly *et al.*, 2019). Tribal influence in other collaboratives, including the Dinkey Landscape Collaborative, is less apparent (Butler *et al.*, 2015). Establishing longer-term experimental studies with Indigenous communities would help to better understand effects of cultural burning and other traditional stewardship practices. For example, a research study on former university lands in Missouri revealed how differences in forest composition and structure can develop under contrasting fire regimes, including frequent fires, over 60 years (Knapp *et al.*, 2015). Tribes and land management agencies could similarly explore opportunities to establish stewardship areas that would support long-term investigations of cultural burning. Many research natural areas (and some wilderness areas) in California have experienced a shortage of fires, yet they also discourage "manipulative" vegetation treatments (Coppoletta *et al.*, 2019). Nevertheless, a recent tribal-agency collaboration in the Indiana Summit Research Natural Area demonstrated how traditional practices and return of fire could safeguard cultural resources and facilitate tribal harvesting of pandora moth larvae (Slaton *et al.*, 2019).

4. Conclusions

Rooted in historical practices and traditional values, tribal cultural burning continues to adapt to meet contemporary challenges. Indigenous people are asserting their rights and responsibilities to

burn to maintain their well-being. The overlap between cultural burning and contemporary agency forest management can encourage mutually beneficial outcomes rather than perpetuating the harmful legacy of fire exclusion. The framework of ecosystem services can relate the goals of Indigenous practitioners to government management systems, while expanding awareness of the many diverse benefits of cultural burning beyond its potential to regulate wildfires. The many benefits of cultural burning are the results of a complex web of material/immaterial and direct/indirect effects. This understanding illustrates why the many benefits are difficult to quantify or evaluate with market-based systems. Nevertheless, scientific approaches can be adapted to better detect and measure many of the physical effects, and collaborative efforts can better reveal the benefits of restoring cultural burning both to tribal communities and to wider society. Distinctive ecological communities that have evolved with Indigenous use of frequent fire in the Pacific West region are especially important to study at long-term and broader spatial scales. Expanding long-term tribal collaboratives, including designating Indigenous stewardship areas with frequent burning, would advance our understanding of restoration in forested landscapes.

Acknowledgments

The authors acknowledge the many knowledge keepers whose ideas and support of tribal traditional practices contributed to this research. Support for the preparation of this article was provided by the USDA Forest Service Pacific Southwest Research Station. The findings and conclusions in this manuscript are those of the authors and should not be construed to represent any official determination or policy by the U.S. Government, U.S. Department of Agriculture, or the North Fork Mono Tribe.

ABSTRACT

Before widespread fire exclusion policies, American Indians used broadcast understory fires or cultural burns to enhance resources integral for their livelihood and cultural practices. To restore ecocultural resources depleted from decades of fire exclusion and to reduce wildfire risks, the Karuk and the Yurok Tribes of Northwest California are leading regional collaborative efforts to expand broadcast fires and fuel reduction treatments on public, private, and Tribal lands in their ancestral territories. Through collaboration with Karuk and Yurok Tribal members and basketweavers, we evaluated the effects of broadcast fires and three fire proxy treatments on California hazelnut shrubs (*Corylus cornuta* var. *californica*) that produce highly valued ecocultural resources for basketry materials. Across a 10 ha Douglas-fir and mixed hardwood forest (500 m a.s.l.) in the Klamath mountains, we established 27 stratified blocks (16 m^2) and within each block applied three fire proxy treatments designed and used by Tribal members with an untreated control. These treatments involved manual hazelnut stem cutting, directly blistering hazelnut stems via propane torch, and igniting surface fuels piled within hazelnut shrubs to top-kill stems. Broadcast fire was applied to 12 separate blocks. After a full growing season (12–18 months post-treatment/burn), shrubs were re-measured. We then harvested these stems (n = 604; 50 shrubs) across treatments and compared results with stems gathered independently by two experienced Karuk/Yurok basketweavers (n = 396 and n = 73) from an adjacent broadcast burned site. Compared to the untreated shrubs, pile burning, propane torching, and broadcast burning increased basketry stem production by 7–10 fold ($p < 0.001$), while the cutting treatment increased production by 4-fold ($p = 0.006$). Shrubs with relatively greater access to sunlight (southern aspect, ≥51% and < 70% canopy cover) produced fewer quality stems when compared to shrubs with an eastern aspect ($p < 0.01$) and ≥70% canopy cover ($p < 0.05$). Harvested stems across all treatments displayed similar stem length distributions to those gathered by one of the two basketweavers ($p > 0.05$). Our results demonstrate that these fire-proxy methods are an effective means to increase the production and quality of basketry materials. Expanding the area and frequency of targeted understory fire-based forest treatments on private, public and Tribal lands in California and the Pacific Northwest would substantially increase the availability of these fire-enhanced ecocultural resources that are currently limited in supply and in high demand.

1. Introduction

As a result of historic fire exclusion policies in the American West, American Indian communities have sought to re-integrate prescribed fire and other fuel reduction treatments to decrease wildfire risks on Tribal lands and across other jurisdictions within their ancestral territories (Carroll et al., 2010; Kolden, 2019; Long and Lake, 2018). Tribes have expressed strong interest to use prescribed fire to improve the density and availability of culturally and economically important plants, fungi, and animals, referred to as 'ecocultural resources' (Anderson, 2018; Carroll et al., 2004; Lake et al., 2017; Long and Lake, 2018). Although ecocultural resources are similar to nontimber forest products (Chamberlain et al., 2018; Charnley et al., 2007; Jones and Lynch, 2007), ecocultural resources are also integral to Indigenous identity (Kimmerer, 2011; Long et al., 2018).

Co-management agreements between Tribes and public land

agencies, such as the United States Department of Agriculture (USDA) Forest Service, reflect recent efforts to integrate Tribal ecocultural resource objectives into management plans (Bussey et al., 2015; Carroll et al., 2010; Catton, 2016; Diver, 2016; Dockry et al., 2017; Donoghue et al., 2010; Jurney et al., 2017; Long and Lake, 2018). Although numerous studies exist on the effects of prescribed fire, along with manual, mechanical, and pile burning fuel reduction treatments on fire severity (Kalies and Kent, 2016), only a few studies in North America examine the effects of such treatments on ecocultural resources (Halpern, 2016; Hankins, 2013; Lake, 2007; Lathrop and Martin, 1982; Peter et al., 2017; Shebitz et al., 2009; Wynecoop et al., 2019). Given that pre-colonial Indigenous burning, coppicing, transplanting, and harvesting sought to enhance ecocultural resources, specifically examining how such treatments affect these resources may provide useful information to support the objectives of Tribes and land management agencies involved in ecological restoration, socio-economic development, and wildfire risk reduction (Anderson, 2018; Charnley et al., 2018; Kalies and Kent, 2016; Senos et al., 2006).

After several decades of limited fuel treatments, the Karuk and the Yurok Tribes in Northwest California are leading regional efforts to expand fuel reduction treatments and prescribed fires on public, private, and tribal reservation lands in their ancestral territories to protect structures and to restore ecocultural resources (Fig. 1A; Diver, 2016; Harling, 2015; Long et al., 2018; Robbins et al., 2016). Fire-enhanced ecocultural resources (e.g., acorns, berries, basketry materials, and wildlife) are integral to the Karuk and Yurok Tribes (Baldy, 2013; Harrington, 1932; Heffner, 1984; Huntsinger and McCaffrey, 1995; Norgaard, 2014). In Karuk and Yurok territory, and elsewhere in California, American Indians refer to their prescribed fires as 'cultural burns', because the burns aim to improve the qualities and densities of ecocultural resources central to subsistence and ceremonial practices (Aldern and Goode, 2014; Long et al., 2018). Cultural burning is a critical component of 'ecocultural revitalization' efforts in Northwest California given the centrality of fire-enhanced resources to cultural practices. Cultural burning distinguishes these fires from the fuel reduction-focused prescribed burns of public land agencies whose primary objective is to reduce fuel loads, and thus, moderate wildfire intensity (Collins et al., 2010; Schwilk et al., 2009).

Since the early 1990s, forest management in the Pacific Northwest and Tribal consultation policies have undergone several major conceptual and programmatic changes coupled with legislation (Thomas et al., 2006; Vinyeta and Lynn, 2015). American Indian political organizing resulted in the passage of legislation to reform the National Historic Preservation Act in 1992 that required US governmental consultation with Tribes surrounding cultural resources in their ancestral territories (Stapp and Burney, 2002). In 1994 and 2000, US President Clinton issued executive orders that expanded consultation requirements to all decisions that had implications for Tribes (Clinton, 2000, 1994). These executive orders along with other internal actions of USDA Forest Service staff catalyzed the hiring of Tribal liaisons and the formation of the Office of Tribal Relations (Catton, 2016). Consequently, to meet these treaty and federal Indian trust obligations, collaborations among Tribes and public land agencies became increasingly formalized (Lake et al., 2018; Long et al., 2018).

With the implementation of the Northwest Forest Plan (NWFP) in the 1990s (Fig. 1B), forest management on public lands in Karuk and Yurok ancestral territories shifted from timber extraction toward ecological restoration and endangered species conservation (e.g., Northern Spotted Owl, *Strix occidentalis*) dependent upon old-growth forests (Thomas et al., 2006). The NWFP also precipitated the development of

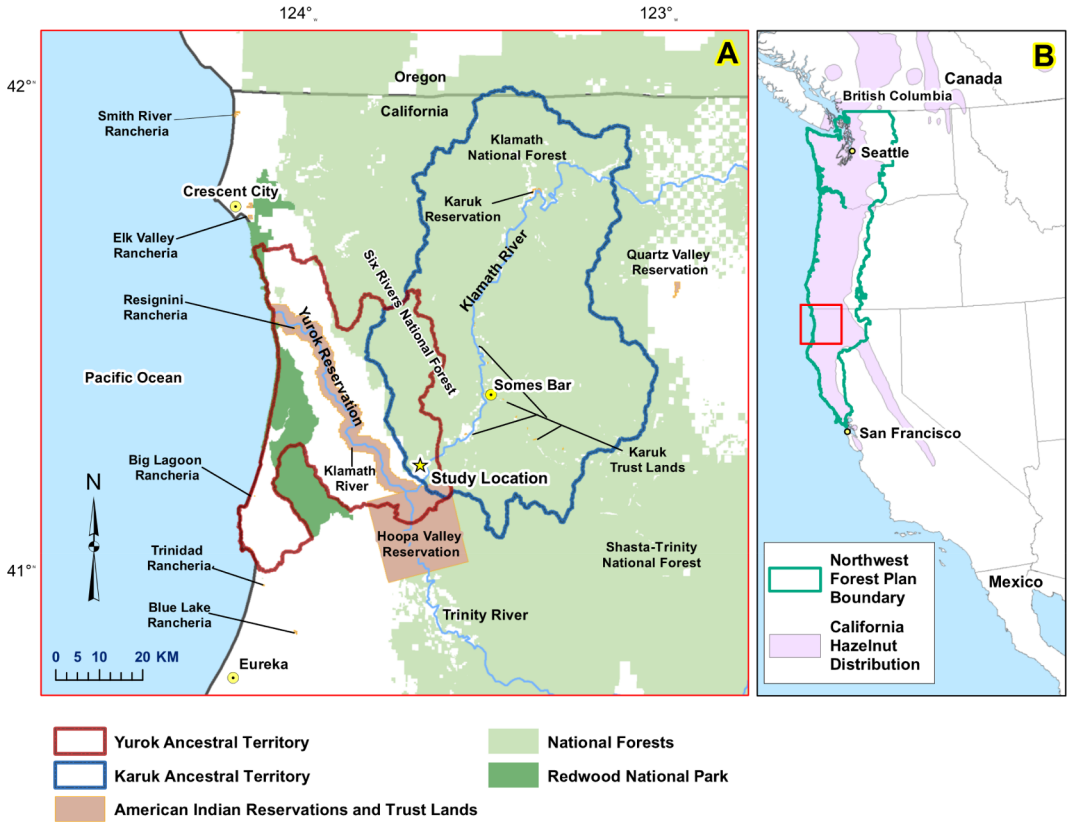

Fig. 1. (A) Study region with federal jurisdictional boundaries and Karuk and Yurok territories. Ancestral territory boundaries, provided by the Karuk and Yurok Tribes, represent reconstructions, but currently are not fixed or rigid boundaries. Ancestral lands of other Northwest California Tribes (e.g., Tolowa, Wiyot, Hupa, Shasta) are not included here, but note that their ancestral lands may partially overlap with the boundaries rendered here (Baumhoff, 1963). (B) Western region of the United States of America, including California hazelnut (*Corylus cornuta* var. *californica*) distribution derived from the *Atlas of US Trees* (Little Jr, 1971) as well as the area encompassed under the Northwest Forest Plan (2002). The study region is depicted by the red square.

new National Forest plans and established regular federal monitoring of Tribal consultation processes that created opportunities for the Karuk Tribe to influence forest policy and resource management within their ancestral territory (Diver, 2016; Long et al., 2018; Senos et al., 2006; Vinyeta and Lynn, 2015). These policy changes as well as the 2001 National Fire Plan and the 2003 Healthy Forests Restoration Act (PL 108-148) established benchmarks and best practices coupled with earmarked funds for fuel reduction treatments, and supported collaborative projects to manage fire in Karuk and Yurok ancestral lands (Lake, 2011). In California and the Pacific Northwest, the USDA Forest Service annually treats more area with understory mechanical thinning than prescribed fire to reduce forest surface fuels (Vaillant and Reinhardt, 2017). Impediments to prescribed fire and fuel reduction include seasonal restrictions on fuel reduction activities for threatened and endangered wildlife, staff reductions associated with the decrease in timber receipts from NWFP mandates, burn restrictions during major wildfire events, and air quality regulations that constrain available burn days (Calkin et al., 2015; Quinn-Davidson and Varner, 2012; Schultz et al., 2018; Stephens et al., 2016; Williams, 2009). However, recent efforts within the USDA Forest Service to increase cross-jurisdictional landscape-scale treatments, known as the 'Shared Stewardship' initiative seek to address several of these constraints (USDA Forest Service, 2018).

Despite these challenges, the Karuk and Yurok Tribes collaborate with the Fire Learning Network (FLN) and other agencies to host annual prescribed fire training exchanges (TREX: Butler and Goldstein, 2010; Harling, 2015; Long et al., 2018; Robbins et al., 2016; Spencer et al., 2015). The FLN is an effort by the USDA Forest Service, US Department of the Interior, and The Nature Conservancy to restore fire-dependent landscapes by engaging in collaborative, community-based planning. On the Yurok reservation, the Cultural Fire Management Council (CFMC) leads efforts to expand cultural burning in partnership with the Yurok Tribe and the California Department of Forestry and Fire Protection (Yurok Tribe, 2015). CFMC is a community-based organization led by Yurok Tribal members that support private and Tribal landowners who seek to conduct cultural burns on their properties by sharing equipment, providing necessary personnel, and submitting permits. The Karuk Tribe is collaborating with the USDA Forest Service, the Orleans-Somes Bar Fire Safe Council, and other community organizations to initiate fuel reduction and cultural burn treatments in their territory through the Western Klamath Restoration Partnership (WKRP; Lake et al., 2018; Long et al., 2018; USDA Forest Service PSW Region, 2018; Vinyeta and Lynn, 2015). The WKRP is composed of NGOs, Tribes, and government agencies that have initiated a pilot project near Somes Bar, CA to apply mechanical and prescribed fire treatments in fire excluded forests. Upon completion, they have proposed to expand these fire treatments across 480,000 ha. (Lake et al., 2018; Long et al., 2018; USDA Forest Service PSW Region, 2018).

Substantial ethnohistorical information exists on the effects of fire on ecocultural resources worldwide (Scherjon et al., 2015; Trauernicht et al., 2015) and in the Pacific Northwest, and California, in particular (Anderson, 2005; Blackburn and Anderson, 1993; Boyd, 1999; Lewis, 1993). However, empirical ecological effects of contemporary fuel reduction treatments on ecocultural resources are not well known, and such studies may serve to inform adaptive and collaborative management projects in American Indian territories (Anderson, 2002; Berkes et al., 2000; Long et al., 2018; Wynecoop et al., 2019). Species-specific studies have demonstrated that prescribed burning improves the densities of blueberries (*Vaccinium* spp., Duchesne and Wetzel, 2004) and reduces insect infestation in tanoak acorns (*Notholithocarpus densiflorus*, Halpern, 2016). Fire has been shown to increase the density and enhance the quality of several plant species (e.g., *Xerophyllum tenax* beargrass, *Muhlenbergia rignes* deergrass, *Anthoxanthum nitens* sweetgrass) used for American Indian basketry resources (Anderson, 1999; Gagnon and Platt, 2008; Griffith et al., 2007; Hart-Fredeluces and Ticktin, 2019; Lathrop and Martin, 1982; Peter et al., 2017; Shebitz et al., 2009; Shebitz and Kimmerer, 2005).

California hazelnut (*Corylus cornuta* Marsh. var. *californica*) is a critically important ecocultural resource for Karuk and Yurok Tribal members. California hazelnut ranges from British Columbia to the southern Sierra Nevada and central coastal mountains of California and extends over ~76% (180,471 km^2) of the NWFP area (Fig. 1B; Little Jr, 1971; Thompson et al., 2015). California hazelnut is a deciduous, multi-stemmed shrub that resprouts vegetatively after disturbance, similar to *Corylus americana* and *Corylus cornuta* var. *cornuta* in central and eastern North America (Buckman, 1964; Pelc et al., 2011). Throughout California hazelnut's range, the nuts are consumed by American Indians (Armstrong et al., 2018; Cuthrell, 2013; Fine et al., 2013; LaLande and Pullen, 1999; Thompson, 1991). Across the Pacific Northwest, California hazelnut stems continue to be used by American Indians for basketry and material culture (Mason and Coville, 1904; Moerman, 1998; Turner, 1998; Zobel, 2002) with similar uses of *Corylus* spp. persisting throughout Europe (Batsatsashvili et al., 2017; Bichard, 2008). The straight and unbranched stems of recently burned hazelnut shrubs are in high demand by California Indians to produce baskets for diverse uses (Fig. 2, Anderson, 1999; Bibby, 2004; Harrington, 1932; Heffner, 1984; Hunter, 1988; Johnson and Marks, 1997; Kallenbach, 2009; Levy, 2005; Mathewson, 2007; O'Neale, 1932; Ortiz, 1998, 1993; Salberg, 2005; Shanks, 2006; Thompson, 1991; Underwood et al., 2003). In 2017, basketweavers reported hazelnut stems selling for $1 per stem, indicating their socio-economic value (T. Marks-Block, *pers. obs.*, 2018). Moreover, the diverse products constructed from these materials reflect their artistry skills, cultural significance, and ancestral history and identity as well as bestow respect for these talented basketweavers (Bibby, 2012; Johnson and Marks, 1997; Mathewson, 1998). One type of basket in high demand is the baby cradle as these cradles remain a central component of child rearing in Northwest California Indian culture (Bibby, 2004). These baskets often require ~300 hazelnut stems to produce and then may be sold for ~$800 dollars (T. Marks-Block *pers. obs.*, 2018).

Based on ethnographic studies, Northwest California Indians such as the Karuk and Yurok reportedly initiated relatively small (< 4 ha)

understory broadcast fires in the summer and fall months every 2–5 years in hazelnut groves to increase concentrations and quality of basketry stems (Anderson, 2005; Busam, 2006; Harrington, 1932; Huntsinger and McCaffrey, 1995; LaLande and Pullen, 1999; Stewart, 2002; Thompson, 1991). As cultural burning diminished due to the enforcement of fire exclusion policies, basketry stems reportedly became scarce because only poor quality gathering areas remained that, in turn, highly constrained basketry production (Bright, 1957; Heffner, 1984; Huntsinger and McCaffrey, 1995; Levy, 2005; Norgaard, 2014; O'Neale, 1932). For example, based upon 43 interviews with basket-weavers in 1929, anthropologist Lila O'Neale reported that:

> "Hazel sticks are conceded by the women of both tribes [Yurok and Karok] to be the best, but the most difficult to procure nowadays. New little shoots from a ground recently burned over are ideal. This statement is followed, however, by the lament that fires cannot be set as they used to be by the old-time weavers, and by the regret that accidental burnings occur seldom in places where they do basket makers any good" (O'Neale 1932:15).

Because of these resource availability challenges, basketweavers and stem gatherers have used permitted techniques to generate hazelnut re-sprouting that serve as substitutes or proxies for cultural burns (F. Lake, *pers obs*; Hunter, 1988).

To evaluate these techniques for potential inclusion into larger-scale fuel reduction management areas, we collaboratively designed a field experiment to compare the efficacy of four practices (Fig. 3) used by Yurok and Karuk Tribal members to increase hazelnut stems for basketry: (1) cutting or the manual coppicing of hazelnut shrubs (Hunter, 1988); (2) pile burning of surface fuels including needle/leaf litter and 1-hour (0.00–0.64 cm diameter) and 10-hour (0.64–2.54 cm diameter) fuels within individual hazelnut shrubs; (3) propane torch burning of individual hazelnut shrubs (Ortiz, 1998); and, (4) prescribed cultural burns set to broadcast, or move through the understory, to top-kill multiple hazelnut shrubs. Among these treatments, we compare and contrast the production of suitable shoots: straight, unbranched basal re-sprouts of hazelnut shrubs (Fig. 2). Then we evaluate if canopy cover, aspect, and the presence of deer browse influence the productivity of basketry stems. Basketry stems were harvested post-treatment and compared and then contrasted by length and diameter with stems harvested independently by two experienced Karuk/Yurok basketweavers from an adjacent broadcast burned site.

Fig. 3. Four hazelnut shrub treatments. (A) Pre- and post-cut treatment. All stems in each shrub were cut to ground level (< 5 cm) to stimulate coppicing, and to mimic mechanical understory clearing and piling for fuel reduction. (B) Pile burn treatment during combustion. Surface fuels (primarily 1-h, 10-h fuels, and surface litter comprised of conifer needles and hardwood/shrub leaves) were placed between hazelnut stems within a shrub to form a burn pile (< 25 cm height). (C) Propane torch burn treatment. Hazelnut shrub stems were burned at ground level to cause bark blistering and stem mortality. (D) Broadcast burn treatment. A fire was set with drip torches to back down-hill and allowed to spread to kill above-ground hazelnut stems.

These treatments and measures were conducted in direct collaboration with Karuk and Yurok basketweavers whose ecological knowledge and harvesting practices informed this study and sampling design (Lake, 2013; McLaughlin and Glaze, 2008). Basketweavers have observed that hazelnut shrubs that grow in areas with relatively greater sun exposure produce extensive lateral branching, thus reducing viable basketry stems post-treatment (Johnson and Marks, 1997; Mathewson, 1998; Ortiz, 1998), but may increase nut production. Basketweavers also report that stem sprouts from coppiced hazelnut are not as pliable as stem sprouts that emerge from burned hazelnut (F. Lake and T. Marks-Block, *pers obs*). While we did not evaluate this stem characteristic, Rentz (2003) demonstrated that burned hazelnut stems contained a greater wood-to-pith ratio than unburned, coppiced hazelnut stems, lending empirical support to basketweavers' observations. Because basketweavers and managers have also reported that deer and elk browse may negatively affect basketry production (Underwood et al., 2003), we also included the presence of this activity in our observations.

Our study combines Indigenous ecocultural and 'western' scientific epistemologies to monitor and manage forests as advocated by American Indian fire and forest managers (Lake et al., 2017; Mason et al., 2012; Mazzocchi, 2006). This integrated participatory approach seeks to identify effective practices for improved ecocultural resource management, such as enhancing both the density and quality of basketry materials (Bussey et al., 2015; Emery et al., 2014; Hummel and Lake, 2015; Mockta et al., 2018).

2. Methods

2.1. Social science methods

To develop an ecological research project focused upon an Indigenous ecocultural resource, we initially drew from Indigenous and anthropological research methods such as participatory and reciprocal study design and observations that serve to foster relationships of trust among academics, Indigenous scientists, and cultural practitioners (Bernard, 2011; Lake et al., 2017; Smith, 1999; Wilson, 2008). We worked with Tribal cultural practitioners and Tribal government staff over several years to integrate ecocultural resource objectives into land management plans. This investment and participation in the community generated trust and led to accountability, reciprocity, and collaboration among researchers and Tribal members (Lake, 2013). The collection of qualitative and quantitative social science data was developed and reviewed iteratively by as the Karuk and Yurok Tribes, who have their own independent research review processes to generate accountability and collaboration with researchers (Karuk Tribe et al., 2017; Sarna-Wojcicki, 2014). These proposals then received approval by our institutional human subject review boards at the Oregon State University and Stanford University.

Sampling design and implementation initially was informed by semi-structured interviews, participant observations and collaborative field work with Karuk and Yurok basketweavers and cultural

practitioners conducted by Lake (2002–2008; Lake, 2007; McLaughlin and Glaze, 2008). Initially, Lake worked closely with key basketweavers to develop research objectives and accountability. Building on collaborations established by Lake, Marks-Block conducted ecological field measurements from 2014 to 2019 of cultural burns (n = 15) for hazelnut stem production supplemented by additional interviews and direct observation of basketry stem gathering with basketweavers (n = 44) that informed the analyses and interpretation of the treatment data.

Our interviews and interactions with basketweavers corroborated that suitable basketry stems were scarce due to fire exclusion (Heffner, 1984; Hunter, 1988; Ortiz, 1998). Interviews also confirmed that in the absence of broadcast burning, basketweavers and friends gathered hazelnut stems from shrubs treated using the three fire treatment proxies (Fig. 3), although the relative efficacy of these treatments remained unclear. Basketweavers also consistently recalled that the departure of supportive USDA Forest Service managers created major set-backs, because they had to re-establish lines of communication with new staff and inform them about their basketry materials and fire treatment needs. Hence, as the National Fire Plan (2001) and the Healthy Forests Restoration Act of 2003 (P.L. 108-148) initiated increased fuel reduction treatments throughout this region (Schoennagel et al., 2009), basketweavers and Tribal members often were not informed about the schedules or locations of understory mechanical treatments and broadcast burns, and thus they missed opportunities to gather hazelnut stems. As a result, basketweavers and collaborators believed that an empirical study on the effects of several fire treatments on hazelnut shrubs could assist managers in incorporating Indigenous resource objectives into their plans.

To evaluate what basketweavers consider to be stems of basketry quality, we attended over 50 basketry classes and workshops supported by the Karuk and Yurok Tribes where we received direct instruction from basketweavers. We also observed over 50 independent hazelnut stem gathering trips to describe stem gathering practices. In these settings, all basketweavers stated that stems must be straight, unbranched, and free of insect intrusions or bark blemishes. Moreover, a wide range of both stem lengths and diameters are used depending on the type and size of basket they are weaving. Stems having lengths (e.g., 10–50 cm) can be used to weave earrings, tobacco pouches, or baby rattles, whereas longer stems (e.g., 50–100 cm) are suitable for producing storage baskets or baby cradles. Small diameter stems (1–3 mm) are preferred by basketweavers conducting fine weaving, although the tapered tips of long stems with 4–12 mm diameters may be used for similar purposes. Other basketweavers may select wide stems (5–12 mm diameter) for fish traps, storage baskets, or baby cradles.

As participant observers in both material gathering and production, we documented basketweaver gathering site preferences and also constraints such as gathering in marginal locations (e.g., clear cuts and mechanically thinned roadsides). Basketweaver Mrs. Verna Reece stated: “it’s kind of hard to get burn[ing done]…When logging…they just burn [slash]…so it wasn’t that good of material…Out in the open…[hazel stems are] kinda stalky, fat. It’s different when you have…a canopy over it. It kind of reaches for the sun and kinda grows long, slender” (Lake, 2007: 600).

From these basketweaver observations, we then broadly defined suitable quality basketry stems, and focused our efforts on measuring the length and diameters of stems produced from multiple treatments under a suite of biophysical conditions. Hazelnut morphology, structural integrity, autecology, and basketry use criteria garnered from basketweavers informed the sampling design, treatments, and measurements used here (Fig. 4).

Fig. 4. Karuk basketweavers Ms. Janet Morehead (left) and Ms. Lillian Rentz (right), peeling and evaluating the quality of hazelnut stems gathered from the treatment area.

2.2. Experimental methods

2.2.1. Study area

Treatments were conducted on a 10 ha forest with abundant hazelnut shrubs on a privately owned parcel that adjoins the Orleans Ranger District of the Six Rivers National Forest in the Klamath River watershed. The study location is within the 1919 km^2 ancestral territory of the Yurok Tribe and the 2728 km^2 ancestral lands of the Karuk Tribe (Fig. 1A; Waterman 1920, Baumhoff 1963). In Karuk territory, the federal government did not establish a reservation, leaving merely 3.83 km^2 of Karuk trust lands in their ancestral territory, with the remainder largely under the jurisdiction of the Klamath and Six Rivers National Forests and scattered private homesteads (Fig. 1A; Davies and Frank, 1992; Norgaard, 2014; US Census Bureau, 2017). As a result, Karuk Tribal members and management agencies must navigate the USDA Forest Service claims on their ancestral territory and have limited options to expand their land base through the acquisition of private land holdings. In Yurok territory, multiple overlapping jurisdictions occur including Redwood National Park (192 km^2, Underwood et al., 2003) and Six Rivers National Forest (577 km^2) outside of the reservation established by the federal government. The reservation is located along a one mile buffer from the Klamath River’s estuary to ~80 km upriver (~225 km^2; Huntsinger and Diekmann, 2010). However, 106 km^2 (47%) of the reservation is under private timber company ownership (Yurok GIS Program, 2015). Consequently, the Yurok Tribe must either coordinate or interact with multiple actors within their ancestral territory, but they presently have greater options for acquiring private properties than the Karuk Tribe.

Douglas-fir (*Pseudotsuga menziesii*) and mixed hardwoods (e.g., *Arbutus menziesii*, *Quercus kelloggii*, *Notholithocarpus densiflorus*, *Acer macrophyllum* and *Umbellularia californica*) comprise the forest overstory at the study site. In California, hazelnut is an understory, multi-stemmed shrub (< 6 m ht in this study region) that typically occurs below 2,100 m above sea level on mesic sites with well-drained soils (Fryer, 2007). Relatively low-intensity fires that historically scarred canopy trees every 10–17 years (Crawford et al., 2015; Skinner et al., 2018; Taylor and Skinner, 1998; Wills and Stuart, 1994) often ‘top-kill’ understory hazelnut stems, which is when above-ground plant tissues are killed, while below-ground plant tissues remain alive (Anderson, 1999).

2.2.2. Fire proxy treatments and prescribed burning of hazelnut shrubs

We replicated fire proxy treatments used by Karuk and Yurok Tribal members to mimic prescribed fires that could be implemented by forest managers at fuel reduction sites with hazelnut shrubs. These fire proxy treatments were: (A) cutting all stems in each shrub to ground level (< 5 cm) as a means to stimulate coppicing, and to mimic mechanical understory clearing and piling for fuel reduction; (B) piling surface fuels

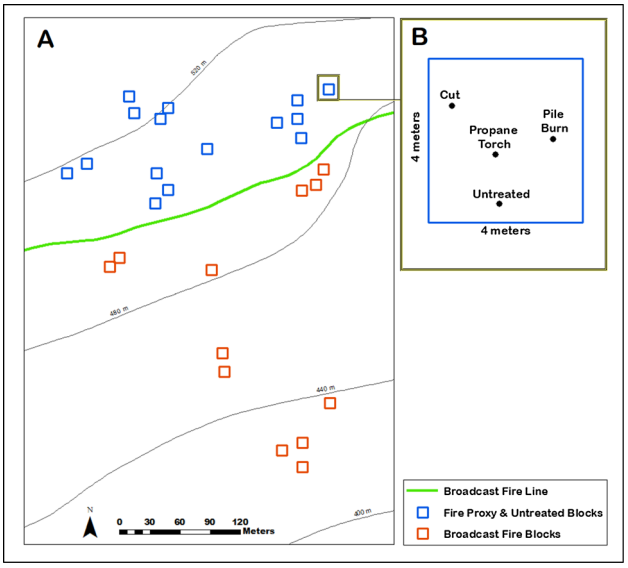

Fig. 5. Study site with treatment block design. (A) Spatial distribution of treatment blocks. The broadcast fire line divides the 15 fire proxy and untreated blocks from the 12 broadcast fire treated blocks. Contour lines depict the elevation and aspect at the site. (B) Schematic block (16 m^2) with four hazelnut shrubs (filled circles) that received fire proxy treatments.

(primarily 1-h, some 10-h fuels, and adjacent surface litter consisting of needles/leaves) between hazelnut stems to form a small pile (< 25 cm height) that was subsequently burned; and, (C) applying a propane torch flame near ground level to hazelnut shrub stems until stems blistered indicating stem mortality (Fig. 3). The prescribed fire treatment, referred to here as a 'broadcast' fire treatment, was allowed to spread across multiple hazelnut shrubs (Fig. 3D), while all other fire treatments were constrained to individually targeted shrubs.

We employed a randomized block design to establish 27 stratified blocks (block = 16 m^2) that included each treatment, except for the broadcast fire treatment (Fig. 5A). Blocks were selected if they contained at least four hazelnut shrubs spaced > 1–2 m apart with similar dimensions (e.g., shrub height, total stems, and stem diameter; Fig. 5B). Subsequently, total stems and the potential 'usable' basketry stems were counted within each hazelnut shrub and shrub height was measured over a 15 day period preceding the implementation of treatments on May 14, 2008. Based on basketweaver selection criteria, basketry stems were defined as straight stems > 10 cm long without branching. Shrub height as well as the slope, aspect, and canopy cover were recorded within each block. Slope was measured using a Suunto PM-5/360 PC Clinometer, aspect was recorded using a compass, and canopy cover was measured four times with a spherical concave densiometer at each cardinal direction above each shrub, to obtain a mean value (%) for each individual (Fiala et al., 2006; Lemmon, 1956). Aspects between 135° and 225° were classed as southern (n = 56) and aspects between 45° and 134° were classed as eastern (n = 49). Canopy cover ≤50% (n = 12) was categorized as 'low', cover ≥51% and < 70% as 'medium' (n = 63), and ≥70% as 'high' (n = 30). After our pre-treatment surveys, we randomly treated three of the shrubs within each block with a fire proxy and one shrub was designated as an untreated control (Fig. 5B).

Historically in Karuk and Yurok territory, cultural burns primarily were applied in the fall months (Harrington, 1932; O'Neale, 1932; Stewart, 2002; Thompson, 1991) with some occurring in spring months (Halpern, 2016; Lake, 2007). Given the unpredictable availability of broadcast burn conditions, the experimental and sampling design was conservative with all three fire proxy treatments and controls replicated as we were unsure whether broadcast burns could be included in this study. Fortunately, suitable prescribed fire conditions occurred on October 28, 2008 and a broadcast burn was applied to ~5 ha affecting 12 of the 27 treatment blocks (Fig. 5A). Fire lines were established to preserve ~50% of the previously treated blocks in order to compare the intact fire proxy treatments to the broadcast burn treatment (Fig. 5A). A backing fire with strip ignitions (3–5 m apart) was set with drip torches, and the fire burned from 14:20 to 16:30 h (Fig. 3D). Temperature ranged from 69.5° F to 75.0° F, relative humidity spanned 39.5–48.0% and the Yurok RAWS station (9 km from site) recorded fuel moistures between 7.4% and 12.3%. The fifteen blocks with three fire proxy treatments and a control that were not affected by the prescribed broadcast fire were then re-surveyed the following year (May 2009) when stems were suitable for harvest (n = 60 shrubs). Only one of the fifteen pile burned shrubs died. After a full growing season (18 months post-burn; April 2010), we re-surveyed 45 out of 48 shrubs in the 12 broadcast burned blocks as three tagged shrubs could not be re-located. Post-treatment measurements included the density of basketry stems, total live stems, and the presence of deer browse within each shrub.

2.2.3. Hazelnut stem measurements

On May 8, 2009, we harvested basketry stems (n = 604) produced from 50 shrubs in the cut (n = 233), propane (n = 205), pile burn (n = 148), and control (n = 18) treatments. Stems were cut < 5 cm from the ground, labeled, and then bark was removed to prepare the stem for weaving. Stem diameter was measured with a digital caliper and stem length with a meter tape. These stems harvested from the fire proxy treatments were then compared to hazelnut stem collections gathered on May 3, 2008 by two experienced Karuk/Yurok basketweavers (n = 396 and n = 73) from an earlier prescribed broadcast burn (October 2006) adjacent to the experimental study site.

2.2.4. Data analyses

To evaluate the production of post-treatment basketry stems in each shrub among the different treatments, we developed a negative-binomial generalized linear mixed model (GLMM) using the glmmTMB package in R (Magnusson et al., 2017; R Core Team, 2014). Block was set as a random effect, and treatment, aspect class, slope, the presence of deer browse, pre-treatment total stems, and canopy cover classes were included as covariate fixed effects. Pre-treatment total stems were also included as a fixed effect to evaluate if shrub size affected the quantity of post-treatment basketry stems. We used Type III Wald Chi Square tests to perform backwards selection to find the model of best fit. To analyze the differences within categorical variables that showed significance in the GLMM, we generated Estimated Marginal Means (EMMs) to address imbalances in the study design (e.g., 45 broadcast shrubs versus 15 pile burned shrubs) using the emmeans package and compared 95% confidence intervals using the Tukey and Dunnett methods (Lenth, 2018).

To analyze the length and diameter of stems gathered from the fire proxy treated and control shrubs, we developed two gamma distributed GLMMs using the glmmTMB package. Each shrub was set as a random effect in the model, and treatment, pre-treatment shrub height, aspect class, and canopy cover class were treated as covariate fixed effects. We generated models of best fit using backwards selection with Type III Wald Chi Square tests, and produced EMMs to analyze differences in stem lengths and diameters within categorical variables using the Tukey method. Stem length and diameter distributions from our treatment samples were compared with the collections of two basketweavers using a multiple comparison Wilcoxon Rank Sum test (Kabacoff, 2015).

3. Results

The 86 treated hazelnut shrubs produced a total of 923 basketry stems (10.73 per shrub ± 1.02), whereas the 19 control shrubs produced only 20 basketry quality stems (1.05 per shrub ± 0.45). Within the broadcast burned blocks, six shrubs had died while four shrubs were

Table 1
Effects of the fire proxy and broadcast burn treatments (e.g., cut, pile burn, propane, broadcast) on hazelnut basketry stem production compared with the untreated control. Estimated Marginal Mean (EMM) is back-transformed from the log scale and averaged over the values of aspect and canopy classes. The contrast to control ratio is the treatment EMM to untreated control EMM (1.54, SE = 0.60). The confidence intervals, *t*-statistic and *p*-values were generated using the Dunnett method.

Treatment	n	EMM	Contrast to control ratio	Contrast SE	CI	*t* ratio	*p* value
Cut	15	6.45	4.19	1.87	1.38–12.7	3.22	0.0066
Pile Burn	15	10.98	7.13	3.05	2.46–20.7	4.59	0.0001
Propane	15	15.45	10.05	4.16	3.57–28.2	5.57	< 0.0001
Broadcast	41	11.54	7.50	3.07	2.70–20.9	4.92	< 0.0001

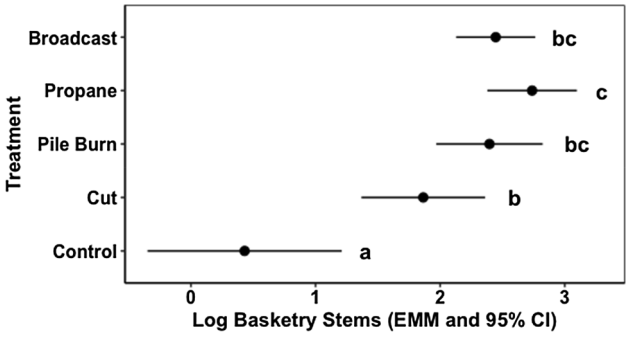

Fig. 6. Fire proxy treatment, broadcast burn, and untreated control effects on hazelnut basketry stem production. Estimated marginal means (EMM) of basketry stems with 95% confidence intervals (log scale) within the control and four fire proxy treatments. Letters indicate significant differences between treatments ($p < 0.05$).

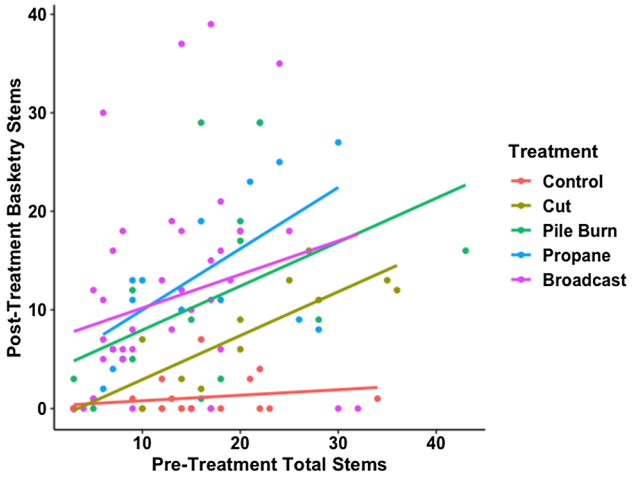

Fig. 7. Pre-treatment total stems (shrub size) positively affect post-treatment basketry stem production. Pre-treatment total stems and post-treatment basketry stems are plotted by treatment with lines of best fit determined by ordinary least squares regression.

unburned and were then included in the untreated (control). All hazelnut shrubs that were treated with either pile burning, propane torching, and, or a prescribed broadcast burn increased the production of basketry stems from 7 to 10-fold in comparison with the shrubs in the untreated controls ($p < 0.001$, Table 1, Fig. 6). However, the quantity of basketry stems per shrub produced by the cut treatment (EMM = 6.5, SE = 1.61) was only 4-fold greater than the untreated controls (EMM = 1.54, SE = 0.60, $p = 0.006$, Table 1). The EMM of the cut treatment was reduced significantly when compared with the EMM of the propane treatment (EMM = 15.45, SE = 2.79, $p = 0.025$, Fig. 6). Basketry stems among the propane, pile burn (EMM = 10.98, SE = 2.36), and broadcast (EMM = 11.54, SE = 1.84) treatments did not exhibit significant differences (all = $p > 0.25$, Fig. 6).

Pre-treatment total stems ($p < 0.001$), aspect class ($p < 0.01$), and canopy cover class ($p < 0.05$) imparted significant effects on basketry stem production in hazelnut shrubs (Wald Type III Chi Square test; Table 2). Shrub size (pre-treatment total stems) and basketry stem production exhibited a strong positive relationship ($p < 0.001$, Fig. 7).

Table 2
Variables affecting basketry stems within study blocks. Results of a Wald Type III Chi Square test on the significance of the treatments (control, cut, pile burn, propane, broadcast), pre-treatment total stems, aspect class, and canopy class on basketry stems generated from a negative-binomial generalized linear mixed model (GLMM). Aspects between 135° and 225° were classed as southern ($n = 56$) and aspects between 45° and 134° were classed as eastern ($n = 49$). Canopy cover ≤50% ($n = 12$) was categorized as 'low', cover ≥51% and < 70% as 'medium' ($n = 63$), and ≥70% as 'high' ($n = 30$). Two additional biophysical variables (deer browse, slope) did not exhibit strong effects on basketry stems ($p > 0.05$) and were removed from the model. Hazelnut shrub blocks ($n = 27$; 16 m^2) are set as random effects.

Fixed effect	χ^2	Df	$p(>\|\chi^2\|)$
Treatment	35.38	4	< 0.001
Pre-treatment total stems	23.11	1	< 0.001
Aspect class	6.99	1	0.008
Canopy class	7.14	2	0.028

Shrubs within eastern aspect classes produced 1.73-fold more basketry stems ($n = 49$, EMM = 9.48, SE = 1.18) than those in southern aspect classes ($n = 56$, EMM = 5.47, SE = 1.19, $p < 0.01$). Within the canopy cover classes, the shrubs within the medium canopy cover class ($n = 63$) produced a 5.08 EMM (SE = 0.86) of basketry stems, whereas shrubs within the high canopy cover class ($n = 30$) produced 1.84-fold greater basketry stems (9.36 EMM, SE = 1.75, $p = 0.03$) than the medium canopy cover class. Shrubs within the low canopy class ($n = 12$) had a 7.87 EMM (SE = 2.00) and did not differ significantly from shrubs in the high ($p = 0.83$) or medium canopy cover classes ($p = 0.27$). Within the initial negative-binomial GLMM, deer browse and slope did not impart significant effects on basketry stem production ($p > 0.05$).

Basketry stem lengths gathered from the treated and control shrubs ranged from 11.00 to 118.60 cm (μ = 43.24, SE = 0.83) and stem diameters ranged from 0.53 to 5.76 mm (μ = 2.30, SE = 0.04, Fig. 8). Basketweaver1 gathered stem lengths ranging 14.10–81.20 cm (μ = 38.97, SE = 0.58), and Basketweaver2 gathered stem lengths ranging 27.80–73.40 cm (μ = 47.76, SE = 1.29, Fig. 8B). From basketweavers' sourced materials, stem diameter ranged from 0.96 to 4.11 mm (μ = 2.13, SE = 0.03) and 1.64–4.45 cm (μ = 2.89, SE = 0.07), respectively (Fig. 8A). The distribution of basketry stem lengths and stem diameters gathered by Basketweaver2 were greater than those gathered by Basketweaver1 as well as those stems harvested from the fire proxy treatment blocks and broadcast burn (Wilcoxon rank sum; $p < 0.001$, Fig. 8). However, similar stem length and diameter distributions were recorded from stems harvested in the fire proxy treatment blocks and broadcast burn as well as those gathered by Basketweaver1 ($p > 0.05$).

Results from the gamma GLMMs showed that pre-treatment shrub heights and aspect classes had a significant affect on basketry stem lengths and diameters from treated and control shrubs. A strong positive relationship was detected between pre-treatment shrub height and

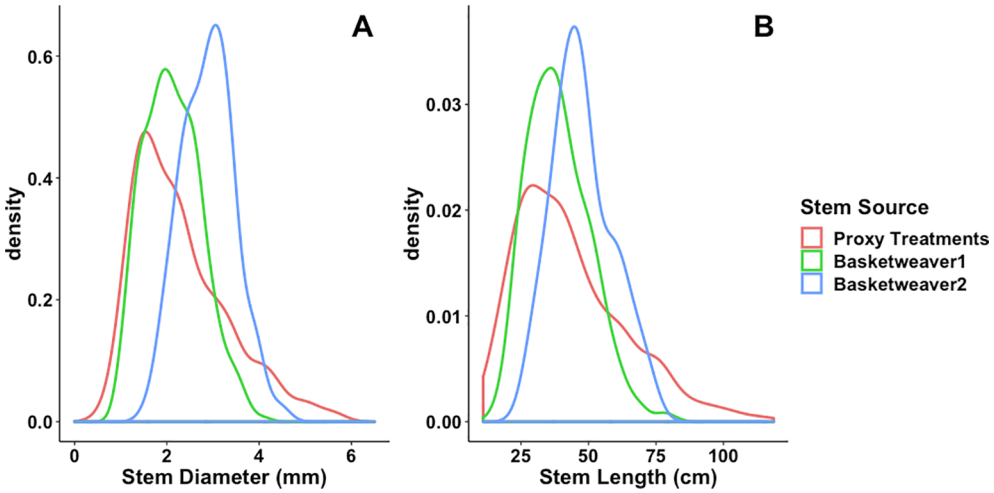

Fig. 8. Treatment effects on hazelnut basketry stem size distributions compared with basketweavers' harvests. Samples were gathered from 46 treated and 4 untreated shrubs (n = 604), and collected by Basketweaver1 (n = 396) and Basketweaver2 (n = 73). Fire proxy treatment and control stem size distributions did not differ significantly from the distributions gathered by Basketweaver1 (Wilcoxon Rank Sum; p = 0.5). However, the stem size distributions from Basketweaver2 differed significantly from all treatments and Basketweaver1, but based on a relatively small sample size (Wilcoxon Rank Sum; p < 0.001). (A) Stem diameter (mm) and (B) stem length (cm). Distributions shown as kernel density plots.

post-treatment stem lengths and diameters (p < 0.001). Shrubs within the southern aspect class produced both shorter length (EMM = 34.4 cm, SE = 1.62) and smaller diameter (EMM = 1.87 mm, SE = 0.08) stems post-treatment than eastern aspects (diameter EMM = 2.52 mm, SE = 0.15; length EMM = 47.6 cm, SE = 2.79, p < 0.001). Between the treated and control shrubs, basketry stem length did not differ significantly. However, the stem diameters harvested from the pile burn (EMM = 2.00 mm, SE = 0.12) and cut (EMM = 2.49 mm, SE = 0.127) treatments were significantly different (p = 0.02). Propane treated stem diameters (EMM = 2.14, SE = 0.11) were nonsignificant in the model (p = 0.15). No discernable effects of canopy cover classes on stem diameter or length were detected.

4. Discussion

The application of three fire proxy treatments and a prescribed broadcast fire treatment indicate that all treatments generated 4–10-fold increases in basketry quality hazelnut stems when compared with the untreated hazelnut shrubs. Untreated (control) hazelnut shrubs contained only 1.54 ± 0.60 basketry stems per shrub, and thus, are deemed marginal, or too limited in value for California Indian basketweavers (Anderson, 1999). Thus, broadcast fires or substitute treatments are required to generate basketry quality stems.

Basketweavers prefer cultural burns to treat hazelnut shrubs for basketry because they efficiently top-kill many hazelnut shrubs relatively rapidly, and thus, create improved gathering rates for basketweavers. Cultural burns also may have positive effects upon additional ecocultural species and may reduce understory fuels. Although our broadcast burn treatment was effective at producing basketry stems, ~15% of broadcast burned hazelnut shrubs died, and thus reduced the basketry stems expected from this treatment. While we did not assess pre-burn surface fuel loads before ignition, the landowner had not previously conducted fire treatments in the broadcast burn area, suggesting that surface fuel loads may have been relatively higher than in a historically, and thus, more frequently burned forest. Decades of fire exclusion increase surface fuel loadings that generate increased fire intensities and shrub mortality during prescribed burns (Kauffman and Martin, 1990; Thaxton and Platt, 2006). In the absence of broadcast burns, pile burning and propane torch burning treatments also are effective methods to top-kill hazelnut shrubs. When creating piles within hazelnut shrubs practitioners may avoid piles with high fuel loads and inordinate fire residence time to prevent shrub mortality resulting from excessive direct heat (Siefkin et al., 2002). Only ~7% of monitored shrubs died from our surface fuel piles when they were composed of 1-h, 10-h, and surface litter fuels with height limited to < 25 cm, but establishing fuel load and fire residence time limits or guidelines through additional research would be useful especially when expanding these applications over large areas.

In contrast to our cutting treatment that focused solely of hazelnut stems, mechanical cutting is widely used by agencies and landowners to create shaded fuel breaks (65–400 m wide) and is typically paired with the pile burning of cut woody debris (Agee et al., 2000; Rhoades and Fornwalt, 2015; Vaillant and Reinhardt, 2017). When burned hazelnut shrubs are unavailable or insufficient basketweavers will gather basketry stems opportunistically within these mechanically created fuel breaks if suitable coppiced hazelnut shrubs occur. However, basketweavers report reduced stem strength or pliability from mechanical treatments compared to burn treatments, which is supported by lower wood-to-pith ratios in these stems (Rentz, 2003). The lower stem quality and reduced expected stem density from cut treatments considerably reduces basketweavers' preference for this treatment.

The four environmental variables we measured (e.g., slope, deer browse, canopy cover, and aspect) appear to explain some of the variation observed in hazelnut basketry stems production. Deer browse occurred on only five of the 105 hazelnut shrubs measured, and thus, in this particular case deer browse was inconsequential. Yet, deer herbivory typically occurs at the axil tip of new basal shoots. Subsequently, the hazelnut shrub typically produces two or more lateral branches below where the apical bud and leaves were eaten, producing an unsuitable basketry stem. Thus, if deer or other ungulate browsers are abundant (e.g., at sites further from private residences), browse could become a major factor in the reduction of basketry stems.

Hazelnut shrubs in the 'high' canopy cover class produced 1.84-fold more basketry stems than those in the 'medium' canopy cover class. These results support Karuk and Yurok basketweavers' experience and observations. Areas with relatively low canopy cover (i.e., 0–20%) and increased light conditions stimulate lateral branching within hazelnut basal resprouts, reducing the potential density of basketry quality stems (Johnson and Marks, 1997; Lake, 2007; Ortiz, 1998). However, the shrubs within the 'low' canopy cover class produced highly variable basketry stems whose EMM was 1.55-fold greater than shrubs in the 'medium' canopy cover class although the EMM did not differ significantly. Only four shrubs in the low canopy cover class had 30% cover, and the remaining eight shrubs in that class were 50% cover, which reflects limitations in both our sampling effort and truncated range of measured canopy cover (30–85%) within a 10 ha sampled area. Given that southern aspects in the northern hemisphere are exposed to additional solar radiation than eastern aspects, shrubs with southern exposures (EMM = 5.48) produced significantly fewer basketry stems than those in eastern aspects (EMM = 9.48, Barbour et al., 1987: 341). Overall, additional sampling of shrub responses to treatments across the full aspect range would improve these analyses and

our understanding.

Plant branching and architectural responses to sunlight are exceptionally diverse and show phenotypic plasticity (Valladares and Niinemets, 2007). In unburned and non-coppiced temperate deciduous understory trees and shrubs, lateral branching can be stimulated by increased light conditions (Bonser and Aarssen, 1994; Canham, 1988; Charles-Dominique et al., 2012; Hamelin et al., 2015; Pickett and Kempf, 1980). California hazelnut appears to change its plant architecture from a sympodial form in full sun to a monopodial form under forest canopies much like the multi-stemmed shrub, *Rhamnus cathartica* (Charles-Dominique et al., 2012). However, more detailed morphological measurements are required to confirm these hazelnut architecture forms.

Aspect class also affected stem length and diameter in the GLMMs analyses. Stems measured from eastern aspects were 1.38-fold longer and 1.35-fold wider compared with those in southern aspects. These results align with basketweaver knowledge that shrubs with full sun exposure produce shorter stems than those under canopy cover. Similarly, the Mediterranean shrub *Arbutus unedo* has been shown to produce taller resprouts post-fire when growing in northern and eastern aspects compared to southern and western aspects (Konstantinidis et al., 2006). However, our observed decrease in viable basketry stems in southern aspects and medium canopy cover should not be misconstrued to suggest that burning should be limited under these site conditions because shrubs under these conditions still produce at least a 5-fold increase in basketry stems as untreated shrubs.

Treatments did not have a detected effect on stem length. However, the cut treatment produced 1.25-fold greater stem diameters than the pile burn treatment. Cut treatments may not induce as much physiological stress or loss of stored energy as compared with burning treatments, and thus, the shrub may have sufficient resources to produce more robust stems with greater diameter. Several studies have found that high severity fires reduce shrub resprouting vigor and biomass compared with low severity fires and cutting treatments (Clarke et al., 2013; Fernández et al., 2013a; Keeley, 2006; Lloret and López-Soria, 1993), however other studies have found that severity does not correlate with resprout vigor in other shrub species (Drewa et al., 2002; Fernández et al., 2013b; Keeley et al., 2008).

Stem diameter and stem length distributions harvested from the treated and control shrubs ($n = 604$), were similar to those harvested from a broadcast burn by Basketweaver1 ($n = 396$). Thus, our fire proxy and broadcast burn treatments appeared to produce stem qualities that are preferred by basketweavers. However, Basketweaver2 harvested a distinctive set of stems. Admittedly, this stem sample from Basketweaver2 is relatively limited ($n = 73$) when contrasted with our treatments and Basketweaver1. Most importantly, basketweavers reported that some basketry projects may require different sets of stem diameters and lengths. Therefore, basketweavers' aims must be considered when comparing hazelnut stem harvesting activities.

Our results demonstrate that expanding the area and frequency of targeted understory fire-based forest treatments on private, public and Tribal lands in the Pacific Northwest and California would generate greater availability and distribution of basketry hazelnut stems that are currently limited in supply and in high demand (Baldy, 2013; Long and Lake, 2018; Ortiz, 1993). Small-scale (≤ 10 ha) application of these fire proxy treatments appears quite feasible both for private landholders or on public lands that would require minimal permitting as well as limited labor and low material costs. The constraints associated with prescribed and cultural burns, such as the limited burning season and increased liability concerns in close proximity to residences within the Wildland Urban Interface, do not necessarily apply to these fire proxy treatments because they can be conducted when prescribed burning conditions are risky or biophysically not possible (e.g., either elevated or low dead surface fuel moisture). Due to these and other constraints, the USDA Forest Service currently is able to implement understory mechanical fuel reduction treatments across a greater area than broadcast burning to reduce fuels in California and the Pacific Northwest (Vaillant and Reinhardt, 2017). Yet, the three fire proxy practices examined here appear to be highly compatible for integration into larger-scale USDA Forest Service, or other fuel treatment programs (≥ 10 ha), and likely would require only minor adjustments to current understory mechanical fuel reduction practices to meet these additional Tribal ecocultural objectives. For example, if the woody debris from these understory mechanical treatments are pile burned, hazelnut burn piles (< 25 cm) or propane torching could be incorporated into this fuel reduction activity, increasing hazelnut stem productivity. Further, hazelnut stems could be included for removal in mechanical understory thinning treatments, if they were initially excluded from the prescription. While Tribal members prefer broadcast burning for ecocultural resource production, they recognize that mechanical understory treatments are necessary to address decades of fire exclusion, and prepare sites for broadcast burning in the near future (USDA Forest Service PSW Region, 2018). If areas of high hazelnut shrub densities are either known or identified in consultation with Tribes and basketweavers, and align with fuel reduction objectives, the subsequent production of basketry stems from mechanical treatments would provide additional benefits to the fuel reduction value of this treatment. Given that hazelnut is distributed across 75% of the NWFP area, limited efforts are required to identify these suitable areas (Long et al., 2018).

Policies that support Tribal consultation within public land agencies offer effective opportunities for increased and effective collaborations and communication in forest management (Bussey et al., 2015; Dockry et al., 2017; Donoghue et al., 2010; Lake et al., 2017). Since this initial experimental study was conducted, prescribed burning and fuel treatments have expanded throughout northwest California, largely as a result of inter-governmental and community partnerships that aim to manage public, Tribal, and private lands (Harling, 2015; Long et al., 2018; USDA Forest Service PSW Region, 2018; Yurok Tribe, 2015).

Throughout this study, we sought to incorporate Indigenous knowledge and participation with 'western' scientific approaches to support these expanding collaborative efforts among Tribal governments and public land agencies. Fire exclusion policies forced California Indian communities and forest managers to curtail their routine cultural and prescribed burning practices. Despite these policies, Karuk and Yurok basketweavers retained their knowledge, maintained their practices and, most importantly, developed several innovative techniques to replicate fire's effects on hazelnut to produce essential basketry materials. To support their efforts, we quantified their hazelnut fire treatment outcomes with the aim to inform managers of their efficacy and material importance, to facilitate increased forest access, and to reduce bureaucratic processes required for Tribal members who seek to employ these fire proxy treatment methods and broadcast burns. Moreover, we encourage efforts to explore creative applications that aim to incorporate these hazelnut fire proxy practices within government-led understory mechanical fuel thinning and large-pile burning treatments. Through such collaborative processes, basketweavers and Tribes may be able to receive financial and logistical support, and, most importantly, recognition and respect for their priorities and experience in managing hazelnut as well as other critical ecocultural resources.

Declaration of Competing Interest

The authors declare no competing interests.

Acknowledgements

We truly appreciate the Karuk and Yurok Tribal Councils for their permission and continuing support to conduct this work on their lands and within their communities. Tribal GIS programs provided mapping data resources. The Orleans-Somes Bar Fire Safe Council, Ben Riggan, and the Karuk Indigenous Basketweavers graciously offered field assistance with burning activities. Our research design benefited

immeasurably from the critical input and generous involvement of Karuk and Yurok basketweavers and gatherers: Elizabeth Azzuz, Laverne Glaze, Chook-Chook Hillman, Lisa Hillman, Robert McConnell, Robert McConnell Jr., Kathy McCovey, Janet Morehead, Bertha Peters, Maggie Peters, Verna Reece, Lillian Rentz, Margo Robbins, Brittany Souza, and Bill Tripp. For their efforts in developing collaborations that facilitated this project, we thank Rebecca Bliege Bird and Douglas Bird. Theresa Alves and Rose Leonard (USDA Forest Service PSW research station Redding lab) assisted with preliminary data analyses. We thank Nels Johnson (USDA Forest Service PSW research station) for providing invaluable statistical contributions. Stanford IRB supported with human subjects approvals (#33064). Two anonymous reviewers provided constructive feedback and suggestions that greatly improved this manuscript.

Financial funds instrumental in the initial development of this project were received from the United States National Science Foundation (NSF)'s Coupled Natural and Human Systems grant (DEB-1232319) to Rebecca Bliege Bird and Curran at Stanford University. For this project and ongoing collaborative programs with the Tribes, Curran and Marks-Block appreciate the financial support from the United States Joint Fire Science Program (#L17AC00214) and NSF Doctoral Dissertation Improvement Grant (1657569). Marks-Block received additional support from a NSF Graduate Research Fellowship (DGE-114747), Stanford's Department of Anthropology, VPGE Diversity Dissertation Research Opportunity, and School of Humanities and Sciences Community Engagement grant.

All opinion, findings, and conclusions or recommendations expressed here are those of the authors and do not necessarily reflect the views of the NSF, USDA Forest Service, or Tribes.

Revitalized Karuk and Yurok cultural burning to enhance California hazelnut for basketweaving in northwestern California, USA

Tony Marks-Block[1*], Frank K. Lake[2], Rebecca Bliege Bird[3] and Lisa M. Curran[4]

Abstract

Background: Karuk and Yurok tribes in northwestern California, USA, are revitalizing the practice of cultural burning, which is the use of prescribed burns to enhance culturally important species. These cultural burns are critical to the livelihoods of indigenous peoples, and were widespread prior to the establishment of fire exclusion policies. One of the major objectives of cultural burning is to enhance California hazelnut (*Corylus cornuta* Marsh var. *californica*) basketry stem production for Karuk and Yurok basketweavers. To evaluate cultural burning as a form of human ecosystem engineering, we monitored hazelnut basketry stem production, qualities, and shrub density in 48 plots (400 m^2) within two prescribed and 19 cultural burn sites. Socio-ecological variables that were analyzed included burn frequency, burn season, overstory tree (≥10 cm diameter at breast height) basal area, ungulate browse, and aspect. We also observed basketry stem gathering to compare travel distances, gathering rates, and basketweaver preferences across sites with different fire histories and land tenure.

Results: Hazelnut shrubs, one growing season post burn, produced a 13-fold increase in basketry stems compared with shrubs growing at least three seasons post burn ($P < 0.0001$). Basketry stem production and stem length displayed negative relationships with overstory tree basal area ($P < 0.01$) and ungulate browse ($P < 0.0001$). Plots burned at high frequency (at least three burn events from 1989 to 2019) had 1.86-fold greater hazelnut shrubs than plots experiencing less than three burn events ($P < 0.0001$), and were all located on the Yurok Reservation where land tenure of indigenous people is comparatively stronger. Basketweavers travelled 3.8-fold greater distance to reach gathering sites burned by wildfires compared with those that were culturally burned ($P < 0.01$). At cultural burn sites, wildfire sites, and fire-excluded sites, mean gathering rates were 4.9, 1.6, and 0.5 stems per minute per individual, respectively.

(Continued from previous page)
Conclusions: Karuk and Yurok cultural fire regimes with high burn frequencies (*e.g.,* three to five years) promote high densities of hazelnut shrubs and increase hazelnut basketry stem production. This improves gathering efficiency and lowers travel costs to support the revitalization of a vital cultural practice. Our findings provide evidence of positive human ecosystem engineering, and show that increasing tribal sovereignty over fire management improves socio-economic well-being while at the same time supports measures of ecosystem structure and function.

Resumen

Antecedentes: Las tribus Karuk y Yurok del noroeste de California, EEUU, están revitalizando la práctica cultural de quemas, que es el uso del fuego prescripto para aumentar las especies culturalmente importantes. Estas quemas culturales son críticas para sustentar la vida de los pueblos indígenas, y fueron sumamente extendidas antes del establecimiento de las políticas de exclusión del fuego. Uno de los principales objetivos de las quemas culturales es aumentar la producción de tallos del avellano de California (*Corylus cornuta* Marsh var. *californica*) que es usado para la construcción de cestos por los fabricantes de cestos (cesteros) de las tribus Karuk y Yurok. Para evaluar las quemas culturales como una forma de ingeniería ecosistémica, monitoreamos la producción de cestos realizados con tallos de avellano, la calidad y densidad de esos tallos, en 48 parcelas (400 m^2) dentro de dos quemas prescriptas y en 19 lugares con quemas culturales. Las variables socio-ecológicas que fueron analizadas incluyeron la frecuencia de quemas, la estación de quemas, el área basal (≥10 cm de diámetro a la altura del pecho) de árboles del dosel superior, el ramoneo por ungulados, y la exposición. Observamos asimismo el lugar de colección de los tallos para comparar distancias recorridas, tasas de recolección, y las preferencias de quienes fabrican los cestos a través de sitios con diferentes historias de fuego y tenencia de la tierra.

Resultados: Una estación luego del fuego, los arbustos de avellano de California produjeron un incremento de 13 veces la producción de tallos factibles de ser usados en cestería comparados con arbustos creciendo al menos tres estaciones post fuego ($P < 0.0001$). La producción y el largo de los tallos desarrollaron relaciones negativas con el área basal de árboles del dosel superior ($P < 0.01$) y el ramoneo de ungulados ($P < 0.0001$). Las parcelas quemadas a alta frecuencia (al menos tres eventos de fuego de 1989 a 2019) tuvieron 1,86 veces más arbustos de avellano que aquellas parcelas que experimentaron menos de tres eventos de fuego ($P < 0.0001$), y fueron todos ubicados en la reservación de Yurok, donde la tenencia de la tierra por parte de la comunidad indígena es comparativamente más fuerte. Los fabricantes de cestos viajaron distancias 3,8 veces más largas para alcanzar lugares quemados por fuegos naturales comparados con aquellos que fueron sujetos a quemas cultuales prescriptas ($P < 0.01$). En los sitios quemados por prácticas culturales, por incendios naturales u aquellos lugares excluidos de fuegos, el tiempo promedio de recolección fue de 4,9, 1,6, y 0.5 tallos por minuto por individuo, respectivamente.

Conclusiones: Los regímenes de quemas culturales por parte de las tribus Karuk y Yurok con altas frecuencias de quema (*e,g,* de tres a cinco años), promueven una alta densidad de arbustos de avellano e incrementan la producción de tallos para cestería. Esto mejora la eficiencia en la recolección y reduce los costos del viaje, lo que ayuda a la revitalización de una práctica cultural vital. Nuestros hallazgos proveen evidencias positivas de ingeniería ecosistémica humana, y muestran que el incremento de la soberanía tribal sobre el manejo de fuego mejora las condiciones de bienestar socio-económico, mientras que al mismo tiempo aportan a la estructura y el funcionamiento del ecosistema.

Background

Across diverse ecosystems worldwide, prescribed burning by indigenous peoples, known colloquially as cultural burning, has been shown to impart positive effects on human and ungulate foraging returns, habitat diversity, and species abundance as well as the mitigation of wildfire spread by reducing fuel loads and fire intensities (Laris 2002; Bilbao et al. 2010; Bliege Bird et al. 2012; Fowler 2012; Seijo et al. 2015). Given the substantial shifts in ecosystem functioning generated by cultural burning practices of indigenous peoples, several authors have suggested that these practices provide critical ecosystem engineering functions that generate or maintain a distinctive suite of non-human species and

communities adapted to the pyrodiversity created by indigenous peoples' fire regimes (Jones et al. 1994; Smith 2011; Bliege Bird et al. 2013; Odling-Smee et al. 2013).

In California, USA, fire serves as a critical biophysical process (Sugihara et al. 2018). Preceding Spanish and American colonialism, fires set by California Indians imparted profound ecological effects by reducing fire severity and fuel continuity (Mallek et al. 2013; Taylor et al. 2016). These cultural fires enhanced California Indian subsistence and ceremonial resources and, thus, are integral to the culture and economy of California Indians (Lightfoot and Parrish 2009; Anderson 2018). However, in 1905, the USDA Forest Service initiated fire exclusion policies to protect timber commodities and built structures, and by the 1920s, these policies had solidified throughout the State of California to exclude cultural burning (Pinchot 1905; Ayres and Hutchinson 1931; Clar 1959; Cermak 2005). Fire exclusion policies reduced indigenous peoples' cultural burning practices and limited the availability of their key ecocultural resources (Huntsinger and McCaffrey 1995; Aldern and Goode 2014; Eriksen and Hankins 2014; Lake et al. 2017; Norgaard 2019). By the 1990s, US federal land management agencies revised their fire policies to recognize the potential benefits of prescribed fires as a management tool, generating opportunities to revive indigenous people's cultural burning practices (Butler and Goldstein 2010; Long and Lake 2018; Stephens and Sugihara 2018).

In northwestern California, indigenous peoples such as the Karuk, Yurok, and Hoopa Valley tribes (AKA Hupa), are leading efforts to re-introduce cultural burning by forming partnerships with public land and fire agencies as well as non-governmental organizations (Underwood et al. 2003; Levy 2005; Salberg 2005; Long and Lake 2018). In 2013, institutional support for cultural burning in northwestern California was initiated through the Prescribed Fire Training Exchanges (TREX; Terence 2016), and, in 2014, the Six Rivers National Forest began the Roots and Shoots project on the Lower Trinity, Orleans, and Ukonom ranger districts (Colegrove 2014). The TREX program falls under the Promoting Ecosystem Resilience and Fire Adapted Communities Together agreement between the USDA Forest Service and The Nature Conservancy that invests in cooperative and collaborative burning on private, tribal, and public lands across the United States (Butler and Goldstein 2010; Spencer et al. 2015). In Karuk and Yurok territory, TREX provides financial and logistical support to develop burn plans, process permits, supply equipment, and mobilize fire personnel to support intergovernmental, inter-agency, and civil society partnerships. (Harling 2015; Terence 2016). The Roots and Shoots project is a Six Rivers National Forest effort developed by the USDA Forest Service and Tribal members to burn 176 acres within 25 forest areas containing ecocultural resources integral to indigenous peoples (Colegrove 2014).

While cultural burns are utilized in different seasons and at different scales and intensities for a wide range of ecocultural species (Hankins 2013), in recent decades, one of the major objectives for conducting cultural burns in Karuk and Yurok ancestral territories (Fig. 1) has been to enhance the production of basketry materials for indigenous basketweavers (Hunter 1988; Ortiz 1998; Senos et al. 2006). California Indians use baskets in a wide range of contexts: child-rearing; food harvesting, processing, and storage; for everyday clothing; and in ceremonies (Johnson and Marks 1997; Bibby 2004; Shanks 2006; Mathewson 2007). Baskets are also economically important, sold both within and outside the indigenous community to supplement income (Cohodas 1997; Smith 2016). In turn, baskets provide spiritual connections to land and ancestors, through the materials used as well as the form of the basket design (Lang 1994; Johnson and Marks 1997; Smith 2016). Northwestern California Indian basketweaving exists as one of many manifestations of socio-ecological relationships within this fire-dependent culture (Lang 1991; Hillman and Salter 1997; Buckley 2002; Smith 2016; Baldy 2018).

One of the most highly valued and critically important species for basketweaving is California hazelnut (*Corylus cornuta* Marsh var. *californica*; Ortiz 1993; 1998; Smith 2016), a multi-stemmed, deciduous shrub. Hazelnut stems are integral to the weaving of baby baskets (cradles), which are composed of ~300 stems and currently are sold for ~$800. As Maggie Peters, a Yurok basketweaver, shared, "These baskets are in high demand by northwest California Indian families who want their children to begin their lives in a cultural way." Cultural burns for hazelnut are designed to manipulate the post-fire growth response of California hazelnut, stimulating it to re-sprout from underground buds (Fryer 2007; Clarke et al. 2013), and to produce straight, unbranched shoots suitable for use in basketweaving. Historically, cultural burning for hazelnut basketry stems occurred predominantly in the summer and fall months, although occasionally in the spring (Lake 2007). Hazelnut stem regrowth would then be harvested in the following spring (April and May) after one full growing season (spring burn, ten to12 months post burn; fall burn, 18 to 21 months post burn; Thompson 1991; O'Neale 1932; Lake 2007).

From the 1920s to the 2000s, fire exclusion policies and regulations against cultural burning increased the scarcity of suitable basketry stems for basketweavers (Heffner 1984; Ortiz 1993; Smith 2016). In response, some basketweavers developed alternative techniques to stimulate the

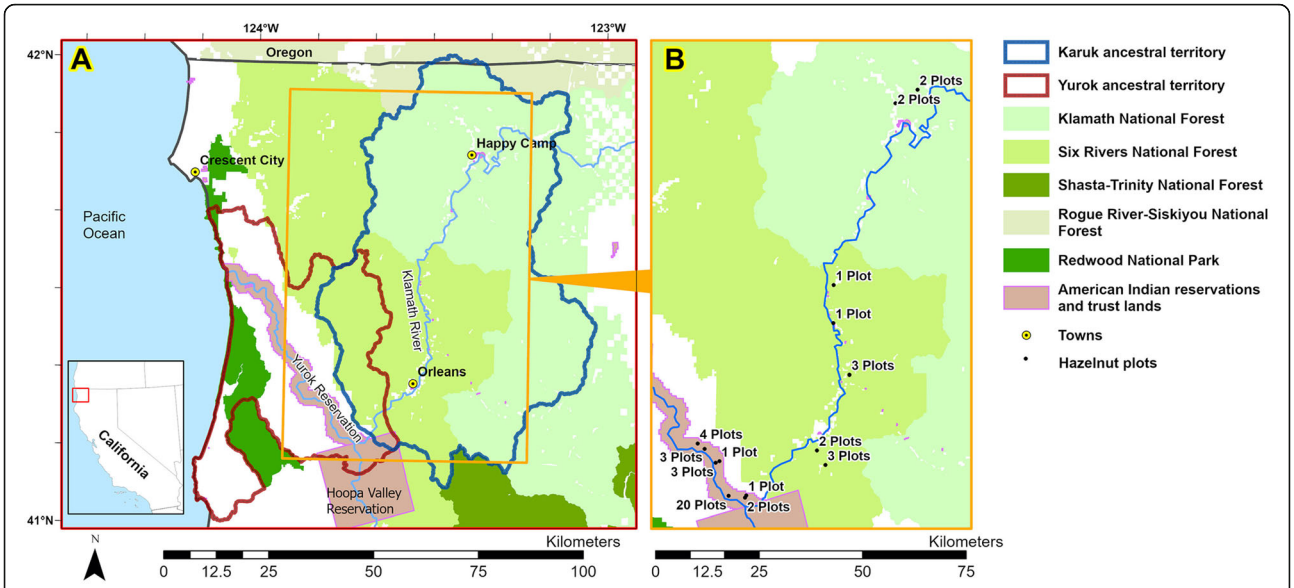

Fig. 1 (**A**) Study region with federal jurisdictional boundaries and Karuk and Yurok ancestral territories, northwestern California, USA. Ancestral territory boundaries, provided by the Karuk and Yurok Tribes, represent reconstructions, but currently are not fixed or rigid boundaries. Ancestral lands of other northwestern California Tribes (*e.g.,* Tolowa, Wiyot, Hupa, Shasta) are not included here, but their ancestral lands may partially overlap with the boundaries rendered here (Baumhoff, 1963). (**B**) Hazelnut monitoring plot locations. Forty-eight plots (each 400 m^2) were established and monitored at two prescribed burn sites and 19 cultural burn sites in Karuk and Yurok territory (2015 to 2019)

growth of hazelnut basketry stems, such as cutting (coppicing), propane torch burning, and pile burning (Heffner 1984; Hunter 1988; Ortiz 1998; Marks-Block et al. 2019). Others were able to maintain burning for basketry materials—albeit in limited areas—throughout the fire exclusion era (Bower 1978; Heffner 1984; Hunter 1988; Ortiz 1998). With the relatively recent expansion of cultural burning in this region initiated by TREX and the Roots and Shoots initiatives, opportunities emerged to evaluate the effects of cultural burning on hazelnut basketry stem production, shrub density, and basketweaver stem harvesting across sites with distinctive fire regimes and land tenure arrangements: for example, between sites with relatively short burning intervals in recent decades (*i.e.,* every three to ten years) in Yurok territory, and at sites in Karuk territory that only recently have been burned after years of fire exclusion.

Our study was motivated by three broad questions. First, is cultural burning by indigenous peoples a form of ecosystem engineering that has positive feedback on ecological and cultural processes? If so, we expected that cultural burning may increase basketry stem productivity, hazelnut shrub density, or reduce the harvesting costs (in search, collection, and travel time) of gathering suitable stems. Basketweaver ecological knowledge and previous experimental studies (O'Neale 1932; Ortiz 1998; Anderson 1999; Lake 2007; Marks-Block et al. 2019) led us to predict that basketry stem production and quality are affected by time since fire and shrub size (*i.e.,* shrub stem densities), and that burn characteristics (*e.g.,* season, severity, and frequency) and site characteristics (*e.g.*, canopy closure or solar access, aspect, forest stand structure, and deer browse) may be other important factors.

Second, does cultural burning alter species' assemblages, such that in the absence of such fire perturbation, plant communities may shift to alternative stable states (Beisner et al. 2003)? We hypothesized that repeated, short-interval cultural burning acts as a beneficial, culturally desired perturbation in hazelnut groves, and that cultural burning maintains high shrub densities and other forest stand characteristics (*e.g.,* relatively low overstory basal area; Anderson 1999; 2018). Following this, if burning is inconsistent or absent, then hazelnut vigor was expected to decline with reduced densities and basketry stems post burn.

Third, how does fire and resource governance in precolonial and contemporary contexts affect cultural fire geography, basketry stem availability, and gathering practices? Here, we examined how centralization in governance structures (Larson and Soto 2008) as well as differences in land tenure (Huntsinger and Diekmann 2010; Norgaard 2014) affected fire-enhanced resource use in Karuk and Yurok territory. We predicted that distinctive Karuk and Yurok land tenure history and current resource access configurations likely influence hazelnut basketry stem gathering decisions. These histories and configurations affect cultural fire frequencies, hazelnut shrub densities, and site productivity that also affect gathering rates of hazelnut basketry stems and travel

distance to gathering sites. The use of these rates and metrics were informed by human behavioral ecology and foraging theory, which suggested that resource acquisition decisions were informed by micro-economic costs and tradeoffs (Stephens and Krebs 1986; Winterhalder and Smith 2000) as well as property regimes and land tenure (Smith 1988; Aswani 1998).

Methods

Study area

Our study area was the 1919 km^2 ancestral territory of the Yurok Tribe and the 2728 km^2 ancestral territory of the Karuk Tribe (Fig. 1; Waterman 1920; Baumhoff 1963) in the mid-Klamath watershed of California. Settlements historically were concentrated along the Klamath River and the Pacific coast (Waterman 1920; Kroeber 1936), and hunting and gathering grounds for critical ecocultural resources were owned and tended by either families or individuals (Waterman 1920; Bettinger 2015). Today, the Yurok and Karuk tribes include approximately 6000 to 7000 members, and make up two of the most populous federally recognized tribes in California (currently 109 tribes; United States Census Bureau 2010). In Karuk territory, the federal government did not establish a reservation or ratify treaties, but instead unilaterally created Forest Reserves in the majority of their territory that are now the Klamath and Six Rivers national forests (Rawls 1986; Davies and Frank 1992; Conners 1998; Miller 2017). Currently, the Karuk Tribe has merely 3.83 km^2 of their ancestral territorial lands held in trust by the federal government, with the remainder largely under the jurisdiction of the USDA Forest Service and scattered private homesteads (Fig. 1; Davies and Frank 1992; Norgaard 2014; US Census Bureau 2017). In Yurok territory, multiple overlapping jurisdictions occur, including Redwood National Park (192 km^2; Underwood et al. 2003) and Six Rivers National Forest (577 km^2) outside of the reservation established by the federal government. The reservation is located along a 1.6 km buffer following the Klamath River from its estuary to ~80 km upriver near the confluence of the Klamath and Trinity rivers (~225 km^2; Huntsinger and Diekmann 2010). However, 106 km^2 (47%) of the reservation is under private timber company ownership (Yurok GIS Program 2015). While we did not formally collaborate with the neighboring Hoopa Valley Tribe, several Hoopa Tribal members collaborated on this project.

The Cultural Fire Management Council (CFMC) organizes cultural burns within Yurok territory, and all members are either basketweavers or have basketweavers within their families. When deciding and planning burn locations with limited resources, the presence of hazelnut groves increases the ranking of a potential CFMC burn site. The Hoopa Valley Fire Department also conducts burns for hazelnut stems (Salberg 2005), and the Karuk Tribe works directly with the Forest Service, the Orleans/Somes Bar Fire Safe Council, and private landowners to burn hazelnut groves (Senos et al. 2006; Long and Lake 2018).

Hazelnut basketry stem measurements and surveys

To evaluate whether cultural burning generates positive feedback to tribal members in the form of increased hazelnut basketry stem production, stem quality, and hazelnut shrub density, we established and monitored 48 20 × 20 m plots (each plot = 400 m^2) from January 2015 to March 2019. Given the unpredictability of cultural burns, plots were established when we learned of recent and potential burn locations. Limited resources and environmental variability prevented all plots and shrubs from being burned within and across burn sites each year.

Plots were placed in relatively high-density hazelnut groves (≥10 shrubs) within two prescribed burn sites and 19 cultural burn sites (Fig. 1). Plots were located >2 m from roads and fire control lines and established after identifying easily accessible hazelnut groves from burn unit perimeters or game trails. Multiple plots (two to five) were placed within burn units that contained numerous hazelnut groves to evaluate the effects of environmental heterogeneity on basketry stem productivity within those locations. After the plot was established, site aspect was measured with a compass and classed as: east (67.5° to 112.5°), southeast (112.5° to 157.5°), south (157.5° to 202.5°), southwest (202.5° to 247.5°), or west (247.5° to 292.5°). Slope and elevation were measured using a global positioning system. Canopy closure measurements were taken facing inward at the four corners of each plot using a spherical densiometer, and then averaged (Lemmon 1956; Fiala et al. 2006). Basal area of each plot was determined by measuring all trees (>10 cm diameter at breast height [dbh]) with the dominant overstory tree species designated by proportional basal area: black oak (*Quercus kelloggii* Newb.), Pacific madrone (*Arbutus menziesii* Pursh), bay laurel (*Umbellaria californica* [Hook. & Arn.] Nutt.), Douglas-fir (*Pseudotsuga menziesii* [Mirb.] Franco), and ponderosa pine (*Pinus ponderosa* Douglas ex Lawson & C. Lawson), and subsequently classified as conifer or broadleaf hardwood.

Plot surveys

In each plot, we recorded individual hazelnut shrub density; due to its multi-stemmed growth habit, a shrub was considered a single individual if it was a minimum of 15 cm from other shrubs. We randomly selected and tagged ten shrubs for long-term monitoring. We counted quality basketry stems and total stems in each of the ten tagged shrubs. We defined suitable quality basketry stems as straight and unbranched stems >10 cm in length. After the plot was established, we recorded and re-sampled shrub stem data every year in the dormant season (October to April), as

dormant stem morphology does not change until budbreak and gathering season in April or May. We grouped our hazelnut shrub and stem measurements according to growing seasons post burn based on a May to September growing season each year. We developed three post-burn temporal classes: one growing season post burn (5 to 20 months; n = 302 shrubs); two growing seasons post burn (21 to 30 months; n = 144 shrubs); and ≥3 growing seasons post burn (>31 months, n = 507 shrubs). The burn season affected the post-burn growing season time span before our post-burn survey because winter- and spring-burned shrubs re-sprouted quickly after the burn, whereas summer- and fall-burned shrubs did not re-sprout until the following spring. Given basketweaver interest in the effects of seasonality of burning on hazelnut stem re-growth, we classified burn season by Julian day, defining winter as days 355 through 78, spring as days 79 through 171, summer as days 172 through 265, and fall as days 266 through 354.

Because plant growth is influenced by prior rainfall, we also compiled precipitation (cm) records for a 12-month period beginning in August of the year preceding the survey from the closest Remote Automated Weather Station (RAWS) to the plot (Yurok, Slate Creek, Somes Bar, Dutch-Indy, and Slater Butte, California; https://raws.dri.edu/ncaF.html). We compiled fire frequency data (burn events from 1989 to 2019) within each plot to evaluate effects on shrub density. Fire frequency was converted into a dichotomous variable: less than three burn events or at least three burn events and was ascertained through conversations with landowners and fire managers, and by examining the California Department of Forestry and Fire Protection's prescribed fire GIS database (https://frap.fire.ca.gov/mapping/gis-data/).

One growing season post-burn surveys

Given that basketweavers prefer to gather in areas burned after only a single growing season, typically in April or May (10 to 20 months post burn), we recorded additional data from shrubs and plots (n = 36) within the one growing season post-burn temporal class. Because basketweavers select basketry stems based both on their diameter and length, we recorded the length of the longest basketry stem in each shrub, and we took the average of the largest and smallest diameters of basketry stems in each shrub. We also recorded the proportion of stems browsed by deer, elk, and other ungulates for each shrub, and the post-burn char height on trees (>10 cm dbh) to the nearest 0.5 m to evaluate whether fire severity affected hazelnut stem re-growth.

Hazelnut stem gathering observations

To supplement our ecological surveys, we monitored hazelnut basketry stem gathering to evaluate whether land tenure and fire governance differences as well as fire type (wildfire and cultural fire) effect resource acquisition decisions in Karuk, Yurok, and Hupa territories. From 2015 to 2019, we developed working collaborative relationships with basketweavers and hazelnut stem gatherers by attending 13 cultural fire planning meetings and 15 basketweaving classes, and by discussing our research interests at Karuk and Yurok Tribal government meetings. Through these collaborative exchanges, we attended hazelnut stem gathering trips, and requested and collected six gathering diaries from three basketweavers to evaluate where and why basketweavers select hazelnut stem gathering areas. Moreover, we conducted 13 in-depth semi-structured interviews (30 to 60 minutes per interview) with Karuk and Yurok resource users and seven fire managers about fire-enhanced resource use and cultural burning that included questions on hazelnut burning, hazelnut stem and nut gathering, basketweaving, and the type of property ownership at burn sites. Interviewees were identified and recommended by Karuk staff in the Department of Natural Resources and Yurok leaders on the Tribe's culture committee. The Karuk and Yurok Tribal councils and the Stanford University Institutional Review Board (IRB) approved these human subjects methods, and individuals provided consent to record gathering practices and statements surrounding hazelnut stem gathering.

During hazelnut stem gathering season (April and May of each year from 2015 to 2019), we attended 17 hazelnut stem gathering trips, during which we observed individuals gathering hazelnut stems and asked semi-structured and open-ended questions regarding basketry stem quality, basketweaver gathering site and stem preferences, and the availability and accessibility of hazelnut

Fig. 2 Three generations of Yurok Indians gathering hazelnut basketry stems at a cultural burn site near Weitchpec, California, USA (left to right): Phillis Donahue (mother), Chris Peters (son), and Nicki Peters (granddaughter). Cultural fires generate significant resources to sustain Karuk and Yurok basketweaving. Photo credit: F.K. Lake, taken *circa* 2010. Each of the three people in the photograph gave permission for their image to be used by the authors

basketry stems. Gathering hazelnut stems is an intergenerational activity that brings together friends and relatives, and basketweaving teachers and their students (Fig. 2). From 2015 to 2019, 90 people were observed gathering hazelnut stems. Observed hazelnut basketry stem harvesters were 75% women, and, on average, gathered in groups of three (range = 1 to 8 individuals). The majority (57%) of 30 gathering groups were intergenerational, with a mix of elders (>60 years), middle-aged gatherers (25 to 60 years), and youth (<25 years), and 66% of groups were composed of basketweaver mentors and their students (including familial mentorships). Of the 72 recorded gathering trips, those made by family-member groups were most common (63%), whereas trips made by groups of friends (21%), and trips made by individuals (17%) were less frequent.

During these trips, the sum of an individual's harvested stems and their time spent in a hazelnut grove were recorded to produce 55 independent gathering rates. Distances to hazelnut stem gathering areas recorded from these trips and from basketweaver reports were converted to a standard 80 km hr^{-1} rate, chosen conservatively due to winding mountainous roads with a 55 miles per hour (88 km hr^{-1}) automobile speed limit. The gathering site's fire history was also recorded and then classified either as a cultural fire site, wildfire site, or a fire-excluded site. We also recorded the site's land ownership (USDA Forest Service, private, or tribal) along with ancestral territory (Karuk, Yurok, Hupa) of the gathering site, and categorized site quality as relatively good or poor based on basketweaver post-harvest evaluations. From these data, we generated simulations of hazelnut stem foraging that included searching and gathering rates within cultural fire sites, wildfire sites, and unburned sites.

Statistical methods

To evaluate the effects of growing seasons post burn on hazelnut basketry stem production (quantity of basketry stems per shrub), we employed a negative-binomial generalized linear mixed model (GLMM) using the `glmmTMB` package in R (R Core Team 2014; Magnusson et al. 2017) and used Type III Wald Chi Square tests using the `car` package (Fox and Weisberg 2018) to perform backward model selection. Growing season post burn (class), aspect (class), elevation (meters above sea level), sample year, basal area (>10 cm dbh), precipitation (cm), dominant overstory tree (>10 cm dbh), and slope (degrees) were modeled as co-variate direct effects, and each plot was set as a random effect.

Given basketweaver preferences for harvesting stems one growing season post burn, we developed another negative-binomial GLMM that applied only to 30 plots surveyed one growing season post burn. Then, we performed a backward model selection process and analyzed additional variables. The initial model set the plot as a random effect and included the following direct effects as covariates: proportion of ungulate browse, burn char height, burn season (winter, spring, summer, and fall), pre-burn total stems, precipitation, canopy closure, basal area (>10 cm dbh), elevation, aspect (east, south, southwest, and west), dominant overstory tree (>10 cm dbh), sample year (2015 to 2019), and slope.

To assess the density of hazelnut shrubs, we applied a multi-variate gamma generalized linear model (GLM) using Type III Wald Chi Square tests to perform backward model selection using the `car` package in R (Fox and Weisberg 2018). Burn frequency (either less than three burn events or at least three burn events from 1989 to 2019), basal area (>10 cm dbh), canopy closure, dominant overstory tree (>10 cm dbh), elevation, aspect, and slope were all evaluated as potential explanatory variables. A univariate gamma GLM was also used to compare the relationship between basal area and shrub density, and a Wilcoxon rank sum test was employed in R (R Core Team 2014) to evaluate the relationship between territory (Karuk and Yurok) and shrub density.

To examine average stem diameter and length of basketry stems within shrubs surveyed after one growing season post burn, we selected gamma distributed GLMMs, as length and diameter distributions were skewed toward smaller sizes. Potential explanatory variables that were treated as direct effects in the initial stem diameter model were: basal area (>10 cm dbh), plot canopy closure, annual precipitation, aspect, slope, dominant overstory tree (>10 cm dbh), and burn season (*e.g.,* fall, winter, spring, summer). These explanatory variables were then included in the initial stem length model with the addition of ungulate browse proportions. As with other GLMMs, the plot was set as a random effect, and Type III Wald Chi Square tests were used to perform backward model selection.

Model diagnostics were analyzed using the `DHARMa` package in R (Hartig 2019). To analyze the differences within categorical predictor variables that showed significance in the GLMMs, estimated marginal means ($\bar{x}$) were generated and then 95% confidence intervals were compared using the Tukey method using the `emmeans` package (Lenth 2018). Estimated marginal $\bar{x}$ values for categorical values are averaged over the values of other significant model co-variates, which helps account for imbalances in sampling effort. The `sjPlot` package (Lüdecke 2019) was used to analyze and visualize the effects of significant continuous predictor variables in the GLMMs.

Foraging gains from basketweaver gathering trip observations were modeled as logistic functions using the `growthcurver` package in R (Sprouffske and Wagner 2016) based upon assumptions of the marginal value theorem and foraging theory that predict diminishing gathering returns resulting from the depletion of basketry stems through harvesting (Charnov 1976; Stephens and Krebs 1986).

Across observed gathering sites, we evaluated associations between gathering site fire type (wild, cultural) and territory (Karuk, Yurok, Hupa) by employing Pearson's Chi-square (χ^2) test of independence using R statistical software (R Core Team 2014). Separately, the travel distances to hazelnut gathering sites within cultural burn, wildfire, and unburned (fire excluded) locations were compared in R using a Wilcoxon rank sum test.

Results

Hazelnut basketry stem productivity

We found that fire strongly increased basketry stem productivity, but the effect declined rapidly over time (Fig. 3). Hazelnut shrubs one season post burn produced a 13-fold increase in basketry stems (estimated marginal $\bar{x}$ = 10.776, SE = 0.87), compared to shrubs three or more growing seasons post burn (estimated marginal $\bar{x}$ = 0.801, SE = 0.08), and six times more stems than shrubs two growing seasons post burn (estimated marginal $\bar{x}$ = 1.807, SE = 0.25, Fig. 3). Other covariates also emerged as important predictors: stem production declined with overstory tree basal area (Fig. 4), while sample years exhibited significant differences in basketry stems due to imbalances in yearly burning (χ^2 = 19.9, df = 4, P < 0.001).

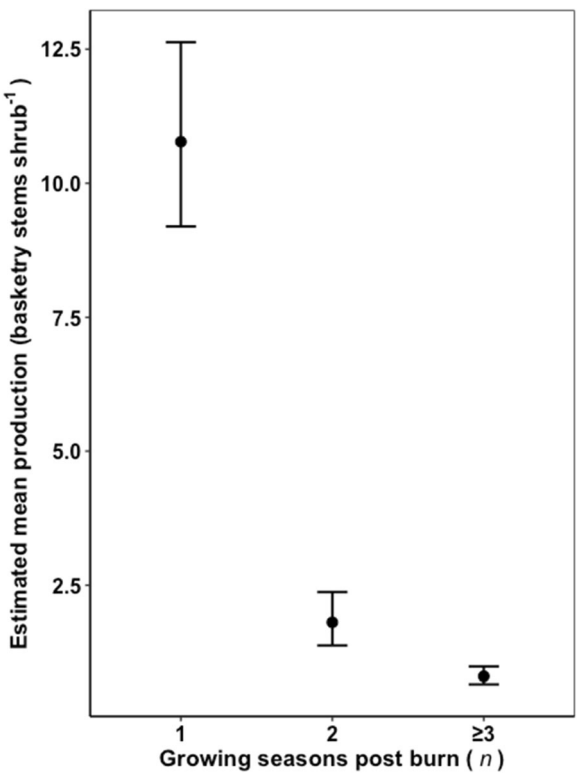

Fig. 3 Hazelnut basketry stem production (plus 95% confidence interval) with growing seasons post burn (2015 to 2019) in Karuk and Yurok territory, northwestern California, USA. Estimated marginal means are based on values generated from a negative-binomial generalized linear mixed model, and averaged over sample years due to imbalances in the data

Considering only shrubs growing one season post burn, a number of covariates significantly predicted basketry stem productivity (Table 1). Shrub vigor, measured by pre-burn total stems, had a strong positive relationship on basketry stem production (Table 1), whereas ungulate browse reduced basketry stems (estimate = −0.706, SE = 0.146, Z = −4.826; Fig. 5; Table 1). Burn season and aspect class also emerged as significant covariates in the single season post-burn model of best fit (Table 1).

Hazelnut shrub density

Hazelnut shrub density within plots was affected by burn frequency, aspect, and elevation (Table 2). Plots that were burned at least three times from 1989 to 2019 had 1.86 times more individual shrubs than plots burned less than three times (Fig. 6). Plots within eastern aspects had 2.2-fold higher density of hazelnut shrubs (estimated marginal $\bar{x}$ = 93.5, SE = 18.33) than those growing in southern (estimated marginal $\bar{x}$ = 43.5, SE = 3.99) and southwestern aspects (estimated marginal $\bar{x}$ = 42.5, SE = 4.86, P < 0.001; Table 2). Shrub densities also decreased with increased elevation (range = 170 to 934 m a.s.l, estimate = 0.000024, SE = 0.0000115, t = 2.13, P < 0.05; Table 2). Although territory was not a significant covariate in the multi-variate gamma GLM, shrub densities in Yurok territory were 2.19-fold greater than shrub densities within Karuk territory (Wilcoxon test statistic = 74, P < 0.001; Fig. 6). Additionally, overstory tree basal area was nonsignificant in the gamma GLM, but displayed a negative relationship with shrub density in univariate analysis (estimate = −0.00019, SE = 0.00007, t = 2.67, P < 0.05).

Basketry stem length and diameter

Basketry stem length and diameter was affected by burn season. Summer burns produced larger stem diameters (estimated marginal $\bar{x}$ = 4.54 mm, SE = 0.32) when compared with spring (estimated marginal $\bar{x}$ = 3.08 mm, SE = 0.25, P = 0.003) and winter burning (estimated marginal $\bar{x}$ = 3.64 mm, SE = 0.25, P = 0.037; Fig. 7). Spring burns also produced shorter stem lengths than all other burn seasons (estimated marginal $\bar{x}$ = 0.524 m, SE = 0.057, P < 0.05). The diameter and length of stems had an inverse relationship with overstory tree basal area (>10 cm dbh, P < 0.01; Figs. 7 and 8), and the proportion of ungulate browse was negatively correlated with stem length (estimate = −0.357, SE = 0.102, Z = −3.49, P < 0.001) in the gamma generalized linear mixed model. Furthermore, stems growing beneath canopies dominated by hardwoods were significantly longer (estimated marginal $\bar{x}$ = 0.83 m, SE = 0.062) than stems growing beneath coniferous canopies (estimated marginal $\bar{x}$ = 0.65 m, SE = 0.051; Fig. 8).

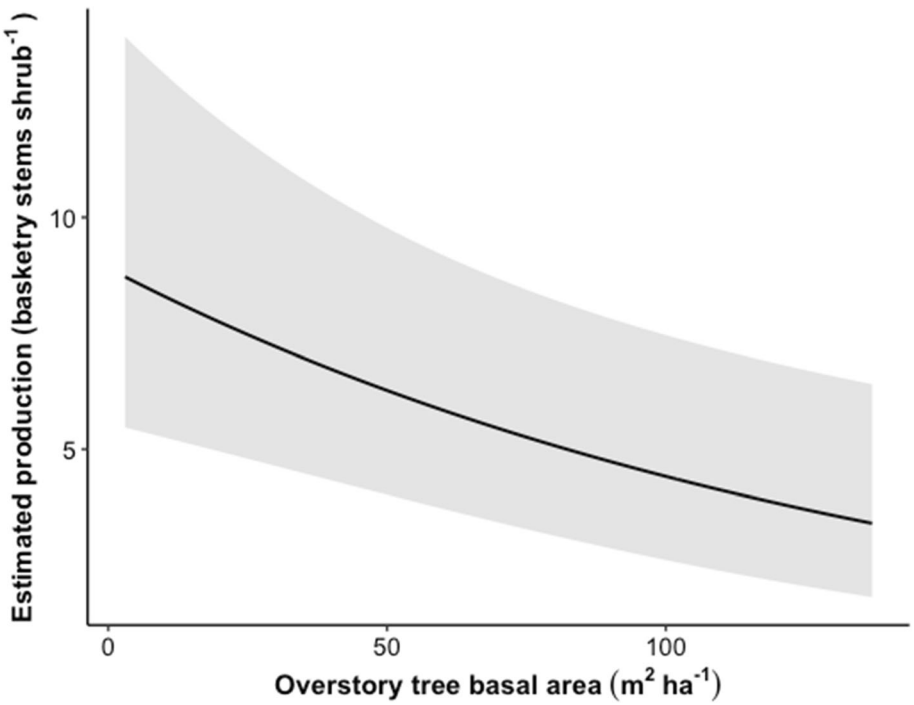

Fig. 4 Estimated hazelnut basketry stem production (plus 95% confidence interval, gray) with overstory tree (>10 cm dbh) basal area in Karuk and Yurok territory, northwestern California, USA, from 2015 to 2019. Estimates include shrubs in all temporal growing season classes (one, two, and three or more growing seasons post burn)

Hazelnut basketry stem gathering

All hazelnut basketry stems were gathered within a few weeks of bud break in the spring, between 20 March and early May, depending on the site aspect and elevation. The majority of basketweavers observed were either retired (14%) or employed by the Tribes, Forest Service, or local school districts (78%). While some employers provide flexible work hours that enable the gathering of ecocultural species like hazelnut, most hazelnut stem gathering observed here occurred on the weekends (84% of gathering trips). Basketweavers expressed that they would prefer to gather close to home, but few suitable burned hazelnut groves were located in close proximity to their residences. Three basketweavers noted that, despite the fact that they had relatively small patches (<500 m^2) of hazelnut on their landholdings that they burned regularly, these sites produced insufficient quantities of basketry stems to satisfy their needs. Thus, individuals with small hazelnut patches on their properties needed to gather at other burned sites to support their weaving.

Of all stem gatherers, we consistently recorded annual harvesting from six individuals from 2016 to 2019. Only one of these individuals gathered exclusively in Karuk territory while the other five individuals consistently gathered within Yurok territory. The five who gathered within Yurok territory, on average, gathered at 1.4 burn sites from 2016 to 2018 (range of total distinct sites = 3 to 5), and in 2019 visited 2.8 sites (six distinct sites visited). Four of these basketweavers reported that they engaged in five or more gathering trips within the hazelnut gathering season.

Gathering hazelnut stems requires a considerable commitment if burned areas are distant and the presence of quality hazelnut stems is unknown. Because some basketweavers now reside relatively far from ancestral territories and burned hazelnut groves, basketweavers were observed to travel considerable distances to gather. Based on 49 recorded trips to gathering patches, harvesters traveled a median distance of 34 km one way (range = 0 to 472 km) and an average of 60 km (±10.9 km). Basketweavers travelled 3.8-fold greater distances to reach wildfire gathering sites ($\bar{x}$ = 129 km, SE = 40 km) compared with cultural burn areas ($\bar{x}$ = 38 km, SE = 6 km, Wilcox test statistic = 72, $P < 0.01$).

From 2015 to 2019, basketweavers and stem gatherers selected 21 independent burn areas to gather hazelnut basketry stems; 76% of these sites were culturally burned and 24% were burned by wildfires. Of these sites, 29% were on US Forest Service land, 48% were privately owned, and 23% were tribally owned fee or trust lands (Yurok and Hoopa Valley reservations). Gathering trips in Yurok territory all occurred at culturally burned sites,

Table 1 Variables affecting hazelnut basketry stem production one growing season post-burn (2015 to 2019) in Karuk and Yurok territory, northwestern California, USA. Results of a Wald Type III Chi Square test (χ^2) on the significance of ungulate shrub browse proportion, pre-burn total stems, burn season (winter, spring, summer, and fall), and aspect class (east, southeast, south, southwest, and west) on basketry stem production generated from a negative-binomial generalized linear mixed model. Aspect classes included east (67.5° to 112.5°); southeast (112.5° to 157.5°); south (157.5° to 202.5°); southwest (202.5° to 247.5°); and west (247.5° to 292.5°). Only shrubs located in southern aspects (n = 124, estimated marginal $\bar{x}$ = 13.62, SE = 0.99) produced significantly different stems compared with those found in eastern aspects (n = 56, estimated marginal $\bar{x}$ = 8.01, SE = 1.23). Shrubs burned in the winter (n = 42, estimated marginal $\bar{x}$ = 15.54, SE = 1.73) produced 1.67-fold greater basketry stems than shrubs burned in the spring (n = 55, estimated marginal $\bar{x}$ = 9.32, SE = 1.05, P < 0.01), and 1.43-fold greater basketry stems than shrubs burned in the fall (n = 113, estimated marginal $\bar{x}$ = 10.89, SE = 0.92, P < 0.05). No other seasonal comparisons exhibited significant differences, and burn char height, dominant overstory tree, canopy closure, annual precipitation, elevation, and slope did not exhibit strong effects on basketry stem production and were removed from the model. Hazelnut shrub plots (n = 30; 400 m^2) are set as random effects. df = degree of freedom

Fixed effects	χ^2	df	*P*
Ungulate browse proportion (%)	23.29	1	<0.0001
Pre-burn total stems (*n*)	116.09	1	<0.0001
Burn season	13.41	3	0.003
Aspect class	10.04	3	0.018

whereas the 20 trips to gathering sites in Karuk and Hupa territories were more likely to occur at wildfire sites (Table 3).

Poor gathering sites (n = 12) tended to be sites gathered two or more growing seasons post burn, or sites that were heavily browsed by ungulates. Within five cultural burn sites on Forest Service land in Karuk territory, harvesters deemed stems to be poor quality due to heavy browsing. This was likely caused by the isolation of sites and lack of burning in surrounding areas, creating a strong patch-choice effect that attracted large numbers of browsers to the small area of the burn. Other sites that were assessed as relatively poor quality were those that were not burned at a sufficient intensity. At low-intensity burn sites, gatherers found that basketry stems were challenging to access given the limited consumption of underbrush and surface and ladder fuels (*e.g.,* down logs with branches, or small trees and shrubs).

Gatherers spent a mean 56 ±16 minutes per hazelnut stem gathering site. At cultural burn sites, mean gathering rates were significantly higher than gathering rates recorded at four wildfire locations and at a fire-excluded site (Fig. 9). While wildfires in this region burn hazelnut shrubs, basketweavers remarked that searching for hazelnut shrubs in these typically remote wildfire areas requires considerable additional time. Ms. Verna Reece, a renowned Karuk basketweaver and teacher, shared that she is one of the few gatherers who invests the necessary time and effort to drive the roads through wildfire areas in Karuk territory to scout and locate suitable hazelnut groves. Because Ms. Reece shares her knowledge of locations of hazelnut patches within wildfire areas, many of her students benefit from her initial reconnaissance and knowledge of local fire history.

Discussion

Basketry stem quality and ecology

Post-burn basketry stem qualities are important to basketweavers, who require a variety of stems of different lengths and diameters depending on what they intend to weave (Lake 2007: 243; O'Neale 1932). Longer stems provide enhanced functionality than shorter stems, as they can be cut depending upon the basketry project (V. Reece, personal communication). Therefore, measurements of stem diameter and length may assist both fire managers and basketweavers to identify and prioritize forest stand characteristics, burn season, and the frequency of cultural fires in hazelnut groves of interest across the landscape and, thus, promote socio-cultural values and ecological heterogeneity.

Overstory basal area was found to be negatively correlated to stem length, and hardwood overstories supported longer stem lengths when compared with coniferous overstories (on average 18 cm longer). These relationships may be attributed to greater understory light transmittance in forest stands with lower basal area, and broadleaf trees such as oaks (Fralish 2004; Barbier et al. 2008). Given that lower basal areas also support overall basketry stem production, canopy thinning in hazelnut groves would likely improve quality and quantity of basketry stems. Targeting relatively young coniferous trees for thinning would also support the recovery and growth of encroached hardwoods, whose populations have become compromised by Douglas-fir in the region (Hunter and Barbour 2001; Engber et al. 2011; Cocking et al. 2012; Schriver et al. 2018).

Shrubs that were burned in the spring produced significantly shorter stems compared to all other burn seasons. This result can be attributed to the truncated growing season caused by these burns, which occurred after bud break. For certain basketry projects that require longer stems (*e.g.,* baby cradles), these stems are less functional. However, shorter stems also tend to have smaller diameters, which is a desired quality for basketweavers producing baskets that require a tight weave (*e.g.,* basket caps; Johnson and Marks 1997). The stem

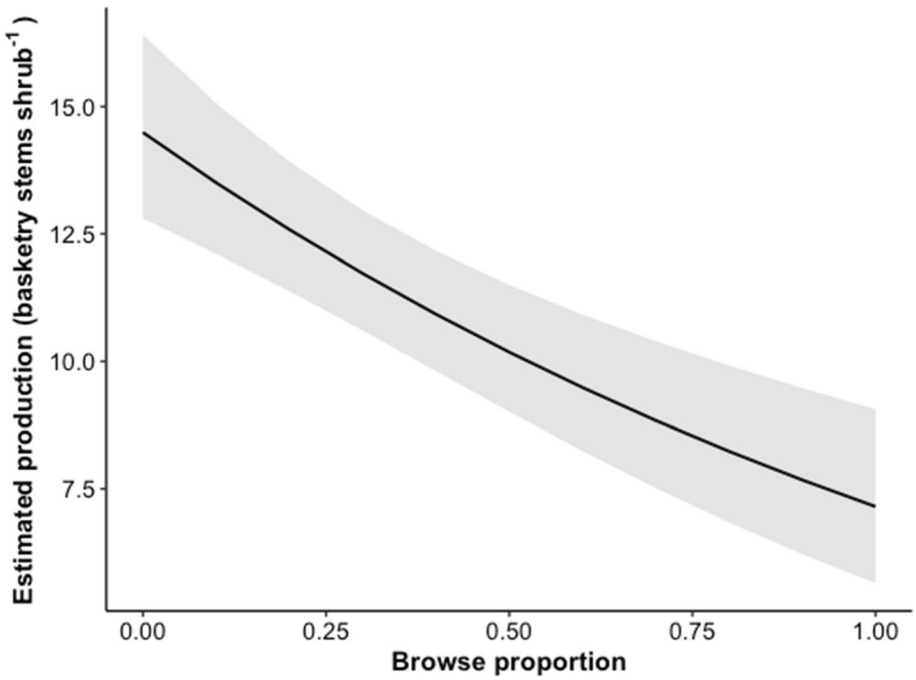

Fig. 5 Proportion of hazelnut shrub browsed with estimated basketry stem production values (plus 95% confidence interval, gray) from the one growing season post-burn temporal class in Karuk and Yurok territory, northwestern California, USA, from 2015 to 2019

wood to pith ratio is also different among spring- versus fall-burned hazelnut shoots, which affects the tensile strength and durability for use in weaving (Rentz 2003; Lake 2007). Moreover, spring burning raises concerns for some tribal members as burning during this season may negatively affect wildlife and was less common preceding colonialism (Knapp et al. 2009; Marks-Block et al. 2019). Tribal members have also taken advantage of recent winter droughts (Griffin and Anchukaitis 2014) and dry periods to increase cultural burning for hazelnut basketry stems. Stems produced from these burns also had a smaller diameter compared with those produced from summer burns, and were longer than stems burned in the spring. Hence, finding receptive burning opportunities in the winter may produce stems of desirable qualities, without the potential negative effects of burning in the spring.

Table 2 Variables affecting hazelnut shrub density (2015 to 2019) in Karuk and Yurok territory, northwestern California, USA. Results of a Wald Type III Chi Square test (χ^2) on the significance of burn frequency, elevation, and aspect class on hazelnut shrub density generated from a gamma generalized linear model. Aspect classes included east (67.5° to 112.5°); southeast (112.5° to 157.5°); south (157.5° to 202.5°); southwest (202.5° to 247.5°); and, west (247.5° to 292.5°). df = degree of freedom

Fixed effects	χ^2	df	*P*
Burn frequency	23.6	1	<0.0001
Elevation	4.8	1	0.027
Aspect class	21.9	4	<0.001

Ungulate browse also shortened stems and initiated lateral stem branching, reducing the functionality and quality of stems. When high proportions of stem browse occurred at cultural burn sites, basketweavers rated their quality as poor, and few basketweavers selected these sites for gathering. While browse occurs at all sites, if burning is conducted near residences, the nearby presence of dogs and people may discourage interspecies competition for post-burn hazelnut resprouts, and have the additional benefit of reducing wildfire hazards. Additionally, expanding the frequency and area (extent and place) of cultural burn sites, and managing wildfires to achieve resource objectives and socio-ecological benefits, may reduce interspecies competition for hazelnut resprouts by providing sufficient high-quality browse for ungulates across the landscape (Wan et al. 2014).

Ecology of basketry stem production and hazelnut shrub density

Our results clearly show that cultural burning optimizes the production of hazelnut basketry stems, but that this effect is the product of short fire intervals (*e.g.*, 3 to 5 yr). Because basketweavers can quickly exhaust a small hazelnut patch, optimizing basketry stem production requires a mosaic of recently burned patches, those regenerating from harvest, and those ready to be burned all within close proximity to residential locales. More

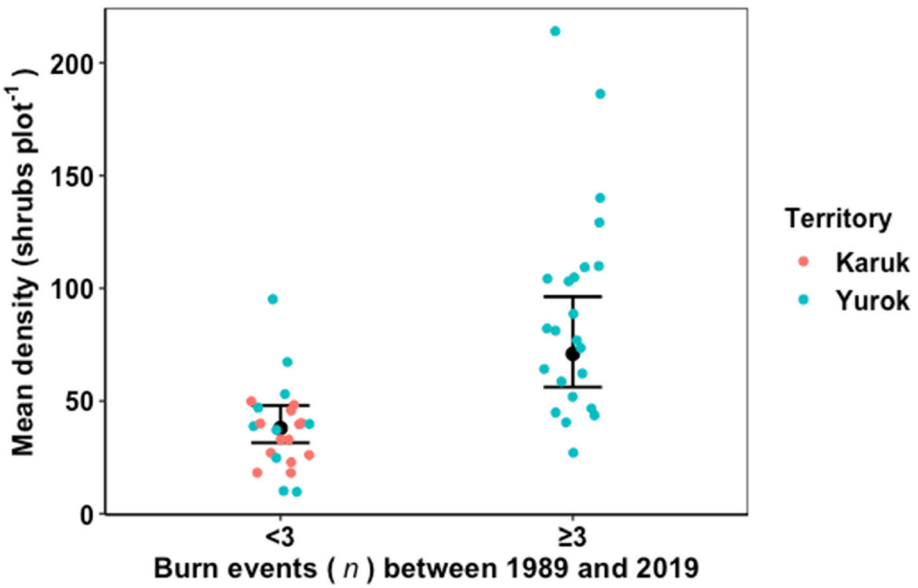

Fig. 6 Hazelnut shrub densities with number of burns in Karuk and Yurok territory, northwestern California, USA, from 1989 to 2019. Data was collected from 2015 to 2019. Scattered colored points are 400 m^2 plot shrub densities. Black points with 95% confidence intervals (bars) are estimated marginal means generated from a generalized linear model. Sites with less than three burn events had significantly greater hazelnut shrubs (estimated marginal $\bar{x}$ = 71.0, SE = 9.53) than plots burned less than three times (estimated marginal $\bar{x}$ = 38.1, SE = 4.02)

common fall burns do not produce basketry stems until ~18 months post burn; thus, different sites need to be burned annually to ensure annual harvests. This fire regime strongly concurs with California Indian basketweaver knowledge of hazelnut fire ecology and practice of cultural burning (O'Neale 1932; Thompson 1991; Ortiz 1998; Anderson 1999), and aids in the interpretation of regional fire history studies regarding fire frequency and seasonality (Taylor and Skinner 1998, 2003; Fry and Stephens 2006; F. Lake, USDA Forest Service,

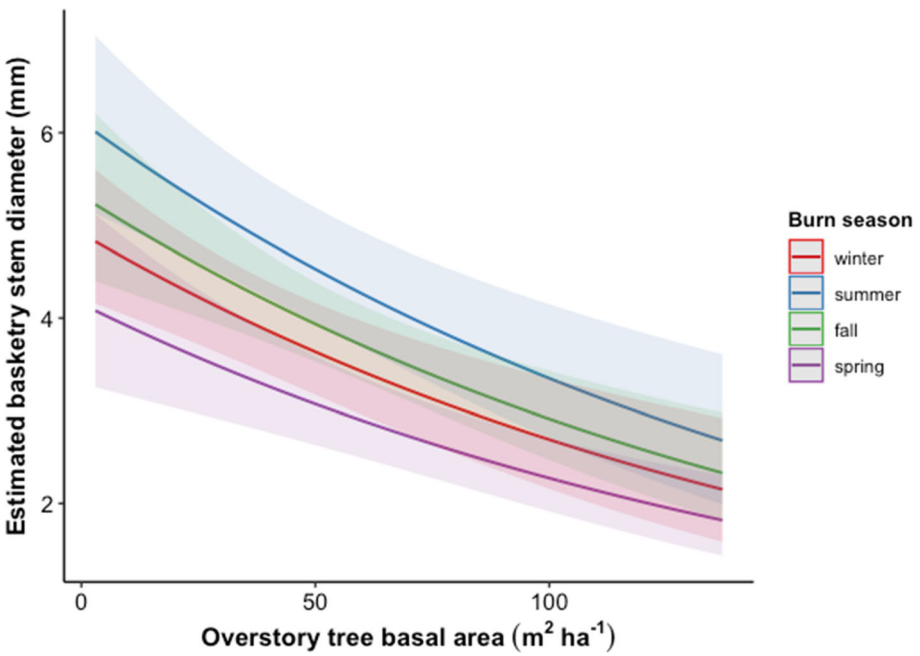

Fig. 7 Overstory tree (>10 cm dbh) basal area with estimated hazelnut basketry stem diameters (plus 95% confidence intervals) and burn season (summer, fall, winter, and spring) in Karuk and Yurok territory, northwestern California, USA, from 2015 to 2019

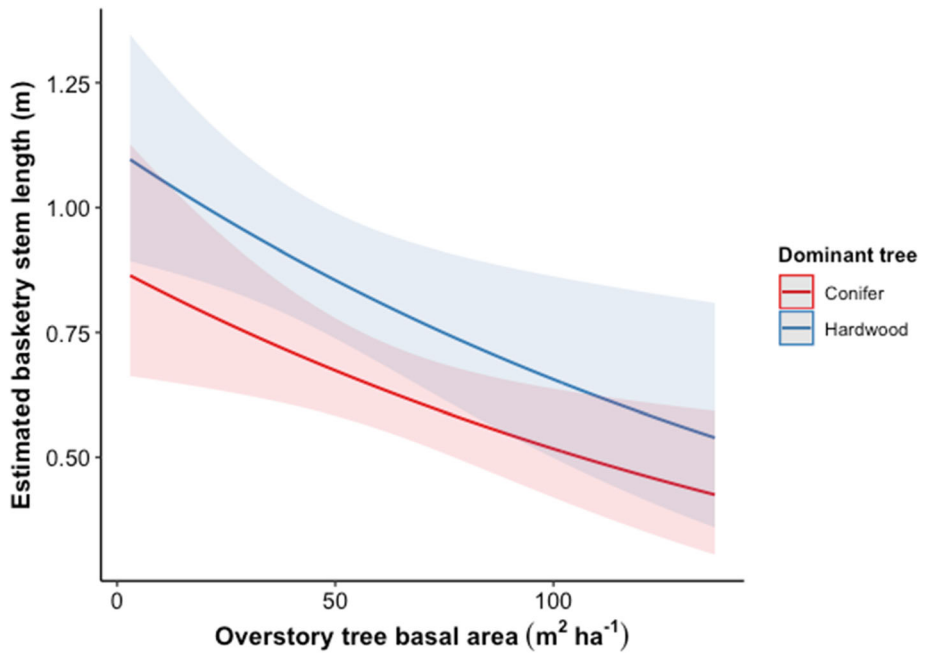

Fig. 8 Overstory tree (>10 cm dbh) basal area and dominant overstory tree with estimated hazelnut basketry stem length (plus 95% confidence intervals) one year post burn in Karuk and Yurok territory, northwestern California, USA, from 2015 to 2019

Arcata, and E. Knapp, USDA Forest Service, Redding, California, USA, unpublished data).

Higher hazelnut shrub densities occur in areas that have burned in ≥3 events within 30 years, increasing the density of basketry stems in these areas post burn compared with hazelnut groves where fire has been excluded and shrub densities are lower. Greater shrub density and basketry stem production in areas with relatively less overstory basal area also suggest that short-interval burning would benefit hazelnut shrubs, as these overstory conditions are promoted by frequent, low-intensity fire regimes (Stephens and Fulé 2005; Scholl and Taylor 2010). Given the vital importance of hazelnut stems in Karuk and Yurok culture, and for many other tribes regionally, burning for hazelnut undoubtedly affected the abundance of hazelnut across the pre-colonial landscape. Greater densities of hazelnut shrubs at lower elevations may be an artifact of the historical settlement of Karuk and Yurok villages along the Klamath River (Waterman 1920; Kroeber 1936), and the repeated cultural burning of hazelnut groves in close proximity to villages and favored resource camps.

Table 3 Hazelnut stem gathering trips by tribal territory and fire type in Yurok, Karuk, and Hoopa territory, northwestern California, USA. Trips were observed or reported by basketweavers and stem gatherers from 2014 to 2019. According to Pearson's χ^2 test, trips to gathering sites in Karuk and Hupa territories were significantly more likely to occur at wildfire sites compared with trips in Yurok territory ($\chi^2 = 41.03$, df = 2, $P < 0.0001$)

	Gathering trips (*n*) per territory		
Fire type	**Yurok**	**Karuk**	**Hupa**
Cultural fire	69	6	3
Wildfire	0	7	3

A staggered, low intensity, and frequent cultural fire regime, as proposed by Lightfoot and Parrish (2009), alters the species assemblage and maintains ecoculturally valuable hazelnut groves in a relatively stable ecological state (Botkin and Sobel 1975; Petraitis and Latham 1999, Beisner et al. 2003). This socio-ecological system is akin to the burned areas that Lewis and Ferguson (1988) referred to as "fire yards and corridors" that were regularly burned to maintain prairies. However, in this case, these yards are not anthropogenic prairies, but the park-like forests often described by early European settlers (Sudworth 1900; Leiberg 1902; Pyne 1982; Muir 2008). Unlike anthropogenic burning in the spinifex desert of Australia (Bliege Bird et al. 2008), or the swidden Mayan milpa that creates a shifting successional mosaic (Nigh and Diemont 2013), hazelnut groves are maintained by frequent low-intensity burning that inhibits successional processes. The focal ecocultural species in a hazelnut grove is woody and has a re-sprouting life history, which suggests that a distinctive burning regime is required to maintain hazelnut, compared to a "yard" of herbaceous perennials or annuals.

This socio-ecological model was described in 1916 by Lucy Thompson, a Yurok woman, who stated that, "The

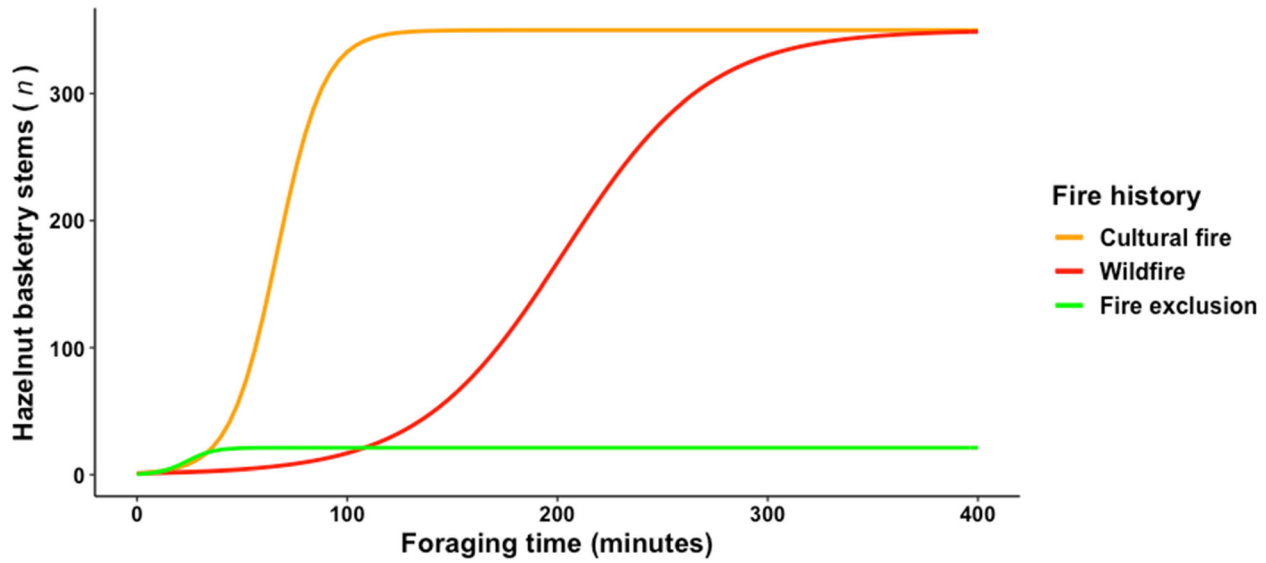

Fig. 9 Fire history and hazelnut basketry stem gathering rates modeled as logistic functions in Karuk and Yurok territory, northwestern California, USA, from 2015 to 2019. Foraging time includes travel and gathering time for stem harvesters. Gathering rates are based on average rates observed in 22 cultural burn areas (five stems per individual per minute), four wildfire areas (two stems per individual per minute), and one fire-excluded area (0.5 stems per individual per minute). Travel time to gathering areas was calculated from the mean distance travelled one way (34 km to cultural burn; 129 km to wildfire; 2 km to fire exclusion area) at a rate of 80 km hr^{-1}. This model assumes that a gatherer aims to harvest 350 stems, based upon the average harvest observed from trips to nine cultural burn areas

Douglas fir timber…has always encroached on the open prairies and crowded out the other timber; therefore they have continuously burned it" (Thompson 1991: 33). This finding was further developed and articulated as a state and transition model by Huntsinger and McCaffrey (1995) that included woodlands, but did not address important understory ecocultural species like hazelnut. Similarly, other ecological studies in northern California montane forests have found that repeated burning by lightning fires maintains steady shrubland states (Odion et al. 2010; Lauvaux et al. 2016), and that, in the absence of fire, oak woodlands transition to Douglas-fir stands (Hunter and Barbour 2001; Engber et al. 2011; Schriver et al. 2018). Hence, this fire-mediated dynamic is quite prevalent in the region, and supports the finding that hazelnut is less abundant in the absence of frequent fire.

Over the long term, positive feedbacks between cultural burning and hazelnut provide a niche-construction mechanism that improves landscapes in a wide variety of ways (Jones et al. 1994, 1997; Smith 2011; Odling-Smee et al. 2013; Bliege Bird 2015). Cultural burning increases stem production for basketweavers, but also increases quality forage for ungulates (Lawrence and Biswell 1972; Kie 1984; Long et al. 2008, Williamson and Weckerly 2020), and may also improve nut production for humans and wildlife (Lake 2007; Fine et al. 2013; Armstrong et al. 2018). Cultural burns may also increase wildlife habitat, supporting biodiversity (Martin and Sapsis 1992; Hankins 2009) and endangered species such as the California Condor (*Gymnogyps californianus* [Shaw, 1797]) and Spotted Owl (*Strix occidentalis* [Xántus de Vésey, 1860]) that feed in edge habitats and clearings (Cowles 1967; Franklin et al. 2000; Roberts et al. 2011; Nabhan and Martinez 2012; Eyes et al. 2017). The improvements in habitat and biodiversity that emerge from understory burning (Webster and Halpern 2010; Knapp et al. 2013; Wynecoop et al. 2019) have cascading effects on a wide range of other plant and animal species, which in turn sustain the cultural traditions, economic livelihoods, and social and physical well-being of the fire-dependent cultures that rely on these species and processes in their ancestral territories (Heffner 1984; Ortiz 1993; Mathewson 2007; Eriksen and Hankins 2015; Smith 2016).

Basketry stem gathering and fire governance

Cultural burning directly supports the maintenance and revitalization of northwestern California Indian basket-weaving by reducing the costs associated with basketry stem gathering. Foraging efficiencies are greatly improved by burning, and subsequently influence the selection of basketry stem gathering sites. Basketry stem gathering rates are 10-fold greater in cultural burn areas compared with fire-excluded hazelnut groves, leaving little incentive to gather in unburned areas (Anderson 1999). Without accounting for the increase in travel time to wildfire areas, cultural burn areas generated gathering rates that are 3-fold greater than those in wildfire areas,

which we attribute to greater shrub densities associated with repeated cultural burning. Accordingly, stem gatherers selected burn sites of higher quality more frequently than those areas of poor quality and lower shrub densities. These results offer strong evidence that stem-gatherer decision-making adheres to basic optimal foraging theories of maximizing efficiency (Stephens and Krebs 1986).

Land dispossession and limited tribal autonomy over burn practices have caused stem gatherers to select less than ideal harvesting sites. In Karuk territory, land dispossession was comparatively greater than in Yurok territory, thus, in recent decades, Tribal members have not been able to maintain as many hazelnut groves with consistent cultural burning. Collaborative burning between the Karuk Tribe and the USDA Forest Service tends to fluctuate with staff who are supportive of burning, but who may often transfer from the region (Diver 2016; Smith 2016). The sites where these collaborative burns occurred have predominantly been in remote locations where overstory basal area is relatively high, shrub densities are relatively low, and ungulate browse has been heavy. As a result, Karuk stem gatherers tend to gather in areas burned by wildfires, where they have found higher quality basketry stems. However, compared with culturally burned sites in Yurok territory, the gathering costs are higher due to increased travel and lower shrub densities. Despite USDA Forest Service policy changes that permit gathering by indigenous peoples (Kalt 2007), several basketweavers expressed that the persistence of racism, as well as its ongoing manifestations of harassment, imprisonment, and violence toward Indigenous peoples for gathering, hunting, and burning on their lands, makes them hesitant to gather hazelnut stems on national forests (Smith 2016; Norgaard 2019).

Gatherers generally do not harvest in hazelnut groves that they perceive as belonging to other families, or in tribal territories where they do not have social ties or permission. Hence, while higher quality groves occur in Yurok territory, individuals without Yurok ancestry or familial ties will gather at lower-quality hazelnut groves out of respect for land affiliations, unless they are invited. This social dynamic reflects the historically decentralized Karuk and Yurok governance structures preceding colonialism, in which usufruct rights to resource tracts were organized at the level of families and individuals (Waterman 1920; Thompson 1991; Huntsinger and Diekmann 2010; Bettinger 2015).

The centralization of resource and fire management by the US government and the fragmentation of tribal land ownership reduced access to ecocultural resources such as hazelnut basketry stems (Huntsinger and Diekmann 2010). Nonetheless, Karuk and Yurok Tribal members initiated successful burning programs that have reduced the relative scarcity of hazelnut stems and support cultural revitalization. To adjust to these new modes of governance, the Tribes developed their own natural resource departments and wildland fire departments, and established partnerships with the USDA Forest Service and non-governmental organizations such as fire safe councils and The Nature Conservancy, to co-manage fire and resources (Long and Lake 2018). Tribal basketweavers have also self-organized to form organizations such as the California Indian Basketweavers Association (LeBeau 1998; Kallenbach 2009) and Karuk Indigenous Basketweavers to address the need for cultural burn partnerships. In Karuk territory, these partnerships have supported the development of long-term cultural fire restoration projects that intend to initiate regular repeated burns in hazelnut groves (USDA Forest Service PSW Region 2018).

In Yurok territory, basketweavers and their families have initiated a successful cultural burning program that reduced the relative scarcity of hazelnut stems. The Cultural Fire Management Council (CFMC) began to burn hazelnut groves annually in 2013, and supported families and the Tribe to maintain regular burns. In 2019, the CFMC President, Margo Robbins (Yurok), shared that, "Ten years ago it wasn't often that you'd see a baby in a basket. Now there are lots of babies in baskets because of TREX." Basketweavers like Margo articulate a clear connection between burning and its role in supporting cultural revitalization.

Conclusion

Partnerships between tribes, non-governments organizations, and government agencies have supported the contemporary burning of hazelnut groves, much like collaborative burning projects in South America and Australia (Fache and Moizo 2015; Mistry et al. 2019; Neale et al. 2019), but increased tribal sovereignty and familial autonomy over burning in ancestral lands will ensure not only its maintenance, but its expansion (Baldy 2013; Robbins et al. 2016). Collaborations between fire managers and American Indian communities will support the revitalization of cultural burning and help achieve multiple socio-ecological management objectives (Lake et al. 2017; LeCompte 2018; Lewis et al. 2018; Long and Lake 2018; Wynecoop et al. 2019). Collaboration with basketweavers is vital when burning objectives include hazelnut basketry stems. Ideally, multiple hazelnut groves in a region will be burned frequently (every three to five years) in a staggered fashion, which will reduce obstacles to access (*e.g.,* downed logs and dense stands of small trees), support high shrub densities, and offer yearly harvesting opportunities.

The revitalization of Karuk and Yurok cultural burning provides an alternative model for restoring fire and

ecological function to landscapes that experienced fire exclusion and industrial timber extraction (Nikolakis and Roberts 2020). Compared with many non-tribal restoration initiatives focused upon conservation and hazardous fuel–fire risk reduction, California Indian initiatives primarily aim to restore socio-ecological relationships with ecocultural fire-enhanced species for cultural, ceremonial, and subsistence use. Because their practices were partially responsible for the historical fire regime, burning practices of indigenous and place-based fire-dependent cultures may be more effective at restoring the desired reference landscapes that conservation organizations and public land agencies intend to re-create (Kimmerer 2011; Lake 2013; Bliege Bird and Nimmo 2018). Moreover, tribes, resource users, and local entities appear to be well equipped to maintain burning over the long term, whereas limited budgets and complex political processes have constrained prescribed burning by land management agencies (Steelman and Burke 2007; North et al. 2015; Schultz and Moseley 2019). Cultural burns observed here indicate that this fire governance model exhibits considerable potential to support fire-adaptive socio-ecological communities (Abrams et al. 2015; Roos et al. 2016).

Acknowledgements
We truly appreciate the Karuk and Yurok Tribal Councils for their permission and continuing support to conduct this work on their lands and within their communities. Tribal GIS programs provided mapping data resources. Our research design benefited immeasurably from the critical input and generous involvement of Karuk and Yurok basketweavers, gatherers, and fire managers: E. Azzuz, C. Chook Hillman, L. Hillman, R. McConnell, R. McConnell Jr., K. McCovey, B. Peters, M. Peters, V. Reece, M. Robbins, B. Souza, and B. Tripp. We thank anonymous reviewers whose feedback greatly improved this paper, and N. Johnson (USDA Forest Service Pacific Southwest Research Station) for providing invaluable statistical contributions.

The Relationships among In-Channel Sediment Storage, Pool Depth, and Summer Survival of Juvenile Salmonids in Oregon Coast Range Streams

CHRISTINE L. MAY* AND DANNY C. LEE

U.S. Forest Service, Pacific Southwest Research Station, 1700 Bayview Drive, Arcata, California 95521, USA

Abstract.—The influence of channel aggradation on water availability and salmonid survival was investigated during the summer dry season in two Oregon Coast Range streams. Deep pools and a deformable streambed of coarse gravel were present in highly aggraded stream reaches. However, these thick, highly porous alluvial deposits caused surface flow to become intermittent, which stranded fish in drying channels. In gravel-bed reaches with thinner alluvial deposits, pool depth was limited by the underlying bedrock, but pools were sustained by hyporheic flow throughout the summer dry season. In these moderately aggraded reaches, pool depth and area decreased throughout the summer, resulting in severe crowding of fish trapped in pools formed over small patches of exposed bedrock and isolated by dry, gravel-bed riffles. Bedrock-dominated stream reaches had slightly smaller pools but were most likely to contain continuous surface flow throughout the summer dry season; these reaches exhibited the smallest decreases in pool depth and area. Repeated snorkel surveys indicated that fish abundance in pools decreased by 59% during the summer, significantly higher losses occurring in gravel-bed pools. Streambed substrate and partitioning of surface and subsurface flow may also have important implications for fish energetics due to differences in water temperature and food availability.

Stream channels in mountainous terrain can progressively build up (aggrade) or erode (degrade) the streambed in response to changes in sediment supply (Lisle 1982) or hydraulic controls such as large, in-stream wood (Nakamura and Swanson 1993; Montgomery et al. 1996; Buffington and Montgomery 1999). These processes are important to natural resource and fisheries managers, in part because: (1) land-use practices and wildfires, particularly preceding large storms, can be associated with massive inputs of sediment to stream channels (Swanson 1981; Madej and Ozaki 1996; Benda and Dunne 1997a; May and Gresswell 2003), and (2) the condition of stream channels may strongly affect the population viability of highly valued endangered species, such as coho salmon *Oncorhynchus kisutch*.

Although many studies have investigated the direct effects of fine sediment on the habitat and physiology of salmonids (e.g., Cooper 1965; Beschta and Jackson 1979; Tappel and Bjornn 1983; Lisle 1989; Lake and Hinch 1999), the effects of coarse sediment inputs have not been established. Many of the effects of fine sediment occur only during the egg-to-fry-emergence stage or when fine sediment is suspended in water during periods of high stream discharge. Because fluxes of coarse sediment can change the overall morphology of the channel, their effects are more persistent. Changes in channel morphology caused by large influxes of sediment may be particularly important during periods of extremely low stream discharge, when salmonids face challenging conditions for survival and growth, and during the incubation period, when stable spawning gravels are necessary. Thus, coarse sediment dynamics are highly likely to significantly affect population viability.

In the Oregon Coast Range, a large proportion of the channel network in mountainous terrain is susceptible to channel aggradation based on reach-scale transport and storage capacity (Montgomery et al. 2003). In this region, stream channels typically have a thin layer of highly mobile alluvium that is composed primarily of coarse gravel that resides directly over the underlying bedrock. The presence of a bedrock or alluvial reach morphology depends on the balance between local transport capacity and coarse sediment supply (Montgomery et al. 1996). This relationship can be influenced by log jams that trap sediment, local variations in sediment supply, and bedload-clast lithology (Montgomery et al. 1996; Massong and Montgomery 2000). Large influxes of sediment from landslides and debris flows can overwhelm the local transport capacity and can lead to sub-

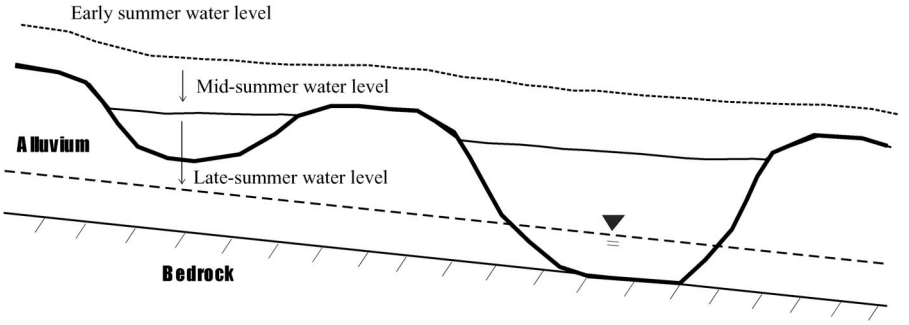

FIGURE 1.—Conceptual diagram of the influence of channel aggradation on water availability during the summer dry season.

stantial aggradation of the channel (Reeves et al. 1995; Benda and Dunne 1997b; Hogan et al. 1998).

Deep pools have the potential to form in aggraded reaches because of a deformable bed created by the stored alluvium. In reaches with less sediment in storage, the underlying bedrock typically limits pool depth (Reeves et al. 1995). Many studies have suggested that large, deep pools create optimal habitat for salmonids (Reeves et al. 1993; McIntosh et al. 1994; Bisson et al. 1997); however, expectations of habitat quality are often based on observations of large numbers of fish occupying deep pools. Such observations may be a misleading indicator of habitat quality because they do not consider how fish survival or growth varies among different pool types.

As an alternative to the conventional view of deep pools, we propose a hypothesis that deep pools formed in areas of thick alluvial deposits have a greater likelihood of going dry during the summer dry season, thereby posing a detriment to fish survival. In deep, highly porous substrates, streamflow levels can drop below the bed elevation during low-flow periods in late summer (Figure 1). This interaction with the hyporheic zone is created by surface water infiltrating through the gravel bed into the interstitial areas in the subsurface. Hyporheic flow eventually returns to the surface of the stream, particularly where patches of bedrock are exposed. There is a growing recognition that the hyporheic zone is an important and dynamic component of aquatic ecosystems (e.g., Hynes 1983; Stanford and Ward 1988, 1993; Findlay 1995; Edwards 1998; Wondzell and Swanson 1999). However, the volume of the hyporheic zone can be greatly increased by changes in sediment supply and retention (Edwards 1998). Alternatively, in areas of low sediment storage, smaller pools may form but these pools may have a higher likelihood of remaining wet throughout the summer because they intercept subsurface flow traveling across the bedrock surface. Patterns of pool drying thus provide a first-order control on fish survival during the summer dry season.

This study had four objectives: (1) to quantify the area and depth of pools in bedrock and aggraded stream reaches, (2) to document which pools persisted throughout the summer dry season, (3) to compare fish survival estimates between bedrock-controlled pools and pools formed in thick deposits of alluvium, and (4) to predict areas susceptible to channel aggradation and pool drying.

Study Basins

The Oregon Coast Range consists of rugged mountains at low elevations (<500 m) that are deeply dissected by an extensive drainage network of steep, V-shaped valleys. The topography is similar to the ridge and ravine topography described by Hack (1960). Landslides and debris flows are important processes in landform development and are dominant mechanisms for routing sediment from hill slopes and headwater streams into mainstem river valleys (Dietrich and Dunne 1978).

Segments of two streams with a mixture of bedrock and alluvial reaches were selected for investigation (Table 1; Figure 2). These sites were selected because they provided examples of channels that experienced recent influxes of coarse sediment and because their disturbance histories were well documented (Reeves et al. 1995; Benda and Dunne 1997a, 1997b; May and Gresswell 2004). Tertiary marine sedimentary rocks of the Tyee Formation (Baldwin 1964) underlie both basins. Harvey Creek, a tributary to the lower Umpqua River, has a history of minimal logging and road construction. Knowles Creek is a tributary to the Siuslaw

TABLE 1.—Channel and basin characteristics of Harvey and Knowles creeks, Oregon.

Variable	Harvey Creek	Knowles Creek
Channel length surveyed (m)	2,990	3,595
Drainage area of surveyed channel (km^2)	8.2–17.8	5.1–19.8
Number of		
Gravel-bed pools	65	18
Gravel pools with bedrock contact	9	22
Bedrock pools	13	26
Gravel-bed glides	7	15
Gravel glides with bedrock contact	0	8
Bedrock glides	2	19

River and is managed for commercial timber production. Two extremely large storms in 1996 triggered more than 20 debris flows in each basin (May 2002; May and Gresswell 2004).

The sandstone lithology of the southern and central Oregon Coast Range produces a unique particle-size distribution. Gravel and sand are the dominant particle sizes, and larger cobbles and boulders are typically limited to discrete patches associated with landslide and debris-flow deposits (Benda 1990). The low abundance of silt and clay produced from this lithology, combined with the loose gravel and sand, produce a highly porous substrate and a strong potential for hyporheic exchange.

The region has a maritime climate characterized by wet, relatively warm winters and dry summers. Average annual precipitation ranges from 165 to 229 cm, falling mostly as winter rain. The summer season is a period of extensive drought that typically persists from June through September. Mean monthly discharge for August at a nearby stream gauge on the undammed Siuslaw River was 4.5 m^3/s for the 26-year period of record. Mean August discharge during the study period (June–August 2002) was 4.1 m^3/s, which is only slightly below average. No increases in streamflow occurred during the sampling period (total June–August precipitation at North Bend Airport was less than 6 mm; National Weather Service, unpublished data).

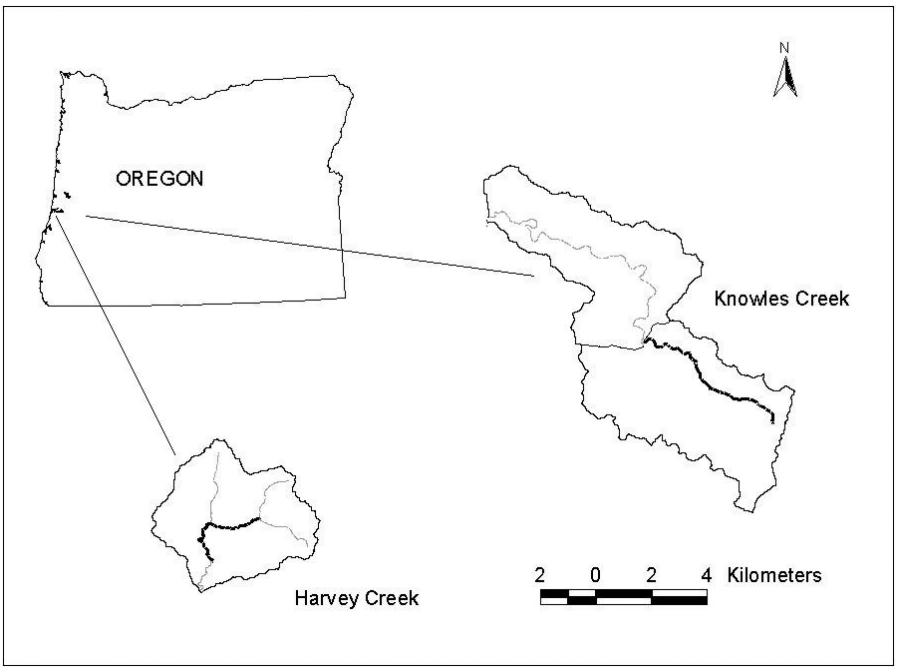

FIGURE 2.—Location of the study basins (Harvey and Knowles creeks) in the Oregon Coast Range, Oregon. Bold lines represent the study reaches.

TABLE 2.—Midsummer (24 June–11 July) and late-summer (25–30 August) connectivity of pools and glides in Harvey and Knowles creeks, Oregon, during 2002. Pools with high connectivity had sufficient streamflow between upstream or downstream riffles to allow fish passage. Low connectivity classifications only considered inflow from upstream in order to assess the potential for invertebrate drift.

Habitat type	Midsummer connectivity			Late-summer connectivity		
	High (%)	Low (%)	None (%)	High (%)	Low (%)	None (%)
Bedrock dominated	83	73	17	5	44	54
Gravel with bedrock contact	76	86	14	2	33	65
Gravel bed	32	37	63	0	1	99

Fish species present during the summer include juvenile coho salmon *Oncorhynchus kisutch*, juvenile steelhead *O. mykiss*, cutthroat trout *O. clarki*, sculpins *Cottus* spp., and dace *Rhinichthys* spp. The dominant forest type is Douglas-fir *Pseudotsuga menziesii* in the uplands; red alder *Alnus rubra* are common in riparian zones.

Methods

Surveys of habitat types and fish abundance were conducted during the dry season in midsummer (24 June–11 July 2002) and late summer (25–30 August 2002). All habitat units within the study area were censused and classified as pools, glides, or riffles (Bisson et al. 1982). Three pool types were identified: (1) pools scoured into alluvium, with no bedrock contact (gravel-bed pools), (2) pools scoured into alluvium, with a bedrock contact at the pool bottom (gravel pools with bedrock contact), and (3) pools formed by bedrock depressions that had little or no alluvium in storage (bedrock pools). Pools included in the survey were at least as long as the bank-full channel width, and at least 30 cm in maximum depth. Glides were classified as low-gradient, shallow (<30-cm maximum depth), homogenous channel units. Glides were similarly classified into three categories of bedrock and alluvial substrates and were included in all analyses except those based on residual pool dimensions. Because habitat classification is a subjective measure, observer bias can seriously compromise the repeatability, precision, and transferability of surveys (Hankin and Reeves 1988; Poole et al. 1997). To increase consistency of the surveys, a single individual, who was highly trained and experienced, classified all habitat units.

Residual pool depth and residual area were measured during midsummer for each pool by use of standard survey equipment and standard protocol (Lisle 1987). Residual depth is defined as the difference in bed elevation between the bottom-most point in a pool and the downstream riffle crest (Lisle 1987). Residual pool depth and area are useful metrics for quantifying pool dimensions because they are independent of discharge. Dimensions of the wetted channel and the maximum pool depth were recorded for each habitat unit during both sampling periods to assess the change in available habitat.

Connectivity to upstream or downstream habitats was documented for each habitat unit. Pools and glides that were completely isolated by dry riffles on the upstream and downstream ends were classified as having no connectivity. Pools and glides with inflow from shallow, upstream riffles that were impassable for fish but that still had the potential to provide a conduit for invertebrate drift were classified as having low connectivity. Pools and glides attached to upstream or downstream riffles that had sufficient flow to allow fish movement were classified as having high connectivity. Two standards were used. In coarse substrate, riffles less than 5 cm deep were considered barriers to fish passage. Coarse substrate provided intermittent pockets of water between individual grains, and no consistent fish passage corridors were apparent in these shallow riffles. For riffles with a bedrock substrate, a minimum of 2 cm of continuous flow was required for passage. This change in criteria was based on our observations of fish passing through extremely shallow riffles with a bedrock substrate where a continuous flow path was present. Because pools or glides with low connectivity on the upstream end could also be classified as having high connectivity on the downstream end, the row sums in Table 2 will not necessarily equal 100%.

The relative abundance of salmonids was estimated by snorkel surveys in each pool and glide during the midsummer and late-summer sampling periods. The midsummer survey was timed to coincide with the period when the majority of pools were becoming isolated, so that fish observed in an individual pool were presumably trapped there for the remainder of the summer. Riffles were usually too shallow for divers and were not included

in the surveys. Divers entered each habitat unit at the downstream end and proceeded slowly upstream. All observations of fish were made between 0900 and 1600 hours on days with little or no cloud cover. Divers identified salmonids as either juvenile coho salmon or juvenile trout. Sculpins and dace could not be estimated reliably because they commonly occupied benthic habitats.

Estimates of fish mortality, presumably due to desiccation, were based on the number of fish observed rearing in midsummer pools and glides that were dry by late summer. Mortality estimates were based on two underlying assumptions: (1) physical isolation of pools by midsummer prevented movement of fish among pools, and (2) all fish stranded in dry pools died. Because streamflow did not increase during the sampling period, we assumed that there were no opportunities for movement between isolated pools.

Stream temperature data were collected at 30-min intervals from 26 to 30 August in three pools within a 1-km section of Harvey Creek. We used Onset Stowaway temperature sensors, which have an accuracy of ±0.2°C. Prior to deploying the sensors in the field, we tested them for accuracy in the laboratory. Each sensor was located in a pool with different substrate and streamflow conditions.

Statistical analyses.—One-way analysis of variance (ANOVA) was used to detect significant differences among pool dimensions for each pool type. If a difference was detected, a Kruskal–Wallis multiple comparison procedure was used to identify which groups differed. The influence of residual pool depth on the likelihood of pools remaining wet throughout the summer was tested with the log-likelihood test in logistic regression.

Changes in fish abundance (i.e., survival from midsummer to late summer) and fish density in each pool type were tested by use of ANOVA, followed by a Kruskal–Wallis multiple comparison procedure to detect significant differences among groups. Data from pools that went dry during the summer were omitted from the analysis of fish density in order to assess the degree of crowding in remnant pools that persisted throughout the summer.

The likelihood of stream reaches going dry and the presence of gravel-bed pools were tested with logistic regression. The initial model included four reach-scale and basin-scale variables: (1) basin, (2) longitudinal distance upstream from the mouth of the basin to the headwaters (calculated from 10-m-resolution digital elevation models), (3) recent debris-flow deposits (identified during field surveys), and (4) depositional reaches that plotted below an empirically derived threshold of drainage area and channel slope (predicted by Montgomery et al. 1996). Reach-scale channel gradient was measured in the field with a clinometer, and drainage area was calculated from 10-m-resolution digital elevation models. Variables included in the final model were selected by the probability level of the parameter (those with $P < 0.05$ were included).

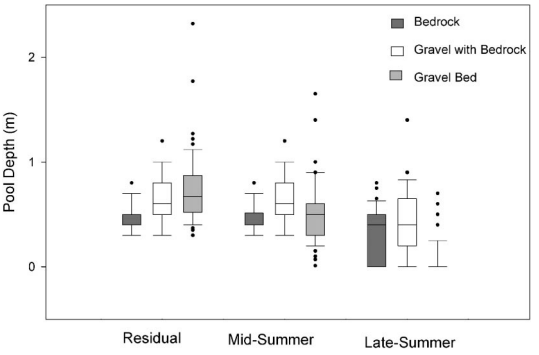

FIGURE 3.—Box-and-whisker plot of residual, midsummer (24 June–11 July), and late-summer (25–30 August) pool depths for three pool types in Harvey and Knowles creeks, Oregon, during 2002. The lower boundary of each box represents the 25th percentile, the midline represents the median, and the upper boundary represents the 75th percentile. The lower whisker represents the 10th percentile, the upper whisker represents the 90th percentile, and circles represent outlying points.

Results

Pool Size and Surface Water Availability

A total of 6.6 km of stream length was surveyed, which contained a total of 153 pools and 51 glides (Table 1). Residual pool depth (Figure 3) was significantly lower in bedrock pools than in the other pool types ($P = 0.0001$, one-way ANOVA). Median depth in each of the three pool types was less than 1 m. A few deep pools were measured in gravel-bed reaches (maximum depth = 2.3 m) and gravel pools with bedrock contact (maximum depth = 1.2 m); these depths were outside the range observed for bedrock pools (maximum depth = 0.8 m). Residual pool area (Figure 4) was slightly larger for gravel pools with bedrock contact than for other pool types ($P = 0.01$, one-way ANOVA).

Twenty-five percent of gravel-bed pools were already dry by midsummer, whereas no pools with bedrock contact were dry during this period (Figure 5). Pools with a bedrock control were more likely to persist throughout the summer dry season

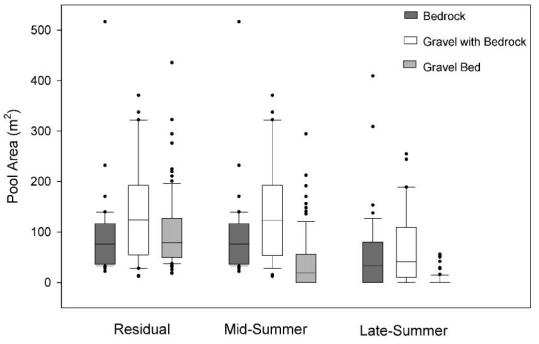

FIGURE 4.—Box-and-whisker plot of residual, midsummer (24 June–11 July), and late-summer (25–30 August) pool area for three pool types in Harvey and Knowles creeks, Oregon, during 2002. The lower boundary of each box represents the 25th percentile, the mid-line represents the median, and the upper boundary represents the 75th percentile. The lower whisker represents the 10th percentile, the upper whisker represents the 90th percentile, and circles represent outlying points.

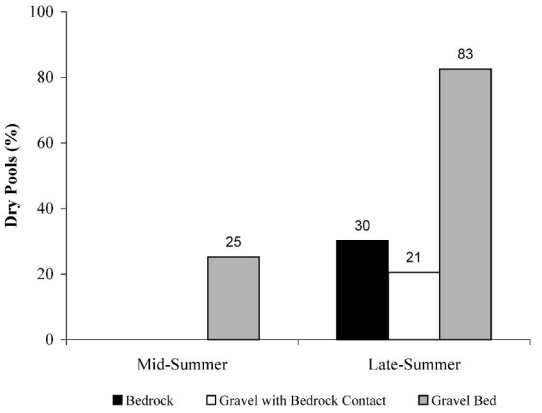

FIGURE 5.—Percentages of three pool types in Harvey and Knowles creeks, Oregon, that were dry by midsummer (24 June–11 July) and late summer (25–30 August) in 2002. Numeric values above the bars represent the actual percentages.

and exhibited the smallest individual decreases in pool depth and area. Seventy percent of bedrock pools remained wet by late summer, and the median decreases in pool depth and pool area were 17% and 40%, respectively. Seventy-nine percent of gravel pools with bedrock contact remained wet by late summer, and the median decreases in pool depth and area were 29% and 50%, respectively. Only 17% of gravel-bed pools persisted through late summer, accompanied by a 100% reduction in median residual pool depth and area.

Among pool types, deeper pools did not have a greater likelihood of remaining wet throughout the summer ($P = 0.05$, log-likelihood test in logistic regression). Within pool types, there was a positive correlation between residual pool depth and the likelihood of remaining wet throughout the summer for gravel-bed pools ($P = 0.02$, log-likelihood test in logistic regression).

Based on residual pool area, the greatest proportion of the total habitat area in both study basins consisted of gravel-bed pools. The majority of this habitat was unavailable, however, during late summer due to a lack of water (Figure 6). Bedrock pools had greater water availability and progressively became the dominant form of available habitat during the summer. By the end of the summer, connectivity was extremely limited for all pool types (Table 2), but the potential for invertebrate drift was highest in bedrock reaches due to the presence of continuous surface flow.

Depositional reaches (hereafter referred to as free-formed alluvial reaches) that plotted below an empirically derived threshold of drainage area and channel slope (Montgomery et al. 1996), recent debris-flow deposits, longitudinal distance from the mouth to the headwaters, and river basin were explanatory variables used to predict the occurrence of dry pools. Debris-flow deposits (a) and free-formed alluvial reaches (b) were highly significant variables ($P = 0.0001$, log-likelihood test) in a logistic regression model ($y = -0.73 + 2.50a + 3.02b$) that correctly predicted the occurrence of 70% of all dry units. No consistent longitudinal pattern ($P = 0.20$, log-likelihood test) or basin effect was detected ($P = 0.06$, log-likelihood test). Pools in free-formed alluvial reaches were 21

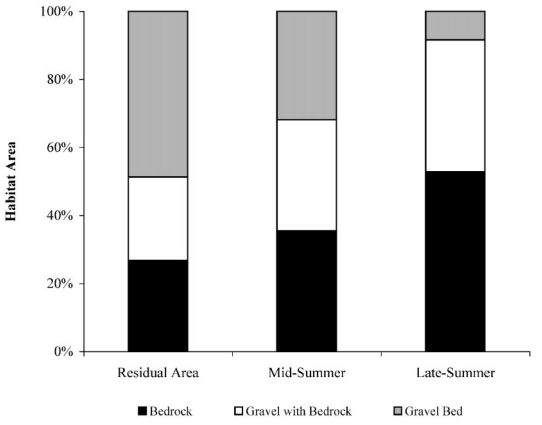

FIGURE 6.—Percentages of available residual, midsummer (24 June–11 July), and late-summer (25–30 August) pool habitat composed of three pool types in Harvey and Knowles creeks, Oregon, 2002.

TABLE 3.—Juvenile salmon abundance and density (SDs in parentheses) in three pool types during midsummer (24 June–11 July) and late summer (25–30 August) of 2002 in Harvey and Knowles creeks, Oregon. Fish densities were calculated based on wetted area.

Pool type	Total number of fish observed midsummer	Residual area median fish density (fish/m^2)	Midsummer median fish density (fish/m^2)	Total number of fish observed in late summer	Late-summer median fish density (fish/m^2)
Bedrock dominated	4,890	0.80 (0.95)	0.80 (0.73)	2,550	0.97 (0.85)
Gravel with bedrock contact	4,050	0.70 (1.20)	0.76 (1.11)	2,260	1.06 (0.91)
Gravel bed	5,110	0.75 (0.65)	1.02 (1.00)	880	1.39 (0.87)

times more likely to go dry than other stream reaches (odds ratio, logistic regression), and pools in debris-flow deposits were 12 times more likely to go dry (odds ratio, logistic regression). In addition to predicting areas susceptible to pool drying, free-formed alluvial reaches and debris-flow deposits correctly predicted the occurrence of 67% of gravel-bed pools in the study streams.

Changes in Fish Abundance

Divers observed a total of 14,050 salmonids (82% juvenile coho salmon, 18% trout) during the midsummer survey. Juvenile coho salmon were evenly distributed during the midsummer sampling period (present in 99% of pools and glides). Trout were less abundant and had a patchy distribution (present in 67% of pools and glides).

Due to the high variability in fish density among pool types (Table 3), no significant differences were detected during either time period ($P = 0.3$ based on midsummer wetted area, $P = 0.4$ based on late-summer wetted area, one-way ANOVA). Fish density remained relatively constant in bedrock pools throughout the summer. Pools in aggraded reaches progressively shrank throughout the summer, resulting in a 46% increase in fish density. This increase in density resulted in substantial crowding of fish in remnant pools. The seasonal increase in fish density was significantly higher in gravel-bed pools and gravel pools with bedrock contact than in bedrock pools (assessed as the change in density between midsummer and late summer within pool types, $P = 0.014$, one-way ANOVA).

Fish abundance decreased substantially in all pool types by late summer (Figure 7); however, the only statistically significant difference was detected for gravel-bed pools ($P = 0.0001$, one-way ANOVA). The decrease in fish abundance, presumably due solely to the desiccation of fish in dry pools, was 36% of the initial population. Mortality of fish desiccated in gravel-bed pools was a minimum estimate, because 25% of pools were already dry during the initial sampling period. Total fish abundance in the study areas decreased by 59% by late summer.

Stream Temperature

The partitioning of surface and subsurface flow in aggraded and bedrock reaches suggests that stream temperature could vary substantially among the different pool types. Our direct investigation was extremely limited, but in the three pools monitored, strong differences in stream temperature were observed (Figure 8). Diurnal temperature patterns fluctuated most in a bedrock pool that received surface flow from a shallow bedrock riffle upstream. In contrast, a bedrock pool that received no surface flow from upstream but that was recharged by subsurface flow discharging from fractured bedrock had relatively low water temperatures and almost no diurnal fluctuation. A gravel pool with bedrock contact that received a mixture of surface flow and hyporheic flow from an upstream riffle containing a thin veneer of alluvium over bedrock was intermediate between the two extremes. The observed temperature patterns should be considered a localized effect and not the result of longitudinal variation within the 1-km section of stream that the pools were located in. This is evident because the pool with the highest water temperature was situated upstream of the pools with lower temperatures. Additionally, there were no significant tributary inputs between the pools that were monitored for temperature.

Discussion

In Mediterranean climates, the summer dry season can be an extremely stressful period for aquatic organisms because of the scarcity of water and potentially high water temperatures. Although the occurrence of a summer drought is very predictable, its magnitude and extent are highly variable. Because the severity of the 2002 dry season was typical for low-flow conditions in the study area, our results have important implications for fish habitat, and inferences drawn from this study are not limited to extremely dry years.

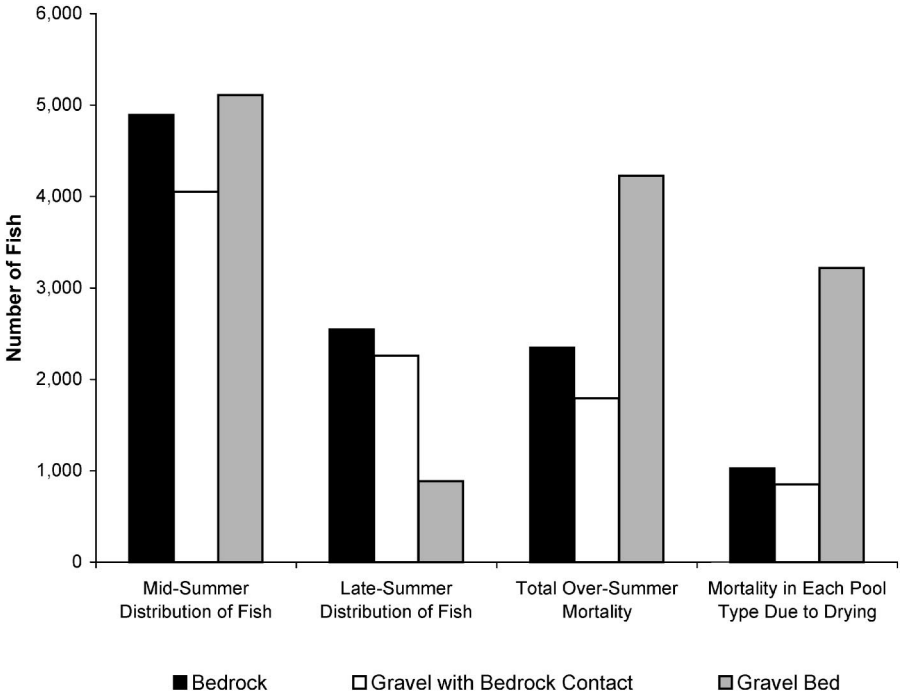

FIGURE 7.—Salmonid abundance in midsummer (24 June–11 July) and late summer (25–30 August), total summer mortality, and desiccation mortality within three pool types in Harvey and Knowles creeks, Oregon, 2002.

Available habitat for salmonids rearing during the summer dry season was strongly correlated with in-channel sediment storage. Residual pool depth was greatest in aggraded reaches; however, the lack of water made the majority of these deep pools unavailable during the summer, and substantial fish mortality occurred when streamflow in gravel-bed pools shifted to subsurface flow. Water was present in these channels for the duration of the summer, but was unavailable at the surface because it passed underneath the streambed as hyporheic flow. In contrast, pools with a bedrock contact had a greater likelihood of remaining wet than pools in aggraded reaches. Small, remnant pools persisted in aggraded reaches when pools were deep enough to contact subsurface flow or when sediment depth was relatively thin, allowing pools to scour to the underlying bedrock. Field evidence suggested that the size of remnant pools was proportional to the area of exposed bedrock at the pool bottom.

A common expectation in coastal regions of the Pacific Northwest is that winter rearing habitat constitutes the primary limiting factor for juvenile coho salmon production (Tschaplinski and Hartman 1983; Nickelson et al. 1992). Results of this study indicate that the summer dry season can also be a period of extremely high mortality in the life cycle of coho salmon and that water availability is one of the primary limitations for survival. Total fish abundance by late summer was 59% lower than midsummer abundance estimates, suggesting that the summer season can be a period of very high mortality. Although estimates of fish abundance based on snorkel surveys can lack the precision of other sampling methods (Hankin and Reeves 1988; Hillman et al. 1992), the magnitude of the difference suggests meaningful biological differences.

To interpret the effects of pool drying on fish survival, we must evaluate several alternative explanations for the change in fish abundance. Indirect effects of pool drying on fish survival include severe crowding and the loss of habitat area, which could cause high levels of physiological stress and/or increased risk of predation. As a direct effect, pool drying could result in acute mortality of fish due to desiccation. However, we cannot rule out the possibility that fish can burrow into the underlying substrate and seek refuge in the hyporheic zone. The effectiveness of the hyporheic zone as a refuge from drying is highly uncertain (Edwards 1998), and this alternative explanation seems unlikely because pools were dry

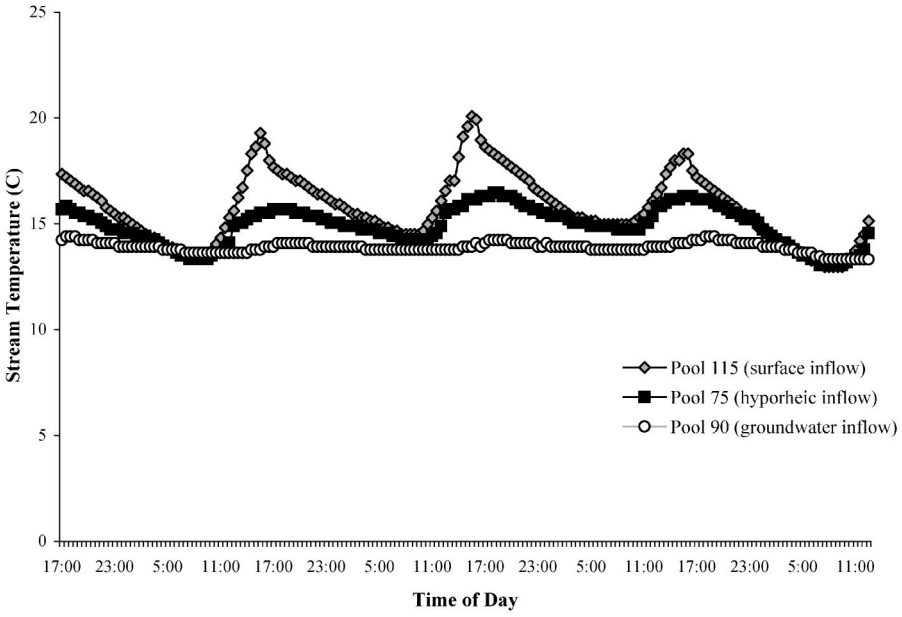

FIGURE 8.—Fluctuations in stream temperature for pools with different substrate and streamflow conditions within a 1-km reach of Harvey Creek, Oregon, during 26–30 August 2002. Pool 115 (bedrock-dominated) was located at the upstream end of the study reach and received surface flow from a shallow bedrock riffle. Pool 90 (a gravel pool with bedrock contact) was located 515 m downstream of pool 115 and received subsurface flow that emerged from fractured bedrock. Pool 75 (a gravel pool with bedrock contact) was located 735 m downstream of pool 115 and received a mixture of surface and subsurface flow from a riffle with a thin veneer of gravel over the underlying bedrock.

for an extended time period (weeks to months). Connectivity between pools was also very limited, so movement of fish to areas that had persistent surface water throughout the summer was also unlikely. Fish abundance did not increase between midsummer and late summer in any of the pools we observed, which suggests that movement was severely limited and that fish were not able to congregate in persistent pools.

The fraction of the initial population of salmonids that were lost to desiccation in dry pools by late summer was proportional to the fraction of bedrock pools and gravel pools with bedrock contact that went dry, suggesting that fish were evenly distributed among these pool types. In contrast, the proportion of gravel-bed pools that went dry (83%) was greater than the proportion of fish desiccation mortalities (63%). Midsummer fish density in gravel-bed pools that persisted throughout the summer was 43% higher (1.09 fish/m^2 residual area) than in gravel-bed pools that eventually went dry (0.62 fish/m^2 residual area). Within the gravel-bed pool type, deeper pools had a greater likelihood of remaining wet throughout the summer, and fish may have preferentially utilized these pools. Similarly, Labbe and Fausch (2000) observed that deeper pools had a higher probability of persisting through the summer dry season in an intermittent stream underlain by thick alluvial deposits. However, it is important to note that shallower bedrock pools had a greater overall likelihood of remaining wet throughout the summer than the deeper gravel-bed pools.

Field observations suggest that three factors influenced water availability in pools: (1) gravel depth, (2) bedrock topography, and (3) subsurface flow paths through fractured bedrock. Gravel depth influenced surface water availability by increasing the proportion of the low-flow stream water that traveled through the hyporheic zone. The relatively small size of pools in the study area suggests that scour was inadequate to create pool contact with the underlying bedrock in alluvial deposits greater than 1 m deep. The uneven surfaces of the underlying bedrock also compounded the problem of predicting water availability. When bedrock was exposed at the bottom of a pool, we could not determine whether the bedrock contact was (1) a slightly elevated ledge within the bank-full channel or (2) a trough where the low-flow stream water

collected. Presumably, this could explain why some of the gravel pools with bedrock contact went dry. In addition, a few bedrock-dominated stream reaches also had intermittent surface flow. Impervious sandstone layers typically formed the channel bed, but the sandstone layers were interbedded with more erosive, more porous siltstone layers. Sandstone layers commonly had large fractures that allowed all or a portion of the streamflow to travel beneath the bedrock surface. Bedrock pools are typically formed by plucking, a process whereby fractures produce loosened blocks that are entrained and transported (Whipple et al. 2000). Plucking of large blocks exposed the porous siltstone layers, and subsurface flow was observed emerging from bedrock ledges. Infiltrating and emerging flow paths through the fractured bedrock have also been observed during studies of hillslope hydrology in this area (Anderson et al. 1997).

In some regions, broad valley floors that contain thick alluvial and glacial deposits function as recharge areas for the hyporheic zone (Stanford and Ward 1993). In upwelling zones, hyporheic exchange has the potential to greatly enhance summer habitat. However, this broad-scale pattern has not been observed in the Oregon Coast Range, where mountain streams are typically constrained within narrow valleys and where the hyporheic zone appears to be limited to the aggraded zone of the bank-full channel.

Predicting Areas Susceptible to Channel Aggradation and Pool Drying

This study established a direct linkage between physical channel structure and ecologically significant habitat characteristics. Two areas subject to pervasive channel aggradation were: (1) stream reaches that fell below a drainage area and channel slope threshold (Montgomery et al. 1996), and (2) thick sediment accumulations stored behind massive log jams that were delivered by debris flows. Based on these predictions, juvenile fish survival during the summer dry season can be estimated or modeled over a broader area.

Montgomery et al. (1996) identified an inverse relationship between drainage area and channel slope that separates bedrock reaches from free-formed alluvial reaches. The threshold is affected by the local influence of log jams, sediment supply, and clast lithology (Montgomery et al. 1996; Massong and Montgomery 2000). Alluvial reaches consistently plot at a lower average slope for a given drainage area, and are therefore expected to exhibit predictable and persistent alluvial bed morphology. Alluvial reaches are inherently depositional and are susceptible to pervasive, long-term channel aggradation. In contrast, stream reaches that plot above the threshold are limited to localized sediment accumulations stored behind log jams, boulder accumulations, and debris-flow deposits (Montgomery et al. 2003). Specific sites of aggradation in these areas are therefore transient and less predictable.

Similar to free-formed alluvial reaches, debris-flow deposits also had a high likelihood of going dry. These results indicate that temporal dynamics of sediment and wood supply, in addition to spatially explicit models based on slope–area relationships, are important considerations for predicting channel aggradation. In the Oregon Coast Range, landslides and debris flows can deliver large volumes of coarse sediment to river channels. These mass wasting processes can form extensive accumulations of wood that completely dam the channel and valley floor; the associated sediment deposits can be several meters thick and can inundate hundreds of meters of stream channel (May 2001, 2002). The architecture of these deposits is unique in small, coastal streams that lack the capacity to transport large volumes of wood by fluvial processes, because wood is typically large relative to channel size (Bilby and Ward 1989). Wood delivered from riparian forests adjacent to the channel typically create in-stream wood structures that consist of individual pieces or small accumulations. Alluvial deposits stored behind wood accumulations are typically thin because the depth of sediment is limited by the height of the wood accumulation; therefore, substantial channel aggradation is not possible in such areas. Debris-flow deposits may assume a greater relative importance in log-jam formation for streams bordered by industrial forests because of decreases in the size of wood recruited from the local riparian area (Montgomery et al. 2003) and increases in debris-flow frequency and magnitude associated with timber harvest and roads (May 2002).

A logistic regression model that included the location of free-formed alluvial reaches and recent debris-flow deposits accurately predicted the presence of 70% of dry pools at the reach scale, and identified the spatial occurrence of 67% of gravel-bed pools. Contrary to a common expectation that the likelihood of pool persistence throughout the summer would increase in a downstream direction due to increased drainage area, no consistent longitudinal pattern in water availability was detected

by the logistic regression model. Patterns of pool drying were also similar between the two study basins.

Discontinuous Flow Patterns and Fish Energetics

Habitat connectivity is an important consideration for fish because it influences movement and the availability of food resources supplied from upstream sources. Pools that lack connectivity may provide only limited opportunities for growth because of the lack of invertebrate drift from upstream. Previous research in the Napa River, California, found that discontinuous flow patterns of dry riffles alternating with wet pools, as well as high water temperatures, resulted in low to negative growth of juvenile steelhead (Stillwater Sciences 2002). In three western Washington streams with a high degree of connectivity, juvenile coho salmon moved out of smaller and shallower habitat units, and fish that moved among habitat units grew faster than fish that remained in the same habitat unit (Kahler et al. 2001). These results indicate that small-scale, habitat- and growth-related movements are important components of summer rearing.

Limited sampling of stream temperature suggests that surface and subsurface flow paths substantially influence stream temperature at very fine spatial scales. The diversity of flow paths creates thermal heterogeneity, allowing fish inhabiting individual pools to experience different environmental conditions. High water temperatures can increase metabolic rates (Brett 1971) and therefore have a direct effect on growth. Based on the differences in temperature and connectivity among the different pool types we investigated, there may be a strong potential for differential growth among the pool types. Bedrock reaches appeared to have a greater supply of food because a higher proportion of riffles remained wet and had the potential to deliver invertebrate drift, whereas isolated pools were limited to in situ production and localized terrestrial inputs. The net effect of potentially greater food availability and increased fish metabolic costs (due to higher water temperatures) in bedrock reaches could not be determined in this study but is an important consideration for future research.

Patterns of seasonal growth and survival of salmonids in the Pacific Northwest are highly uncertain. Previous research has documented a positive correlation between summer streamflow and survival of juvenile coho salmon (Mathews and Olson 1980); however, no underlying mechanisms have been investigated. Summer growth of juvenile salmonids may be critical to population viability because larger fish generally have higher overwinter survival rates than do smaller individuals (Quinn and Peterson 1996). Larger smolts also have a greater likelihood of surviving the ocean phase of their life history (Yamamoto et al. 1999; Zabel and Williams 2002). In the Pacific Northwest, winter growth is often restricted by cold water temperatures, reduced primary production, and the need for juvenile fish to seek cover from high stream velocities (Bilby and Bisson 1992). In coastal streams of northern California, extremely low growth rates of juvenile coho salmon have been observed during the winter, followed by substantial increases in growth during spring (Bell 2001). If food or foraging opportunities are limited in the summer and winter, salmonid fishes may be highly dependent on growth accrued during spring and autumn for achieving a larger body size.

Summary and Implications for Land Management

Field investigations of channel aggradation and water availability during the middle of the summer dry season indicated that areas of high sediment storage were associated with slightly deeper pools. Late-summer surveys revealed that the majority of gravel-bed pools went dry because the streambed was extremely porous and allowed streamflow to drop below the bed elevation. Aggradation caused surface flow to become intermittent, which stranded fish in drying channels. In areas of low sediment storage, pool depth was limited by the underlying bedrock, but these pools were sustained by hyporheic flow and were more likely to persist throughout the summer dry season. These results illuminate an important temporal dynamic that occurs during the summer dry season, and serve as a reminder that field measurements taken at a single point in time can be a misleading indication of habitat quality when habitat conditions are spatially and temporally dynamic (Van Horne 1983).

Our results also address an important question about the influence of large influxes of sediment and wood on aquatic habitat, a subject that is currently undergoing a great deal of speculation. Because channel aggradation was directly linked to water availability and fish survival, this study demonstrates that increases in coarse sediment supply can be associated with sharp reductions in salmonid habitat and productivity. Land-use practices, such as timber harvest and road construction, are often associated with large influxes of coarse

sediment in forested mountain streams, particularly through increases in landslide and debris-flow activity (Swanson and Dyrness 1975; Swanson et al. 1982; Madej and Ozaki 1996; May 2002). Similarly, severe wildfires, which are a major component of the disturbance regime in the Oregon Coast Range (Long et al. 1998), can also result in an accelerated rate of coarse sediment input (Swanson 1981; Meyer et al. 2001; May and Gresswell 2003). However, river systems are dynamic, and disturbance events that result in a short-term loss of habitat may be required to create productive habitat conditions over the long term (Reeves et al. 1995; Labbe and Fausch 2000). Aggraded channels may create important habitat for other life history stages during other seasons. For example, aggraded reaches can create spawning areas in channels that otherwise may be too coarse (Buffington and Montgomery 1999).

Reeves et al. (1995) hypothesized that the most complex habitat conditions and fish assemblages would form in watersheds that are at intermediate stages of disturbance and reorganization. Channels that are interposed between gravel rich and gravel poor may provide optimal habitat conditions, because deep pools can form in the stored alluvium and contact with the underlying bedrock provides consistent water availability and lower water temperatures. However, the biotic interactions caused by increased crowding of fish trapped in isolated pools and the lower food availability associated with discontinuous surface flow may offset the favorable abiotic conditions. Tradeoffs between short- and long-term effects of disturbance remain uncertain, but mountain streams that are susceptible to catastrophic disturbances like fires and debris flows will produce a dynamic condition in which not all habitats are suitable for salmonid production at a specific point in time.

Acknowledgments

Funding for this research was provided by the National Fire Plan, an interagency program supported in part by the U.S. Department of Agriculture Forest Service. We are especially grateful to the watershed sciences team at the Redwood Sciences Laboratory in Arcata, California, Robert Gresswell with the U.S. Geological Survey, and Sherri Johnson with the Pacific Northwest Research Station for providing logistical support and field assistance. Dave Montgomery generously provided slope–area data for Knowles Creek. Bret Harvey contributed substantially to this paper through numerous discussions, analytical insight, and critical reviews of the draft manuscript. Dan Isaak and two anonymous reviewers provided a thorough critique of the submitted manuscript, and their efforts are greatly appreciated.

Large-diameter trees store disproportionally massive amounts of carbon and are a major driver of carbon cycle dynamics in forests worldwide. In the temperate forests of the western United States, proposed changes to Forest Plans would significantly weaken protections for a large portion of trees greater than 53 cm (21 inches) in diameter (herein referred to as "large-diameter trees") across 11.5 million acres (∼4.7 million ha) of National Forest lands. This study is among the first to report how carbon storage in large trees and forest ecosystems would be affected by a proposed policy. We examined the proportion of large-diameter trees on National Forest lands east of the Cascade Mountains crest in Oregon and Washington, their contribution to overall aboveground carbon (AGC) storage, and the potential reduction in carbon stocks resulting from widespread harvest. We analyzed forest inventory data collected on 3,335 plots and found that large trees play a major role in the accumulated carbon stock of these forests. Tree AGC (kg) increases sharply with tree diameter at breast height (DBH; cm) among five dominant tree species. Large trees accounted for 2.0 to 3.7% of all stems (DBH ≥ 1" or 2.54 cm) among five tree species; but held 33 to 46% of the total AGC stored by each species. Pooled across the five dominant species, large trees accounted for 3% of the 636,520 trees occurring on the inventory plots but stored 42% of the total AGC. A recently proposed large-scale vegetation management project that involved widespread harvest of large trees, mostly grand fir, would have removed ∼44% of the AGC stored in these large-diameter trees, and released a large amount of carbon dioxide to the atmosphere. Given the urgency of keeping additional carbon out of the atmosphere and continuing carbon accumulation from the atmosphere to protect the climate system, it would be prudent to continue protecting ecosystems with large trees for their carbon stores, and also for their co-benefits of habitat for biodiversity, resilience to drought and fire, and microclimate buffering under future climate extremes.

Keywords: carbon, climate mitigation, eastside screens, forests, global change, large-diameter trees, 21-inch rule

INTRODUCTION

Forest carbon accumulation is crucial for mitigating ongoing climatic change, with individual large trees storing a substantial portion of the overall carbon in living trees. Globally, forests store about 862 Gt carbon in live and dead vegetation and soil, with 42% of it stored in live biomass (above- and belowground; Pan et al., 2011). Globally, forests removed the equivalent of about 30% of fossil fuel emissions annually from 2009 to 2018 (Friedlingstein et al., 2019), and 44% of that was by temperate forests. Temperate forests of the United States are the largest category of land sinks in the country, consistently offsetting about 14% of the Nation's CO_2 emissions (EPA, 2020). Projections indicate that ecological systems have significant additional climate mitigation potential, with forest carbon accumulation serving as a central component of a natural climate solutions framework (Griscom et al., 2017; Fargione et al., 2018; Moomaw et al., 2019; Cook-Patton et al., 2020).

Large-diameter trees constitute about half of the mature forest biomass worldwide and are key to the ability of forests to accumulate substantial amounts of carbon needed to mitigate climate change (Luyssaert et al., 2008; Lutz et al., 2018). Trees exceeding 60 cm (23.6 in) diameter at breast height (DBH) comprise ∼41% of the world's aboveground live tree biomass (Lutz et al., 2018). Furthermore, on average, 50% of the live tree biomass carbon in all types of forests globally is stored in the largest 1% of trees, but the value for the United States is lower, ∼30% in the largest 1% of trees due to widespread historical logging of large trees (Lutz et al., 2018). A single large tree can add the same amount of carbon to the forest within a year as is contained in a single mid-sized tree of the same species (Stephenson et al., 2014). The relationship between large-diameter trees and overall forest biomass suggests that forests cannot accumulate aboveground carbon (AGC) to their ecological potential without large trees (Lutz et al., 2018). Recognition of the importance of large-diameter trees in determining global atmospheric carbon stocks has led to management recommendations to conserve existing large-diameter trees and those that will soon reach large diameters (Lindenmayer et al., 2014; Lutz et al., 2018; Moomaw et al., 2019).

In addition to comprising a substantial portion of forest carbon storage and accumulation, large-diameter trees fulfill a variety of unique ecological roles such as increasing drought-tolerance, reducing flooding from intense precipitation events, altering fire behavior, redistributing soil water, and acting as focal centers of mycorrhizal communication and resource sharing networks (Bull et al., 1997; Brooks et al., 2002; Brown et al., 2004; Luyssaert et al., 2008; Beiler et al., 2015; Lindenmayer and Laurance, 2017). In the United States Pacific Northwest (PNW), carbon dense old growth forests buffer against increasing temperatures by creating microclimates that shelter understory species from rising temperatures (Frey et al., 2016; Davis et al., 2019a). Forests with large-diameter trees often have high tree species richness, and a high proportion of critical habitat for endangered vertebrate species, indicating a strong potential to support biodiversity into the future and promote ecosystem resilience to climate change (Lindenmayer et al., 2014; Buotte et al., 2020).

In the PNW region of the United States a 21-inch (∼53 cm) diameter criteria (USDA Forest Service, 1995) was enacted in 1994 to slow the loss of large, older trees and old forest patches in national forests east of the Cascade Mountains crest in Oregon and Washington. The forests under consideration shall be referred to as "eastside forests" to be consistent with United States Forest Service (USFS) terminology. In our study, we refer to trees that equal or exceed this value to be "large-trees" or "large-diameter trees." Extensive studies determined that the large tree component of old forest structure had decreased due to human uses, and that sensitive wildlife species associated with old growth forest such as the American Marten and the Northern Goshawk were also in decline (Interior Columbia Basin Ecosystem Management Project, 2000; Wisdom et al., 2000; Bull et al., 2005; Greenwald et al., 2005). Site-specific exceptions have allowed removal of some trees ≥21 in DBH. However, the 21-inch rule has prevented large-scale harvest of trees ≥21 in DBH. For example, the 2010 Snow Basin Vegetation Management Project proposed harvesting over 43,000 trees ≥21 in DBH but was stopped by litigation [League of Wilderness Defenders, et al., v. Connaughton, et al., No. 3:12-cv-02271-HZ (D. Or. Dec. 9, 2014)]. Recently restoration of these forests was claimed to be inhibited by the 21-inch rule that protects large trees from logging (Hessburg et al., 2020). The rationale for harvesting large trees is premised upon the use of historical baselines of stand structure and species composition as management targets, and assuming that by removing large shade-tolerant species like grand fir and Douglas-fir it will promote resilience to future drought and disturbance (Johnston et al., 2018; Merschel et al., 2019; Hessburg et al., 2020). However, ongoing climate change and many other anthropogenic stressors such as habitat fragmentation, invasive species, and declines in biodiversity, heighten concerns over use of historical conditions as management targets (Millar et al., 2007; IPCC, 2018; Ripple et al., 2020). Proposed amendments to the 21-inch diameter limit would allow widespread harvesting of the larger trees up to 30 in DBH (76.2 cm) across six National Forests of eastern Oregon and southwestern Washington with major implications for forest carbon dynamics and important environmental co-benefits (**Figure 1**).

Carbon storage is an increasingly important management objective for National Forest Lands in the United States (Depro et al., 2008; Dilling et al., 2013; Dugan et al., 2017). USFS Forest Inventory and Analysis (FIA) data have been used to develop baseline stocks and trends of forest carbon for every region and individual National Forest, including assessment of the main disturbance, management, and environmental factors that drive changes (Birdsey et al., 2019). Western United States forests show considerable potential to accumulate additional carbon over the coming century, especially forests within the PNW that are projected to have relatively low to moderate vulnerability to future drought and fire (**Figure 1**; Buotte et al., 2020). Strategies to mitigate climate change effects on forests require careful examination of the tradeoffs of proposed forestry practices on forest carbon stock accumulation, water cycling, and additional environmental co-benefits of forests, such as biodiversity and

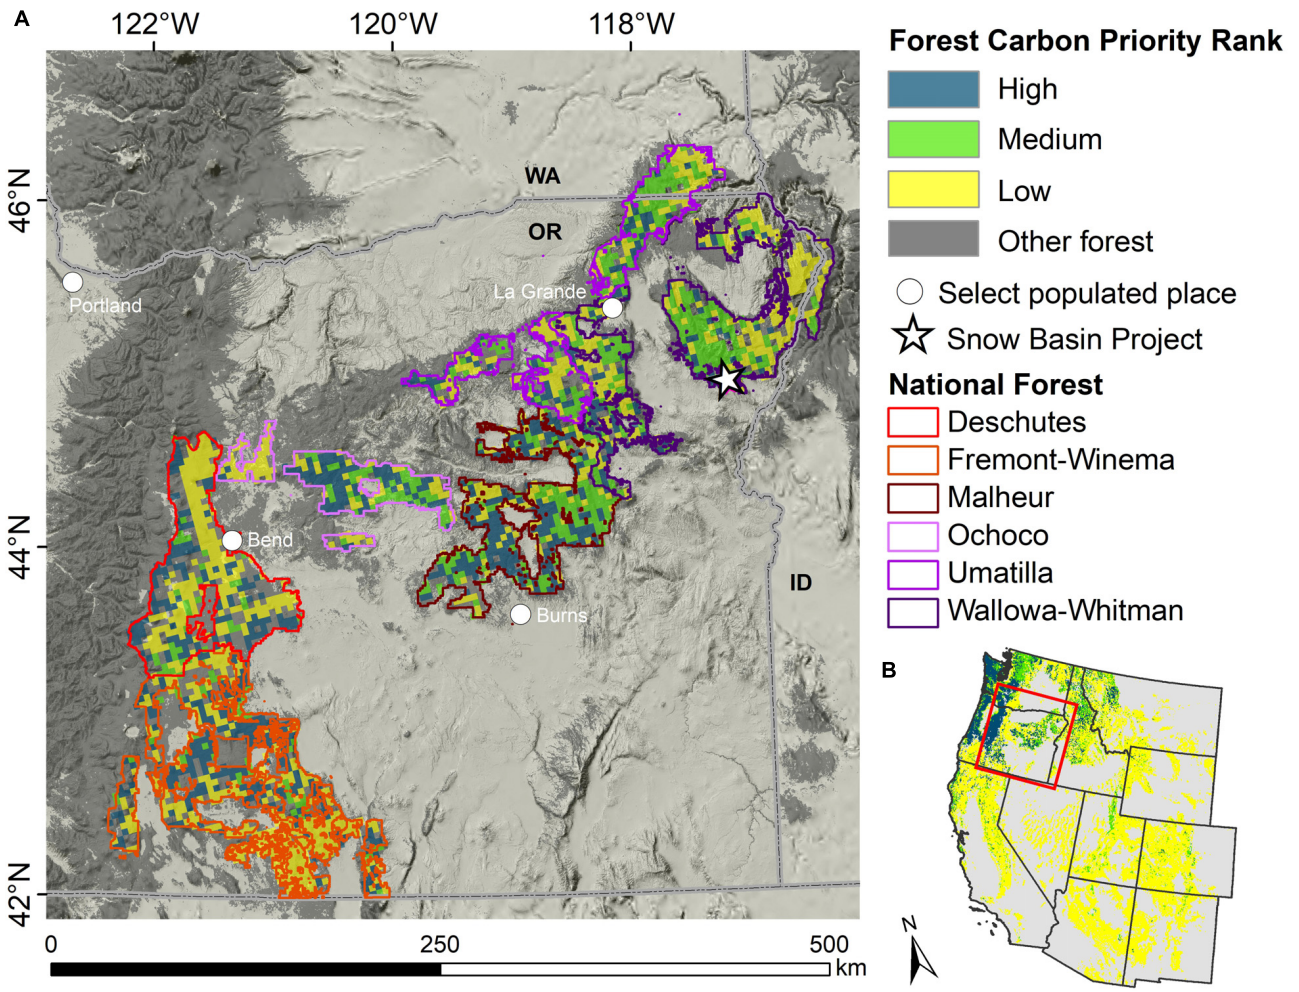

FIGURE 1 | Locations of the six national forests in eastern Oregon, southeastern Washington, and western Idaho, and the proposed Snow Basin Project area **(A)**. The forest carbon conservation priority rank is shown for the national forests and **(B)** for the broader western United States. The forest carbon conservation priority rank is from Buotte et al. (2020) and was derived from simulations of potential forest carbon sequestration and vulnerability to drought and fire over the 21st century. Forest extent is from Ruefenacht et al. (2008).

microclimatic buffering (McKinley et al., 2011; Law et al., 2018; Sheil, 2018; Buotte et al., 2020).

The potential effects of changing the 21-inch rule on carbon storage of eastside forests have not been adequately considered. Proposed changes to the management of large trees should be carefully assessed prior to adoption of new rules given that forest carbon storage is critically important in the context of a warming climate, and that large trees disproportionately store more accumulated carbon, keeping it out of the atmosphere. The objective of this study is to evaluate the potential impact of removal of the 21-inch rule on forest carbon stocks and carbon stock accumulation in eastside forests (**Figure 1**). We examine the relationship between tree DBH and AGC storage at tree to population scales for selected dominant tree species in eastside forests, focusing on the following questions:

1. How does AGC storage change with tree diameter among the dominant eastside tree species?
2. How common are large trees across the eastside forests by species and what proportion of each species total AGC do they account for?
3. What are the potential consequences on carbon stores of widespread removal of large trees in eastside forest restoration projects?

MATERIALS AND METHODS

Study Area

Our study area included the six national forests in eastern Oregon, two of which extend slightly into southwestern Washington and western Idaho (**Figure 1**). Located within the East Cascades and Blue Mountains ecoregions, these national forests together cover approximately 11.5 million acres (4.7 million ha) of complex mountainous terrain, characterized by a broad range of environmental gradients in climate regimes and

TABLE 1 | Summary of forest inventory data and climate conditions for the six National Forests included in the analysis.

National forest	Forest inventory			Climate conditions			
	N. Plots	DBH (cm)	AGC (kg)	Annual precipitation (mm)	Temperature (°C)		
					Annual	Jan.	July
Deschutes	474	16 (187)	131 (11359)	817 (170)	6.1 (0.6)	−1.5 (1.9)	16.1 (1.8)
Fremont-Winema	740	17 (204)	145 (14269)	681 (156)	6.3 (0.6)	−1.4 (1.9)	16.6 (1.8)
Malheur	687	15 (145)	108 (8392)	571 (104)	5.9 (0.7)	−2.9 (2.0)	17.2 (2.1)
Ochoco	253	16 (188)	119 (13462)	484 (101)	7.1 (0.6)	−1.0 (1.9)	17.6 (1.9)
Umatilla	487	14 (139)	99 (8759)	802 (121)	6.8 (0.7)	−1.5 (1.8)	17.5 (2.0)
Wallowa-Whitman	694	13 (164)	91 (8301)	792 (119)	6.0 (0.7)	−3.0 (1.8)	17.3 (2.1)

Forest inventory data were from the USFS Forest Inventory and Analysis program for the period 2000 to 2018. The variables include number of inventory plots and the average (max) diameter at breast height (DBH) and aboveground carbon (AGC) of trees on inventory plots. Average (±1 SD) climate conditions were based on the 40-year period from 1981 to 2019 and derived from 4-km resolution gridded PRISM data (Daly et al., 2008).

associated forest types (Johnson and Clausnitzer, 1992; Peterson and Waring, 1994; Berner and Law, 2015). The Blue Mountains ecoregion functions ecologically and floristically as a transverse bridge between the Cascade Mountains to the west and the Rocky Mountains to the east (Kerns et al., 2017). This "mega-corridor" links together some of the most intact habitat remaining in the PNW region and is of great importance to regional-scale connectivity and carbon storage in response to a warming climate (McGuire et al., 2016; Buotte et al., 2020).

Climatic conditions from 1981 to 2019 were similar across National Forests with regard to January and July average temperatures but show substantial variation in annual precipitation (**Table 1**). The Deschutes and Fremont-Winema National Forests are in the eastern Cascade Mountains and thus receive relatively high annual precipitation (817 mm and 681 mm) due to orographic uplift. National Forests in the southwestern Blue Mountains receive less precipitation (Malheur, 571 mm; Ochoco, 484 mm) due to their location within the rainshadow of the Cascade Mountains. In the northeastern portion of our study area annual precipitation increases to 802 mm and 792 mm, respectively, for the Umatilla and Wallowa Whitman National Forests due to the intrusion of moisture-laden air masses through the Columbia River Gorge. The region's complex precipitation patterns are similarly reflected in the distribution of forest types and biophysical characteristics.

Forest Inventory and Analysis Dataset

We relied on forest inventory measurements from the USFS FIA program and our own selection of biomass equations to evaluate relationships between tree diameter and AGC storage, as well as assess potential effects of tree removal proposed as part of the 2010 Snow Basin project. The FIA conducts systematic forest inventories across the United States, with one field sampling plot for every ∼2,400 hectares (6,000 acres) of forest (O'Connell et al., 2017). In the western United States, the FIA surveys 10% of sampling plots each year, meaning that each sampling plot is revisited every 10 years. At each sampling plot, field crews collect data on tree species, tree size, and other forest attributes. These inventory data are available online through the FIA DataMart[1].

[1]https://apps.fs.usda.gov/fia/datamart/

We downloaded the latest FIA data (FIADB_1.8.0.02) for Oregon, Washington, and Idaho, and then identified inventory plots that occurred within the six national forests based on a spatial overlay with national forest boundaries (n = 3,973 plots). To maintain landowner privacy the FIA plot coordinates available to the public are slightly altered ("fuzzed"), thus our spatial overlay may include some plots just outside the national forests or miss some plots that occur around the edges of these forests. We selected the latest inventory measurements from each surveyed plot for the years 2010 to 2018 (the most recent year available). We filtered these data to include only live trees of the five tree species of interest. A total of 54,651 individual trees were measured on the microplots, subplots, and macroplots, which represented 636,520 trees after applying the expansion factors for each type of plot. Overall, we used data from 3,335 plots in this analysis. A summary of FIA plot conditions within our study area shows that relatively small variations in average DBH across National Forests, between 13 cm and 17 cm, translate into substantial differences in AGC (**Table 1**). The Fremont Winema National Forest had the largest average DBH (∼17 cm) and the largest average AGC stores (∼145 kg), whereas the Wallowa-Whitman had the smallest average DBH (∼13 cm) and the smallest average AGC stores (∼91 kg).

We performed the analysis using the statistical software R (v. 3.6.1; R Core Team, 2020) with add-on packages including data.table (Dawle and Srinivasan, 2019), ggplot2 (Wickham, 2016), maptools (Bivand and Lewin-Koh, 2019), raster (Hijmans, 2019), and rgdal (Bivand et al., 2019).

Estimating Tree Aboveground Carbon Storage

We estimated AGC storage (AGC; kg C) for each tree on the FIA inventory plots using tree biometric measurements from FIA along with species- and component-specific biomass allometric models and traits (**Supplementary Tables 1, 2**). Using species-specific allometric models that include height measurements are essential to capture climate and site effects on taper and height (volume), and reduce uncertainty compared to estimates that are diameter-based and generalized models. For example, Van Tuyl et al. (2005) found that generalized models underestimated

biomass by 50% on the eastside. Specifically, for each tree we estimated AGC as the sum of carbon stored in stem, branch, bark, and foliage biomass. To estimate stem biomass, we first derived stem volume using species-specific allometric models that incorporated tree diameter and height (Cochran, 1985; **Supplementary Table 1**). We then converted stem volume to biomass using published information on the wood density of each species, which we found was important to reducing uncertainty in estimates (Van Tuyl et al., 2005; Ross, 2010; Berner and Law, 2015). We also estimated branch, bark, and foliage biomass using species-specific allometric models, substituting equations for similar species where necessary (Gholz et al., 1979; Means et al., 1994; Jenkins et al., 2004). We assumed dry stem, branch, and bark biomass was 47.6 to 52.5% carbon depending on species (Lamlom and Savidge, 2003) and that dry foliage biomass was 46.1 to 51.4% carbon depending on species (Berner and Law, 2016). For trees smaller than 10 cm DBH, total aboveground biomass was estimated from tree height and then converted to AGC assuming wood carbon content.

Tree-Level Analysis of Relationship Between Tree Diameter and Aboveground Carbon

To better understand how carbon storage varies with tree size in eastside forests, we examined relationships between tree diameter (DBH; cm) and aboveground carbon (AGC; kg) among trees sampled on the FIA plots. Specifically, we rounded the DBH of each tree to the nearest centimeter and then computed the average AGC of trees within each 1-cm size class. To account for sampling uncertainty, we repeatedly computed these metrics using a resampling approach where each draw ($n = 10^4$) utilized data from a random 25% of inventory plots sampled with replacement. We computed the median across these 10^4 draws as our best-estimate of these metrics and also derived 95% confidence intervals.

Population-Level Analysis of Tree Diameter and Aboveground Carbon

We evaluated how the cumulative percentage of tree stems and AGC varied with tree diameter across the six national forests of our study area using forest inventories. This involved quantifying the cumulative percentage of tree stems and total AGC by DBH for each tree species, as well as pooled across tree species. To account for sampling uncertainty, we again implement a resampling approach ($n = 10^4$ draws).

Snow Basin Case Study: Carbon Consequences of Proposed Large Tree Removal

To estimate the carbon consequences of large tree removal we utilized USFS National Environmental Policy Act (NEPA) documentation from the Snow Basin Vegetation Management Project located on the Wallowa-Whitman National Forest, Whitman Ranger District, Baker County, Oregon (**Figure 1**). The project area includes 10,721 ha (26,493 acres) of National Forest land and primarily encompasses two main subwatersheds (Paddy Creek-Eagle Creek and Little Eagle Creek). Elevations within the project area range from approximately 1,340 m (4,400 feet) on the southern boundary to approximately 1,980 m (6,500 feet) at the northern boundary near the border with the Eagle Cap Wilderness. The USFS's preferred alternative plan was to remove over 43,000 large trees (DBH $\geq$ 21 in or 53.3 cm) from the project area. The large tree removal was prevented by litigation, but the project nonetheless provides a realistic framework to evaluate the carbon cost of large tree removal associated with dry forest landscape-scale restoration projects.

The Snow Basin NEPA document estimated the number of large trees to be removed or retained per acre by biophysical environment (Snow Basin DEIS). The USFS's preferred alternative proposed removal of grand fir from cool/moist and warm/dry grand fir biophysical environments, as well as removal of ponderosa pine, Douglas-fir, and western larch from mixed ponderosa pine and Douglas-fir biophysical environments (**Table 2**). Based on this information we computed the total number of large trees proposed for removal vs. retention across the project area by biophysical environment. To evaluate the potential carbon consequences of large tree removal, it was necessary to know tree size class distribution. The FIA only surveyed 13 plots in the Snow Basin project area between 2010 and 2018, of which 12 plots included large trees. After an initial analysis, we deemed this inadequate for rigorous assessment of tree size class distribution and therefore used tree measurements from all FIA plots in the Wallowa-Whitman National Forest that included large trees for the species of interest ($n = 217$ plots). To estimate the size class distribution of large trees, we computed the fraction of large trees that occurred at 0.1 cm DBH intervals between 53.3 cm and the largest observed DBH for grand fir, and after combining ponderosa pine, Douglas-fir, and western larch into a mixed-species group. For each biophysical environment, we then distributed the large trees proposed for removal or retention among these size classes in proportion to the occurrence of trees in each size class. Lastly, we estimated the total large tree AGC that would be removed or retained by multiplying the number of trees in each size class by the mean AGC of trees in that size class and then summing AGC across size classes. To account for sampling uncertainty, we again computed these metrics using a resampling approach where each of 10^4 draws utilized data from a random 25% of inventory plots sampled with replacement. As before, we computed the median across these 10^4 draws as our best-estimate and derived 95% confidence intervals. For verification, we also performed this assessment using only FIA plots in the Snow Basin Project area rather than across the Wallowa-Whitman National Forest and present these findings in the **Supplementary Material**.

RESULTS

Relationships Between Tree Diameter and Aboveground Carbon

Average tree aboveground carbon (AGC; kg) rapidly increased with tree diameter at breast height (DBH; cm) among dominant tree species measured on USFS inventory plots located in the

TABLE 2 | The total number of trees ≥21 in DBH proposed for removal and retention across the Snow Basin project area as reported in the NEPA plan prepared by the USFS (Table 53 of Snow Basin Vegetation Management Project DEIS, 2011).

Biophysical environment	Acres treated	Species removed	Mean number of large trees per acre		Total number of large trees	
			Removed	Retained	Removed	Retained
Cool/moist grand fir	973	Grand fir	5	9	4,865	8,757
Warm/dry grand fir	5,262	Grand fir	5	5	26,310	26,310
Warm/dry Douglas-fir and ponderosa pine Warm/moist Douglas-fir	6,136	Douglas-fir, ponderosa pine, western larch	2	3	12,272	18,408
Grand total	12,371	–	–	–	43,447	53,475

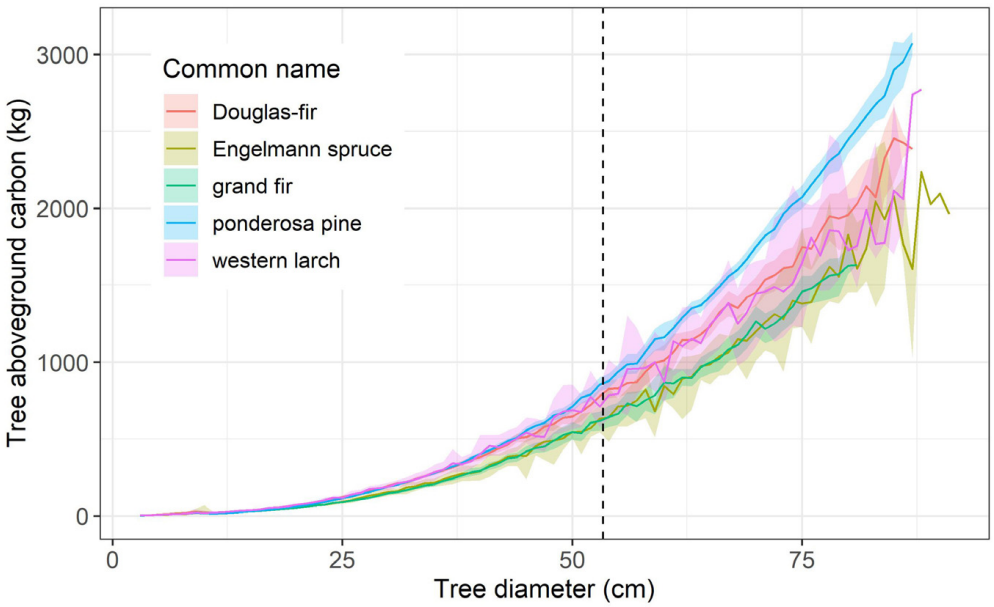

FIGURE 2 | Average tree aboveground carbon (AGC; kg) increases sharply with tree diameter at breast height (DBH; cm) for five dominant tree species measured on USFS inventory plots located in the six eastside national forests. The 21-inch (53.3 cm) DBH limit of the Eastside Screens (vertical dash line) is shown for reference. Tree AGC (≥10 cm DBH) was estimated from tree diameter and height using regional species-specific allometric equations, wood density, and carbon content. Similarly, sapling AGC (DBH = 3–9.9 cm) was estimated from sapling height using regional species-specific allometry and wood carbon content. These estimates and 95% confidence intervals were derived by resampling ($n = 10^4$) measurements from inventory plots (n = 3,335). For visual clarity, the tree diameter limit for each species excludes the largest 0.5% of trees, generally those larger than 80 to 88 cm DBH.

six eastside national forests (**Figure 2**). For instance, an average 25 cm (∼10") diameter tree stored 90–121 kg of AGC depending on tree species, while a 50 cm (∼20") diameter tree stored 541–683 kg of AGC. Thus, doubling tree diameter over this range led to a 5.3–6.2-fold increase in AGC. Similarly, tripling tree diameter from 25 cm to 75 cm led to a 13.8–18.2-fold increase in AGC, with the largest increase observed for ponderosa pine. For any given diameter, ponderosa pine, Douglas-fir and western larch tended to store more AGC than an Engelmann spruce or grand fir.

These results clearly showed that for large trees, a small increase in diameter corresponds to a massive increase in additional carbon storage relative to a small tree increasing by the same diameter increment. Overall, as trees grow larger, each additional centimeter of stem diameter corresponds with a progressively larger increase in tree carbon storage.

Tree Diameter and Aboveground Carbon Storage Within Tree Populations

Large trees (DBH ≥ 21 in or 53.3 cm) accounted for a small percentage of each species' tree stems, but a substantial percentage of the total AGC stored by each species on FIA inventory plots located in the six eastside national forests (**Figure 3** and **Table 3**). Specifically, large trees accounted for ∼2.0 to ∼3.7% of all stems (DBH ≥ 1" or 2.54 cm) among the five dominant tree species; however, these trees held ∼33.3 to ∼45.8% of the total AGC stored by each species (**Table 3**). Grand

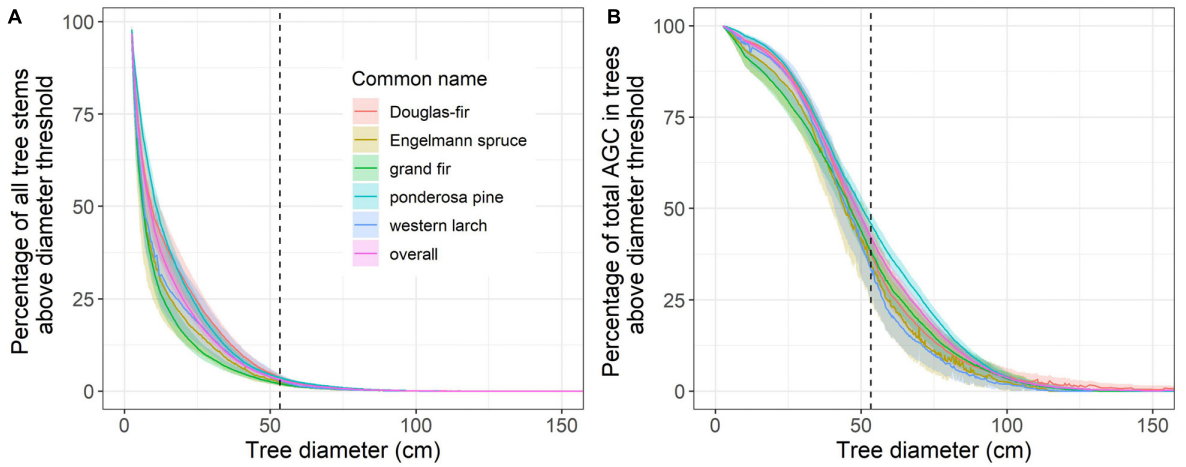

FIGURE 3 | Percentage of **(A)** all tree stems and **(B)** total aboveground carbon that occur in trees above a given diameter threshold by species based on measurements from USFS inventory plots located in the six eastside national forests. The dashed vertical lines represent a 21 in (53.3 cm) tree DBH. These estimates and 95% confidence intervals were derived by resampling ($n = 10^4$) measurements from inventory plots (n = 3,335). For example, trees with ≥21 in diameter represent 3.7 [3.2, 4.2]% of all ponderosa pine and account for 45.8 [42.8, 48.8]% of all aboveground carbon stored by this species on these inventory plots. Only ∼0.002% of trees exceeded 150 cm diameter, so for visual clarity we limited the *x*-axis to 150 cm.

TABLE 3 | Percentage of all trees stems and total aboveground carbon (AGC) occurring in trees above and below the 21 in DBH threshold based on measurements from USFS inventory plots located in the six eastside national forests.

Common name	Number of trees in the population	% of total species stems in trees. . .		% of total species AGC in trees. . .	
		<21 in	≥21 in	<21 in	≥21 in
Douglas-fir	100021	96.3 [95.4, 97.1]	3.7 [2.9, 4.6]	62.5 [58.2, 66.7]	37.5 [33.3, 41.8]
Engelmann spruce	31375	97.6 [96.0, 98.6]	2.4 [1.4, 4.0]	65.3 [54.6, 75.5]	34.7 [24.5, 45.4]
Grand fir	187445	98.0 [97.5, 98.5]	2.0 [1.5, 2.5]	61.6 [57.0, 66.2]	38.4 [33.8, 43.0]
Ponderosa pine	286970	96.3 [95.8, 96.8]	3.7 [3.2, 4.2]	54.2 [51.2, 57.2]	45.8 [42.8, 48.8]
Western larch	30708	97.2 [95.5, 98.4]	2.8 [1.6, 4.5]	66.7 [58.4, 74.8]	33.3 [25.2, 41.6]
Overall	636520	96.9 [96.6, 97.3]	3.1 [2.7, 3.4]	57.8 [55.7, 60.0]	42.2 [40.0, 44.3]

Live trees were measured on 3,335 plots surveyed between 2010 and 2018. The estimates and 95% confidence intervals below were derived by resampling bootstrap sampling. Each bootstrap sample ($n = 10^4$) utilized measurements from 25% of inventory plots selected at random.

fir had the lowest percentage of stems ≥21 in DBH (∼2.0%), while ponderosa pine and Douglas-fir had the highest percentage of stems exceeding this threshold (both ∼3.7%). However, large grand fir trees accounted for 38.4% of total species AGC, whereas large Douglas-fir accounted for 37.5% of total species AGC. Western larch had the lowest percentage of total species AGC in trees ≥21 in (∼33.3%), whereas ponderosa pine had the highest percentage (∼45.8%).

Pooling across the five dominant species, large trees accounted for ∼3.1% of the 636,520 trees occurring on the inventory plots, but stored ∼42.2% of the total AGC. Similarly, based on the FIA's CRM method, the five tree species together accounted for 44.9% of total AGC, with species-specific AGC stores ranging from ∼36.5 to ∼49.3% of the total stored by each species (**Supplementary Table 3** and **Supplementary Figure 1**).

A similar examination for trees >30 in DBH (76.2 cm) showed that among the five species, trees larger than 30 in DBH accounted for 0.4–0.9% of stems, but held ∼9.0 to ∼19.0% of each species AGC (**Table 4**). Ponderosa pine had the highest percentage of stems >30 in DBH (∼0.9%) and accounted for the highest percentage of AGC (∼19.4%) among the five species. Douglas-fir had ∼0.6% of stems >30 in DBH, and these stems held ∼12.9% of total species AGC. Engelmann Spruce, grand fir, and western larch each had ∼0.4% stems >30 in DBH, and accounted for ∼10.3, ∼14.0, and ∼9.2% of each species total AGC, respectively. Overall, trees >30 in DBH represent 0.6% of stems on inventory plots, but stored 16.6% of the total AGC.

Snow Basin Case Study: Carbon Consequences of Proposed Large Tree Removal

As per the USFS NEPA documentation, the Snow Basin project preferred alternative would have removed ∼43,447 large trees (DBH ≥ 21 in or 53.3 cm) across 12,371 acres, while retaining ∼53,475 large trees over this area (**Table 2**). We estimate this would translate into removing ∼131.3 Gg AGC stored in large trees, while retaining ∼164.1 Gg AGC in large trees (1 Gg = 10^9 *g*; **Table 5**). Grand fir from cool-moist and warm-dry environments would together comprise ∼67% (∼87.3 Gg C) of large tree AGC

TABLE 4 | Percentage of all tree stems and total aboveground carbon (AGC) occurring in trees above and below the 30 in diameter threshold based on measurements from USFS inventory plots located in the six eastside national forests.

Common name	Number of trees in the population	% of total species stems in trees. . .		% of total species AGC in trees. . .	
		<30 in	>30 in	<30 in	>30 in
Douglas-fir	100021	99.4 [99.2, 99.5]	0.6 [0.5, 0.8]	87.1 [83.7, 90.2]	12.9 [9.8, 16.3]
Engelmann spruce	31375	99.6 [99.2, 99.9]	0.4 [0.1, 0.8]	89.7 [82.7, 95.7]	10.3 [4.3, 17.3]
Grand fir	187445	99.6 [99.5, 99.7]	0.4 [0.3, 0.5]	86.0 [82.3, 89.3]	14.0 [10.7, 17.7]
Ponderosa pine	286970	99.1 [99.0, 99.3]	0.9 [0.7, 1.0]	80.6 [78.3, 82.7]	19.4 [17.3, 21.7]
Western larch	30708	99.6 [99.3, 99.8]	0.4 [0.2, 0.7]	90.8 [86.2, 94.8]	9.2 [5.2, 13.8]
Overall	636520	99.4 [99.3, 99.4]	0.6 [0.6, 0.7]	83.4 [81.8, 85.0]	16.6 [15.0, 18.2]

Tree AGC was derived using the FIA's Component Ratio Method. Live trees were measured on 3,335 plots surveyed between 2010 and 2018. The estimates and 95% confidence intervals below were derived by resampling bootstrap sampling. Each bootstrap sample (n = 10^4) utilized measurements from 25% of inventory plots selected at random.

TABLE 5 | Removal and retention of aboveground carbon (AGC) in large trees (DBH ≥ 21 in) within the proposed Snow Basin project area.

Common name	Env.	Total AGC in large trees (Gg C)...		% of large tree AGC...	
		Removed	Retained	Removed	Retained
Grand fir	Cool moist	13.6 [12.0, 15.3]	24.5 [21.6, 27.5]	35.7 [35.7, 35.7]	64.3 [64.3, 64.3]
Grand fir	Warm dry	73.7 [65.0, 82.5]	73.7 [65.0, 82.5]	50.0 [50.0, 50.0]	50.0 [50.0, 50.0]
Douglas-fir + ponderosa pine + western larch	Warm dry or moist	43.8 [40.5, 47.3]	65.7 [60.8, 71.0]	40.0 [40.0, 40.0]	60.0 [60.0, 60.0]
Overall	–	131.3 [120.8, 141.5]	164.1 [151.8, 176.2]	44.4 [44.2, 44.7]	55.6 [55.3, 55.8]

Estimates of total AGC are given in gigagrams of carbon (1 Gg = 10^9 g). Values in brackets denote 95% confidence intervals derived by resampling (n = 10^4) inventory plots used to determine tree size class distributions.

removed by the project, while ponderosa pine, Douglas-fir, and western larch from warm-dry and warm-moist environments would comprise the remaining ∼33% (∼43.8 Gg C). The project would have the largest relative and absolute impact on grand fir occurring in warm-dry environments, where 50% (∼73.7 Gg C) of large tree AGC would be removed. We obtained similar results albeit with substantially wider confidence intervals using only FIA inventory plots occurring in the Snow Basin project area (**Supplementary Table 4**).

DISCUSSION

Our study reveals the large carbon stocks associated with large-diameter trees in the region, and the potential for significant losses in AGC with large tree logging. The 21-inch rule was initially conceived to protect remaining late successional and old-growth forest and the native species that depend on these unique ecosystems for survival in forests east of the Cascades Crest in Oregon and Washington (Henjum et al., 1994). The carbon storage associated with the 21-inch rule on the six national forests is a significant co-benefit of this protective measure. Large trees (DBH ≥ 21 in or 53.3 cm) constitute ∼3% of the total stems, but store ∼42% (∼45% with CRM; **Supplementary Table 3**) of the AGC across the six eastside forests (**Table 3**). This finding highlights the important role of large trees in storing carbon in eastside forest ecosystems, and is consistent with previous findings on the disproportionately important role of large trees in the forest carbon cycle (Hudiburg et al., 2009; Lutz et al., 2012, 2018; Stephenson et al., 2014). The sharp increase in carbon storage with increasing tree diameter (**Figure 2**) speaks to the importance of preserving mature and old large trees to keep this carbon stored in the forest ecosystem where it remains for centuries (Law et al., 2018; Lutz et al., 2018). Once trees attain large stature, each additional DBH increment results in a significant addition to the tree's total carbon stores, whereas small-diameter trees must effectively ramp up to size before the relationship between DBH and AGC results in significant carbon gains. Harvest of large-diameter trees, even focused on a specific species (e.g., grand fir) can remove upward of 50% of the large tree AGC from these ecosystems (**Table 5**).

There are substantial differences in wood density among the species examined that contributes to the observed differences in AGC at a given DBH. Wood density tends to be higher for ponderosa pine (∼0.45 g cm^3), Douglas-fir (∼0.52 g cm^3), and western larch (∼0.56 g cm^3) than for Engelmann spruce (∼0.37 g cm^3) or grand fir (∼0.40 g cm^3; **Supplementary Table 2**). An evaluation of the relationship between tree height and diameter suggests the observed differences in AGC are not driven by ponderosa pine, Douglas-fir and western larch tending to be taller at a given DBH than Engelmann spruce or grand fir. Although stem decay is common in mature and old grand fir, a synthesis shows no evidence of carbon consequences of heart rot in grand fir (Harmon et al., 2008). While we could not estimate heart rot loss in grand fir due to lack of sufficient data, heart rot respiration has been estimated for another species and it had a scant contribution to ecosystem respiration (Harmon et al., 2004).

Forestry practices exert significant controls on stand structure and forest carbon dynamics, and alterations of harvest practices can substantially alter carbon storage and accumulation (Masek et al., 2011; Turner et al., 2011; Krankina et al., 2012; Kauppi et al., 2015; Law et al., 2018). Generally, there is a negative relationship between harvest intensity and forest carbon stocks whereby as harvest intensity increases, forest carbon stocks decrease while emissions increase (Hudiburg et al., 2009; Mitchell et al., 2009; Simard et al., 2020). It can take centuries to reaccumulate forest carbon stocks reduced by harvest (Birdsey et al., 2006; McKinley et al., 2011). It would take 180 to 310 years to reach maximum biomass in the Blue Mountains and East Cascades, respectively, after harvest of the large trees (Hudiburg et al., 2009), too long to help reach climate mitigation targets in the next few decades. The amount of harvested carbon that remains stored in wood products is insufficient to offset the loss of carbon stored in the forest. If harvested, life cycle assessment shows that 65% of the wood harvested in Oregon over the past 115 years has been emitted to the atmosphere, 16% is in landfills and only 19% remains in wood products (Hudiburg et al., 2019). Thus, harvesting the large trees will increase, not decrease emissions and end centuries of long-term carbon storage in the forests.

The 21-inch rule has preserved the trees that store and accumulate a disproportionately large amount of carbon in these forests (**Figure 3** and **Table 3**). Of the ∼3% of tree stems over 21 in DBH in the study area, about 81% of these are between 21 in and 30 in DBH and account for ∼61% of the AGC in all large trees (**Supplementary Figure 2**). Trees over 30 inches DBH account for ∼19% of the large tree stems and hold ∼39% of AGC in large trees. These findings are similar to those reported by Stephenson et al. (2014) and emphasize the relative importance of the sub-30 in DBH large trees in the study area, and the value in allowing these trees to continue growing and replenish the stock of trees over 30 inches DBH that are rare on the landscape. This proforestation strategy is among the most rapid means for accumulating additional quantities of carbon in forests and out of the atmosphere (Moomaw et al., 2019).

The importance of forest carbon storage is now greatly amplified by a warming climate that must urgently be addressed with reductions in greenhouse gasses and natural climate solutions (IPCC, 2018; Ripple et al., 2020). The preponderance of forests in our study area have medium to high carbon accumulation potential and low future climatic vulnerability (**Figure 1**), which reinforces the value of protecting large trees to help abate our current trajectory toward massive global change (Fargione et al., 2018; Buotte et al., 2020). Rather than holding ecosystems to an idealized conception of the past using historical conditions as management targets, a good understanding of the environmental co-benefits associated with large tree protection is needed to inform management strategies that contribute toward solving humanity's most pressing Earth system challenges (Millar et al., 2007; Rockström et al., 2009; Barnosky et al., 2017; Ripple et al., 2020). Replacing large diameter trees with seedlings will create a major carbon loss to the atmosphere during harvest (Harris et al., 2016) and not achieve storage of comparable atmospheric carbon for the indefinite future.

Large grand fir trees (DBH $\geq$ 21 in or 53.3 cm) accounted for the lowest proportion of tree stems for the five species we evaluated (2%), possibly reflecting the ingrowth of young, small grand fir within portions of our study area (Merschel et al., 2014; Johnston et al., 2016). One of the main premises for the proposed removals of large-diameter grand fir trees is that they have increased over historic levels, especially in drier biophysical environments. However, our data does not indicate an uncharacteristic abundance of large grand fir trees across these forests. Given the recent history of high-grade logging that focused on large and old trees (Henjum et al., 1994; Rainville et al., 2008), historical abundances of large trees were much greater than today (Wales et al., 2007; Hagmann et al., 2013; Kauppi et al., 2015), and thus would have represented a larger fraction of aboveground biomass than currently found on these forests.

Interestingly, with respect to the overall representation of species abundance based on inventory plots (**Table 3**), the population of grand fir with 187,445 stems is a distant second to ponderosa pine with 286,970 stems, followed by Douglas-fir (100,021 stems), Engelmann spruce (31,375 stems), and western larch (30,708 stems). To the extent that current forest stand structure is skewed toward smaller diameter classes, ponderosa pine, grand fir, and Douglas-fir trees are notable for the number of trees on inventory plots.

It is important to note that a diameter limit that emphasized protection of carbon stores would ideally protect trees starting at a lower DBH limit (∼12–15 inches). The 21-inch rule has provided significant leeway for fuels reduction and ecological restoration toward historical baselines to proceed in eastside forests. Ecological restoration treatments generally recommend giving protection to large and old trees, while reducing surface and ladder fuels, and accompanied by understory thinning treatments where appropriate and reintroduction of low-intensity fire at intervals (Allen et al., 2002; Brown et al., 2004; Agee and Skinner, 2005; Noss et al., 2006). From a forest carbon perspective, it would be prudent to restore an appropriate number of the approximately 97% of tree stems <21 inches DBH to replenish the stock of large trees over time (Lutz et al., 2018; Moomaw et al., 2019), while continuing to protect large trees for their carbon stores and the myriad other benefits that they provide. This approach would achieve the benefits of proforestation in the larger, most fire-resistant trees and reduction of fuel loads and stem density in the smaller diameter tree stems.

The Snow Basin project provides a case study for how amending the 21-inch rule to allow logging large trees could change management across the six eastside National Forests. Overall the Snow Basin project would have removed 44% or 131,000 metric tons of carbon stored in large trees. This is equivalent to ∼0.75% of annual Oregon statewide carbon emissions, and this does not include carbon in tree roots or the AGC losses due to the removal of trees <21 in DBH. Removing nearly half of the carbon content from the large trees over 12,000 acres would create a carbon deficit in the live, dead, and soil carbon pools that will persist for many decades to the end of the century. However, left standing, these 43,445 large

trees continue to grow, sequestering more carbon into long-term stores (Stephenson et al., 2014; Law et al., 2018; Domke et al., 2020). Older trees (∼100 years) are the next generation of old growth and already possess qualities associated with large, old trees, such as large canopies, deep root systems, and thick, fire-resistant bark.

Co-Benefits of Carbon, Habitat, Biodiversity, Water Availability, Resilience to Climate Extremes

High carbon conservation-priority forests support important components of biodiversity and are associated with increased water availability (McKinley et al., 2011; Perry and Jones, 2016; Berner et al., 2017; Law et al., 2018; Buotte et al., 2020). Large-diameter snags persist as standing snags for many years, providing valuable wildlife habitat, and account for a relatively high proportion of total snag biomass in temperate forests (Lutz et al., 2012). In PNW forests, large hollow trees, both alive and dead, are the most valuable for denning, shelter, roosting, and hunting by a wide range of animals (Bull et al., 2000; Rose et al., 2001). In the Interior Columbia River Basin, grand fir and western larch form the best hollow trees for wildlife uses (Rose et al., 2001). Downed hollow logs continue to serve as important hiding, denning, and foraging habitat on the forest floor (Bull et al., 1997; Bull et al., 2000). Large decaying wood influences basic ecosystem processes such as soil development and productivity, nutrient immobilization and mineralization, and nitrogen fixation (Harmon et al., 1986). Continuing to protect large trees in eastside forests provides the greatest benefit for carbon, habitat, and biodiversity.

Water availability and microclimatic buffering are also disproportionately affected by large trees and intact forests (Frey et al., 2016; Buotte et al., 2020). Forest canopies of the PNW buffer extremes of maximum temperature and vapor pressure deficit, with biologically beneficial consequences (Davis et al., 2019a). Removal of large trees quickly leads to a large increase in soil and canopy heating, which increases enough to impact photosynthesis (Kim et al., 2016), seedling survival, and regeneration (Kolb and Robberecht, 1996; Davis et al., 2019b). The climatic changes toward warmer and drier conditions expected in the next decades will likely increase forest stress and mortality (Allen et al., 2015). Eastside forests experienced hotter and drier conditions from 2003 to 2012 concentrated in the months of August and September, especially in drier forest type groups (i.e., ponderosa pine, juniper), whereas spring months (April–June) showed trends toward cooler and wetter conditions (Mildrexler et al., 2016). Projections suggest that proportionally, the largest changes in microclimatic buffering capacity will occur in lower elevation or dry forests, which currently have more limited buffering capacity (Davis et al., 2019a). In these drier regions, microclimatic buffering by forest canopies may create important microsites and refugia in a moisture-limited system (Meigs and Krawchuk, 2018). In an old growth ponderosa pine stand in eastern Oregon, ∼35% of the total daily water used from the upper 2 m was replaced by hydraulic redistribution from deep soil by deep-rooted larger trees in summer (Brooks et al., 2002). The bigger trees rarely reach 80% loss of hydraulic conductivity, and both mature pine and mesic Douglas-fir were better buffered from the effects of drought on photosynthesis compared with young pine (∼20-year old) due to full root development and larger stem capacitance in older trees (Kwon et al., 2018). Redistribution of deep soil water can increase seedling survival during summer drought when young trees lack the root development to reach deep soil water (Brooks et al., 2002). While large tree composition may have shifted today relative to European settlement times, these large trees nonetheless continue to perform important functional attributes related to water and climate such as carbon storage, hydraulic redistribution, shielding the understory from direct solar radiation, and providing wildlife habitat. These functional attributes of large trees, irrespective of species, characterize ecosystems through thousands to millions of years (Barnosky et al., 2017), and are not quickly replaced.

In mesic forest environments, microclimatic buffering and transpirational cooling are amplified because sites with higher moisture availability are better able to shift energy to latent as opposed to sensible heat fluxes (Dai et al., 1999; Mildrexler et al., 2011). During midday in full sun the surface temperature of a closed canopy moist forest is warmer than the temperature beneath the canopy which is protected from direct solar radiation (Thomas, 2011). Microclimates in moist forests are strongly linked to their closed-canopy structure (Chen et al., 1999; Aussenac, 2000). Removal of the overstory creates canopy openings that increase solar radiation penetration resulting in increased drying of the understory vegetation and the forest floor, and a thermal response of rising land surface temperatures (Chen et al., 1993, 1999). This alteration in the subcanopy thermal regime changes atmospheric mixing between the ground, subcanopy, and canopy, which in turn modifies the microclimate condition of the affected stand. Microclimate modifications associated with forest harvesting are expected to be greatest in moist forests and may affect resilience to climate change and increase the risk of occurrence and severity of wildfires (Lindenmayer et al., 2009). Maintaining mesic microclimates may give undisturbed moist forests and the species they support some inherent resilience to climate change. Moreover, an evaluation of the effects of water limitations on forest carbon cycling in the eastern Cascade Mountains found that grand fir radial growth was not strongly associated with variability in temperature or water variability (Berner and Law, 2015). A lengthening of the growing season may increase productivity in high-elevation grand fir stands. The microclimatic buffering, current and future potential carbon stores, and intact nature of previously unlogged grand fir and Douglas-fir forest types are co-benefits of protecting large trees that need to be considered in future management decisions.

Potential Solutions

The consequences of reducing protection of large trees are significant reduction in forest carbon stores and their climate mitigation, impacts on habitat for animals including birds, and

resilience to a changing climate for decades to centuries to come. Given the rarity of large trees across the landscape, and their outsized role in *storing carbon removed from the atmosphere*, our findings call into question the value of removing large trees for forest modification in eastside forests.

If the 21-inch rule were retained on these lands, continued protection of the existing carbon stock would prevent large quantities of harvest related biogenic carbon from being released to the atmosphere. It is also essential to let a sufficient number of sub-21 inch trees remain to become additional large, effective carbon stores, and assure that carbon accumulation continues in these forests. Rather than weakening the 21-inch rule, we suggest strengthening this important measure and expanding large tree protections to other western United States public lands that have been adversely affected by a similar history of large-tree logging. Protecting and growing more large trees is the most effective near-term option for accumulating more carbon out of the atmosphere, and will benefit other ecosystem services as well.

Some public lands (local, state, and federal) could become part of a *designated reserve system* that includes intact forest landscapes, and carbon rich forests, that hold most of these large, older trees. This is an appropriate use of public lands because the services they provide including biodiversity, water retention, carbon accumulation and storage, and regional cooling by evapotranspiration serve the public interest, and promote sustainable economies that benefit from land protection and restoration.

The critical need to adapt to more wildfire in the west is congruent with protecting large-trees in fire-prone forests. Older forests experience lower fire-severity compared with younger, intensively managed forests, even during extreme weather conditions (Zald and Dunn, 2018). A shift in policy and management from restoring ecosystems based on historical baselines to adapting to changing fire regimes and from unsustainable defense of the wildland–urban interface to developing fire-adapted communities is needed (Schoennagel et al., 2017). Improved fire and forest management is part of the solution, but the most effective changes in terms of protection of people and property, will be near homes and on private property. Prioritizing federal fuel treatments around communities and creating better mechanisms for reducing fuels on private land can help reduce home loss and better protect communities (Moritz et al., 2014; Schoennagel et al., 2017). Given the natural role of fire in the West, managing more wild and prescribed fires with a range of severities will help reduce future wildfire threats and increase ecological benefits in many systems (Schoennagel et al., 2017).

Eastside forests are surrounded predominantly by rural communities. For production forests, lengthening the forest cycle will keep a larger amount of carbon in trees and soils rather than in the atmosphere (Law et al., 2018). Rather than coupling funding of forest restoration or community payments to logging large trees and disturbing older forests, new policies could be enacted that compensate rural communities for protecting large trees in older forests and some of the younger trees that will become large with their associated carbon stores. To implement such policies, the amount to be paid to a community needs to be marginally greater than the revenue earned from cutting these large trees and the older forests in which they are located. Policies that provide compensation for setting aside reserves and individual trees with microhabitats are already in place in Europe (European Commission, 2015). Because this service benefits society as a whole and is an irreplaceable part of the natural climate solutions framework urgently needed for climate stabilization, the payment funds should come from the treasury since all citizens benefit from carbon accumulation by these trees and forests. With over half of Oregon's forest east of the Cascade Mountains crest, these forests are key to the State's climate mitigation and biodiversity conservation goals.

CONCLUSION

Conducting a quantitative assessment using empirical data has determined the large carbon stock that would be lost and the resulting climate consequences if these large trees are harvested. Research indicates that 2021 begins a pivotal decade for humanity to transition off of fossil-fuels (IPCC, 2018) and move "to achieve ... stabilization of greenhouse gas concentrations in the atmosphere at a level that would prevent dangerous anthropogenic interference with the climate system." (UNFCCC, 1992, Article 2). To meet net-zero carbon goals by 2050, it is estimated that reductions in net carbon emissions must be 7.6% per year over the decade of the 2020s (UNEP, 2019). This is most readily accomplished by reducing fossil fuel, bioenergy and industrial carbon dioxide emissions while simultaneously accumulating more carbon dioxide by protecting existing older forests that contain the largest share of carbon, and by allowing more forests to continue to accumulate carbon through proforestation (IUCN, 2020). Proforestation allows existing forests to continue growing without harvest or other management practices so that more trees can reach the large tree size that accumulates more carbon in the near and long term than do reforestation and afforestation (Moomaw et al., 2019). No additional land is required as is the case with afforestation, and proforestation is the lowest cost opportunity for reaching the zero net carbon goal by 2050. In fire-prone forests such as in our study area, a diameter limit strikes the balance between protecting the most fire-resistant trees that store the most carbon and allowing fuels reduction with reintroduction of fire in dry biophysical environments. Intact mesic forests are ideal locations for proforestation. Harvesting large trees will add very large amounts of biogenic carbon to the atmosphere (Harris et al., 2016), and make the net zero carbon goal difficult or impossible for Oregon to achieve. The young trees will never be able to recover and accumulate the amount of carbon that is in the growing and older forests during these next critical decades, and will only equal current levels a century or more from now.

Protecting large trees to help stabilize climate is critically important for managing forest ecosystems as social-ecological

systems. Knowledge of the disproportionately large amount of carbon stored in a small fraction of trees creates an opportunity to engage the public, decision makers, and forest managers in their importance as an integral part of the climate solution.

DATA AVAILABILITY STATEMENT

Publicly available datasets were analyzed in this study and are available through the FIA DataMart: https://apps.fs.usda.gov/fia/datamart/CSV/datamart_csv.html.

AUTHOR CONTRIBUTIONS

DM and LB conceived the ideas and designed the study with critical suggestions from BL and RB. DM and LB collected the data. LB processed the data and carried out the modeling. DM and LB analyzed the data and led the writing of the manuscript. BL, RB, and WM assisted with writing, and contributed critically to the drafts. All authors gave final approval for publication.

FUNDING

This research was supported by United States Department of Energy (Grant DE-SC0012194) and Agriculture and Food Research Initiative of the USDA National Institute of Food and Agriculture (Grant numbers 2014-67003-22065 and 2014-35100-22066) for our North American Carbon Program study, "Carbon cycle dynamics within Oregon's urban-suburban-forested-agricultural landscapes." WM received support from Rockefeller Brothers Fund. DM received support from Eastern Oregon Legacy Lands.

ACKNOWLEDGMENTS

Thanks to Dr. Mark Harmon for supporting the initiation of this research.

SUPPLEMENTARY MATERIAL

The Supplementary Material for this article can be found online at: https://www.frontiersin.org/articles/10.3389/ffgc.2020.594274/full#supplementary-material

Abstract

Protecting the climate system requires urgently reducing carbon emissions to the atmosphere and increasing cumulative carbon stocks in natural systems. Recent studies confirm that large trees accumulate and store a disproportionate share of aboveground forest carbon. In the temperate forests of the western United States, a century of intensive logging drastically reduced large-trees and older forest, but some large trees remain. However, recent changes to large tree management policy on National Forest lands east of the Cascade Mountains crest in Oregon and southeastern Washington allows increased harvesting of large-diameter trees (≥53 cm or 21 inches) that account for just 3% of all stems, but hold 42% of total aboveground carbon. In this article, we describe synergies with protecting large trees for climate mitigation, biodiversity, and forest resilience goals to shift species composition, reduce fuel loads and stem density, and adapt to climatically driven increases in fire activity in eastern Oregon.

KEYWORDS

aboveground forest carbon, biodiversity, climate change, eastern Oregon, large trees

1 | INTRODUCTION

Society has a narrow window of opportunity left to avert catastrophic consequences from the intertwined climate and biodiversity crises (IPCC, 2022), and forests offer major solutions at the intersection of these urgent imperatives. Forests account for 92% of all terrestrial biomass globally (Pan et al., 2013), store about 45% of the total organic carbon on land in their biomass and soils (Bonan, 2008), and removed the equivalent of about 30% of fossil fuel emissions annually from 2009 to 2018, of which 44% was by temperate forests (Friedlingstein et al., 2019). Moreover, forests provide critical habitats to more than half of all known plant and animal species on Earth (Gibson et al., 2011; Vié et al., 2009). As climate change increases and accelerates amplifying feedbacks, preserving species- and carbon-rich forests becomes ever more important, alongside a rapid transition to net-zero fossil fuel CO_2 emissions (Matthews et al., 2022).

Forests of the western US contain large stocks of carbon and remove significant quantities of CO_2 from the atmosphere to help protect climate, biodiversity, and water security (Buotte et al., 2020; Law et al., 2021). But how we manage these forests will play a large role in determining future outcomes (Fargione et al., 2018; Hudiburg et al., 2009; Law et al., 2018). Oregon stands

out with the most forested area in the western USA, yet the lowest proportion of its forests protected (Law et al., 2021), and significant opportunities to create strategic forest reserves (Law, Berner, et al., 2022). About 80% of tree mortality in Oregon and Washington is attributed to harvest (Berner et al., 2017). In this article we provide insights from a recent study that quantified large tree carbon stocks in diverse forests of eastern Oregon (Mildrexler et al., 2020), and describe synergies with protecting disproportionately valuable large trees for biodiversity and climate mitigation, and forest resilience goals.

2 | LARGE TREES DOMINATE ABOVEGROUND CARBON STORAGE

Trees capture and store massive amounts of carbon, thus forests are an essential component of limiting global warming to 1.5–2°C (IPCC, 2018). However, trees are not all equal in their capacity to slow climate change in the coming critical decades. Large trees play an inordinately large role in removing carbon from the atmosphere and storing it in long-lived tissues (Figure 1; Lutz et al., 2012; Leverett et al., 2021). Globally, studies have found that about half the aboveground carbon is concentrated in a small proportion of large trees (1%–5% of total stems) (Lutz et al., 2018; McNicol et al., 2018). Because most global forests are well below their potential carbon stocks due to past and current land management practices, they could store twice the carbon than now (Erb et al., 2018). As large trees grow larger, small increases in diameter add a relatively large amount of volume and biomass (Mildrexler et al., 2020; Stephenson et al., 2014). Protecting existing forests with large trees and letting more forests mature and develop additional large trees is crucial for preventing carbon emissions and for continued accumulation of carbon from the atmosphere in the coming decades (Birdsey et al., 2023; Law, Moomaw, et al., 2022; Moomaw et al., 2019).

2.1 | The 21-inch rule and carbon stocks

Forests in eastern Oregon and southeastern Washington are recovering from a century of intensive logging that eliminated much of the region's large trees by selective harvest of the largest, most robust trees including clear-cutting older forests. Nevertheless, the United States Forest Service (USFS) recently weakened protection for trees 21 inches diameter at breast height (DBH) and larger ("21-inch rule") across six national forests in this region. The 21-inch rule specifically applied to large-diameter trees on millions of acres of federal public lands. To assess the consequences of the loss of these trees it is essential to quantify large tree carbon stocks prior to changes in management actions. Mildrexler et al. (2020) evaluated carbon storage in large-diameter trees across the six national forests located east of the Cascade Crest in Oregon and Washington ("eastside forests") (Figure 2). Specifically, we quantified the relative contribution of large trees (≥21 inches DBH) to aboveground carbon (AGC) storage based on analysis of 636,520 trees on 3335 USFS Forest Inventory & Analysis (FIA) plots, and also assessed the carbon implications of relaxing the 21-inch rule. In these forests, large trees compose a small fraction of total stems (2.0% to 3.7% of all stems among five dominant tree species) yet hold 33% to 46% of total AGC stored by each species (Figure 3). The very largest trees, >30 inches DBH, held an even greater proportion of carbon (16.6%) relative to their small numbers (0.6%) demonstrating the importance of letting large trees grow larger and accumulate more carbon. Our research contributes to growing recognition that forests with large trees play a

FIGURE 1 Large-diameter grand fir (*Abies grandis*) in a mesic, mixed-conifer forest of northeast Oregon. These carbon-rich forests have a large cooling effect on maximum temperatures, provide thermal refugia for biodiversity including sensitive species, and are a high priority for protection. Large grand fir form the best hollow trees for wildlife (Rose et al., 2001).

very important role in climate mitigation now and in the near future (Lutz et al., 2018; Stephenson et al., 2014).

2.2 | A wildlife protection measure with a crucial carbon co-benefit

The 21-inch rule was implemented in the early 1990s as a habitat and species protection measure to recover large tree structure and to protect remaining late successional and old-growth forest and associated species (e.g., American Marten, Northern Goshawk) (Bull et al., 2005; Bull & Hohmann, 1994; Henjum et al., 1994), similar to the Northwest Forest Plan (NWFP) that was implemented to ensure persistence of old-growth forest species and their habitat in the western portion of the region (FEMAT, 1993). The NWFP resulted in a strong carbon benefit for climate mitigation, in addition to protecting sensitive species and riparian

systems (Turner et al., 2011). Mildrexler et al. (2020) showed that carbon storage associated with the 21-inch rule on the six eastside national forests is a significant co-benefit of this protective measure (Pörtner et al., 2021).

Detailed analysis of stand structure and carbon impacts is essential for science-based decision-making about large-tree forest management policies because such policies affect many different values and services provided by forests (Davis et al., 2019; Teich et al., 2022), including consequences on greenhouse gas emissions and for increasing atmospheric carbon removal and accumulation in forests (Fargione et al., 2018; Griscom et al., 2017). Moreover, large live trees eventually create large-diameter snags and downed wood that continue to store carbon for decades and contribute directly to biodiversity by providing unique specialized habitats such as hollow trees and logs, and microenvironments (Lutz et al., 2021; Rose et al., 2001). However, the USFS General Technical Report on the 21-inch rule did not assess large tree carbon stocks (Hessburg et al., 2020), even though storage and accumulation of carbon in forests is an increasing priority in National Forests (Depro et al., 2008; Dilling et al., 2013; Dugan et al., 2017). Consequently, quantitative assessments of management effects on both forest carbon and biodiversity are important, including assessment of the effects of long-standing rules before they are eliminated or weakened (Mildrexler et al., 2020).

The 21-inch rule has since been amended. Grand fir (DBH ≥53 cm and <150 years) has lost protections in stands not designated as Late and Old Structure, and protections for all tree species have been significantly weakened from a standard to a guideline (USDA, 2021). This represents a major shift in management of large trees across the region, highlighting escalating tradeoffs between goals for carbon sequestration to mitigate climate change, and efforts to increase the pace, scale, and intensity of cutting across national forest lands. The potential impacts of removal of large grand fir on wildfire are unclear, although a trait-based approach to assess fire resistance found that the grand fir forest type had the second highest fire resistance score, and one of the lowest fire severity values among forest types of the Inland Northwest USA (Moris et al., 2022).

3 | ARE LARGE GRAND FIR OUTCOMPETING LARGE PONDEROSA PINE AND LARCH?

The key rationale for amending the 21-inch rule is that increased cutting of large-diameter fir trees (≥53 cm DBH and <150 years) is needed to facilitate the conservation and recruitment of early-seral, shade-intolerant old ponderosa pine (*Pinus ponderosa*) and western larch (*Larix occidentalis*) by reducing competition from shade-tolerant large grand fir (*Abies grandis*) (USDA, 2021). Previous studies have looked at tree age-size relationships (Merschel et al., 2019; Perry et al., 2004), large tree numbers, and changes in basal area (Hessburg et al., 2022), but there has been no spatial analysis of close-range co-mingling of large-diameter tree species across the six national forests covered by the 21-inch rule. This is an important consideration because the competitive interaction among large-diameter trees, and their protection under the 21-inch rule, should not be conflated with small tree dynamics and common dry forest restoration strategies to reduce small tree density and favor retention of early-seral species.

We therefore examined how often large trees (≥53 cm DBH) of these species co-mingle on USFS FIA plots (~1 acre) across the same six eastside national forests where we previously examined carbon storage by large trees (Mildrexler et al., 2020). Drawing on the same USFS FIA measurements as our prior study, we found that large ponderosa pine, grand fir, and western larch were present

TABLE 1 Coverage, mean annual precipitation from 1981 to 2010, and mean annual maximum land surface temperature from 2003 to 2020 for the major FTG's within the six national forests, standard deviations in parenthesis (excludes lands in Washington and Idaho).

		Mean annual precipitation		Mean annual maximum LST	
Forest type group	**Area (km^2)**	**mm**	**in**	**°C**	**°F**
Douglas-fir	2372	679.9 (187.3)	26.8 (7.4)	37.8 (3.5)	100.1 (6.3)
Fir/Spruce/Hemlock	12,224	974.3 (369.5)	38.4 (14.5)	33.2 (2.8)	91.8 (5.0)
Lodgepole pine	3573	822.0 (274.6)	32.4 (10.8)	37.2 (3.8)	99.0 (6.8)
Pinyon/Juniper	634	329.5 (96.0)	13.0 (3.8)	50.4 (3.7)	122.7 (6.6)
Ponderosa pine	18,514	548.3 (139.2)	21.6 (5.5)	39.8 (3.5)	103.6 (6.3)
Western larch	47	746.9 (78.9)	29.4 (3.1)	31.5 (2.4)	88.7 (4.3)

on 56%, 18%, and 7% of all plots ($n = 3335$). Large ponderosa pine co-mingle with large grand fir about 14% of the time (259 plots), leaving 86% of plots with large ponderosa pine without large grand fir (1616 plots). Similarly, large western larch co-mingle with large grand fir about 56% of the time. Large ponderosa pine and grand fir are found together on only 8% of all plots in the region, while large larch and grand fir are found together on only 4% of all plots in the region. In other words, large ponderosa pine are by far the most common tree species found in these six National Forests and infrequently co-mingle with large grand fir at the FIA plot scale, whereas large western larch are far less common and co-mingle with large grand fir about half the time, which is expected since these species occupy similar environmental settings that receive more moisture (Table 1, Johnson & Clausnitzer, 1992).

The relative prevalence of large ponderosa pine in eastside forests is good for climate resilience given that large-diameter pines are exceptionally drought and fire-resistant trees (Irvine et al., 2004; Irvine et al., 2007). In the drought-prone region of central Oregon, mature and old ponderosa pine forests had 60% to 85% higher seasonal gross photosynthesis than a young forest (Irvine et al., 2004). Large ponderosa pine trees experienced only 34% mortality in moderate severity fire, and accounted for 91% of post-fire stemwood production, while small trees experienced 82% mortality (Irvine et al., 2007).

Across the entirety of all six national forests large grand fir represent 2% of the total species population, a proportion slightly lower, but roughly on par with other dominant species (Figure 3, Mildrexler et al., 2020). It is not uncommon for grand fir to reach 250 to 300 years of age (Howard & Aleksoff, 2000). Thus, large grand fir ≥53 cm DBH and <150 years of age can continue growing and play an important role in storing and accumulating carbon from the atmosphere to help abate the climate crisis.

Synergy: Enhancing forest resilience does not necessitate widespread cutting of any large-diameter tree species. Favoring early-seral species can be achieved with a focus on smaller trees and restoring surface fire, while retaining the existing large tree population.

4 | LARGE TREES, VULNERABILITY, STAND DYNAMICS, AND THE CARBON COST OF THINNING

As eastside forests recover from a century of intensive logging, it is important to distinguish between the shift of AGC stocks into small-diameter, fire-sensitive trees and the retention of a small fraction of the largest more fire-resistant trees that store disproportionately massive amounts of carbon. Small tree carbon stores are relatively unstable and at risk of loss to fire and drought, whereas large tree carbon stores are relatively stable and resistant (Hurteau et al., 2019). Physiological-based studies in ponderosa pine forests of Oregon have found that small trees are most vulnerable during drought relative to mature trees that have reached full root, bark and canopy development and respond to climate variability better than smaller trees (Domec et al., 2004; Irvine et al., 2004; Vickers et al., 2012). Buotte et al. (2019, 2020) identified forests in the western U.S. with high potential carbon accumulation and low vulnerability to future drought and fire using the Community Land Model and two climate models with high CO_2 emissions (RCP8.5), and species-specific traits capturing sensitivity of different species to water limitations and to drought and fire. The Eastern Cascades and Blue Mountains contain substantial area with opportunity to enhance forest carbon in large trees (Buotte et al., 2020; Law et al., 2018).

In dry forests historically maintained by a frequent, low-severity fire regime, the priority ought to be restoring the process of periodic surface fire. Prescribed fires create landscape heterogeneity, reduce surface and ladder fuels, lower stand density, and confer drought resistance to surviving trees (Knapp & Keeley, 2006; van Mantgem et al., 2016). In

25784854, 0, Downloaded from https://conbio.onlinelibrary.wiley.com/doi/10.1111/csp2.12944, Wiley Online Library on [25/04/2023]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

these forests prescribed fire can modulate future fire activity (Schoennagel et al., 2017), and favor early-seral species such as ponderosa pine, western larch and Douglas-fir. Large trees of these species and grand fir are resilient to prescribed fire because they have attained the thick bark that provides resistance to low- and moderate-severity fire (Howard & Aleksoff, 2000; Pellegrini et al., 2017).

Thinning also has an inherent carbon cost that increases as larger trees are harvested, thereby putting thinning of larger trees in conflict with carbon goals because it takes so long to replace the harvested biomass (James et al., 2018; Law & Harmon, 2011). The underlying principle for these losses is the negative relationship between harvest intensity and forest carbon stocks whereby as harvest intensity increases, forest carbon stocks decrease and emissions increase (Hudiburg et al., 2009; Mitchell et al., 2009; Simard et al., 2020). Claims that carbon stores will be "stabilized" by increasing harvest of large-diameter trees that store and accumulate the most carbon (Johnston et al., 2021) are inconsistent with basic science on thinning (Zhou et al., 2013) and the carbon cycle (Campbell et al., 2012; Law et al., 2018). These claims ignore the large amounts of CO_2 rapidly released to the atmosphere following harvest (Hudiburg et al., 2019), and that large trees cannot be replaced in short timeframes. It can take centuries to reaccumulate forest carbon stocks reduced by harvest of large trees (Birdsey et al., 2006).

Even thinning smaller trees involves substantial carbon tradeoffs in the short term, a 30%–40% reduction in live tree carbon stores in some forests (Krofcheck et al., 2017; North et al., 2009). To minimize reductions in carbon stocks and emissions, focus on removing smaller-sized trees, restoring surface fire, and managed wildfire in favorable weather conditions (Mitchell et al., 2009; Stenzel et al., 2021).

Synergy: Small trees are more relevant to drought and fire vulnerability and store less carbon, whereas large trees are more resilient to fire and drought and are the highest priority for keeping carbon in the forest.

5 | DIVERSE CLIMATE REGIMES AND FOREST TYPES REDUCE CLIMATIC EXTREMES

It is critical to accurately represent the diversity of climatic regimes and forest types in decisions affecting large tree management because large trees play unique roles in ecosystem water and energy cycles, and these biophysical effects can promote local climate stability by reducing extreme temperatures in all seasons and times of day (Lawrence et al., 2022). Forest modulation of summer maximum temperature is especially powerful (Mildrexler et al., 2018) and can partly offset the projected increases in temperature due to anthropogenic climate change (de Frenne et al., 2019). With heatwave frequency and severity projected to increase, the capacity of forests to buffer against temperature extremes and provide refugia is increasingly recognized as important to sustaining biodiversity in a warming world (Davis et al., 2019; de Frenne et al., 2019).

The six eastside national forests affected by the 21-inch rule cover a region of pronounced geographic and climatic variation and associated forest types (Figure 2; Johnson & Clausnitzer, 1992; Wyatt, 2017). Mean annual precipitation varied from 484 to 571 mm per year on the Ochoco and Malheur National Forests, to ~800 mm per year on the Deschutes, Umatilla and Wallowa Whitman National Forests (Mildrexler et al., 2020). We further examined the climatic regimes of the major forest types across the six national forests using satellite-based annual maximum land surface temperature (LST_{max}) and mean annual precipitation datasets (Figure 2D, Table 1). Our analysis shows that ponderosa pine and fir/spruce/hemlock types cover the largest area on the six national forests. The fir/spruce/hemlock type received the most total precipitation (~974 mm yr^{-1}) and had the second lowest annual LST_{max} (33.2°C). Average LST_{max} for the fir/spruce/hemlock type was 6.6°C (~12 °F) cooler than ponderosa pine (39.8°C), and 4.6°C (~8 °F) cooler than Douglas-fir (37.8°C). The pinyon juniper type had the lowest total precipitation (329 mm yr^{-1}) and highest annual LST_{max} (50.4°C) due to low canopy cover and heating of the dry surface during summer. These results show the region's pronounced variability in hydrologic and forest thermal regimes and highlight the thermal offsetting capacity of closed-canopied mesic forest systems. These valuable ecosystem services can be severely degraded by industrial logging (Lindenmayer et al., 2009).

Synergy: Mature and old mesic forests are a high priority for protection, provide crucial biophysical benefits on climate, including a large cooling effect on maximum temperatures regulating climate extremes and protecting biodiversity. Large grand fir is essential to this ecology.

6 | CONCLUSIONS

The 21-inch rule is an excellent example of a policy initiated for wildlife and habitat protection that has also provided significant climate mitigation values across extensive forests of the PNW Region. The rule resulted in a valuable resource of large-diameter trees in a landscape that remains below historical levels for large live trees and large snags due to historical logging (Bell et al., 2021). We have described synergies between protecting these disproportionately valuable large trees and forest resilience goals, providing common potential solutions for these urgent challenges.

Inland PNW forests can make a significant contribution to climate mitigation goals by protecting and enhancing carbon stores in large trees that accumulate and store the most carbon and are much more resistant to fire and drought than small trees, even when the current status of ecosystems has changed from historical baselines. Climate science makes clear that we do not have time to wait for regrowth after logging to accomplish these important ecosystem services (IPCC, 2022).

AUTHOR CONTRIBUTIONS

David J. Mildrexler led the writing. David J. Mildrexler and Logan T. Berner performed data analysis, investigation, and visualization. All authors commented on drafts, and assisted with writing, review and editing. All authors gave final approval for publication.

ACKNOWLEDGMENT

We thank two anonymous reviewers for their helpful comments.

FUNDING INFORMATION

David J. Mildrexler was supported by Eastern Oregon Legacy Lands. Beverly E. Law was funded by OSU Agricultural Research Foundation. William R. Moomaw was supported from Rockefeller Brothers Fund. Richard A. Birdsey received support from the Woodwell Climate Research Center.

CONFLICT OF INTEREST STATEMENT

The authors declare no conflicts of interest.

DATA AVAILABILITY STATEMENT

This study relied on data from prior studies that are publicly available: Forest Inventory Data from the United States Forest Service (https://apps.fs.usda.gov/fia/datamart/datamart.html), MODIS Land Surface Temperature data from the Land Processes Distributed Active Archive Center accessed through Google Earth Engine, and gridded precipitation climatologies from Oregon State University PRISM Climate Group (https://prism.oregonstate.edu/normals/).

ABSTRACT

Benthic invertebrates, water quality variables, chlorophyll *a* and particulate organic matter (POM) were studied in 18 sites of mountain streams in Patagonia (Argentina) subjected to six different land uses: native forest, pine plantation, pasture, harvest forest, urban and reference urban. Three streams of each land use were studied in March 2006. Macroinvertebrates were sampled in three riffles and three pools ($n = 108$) and biomass of detrital fractions of POM were quantified. Overall benthic POM biomass was higher at native and harvest forest than pastures, whereas fine fraction (FPOM) was higher in harvest forest than in pastures. Regarding to autotrophic subsidies bryophytes were the only that changed consistently among uses. These differences in energy resources were correlated with changes in community attributes. Shredder richness was clearly higher at native and harvest forest than exotic pine plantations, collector gatherers density was consistently high at harvest sites, and total density was significantly higher at urban and harvest forest. Multidimensional scaling ordination based on macroinvertebrate density data showed a clear separation of forested (either native or exotic species) from riparian modified areas (pasture, urban and harvest sites). Environmental variables having explanation power on macroinvertebrate assemblages were mostly related with: detritus availability (wood and leaves biomass) and impairment (total phosphorous and % sand). These results confirm that macroinvertebrate assemblage structure in Patagonian low order streams can be altered by land use practices. Among guild structure measures, those indicators based on benthic community functional attributes, shredders richness and collectors density, resulted good candidates to assess land use impacts. On account of riparian corridor management may be critical to the distribution of benthic taxa, the maintenance of good conditions of vegetation adjacent to rivers will enhance water quality and the environment for highly endemic headwater communities of Patagonian streams.

1. Introduction

Land use changes have resulted in profound modifications of running waters in mountain streams of temperate areas (Allan et al., 1997). In developed basins the conversion of riparian margins from forest to grassland has been one of the most widespread phenomena. Moreover, shifts in land use practices (agriculture to silviculture) have also determined the replacement of native by exotic vegetation as for example pine plantations, sometimes affecting riparian corridors (Baillie and Davies, 2002; Albariño and Balseiro, 2002). Changes in the adjacent vegetation can alter the complex biotic and abiotic processes that govern the function and attributes of aquatic communities including benthic macroinvertebrates (Roy et al., 2003; Thompson and Towsend, 2004; Utz et al., 2009). Early works revealed the consequences that the loss of riparian vegetation can have on physical properties of streams (Newbold et al., 1980). The extirpation of riparian corridors can alter the light and temperature regimes and lead to increases in nutrients and augment primary production (Scarsbrook and Halliday, 1999; Kratzer et al., 2006). The establishment of pastures for agricultural grazing can significantly reduce the amount of allochthonous leaf material entering the river, which consecutively produces a significant effect on trophic structure (Abelho and Graça, 1998; Miserendino, 2005). Scrimgeour and Kendall (2003) found that shredder biomass was significantly lower in Canadian streams under intense pasture development than in those without pastoral use. Loss of insect species (Collier et al., 2001) and higher invertebrate densities have been documented in New Zealand streams in which forest was converted to pasture (Quinn et al., 1997). Thompson and Towsend (2004) observed significant differences between shredders and collector filterer biomass in basins under different land uses such as pasture conversion, native, or exotic vegetation. In a recent

Author's personal copy

study of 60 sites in streams subjected to different land uses Kratzer et al. (2006) found that macroinvertebrate communities responded considerably to land use and most species variation was accounted by variables related to watershed and riparian conditions. Similarly, Compin and Céréghino (2007) detected significant responses of functional feeding groups to landscape alterations. They recognized macroinvertebrate trophic measurements useful for assessing river health with development along riparian zones with collector gatherers showing higher percentages in urban landscapes and scrapers and predators increasing in agricultural landscapes.

The functional structure along streams in Patagonian mountains seems to correspond well with the predictions of the RCC (River Continuum Concept, Vannote et al., 1980) with biomass of shredders decreasing and collector's biomass increasing downstream from the headwaters (Miserendino and Pizzolón, 2003; Miserendino, 2007). Some differences in the functional attributes of benthic communities between rivers bordered by the native *Nothofagus* forest and those dominated by *Salix* spp. have been observed, the former showed higher biomass of shredders while *Salix* bordered rivers had dominance of collector and filterers (Miserendino and Pizzolón, 2003, 2004). In recent experimental studies, Albariño and Balseiro (2002) suggested that the litter processing mechanisms would be affected as a consequence of the substitution of native *Nothofagus* forest by exotic pine plantations.

Streams in Patagonian mountains are subjected to different land use practices; the most common are pasture conversion, exotic plantations, and wood collection/deforestation. The consequences that these activities are having on functional structure of the local, highly endemic biota are not explicitly known. A better understanding of these relationships may contribute to the development of improved land use management practices and to purpose mitigation plans on freshwater ecosystems (Morley and James, 2002; Danger and Robson, 2004).

The aim of this study was to assess the impacts of different land use practices (native forest, exotic, pasture, wood collection, reference urban and urbanizations) on physicochemical characteristics and macroinvertebrate community, and also to evaluate

the usefulness of guild structure indicators in mountain streams of northwest Patagonia (Argentina).

2. Materials and methods

2.1. Study area and site selection

The study area is located in the Northwest of Chubut Province (Fig. 1) in the ecotone between the Subantarctic forest and the Patagonian steppe, and exhibits a marked altitudinal gradient. Perennial (*Austrocedrus chilensis*, *Nothofagus dombeyi* and *Maitenus boaria*) and deciduous tree species (*Nothofagus pumilio*, *Nothofagus anctarctica*) constitute the Subantarctic forests. The shrub and herbaceous strata are characterized mainly by *Chusquea culeou*, *Berberis buxifolia*, and *Fuchsia magellanica*. The valleys are dominated by the herbaceous, shrub-like steppe vegetation (Tell et al., 1997). Exotic vegetation is composed mainly by the implanted forest of *Pseudotsuga menziesii*, *Pinus ponderosa*, *Pinus radiata* and *Pinus lambertiana*, in many cases species are included in the riparian corridor and replacing most of the native species.

The survey was conducted on March 2006 on 18 sites in 15 rivers. We choose this month because most streams have stable flow conditions (Coronato and del Valle, 1988). Three sampling sites were placed on non-impacted native *Nothofagus* forest (Chiquito, Comisario, and Loro), these sites were considered as reference sites to test for impacts: pasture, pine plantation and wood collection.

Three sites on streams with native *N. antarctica* and *N. pumilio* forest with wood collection or extraction (Glyn, Cabeza de vaca, Pipo) were selected. At these sites the harvest was achieved during previous spring (3 months before the survey). The logging operations imply a selective cut of trees, which should exclude specimens from the river corridor. Operators also have to keep free the streams of debris and branches once the tree is logged. However during the survey we observed some river corridors having logged trees, and some watercourses obstructed with debris.

For pasture sites we selected three sites that had been cleared from the native *Nothofagus* forest and had been grazed intensively (Nant y Fall, Manguera and Los Ñires). At the present pasture sites sustain cattle livestock mainly cow and sheep. The pine plantations sites corresponded to streams running (950–1200 m) through plantations of *Pseudotsuga menziesii*, *Pinus ponderosa*, *P. radiata* and *P. lambertiana* (Golondrinas, Patriada and Ifona). Three urban rivers (Las Minas, Carbón and Esquel) plus their respective reference sites (Las Minas ref, Carbón ref and Esquel ref) were also included in the survey (Fig. 1).

In order to know basin features, vegetation types and coverage, a LandSat image was analyzed and processed in the Dirección General de Bosques y Parques. Per each surveyed site we obtained sub-basin area, % of native vegetation coverage, % of exotic vegetation coverage, % pasture and % of urban areas. We included percentage of the basin corresponding to lakes and areas above the timberline.

2.2. Environmental characterization and macroinvertebrate analysis

Percentages of boulder, cobble, gravel, pebble, and sand in the reach were estimated at each site using a 1-m^2 grid. Current speed was measured in mid-channel on three occasions by timing a float (average of three trials) as it moved over a distance of 10 m (Gordon et al., 1994). Average depth was estimated from five measurements along one transversal profile across the channel with a calibrated stick. Discharge was obtained by combining depth, wet width and current velocity as in Gordon et al. (1994). At each site, air and water temperature were measured with a mercury thermometer.

Specific conductance ($\mu S\,cm^{-1}$), pH, dissolved oxygen (DO, $mg\,O_2\,l^{-1}$) were measured with a Horiba U2-probe. For nutrient analyses water samples were collected below the water surface and kept at 4 °C prior to analysis and transported to the laboratory. Total suspended solids (TSS), total nitrogen (TN), total phosphorus (TP), nitrate plus nitrite nitrogen ($NO_3 + NO_2$), ammonia (NH_4), and soluble reactive phosphate (SRP) were analyzed following standard methods (APHA, 1994).

Quantitative macroinvertebrate samples were taken with a Surber sampler (0.09 m^2; 250 μm mesh size). On each reach, three samples were taken from riffles and three from pools ($n = 6$). Samples were fixed *in situ* with 4% formaldehyde, and sorted in the laboratory under at least 5× magnification. Macroinvertebrate species were identified using available keys (Fernández and Domínguez, 2001). Functional feeding groups (FFGs) were assigned using available references, knowledge of feeding modes (mouthpart morphology and behaviour), and analysis of gut contents (Merritt and Cummins, 1996; Albariño and Balseiro, 2002).

Macroinvertebrate total density (TD), total richness of taxa (TR), diversity (H: Shannon Weaver diversity index) and dominance (BPD; Berger–Parker dominance index) were calculated per site. Species richness, percentage and total density of shredders (S), grazer/scrapers (SG), collector filterers (CF), collector gatherers (CG) and predators (P) were also obtained (Ludwig and Reynolds, 1988).

2.3. Particulate organic matter and chlorophyll analysis

Detritus from benthic samples was divided into fine (250–1000 μm) and coarse (>1000 μm) particulate fractions (FPOM and CPOM, respectively). CPOM was separated into wood, leaves (mainly entire leaves), macrophytes, bryophytes and others (fragments of leaves, grass, seeds, roots, buds, etc.) (Miserendino, 2007). All fractions were dried (105° C for 4 h) and weighed on an electronic balance (Scout Pro) to ±0.003 g. Total benthic particulate organic material (BPOM) was obtained by adding FPOM and CPOM.

Algal biomass (as chlorophyll *a*) was determined by scraping algae from five randomly selected rocks (length range: 5–16 cm) collected within a 20 m run/riffle reach at each site. Scrapings were brought back to the laboratory and drawn on to GF/FF filters. Chlorophyll *a* was extracted from pulverized filters in 90% acetone and the extract was measured, spectrophotometrically as described by Wetzel and Likens (1991).

2.4. Statistical analyses

Land use differences in physicochemical parameters and functional groups attributes were tested using one-factor analysis of variance, or where assumption of normality was violated, Kruskal–Wallis tests. Location of significant differences was tested using Tukey's post hoc test for ANOVA and Duncan test for Kruskal–Wallis (Sokal and Rohlf, 1995). Variability within and among groups of selected streams was assessed by means of a similitude matrix based on taxa percentage composition (Bray Curtis matrix) (Ludwig and Reynolds, 1988), this was performed using the program Bio Diversity Pro. A Pearson correlation matrix based on quantitative macroinvertebrate data was performed, this matrix was employed to produce a non-linear ordination using the Multidimensional Scaling method. This is an alternative to the factorial method and the objective is to display significant distances among investigated objects (Ludwig and Reynolds, 1988). The associations between the MDS ordination scores and environmental variables were tested by mean Spearman rank correlations.

3. Results

3.1. Environmental features

Stream shade was lower at Pas and Ur than at forested sites, as a consequence lower water temperatures were recorded in canopied sites (Table 1) thus NF sites had significantly lower water temperature than Pas and Ur sites (ANOVA, Tukey test $p < 0.01$). Both wet (range 0.9–21 m) and channel width (range 1.8–31.5 m) varied considerably between sites, having Pas and Ur the most expanded channels, however differences were only significant when comparing pasture dry width with all types of forested channels (ANOVA, Tukey test $p < 0.01$). At most sites the substrate particle size was mainly boulder, cobble and pebble. However, a higher proportion of sand was observed in some particular sites (LÑ, PAT, PIP) having sedimentation symptoms (Table 1). Current velocity was comprised between 0.1 and 3 m seg^{-1} but did not vary in a systematic manner among different uses.

There were also evident differences in physico-chemistry, with dissolved oxygen contents higher ($F_{(5,12)} = 4.0$, $p < 0.02$) and conductivity lower (Kruskal–Wallis, $p < 0.02$) at NF sites than the rest. Most chemical variables including SRP, TP, NO_3 and NH_4 showed higher mean values at Ur use than at the rest, including R-ur sites. However, values were highly variable, possibly explained by extreme values at ED urban site. A comparison of the same variables, excluding Ur sites from the analyses, highlighted that SRP was slightly lower at Pn sites, TP increased at Pas sites, NO_3–NO_2, TN and NH_4 values were higher at HF, but none of these results was statistically significant ($p > 0.05$). Nonetheless, the trend was that lowest values of NH_4, TN, and TP were recorded at reference native forest sites (Table 1).

The land coverage with exotic (pine) plantation at selected sites ranged between 3.1 and 7.3% and land coverage with pastures primarily dedicated to sustain livestock varied between <1% and 25%. Urbanization affected between 0.4% and 9% of the basins however, rural/agricultural areas affected near of 18.7% of some basins as was the case of ED.

3.2. Particulate organic matter and chlorophyll a

Differences in energy availability with land uses were also evident particularly in the POM fractions: wood, leaves, CPOM, BPOM, and FPOM (Fig. 2). HF streams contain significantly higher leaves than Ur sites (Mann–Whitney U test, $p < 0.04$) and NF showed more wood than Pas and Ur sites (Kruskal–Wallis, $p < 0.04$). As expected, BPOM biomass was higher at NF and HN than Pas (Mann–Whitney U test, $p < 0.05$). Although FPOM did not varied in a consistent manner among land uses (ANOVA, $p = 0.30$), HF sites had higher FPOM biomass than Pas sites (Mann–Whitney, $p < 0.04$, $n = 6$, Fig. 2).

Regarding to autotrophic subsidies differences observed in chlorophyll a (range 2.3 and 17.9 mg m^{-2}) and macrophytes biomass (0 and 15.56 g m^{-2}) were not significant among land uses ($p = 0.84$, 0.77, respectively). However, bryophytes biomass was significantly higher at native forest sites than at Pn, Ur, Pas and R-ur sites (Kruskal–Wallis, $p < 0.01$, Fig. 2).

3.3. Functional metrics and land use

A total of 112 taxa were identified in the survey, being 22 shredders, 27 collector gatherers, 13 collector filterers, 23 scrapers/grazers and 27 predators. Taxa richness ranged between 20 and 48 taxa, and as expected the lowest value (20 taxa) corresponded to ED an urban site (Table 2).

Significant differences in shredder richness were observed among land uses with more shredders species found in HF and NF

than Pn and R-ur sites (Kruskal–Wallis, $p < 0.026$, Table 3, Fig. 3). Collector gatherers richness was highly variable (range: 4–13 taxa) and collector filterers (range: 1–5 taxa) were poorly represented mostly at Pas, Pin and NF sites.

As expected total density of macroinvertebrates was significantly higher at Ur and HF than at Pn, NF and R-ur sites (Kruskal–Wallis, $p < 0.016$). Collector's gatherers were significantly more abundant at HF sites than at the rest of uses, moreover, Pas, NF and R-ur had higher density of collector's gatherers than Pn (Kruskal–Wallis, $p < 0.012$). Abundance of shredders was significantly lower at Pn sites than at Pas and HF. Density of scrapers/grazer was higher at HF compared to Pn, Pas and NF (Mann–Whitney U test, $p < 0.05$) (Table 3, Fig. 3). More predators were recorded at Ur sites than at Pas and NF sites.

Diversity values ranges between 1.86 and 2.93 and lowest values were found at Pas and Pn sites. Dominance values were high at HF, Pn and Pas uses. However, some particular sites showed extreme values as GLY by recruitment of the stonefly *Antarctoperla michaelseni* (Gripopterygidae) and ED by high density of *Hyalella araucana*, *Limnodrilus* spp. and Orthocladiinae species.

Regarding to species composition, similarity percentages showed that sites in Pas overlapped more with Ur, R-ur, and HF (Table 4), than with Pn and NF. Similarities between sites within land uses were relatively high, although Ur sites were more variable probably reflecting differences in degrees of impairment. NF selected sites showed a reasonable similitude among each other (55.8%), the same as HF sites (57%). However, the within similarity of land cover types ranged 36.9–64.3%. This might show a fairly

Harvest forest	53.1	55.6	46.7	47.7	51.6	57

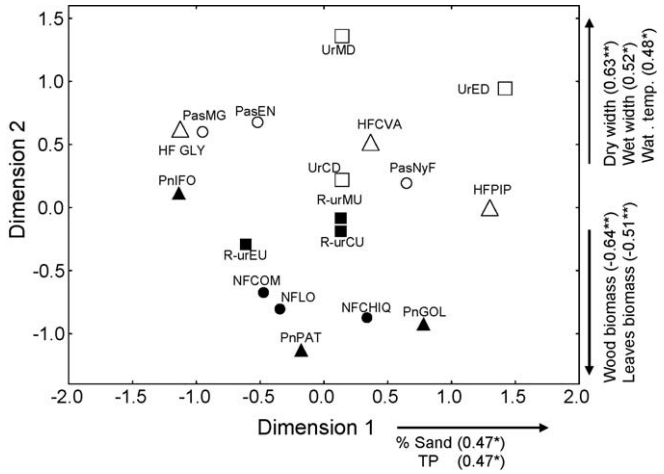

Fig. 4. Results of the multidimensional ordination of macroinvertebrate community data collected from 18 sampling sites subjected to different land uses (Chubut, Argentina). Symbols are: (□) urban sites; (△) harvest forest; (○) pasture; (■) reference urban sites; (●) reference native forest and (▲) pine plantations. Significant correlation coefficients (Spearman rank) with dimension 1 and 2 are given ($^{*}p < 0.05$, $^{**}p < 0.005$).

high within-type variability, which was largest in Ur and Pn forest sites.

3.4. Environmental relationships

The separation of forested either with native or exotic species, plus reference sites (dark symbols) from pasture, urban and harvest sites (open symbols) was clearly evident in the site ordination using density data of macroinvertebrate species (dimension 2, Fig. 4). Thus, NF, R-ur and Pn sites were grouped to the negative end of dimension 2, whereas Pas, HF and Ur were positioned to the positive end of dimension 2. When identifying variables associated with dimension 2, wood and leaf biomass which were negatively correlated, resulted as significant variables explaining sites ordination (Fig. 4). Other significant variables were water temperature and dry and wet width, which were positively correlated with dimension 2. On the other hand, dimension 1 highlighted a water quality impairment gradient or sedimentation; variables that were positively correlated with dimension 1 were TP and sand percentage (Fig. 4).

4. Discussion

Our results suggest that distribution of detritus and trophic structure were different among land uses, this is in agreement with what has been reported for streams draining in developed catchments (Delong and Brusven, 1993; Riley et al., 2003; Thompson and Towsend, 2004; Danger and Robson, 2004). Changes in physical attributes of streams produced by some land use practices were also documented in this study. The buffering effect of the riparian corridors on water temperature (Collier et al., 2000; Scrimgeour and Kendall, 2003; Leunda et al., 2009) was evident at native forested sites. Similarly the percentage of fine sediment on the streambed varied among uses and explained some differences in benthic assemblages. Agricultural land use and pasture development often results in an increased supply of fine sediments (Scarsbrook and Halliday, 1999; Brisbois et al., 2008). Niyogi et al. (2007) found that fine sediment covered 33% of the stream bottom at agricultural streams in New Zealand. We observed that LÑ showed a high percentage of sand as consequence of the constant supply from the severely eroded banks while post-harvest sedimentation effects were evident at Pipo (HF). At this site several trees from the riparian zone were cut and the channel was obstructed by debris (branches and leaves) after the harvest. Logging operations can produce increases of sand and silt in the streambed and this is more significant in small streams (Death et al., 2003). Some groups favored by the presence of fine sediments such as the collector gatherers *Lumbriculus variegatus* and *Pseudochironomus* sp. were abundant at these sites.

We expected higher values of chlorophyll *a* at pasture sites as a consequence of higher temperatures or nutrients levels. On the contrary, chlorophyll *a* pattern was highly variable as were nutrients, which is consistent with observations of Scrimgeour and Kendall (2003) and Scarsbrook and Halliday (1999). They did not report any significant difference in chlorophyll patterns and land uses, although values increased with distance to forested areas. In our study, even though nutrients did not show any significant differences among land use practices, lower values of NH_4, TN, and TP were recorded at reference native forest sites. Likely we were unable to separate cattle effects from other effects in our sampling design, thus cattle is an all-pervading land use in the area. Then some of the patterns observed at harvest sites could result of the combined effect of wood collection and pasturing.

A noteworthy feature in our study was that bryophyte biomass was significantly higher at native forest than at other land uses. Similarly, Riley et al. (2003) found lower moss coverage of streambeds at developed pasture streams than at undeveloped or lightly grazed native grassland catchments. They concluded that the presence of moss can be influenced by substrate stability (bedrock, boulder vs. gravel, sand), trampling by stock and nutrient concentrations.

As reported in other studies (Delong and Brusven, 1993; Benfield, 1997), forested sites showed consistently more allochthonous material than pastures, thus BPOM was significantly higher at NF and HF than at Pas. However, BPOM varied in a non-systematic manner among Pn sites. Scarsbrook et al. (2001) found more detritus material in pine plantations than in pasture sites and Thompson and Towsend (2004) reported a decreasing gradient of detritus biomass from pine, native forest to pasture grasslands. Likely differences observed in the attributes of the riparian corridors (composition, coverage and age) at our Pn sites, were the cause of high variation in detritus biomass.

The contribution of shredders to benthic community at pasture sites was higher than expected (12.8–48%). Most selected pasture sites have remnant forest upstream and this probably had some positive effects on detritus supply. From all of our pasture sites, the most extreme situation was Los Ñires with benthos community basically dominated by filterers (Hydropsychidae: *Smicridea annulicornis*). Predominance of filtering and gathering collectors in rural and agricultural landscapes has been well documented (Shieh et al., 2003, Ometto et al., 2004; Utz et al., 2009) and as suggested by Strand and Merritt (1999) a high proportion of filterers reflect the relative amount of fine particulate organic matter in transport in the water column. In addition, in our study collectors dominated or co-dominated at all urban sites (Compin and Céréghino, 2007) but also at most harvest forest sites. Thus, the

Author's personal copy

relative proportion of collectors was higher at HF sites than forest reference sites suggesting a compositional shift from CPOM feeders to FPOM feeders. McCord et al. (2007) observed that increases of collector's relative abundance was a significant response indicating detrimental effects of silviculture operations when comparing harvest from reference sites. As we mentioned the accumulation of logging slash due to the incorrect treatment of debris was evident at least in one site (Pipo).

Whiles and Wallace (1997) stated that conversion of forest to pine monoculture can influence benthic taxonomic composition. In our study, when assessing the possible effects of exotic plantation on functional feeding groups, the most marked finding was that shredder richness was consistently higher at HF and NF than Pn sites. Besides, total density of shredders was significantly lower at Pn than at Pas and HF. Valdovinos (2001) found more density and biomass of shredders in leaf packs of *N. pumilio* (native) than *Pinus radiata* in experimental trials in Chilean streams. In other experiments, Albariño and Balseiro (2002) noticed that large shredders (*Klapopteryx kuscheli* and *Parasericostoma cristatum*) fed only on *N. pumilio* and not on *Pinus ponderosa* leaf packs in Patagonian streams. The most dramatic situation in our study was the site PAT, in which the riparian corridor is completely replaced by *Pseudotsuga menziesii* and the stream runs through 1200 m of the exotic forest. Paradoxically, the shredder *Myotricha murina* was well represented at this site and constitutes almost 35% of the benthic community. However, other common shredders such as *Senzilloides panguipulli*, *Antarctoperla michaelseni*, and *Udamocercia arumifera* that were well represented at HF and HF sites were practically absent at Pn sites.

As was showed in the ordination analysis, pasture sites were clearly separated from forested sites (either native or exotic) in agreement with reports from similar studies (Hall et al., 2001; Death et al., 2003; Thompson and Towsend, 2004; Compin and Céréghino, 2007). Moreover, in our study harvest forest sites were also clearly separated from undisturbed native forest suggesting changes in composition and structure of benthic community. Detritus biomass, sedimentation processes and habitat impoverishment, factors associated with the removal of the forest canopy and harvesting procedure, appear as important variables determining those assemblages. As we tested here there is also a potential usefulness of functional metrics in particular shredders richness and collectors density to indicate the impact of land use change on macroinvertebrates.

This study reinforces the idea that riparian corridor management may be critical to the distribution of benthic taxa as well functional organization in headwater Patagonian streams. For this reason maintenance of good conditions of vegetation adjacent to rivers will enhance water quality and the environment for stream communities.

Acknowledgments

This study was supported by CONICET (PIP 5733) and Project A.W.A.R.E. Foundation (P-001036). We thank Dr. M. Archangelsky for helpful comments on the English style and Dr. Adriana Kutschker, Cecilia Brand and Cecilia Di Prinzio for fieldtrip assistance. Thanks to anonymous reviewers for valuable comments that greatly improved the manuscript. This is Scientific Contribution no. 36 from LIESA.

PERSPECTIVES

ENVIRONMENTAL SCIENCE

Reform forest fire management

Agency incentives undermine policy effectiveness

By **M. P. North,[1,2]* S. L. Stephens,[3] B. M. Collins,[1,3] J. K. Agee,[4] G. Aplet,[5] J. F. Franklin,[4], P. Z. Fulé[6]**

Globally, wildfire size, severity, and frequency have been increasing, as have related fatalities and taxpayer-funded firefighting costs (*1*). In most accessible forests, wildfire response prioritizes suppression because fires are easier and cheaper to contain when small (*2*). In the United States, for example, 98% of wildfires are suppressed before reaching 120 ha in size (*3*). But the 2% of wildfires that escape containment often burn under extreme weather conditions in fuel-loaded forests and account for 97% of fire-fighting costs and total area burned (*3*). Changing climate and decades of fuel accumulation make efforts to suppress every fire dangerous, expensive, and ill advised (*4*). These trends are attracting congressional scrutiny for a new approach to wildfire management (*5*). The recent release of the National Cohesive Wildland Fire Management Strategy (NCWFMS) (*6*) and the U.S. Forest Service's (USFS's) current effort to revise national forest (NF) plans provide openings to incentivize change. Although we largely focus on the USFS, which incurs 70% of national firefighting costs (*7*), similar wildfire policies and needed management reforms are relevant throughout the United States and fire-prone areas worldwide.

POLICY

Accumulated fuels in dry forests need to be reduced so that when fire occurs, rather than "crowning out" and killing most trees, it is more likely to burn along the surface at low-moderate intensity, consuming many small trees and restoring forest resilience to future drought and fire. Mechanical thinning can reduce tree density and some fuels but is often limited by legal (wilderness and park areas), operational (steep or remote ground), and cost constraints (*8*). Fire can also be used to reduce fuels either intentionally (prescribed burning) or opportunistically (letting a natural ignition burn as "managed wildfire") under moderate weather conditions. Although these burns are much less precise than mechanical thinning, in remote locations, fire is usually more efficient, cost-effective, and ecologically beneficial than mechanical treatments (*9*).

Many severe wildfires are due to past fire suppression. Firefighters during the Rim Fire near Yosemite National Park, California, 25 August 2013.

ENTRENCHED DISINCENTIVES. Management reform in the United States has failed, not because of policy, but owing to lack of coordinated pressure sufficient to overcome entrenched agency disincentives to working with fire. Responding to established research, official agency policy now supports a more flexible response to fire than ever before (*6*). Actual wildfire response, however, has changed little because of substantial management impediments. Suppression generally begets larger, more intense wildfires, which in turn intensifies agencies' suppression response (*10*). The alternative, working with fire, is rarely used because of liability and casualty risks and little tolerance for management errors.

Downloaded fro www.sciencemag.org on September 18, 2015

Published by AAAS

For example, during the most recent decade when data were collected (ending in 2008), only 0.4% of ignitions were allowed to burn as managed wildfires (*7*). For individual NFs, there is little economic incentive to change because fire suppression is steadfastly financed through dedicated congressional appropriations, which are augmented with emergency funding, whereas fuels reduction and prescribed burning costs come out of a limited budget allotted to each NF and is often borrowed to cover wildfire suppression costs. With these deterrents, "battling" fire and "only you can prevent wildfire" campaigns have more traction than recognizing that many severe fires result from accrued management decisions. This skewing of agency motivation also distorts economic, insurance, and local regulatory incentives that influence development in fire-prone regions (*11*).

Although agencies are slow to reform internally, they may more rapidly respond to local stakeholder pressure. The core problem has been the lack of a public constituency that advocates for reform of fire-use practices (*11*). The benefits of greater fire use have been a difficult sell because of public objections to smoke and a negative perception of forest fires. This has begun to change as communities increasingly threatened by large fires are urging land-management agencies to accelerate fuel reduction efforts, including the use of managed fire (e.g., yosemitestanislaussolutions.com and 4FRI.org). Timber companies would also benefit from more fire-resilient landscapes in which their private lands are embedded. There is growing awareness that large, severe fires are inevitable in many dry forests, especially in a warming climate. Smoke, safety threats, fire intensity, and human health risks can be better managed for public benefit with proactive fire use under favorable weather and wind dispersal conditions (*12*).

EFFECTING CHANGE. Public support for expanded fire use could thus be directed toward revision of each NF plan, which provides standards and guidelines for daily management decisions. Plans can divide the landscape into zones for different fire management strategies, an approach used by Parks Canada. U.S. forest plans could zone areas close to homes (wildland-urban interface) as an area where most fuels reduction relies on mechanical thinning and fires are suppressed. Beyond this could be an intermediate area where prescribed fire and mechanical treatment are used to optimize fuels reduction. More remote forests could be intentionally burned with prescribed fire, or lightning ignitions allowed to burn as managed wildfires under moderate weather conditions.

Three of the first eight NFs to develop new plans have proposed that more than half of their area in the southern Sierra Nevada be zoned for prescribed and managed fire use. Over the next decade, most of the 155 NFs will begin writing new plans and holding public forums. Engaged local stakeholders will need to look beyond short-term impacts of fire use (e.g., smoke, limited access, and risk of escape) to support managers working with fire and challenge suppression in remote forest zones.

Public support of NCWFMS may help overcome reform disincentives by stressing national interagency collaboration. In response to decades of problem wildfires, the U.S. Congress passed the FLAME Act in 2009 requesting development of NCWFMS, a coordinated strategy to support landscape restoration and fire-adapted communities. Coordination is essential as large, intense wildfires often cross ownership boundaries. For example, in California's 2013 Rim Fire, large patches of old-growth trees in Yosemite National Park were killed when fuel-loaded forests on nearby NF land generated extreme fire behavior that crossed into the park (*13*). NCWFMS can exert peer pressure between agencies and provide support for tough decisions. To accomplish these changes, some policy and resource-deployment decisions supporting fire use could be made at the national level. In the United States, federal land agencies each fund their own fire crews but the National Interagency Fire Center (NIFC) coordinates resource deployment between agencies and nationally across geographic areas. Dedicated crews could be hired and trained for managed fire use, and NIFC could be charged with deploying them for beneficial burning (*14*). Some local and regional agencies have briefly created such crews, but they were often pulled into fire suppression when wildfire activity increased. By giving NIFC deployment authority, it could ensure that these crews are only used for working with fire and are available to burn when weather conditions are favorable. Optimal weather and smoke dispersal conditions occur even in heavily populated and regulated areas such as California, but many burn windows are missed because crews are at or being held for wildfire deployment (*9*). Air-quality regulations limit prescribed fires, although they have much lower emissions than the inevitable wildfire. The Environmental Protection Agency could consider treating prescribed fire smoke like wildfire, as an unregulated "exceptional event."

National government also has an incentive to reduce wildfire expenses and forest agencies' emergency fire borrowing. In many years, suppression costs consume 50% of agency annual budgets, which, after operating expenses, leaves little money for proactive fuels treatment or forest restoration (*11*). Costs and injuries, however, are much lower on managed fires than on escaped wildfires (*7*, *15*). The estimated cost savings for using managed fire compared with wildfire suppression over the same area (*15*) could be reported to Congress to highlight the economy of using proactive restoration rather than reactive triage.

Increased fire use will necessitate management changes (*16*). Mechanical fuels reduction could also be used not only for fire containment but also to establish safe-zone anchors to facilitate greater fire reintroduction (*8*). Large prescribed burns commonly used in Western Australia are possible because a network of these anchors allows 6 to 8% of the forest to be burned annually (*16*). Australian foresters make substantial efforts to educate the public about the inevitability of fire and its ecological benefits and to build support for fire use and smoke tolerance.

We will not eliminate wildfire, but public support for proactive use of managed fires can help restore millions of hectares of forest ecosystems. ■

Managing fire-prone forests in the western United States

Reed F Noss[1], Jerry F Franklin[2], William L Baker[3], Tania Schoennagel[4], and Peter B Moyle[5]

The management of fire-prone forests is one of the most controversial natural resource issues in the US today, particularly in the west of the country. Although vegetation and wildlife in these forests are adapted to fire, the historical range of fire frequency and severity was huge. When fire regimes are altered by human activity, major effects on biodiversity and ecosystem function are unavoidable. We review the ecological science relevant to developing and implementing fire and fuel management policies for forests before, during, and after wildfires. Fire exclusion led to major deviations from historical variability in many dry, low-elevation forests, but not in other forests, such as those characterized by high severity fires recurring at intervals longer than the period of active fire exclusion. Restoration and management of fire-prone forests should be precautionary, allow or mimic natural fire regimes as much as possible, and generally avoid intensive practices such as post-fire logging and planting.

Front Ecol Environ 2006; 4(9): 481–487

The management of fire-prone forests, especially within the national forests of the west, is one of the most contentious natural resource issues in the US today. One recent response to the controversy is the Healthy Forests Restoration Act (HFRA) of 2003 (Public Law 108-V148). This law has potentially profound consequences for forests and their biodiversity and must therefore be implemented on the basis of the best scientific information and guidance. Towards this end, the North American Section of the Society for Conservation Biology convened a scientific panel to review issues related to the ecology and management of fire-prone forests of the western US. This article is adapted from the unpublished report of that panel (Noss *et al.* 2006a).

The vegetation of North America has been shaped by recurring fires over millions of years. Fossils of pines (*Pinus* spp), which are closely associated with fire, date from the Cretaceous Period, more than 100 million years ago (Millar 1998). Fire remains the primary natural disturbance influencing plant and animal communities across much of the continent today (Habeck and Mutch 1973; Agee 1993). Many forests, however, have been degraded over the past century by misguided fire management, as well as other impacts such as logging and livestock grazing. Uncharacteristic fuel loads contribute to altered fire regimes in some forest types (Covington and Moore 1994; Schoennagel *et al.* 2004). Key structural elements (eg old "veteran" trees), terrestrial and aquatic biodiversity, and habitats of many threatened and endangered species are already greatly diminished and at continuing risk of loss. Increased human habitation of wildlands has intensified problems of managing fire, especially at the wildland–urban interface (Dombeck *et al.* 2004).

For this paper we evaluated the scientific literature that is relevant to conservation, restoration, and management of forests in the western US (excluding Alaska). Our review addresses ecological science relevant to developing and implementing fire and fuel management policies, including activities conducted before, during, and after wildfires. Our focus is primarily on wildlands, rather than the wildland–urban interface, where ecological values may be secondary to fire-risk mitigation to protect people and homes (DellaSala *et al.* 2004). In wildlands especially, sustainable forest management must be based on well-grounded ecological principles.

In a nutshell:

- The complexity created by variability in fire regimes defies a one-size-fits-all management prescription
- Restoration is warranted where fire exclusion has led to substantial alterations in ecosystem qualities
- Post-fire logging usually has no ecological benefits and many negative impacts; the same is often true for post-fire seeding
- Although many forests will require continued management, a common sense conservation goal is to achieve forests that are low maintenance and require minimal repeated treatment

young trees, creating and shaping wildlife and fish habitat, structuring the spatial pattern of landscapes, and influencing water and sediment delivery across watersheds. Many plant and animal species are adapted to post-fire conditions, and populations of some (eg many bird species; Figure 1) decline after fire exclusion or post-fire logging (Hutto 1995). Different species benefit from different fire severities and intervals between fires.

Given fuel, lightning, and dry weather, wildfire is inevitable. Nevertheless, the characteristic fire regime, especially the extent and severity of fire and how often it recurs, varies over a surprisingly large spectrum. Fires recur in western forests from once a decade or less in some dry ponderosa pine (*Pinus ponderosa*) forests to a cycle of 250–400 years or more in coastal forests (Hemstrom and Franklin 1982; Covington *et al.* 1997; Agee 1998). Even within a forest type, fire frequency may vary by two orders of magnitude across sites, for example, from 6 to 600 years in redwood (*Sequoia sempervirens*) forests (Noss 2000). Frequent fires are typically lower in intensity (energy output) and severity (impact on vegetation) than infrequent fires, such as those that occurred in and around Yellowstone National Park in 1988 (Turner *et al.* 2003).

Characteristic fire regimes (Panel 1) result from a combination of forest type, fuels, topography, climate, and ignition sources (Schoennagel *et al.* 2004). Forests subject to high severity fire typically support high tree densities. When dense fuels dry out and an ignition source is present, the resulting fires can spread rapidly and are almost impossible to suppress. High severity fires kill most or all trees in substantial portions of the burn, although fire pattern is often a mosaic that includes areas of unburned or less severely burned forest (Figure 2). This is true in such diverse forests as productive coastal Douglas-fir (*Pseudotsuga menziesii*; Agee 1993) and low productivity, high elevation lodgepole pine (*Pinus contorta*) in the Rocky Mountains (Wallace 2004). Many large, high severity fires are associated with infrequent, severe droughts (Westerling *et al.* 2003), often related to broad-scale climatic anomalies (Gedalof *et al.* 2005). Fire exclusion has had minimal effect on most forests characterized by high severity fire – a fact that is especially relevant to fire policy. High severity fires are infrequent (from one to many centuries; Romme and Despain 1989; Agee 1993; Kipfmueller and Baker 2000), whereas the period of active fire exclusion in North America is 50 years at most. Furthermore, many of these forests are remote and occur at high elevations, making access for fire fighting difficult.

In contrast, dry, less productive forests may have annual droughts that promote frequent fires. As a consequence of lower productivity and higher fire frequencies, fuel accumulations and fire intensities are characteristically lower in such forests than in coastal or subalpine forests. Low-severity fire regimes characterized many pine and mixed-conifer forests at warm, dry sites prior to European settlement (Table 1). Fires in ponderosa pine and dry, mixed-conifer forests historically burned fine fuels (eg grasses and litter on the forest floor) at regular intervals (Veblen *et al.* 2000; Heyerdahl *et al.* 2001; Stephens and Collins 2004). These surface fires rarely killed large, fire-

Panel 1. What are "characteristic" and "uncharacteristic" fire regimes?

"Characteristic" is a controversial concept among ecologists. We use this term in reference to the dominant natural disturbance regime and associated structural characteristics for a particular forest type or site historically, before major disruption by Euro-Americans. Conversely, the term "uncharacteristic" refers to disturbances, forest structure, or fuel loads of a scale or type outside the historical range of variability, based on site-specific vegetation reconstructions using tree rings, fire scars, pollen, charcoal, or early historical records. Characteristic does not imply uniformity, because substantial variability occurs within as well as among forest types in fire regime and structure. A forest type that was "historically characterized" by low severity fire may, on many sites, experience high or moderate severity fire (Ehle and Baker 2003). What is characteristic also changes over time, sometimes radically, for example with changing climate (Pierce *et al.* 2004). Despite difficulties with the concept, some idea of the characteristic fire regime for a given forest is needed, to give management strategies proper direction.

© The Ecological Society of America

resistant trees, but did kill smaller trees of all species, thereby helping to maintain sparse, open stands. Human activities following European settlement – including fire exclusion, grazing, logging, and tree planting – dramatically modified the fuel structure in these forests. Grazing reduced the fine fuels that carry surface fires and facilitated dense tree reproduction by reducing or eliminating herbaceous competition (Rummell 1951; Savage and Swetnam 1990; Belsky and Blumenthal 1997). Logging also promoted higher stand densities in many dry ponderosa pine forests by stimulating dense natural regeneration (Agee 1993; Kaufmann *et al.* 2000). These forests therefore changed from relatively open stands with low fuel loadings to dense stands that can carry crown fires (Skinner 1995). Restoration of such forests (ie guiding their composition, structure, and function to a condition within the historical range of variability) is often desirable (Figure 3) and can involve active techniques such as thinning of small trees and prescribed burning or passive management such as allowing natural fires to burn and removing livestock (Allen *et al.* 2002; Brown *et al.* 2004; Schoennagel *et al.* 2004). Large wildland landscapes are especially well-suited to passive restoration (Noss *et al.* 2006b).

Figure 2. *A mosaic fire pattern in Madison Canyon, Yellowstone National Park, approximately one year after the major 1988 fires.*

Fire is variable in severity in certain mid- and low-elevation forests of moderate to high productivity. In addition to the effects of shifts in the weather during a fire, variable fire severity can result from spatial heterogeneity in topography (which affects microclimate), the relative abundance of fuels, and the legacies of past episodes of fire and other disturbances. Topographically complex mountain landscapes may be especially prone to mixed severity fire, because drier, south-facing slopes with lower fuel loads may burn at low severity while adjacent, moister, north-facing slopes that support higher tree densities experience high severity fire (Taylor and Skinner 2003; Spies *et al.* 2006) or escape fire due to wetter conditions. Evidence of mixed severity fire in moist ponderosa pine forests and mixed evergreen–conifer forests is accumulating (Shinneman and Baker 1997; Brown *et al.* 1999; Odion *et al.* 2004). The inherent variability of mixed-severity fire regimes precludes easy analysis of fire-exclusion effects, because high tree density or an abundance of shade-tolerant trees is not necessarily the result of fire exclusion.

The complexity created by variability in fire regimes defies a simple, one-size-fits-all prescription for restoration. Fortunately, plant association groups, which have predictable relationships to fire regimes (Table 1), provide a classification of this diversity that is useful for managers, albeit plant association–fire relationships can be expected to change as climate changes (McKenzie *et al.* 2004; Pierce *et al.* 2004).

Forest management prior to wildfire

How can forests be managed to ensure that fire will play its characteristic role in maintaining composition, structure, and function of forest ecosystems? Management will vary greatly with the type of forest and its dominant fire regime (Table 1). Developing a management and restoration program requires that the effects of past land uses be identified so that they can be remedied. In forests characterized by low-severity fire regimes, restoration varies along a continuum from restoring structure (eg reducing densities of small trees and increasing the density of large trees) to restoring the processes (eg low severity fire, competition between grasses and tree seedlings) that create and maintain that structure (Figure 4). The continuum also represents a gradient from symptoms (eg uncharacteristically high tree densities) to causes (eg exclusion of fire). The following are some of our key findings that relate to decisions about fire management. (1) Fire exclusion and other human activities led to significant deviations from historical variability in some, but not all, forests. Restoration treatments are warranted, sometimes urgently, only where such activities have resulted in major alterations in ecosystem structure, function, or composition. (2) Fire exclusion has had little effect on fuels or forest structure in forests characterized by high severity (stand-replacement) fire. High severity fires are relatively infrequent, occurring at intervals of one to many centuries,

whereas active fire exclusion, especially in remote forests, began only decades ago. Because fuel structures or tree densities are usually within the historical range of variability, active restoration is ecologically inappropriate in these forests. (3) Restoration of dry ponderosa pine and dry mixed-conifer forests – where low severity fires were historically most common – is ecologically appropriate on many sites. Active (eg mechanical thinning of small stems, prescribed fire) or passive (eg wildland fire use, livestock removal) management can restore stand densities to the levels that existed prior to fire exclusion, livestock grazing, logging, and plantation establishment. Retention of old live trees, large snags, and large logs in restoration treatments is critical. Also, restoring other key components of these ecosystems, such as native understory plants, is essential for full recovery of natural conditions, including the characteristic fire regime. (4) Scientific understanding of mixed severity fire regimes is limited, making it difficult to provide defensible guidelines for restoration. These are often complex landscape mosaics; it is therefore necessary to plan and conduct activities at large spatial scales. Where sufficient ecological and fire-history information is available, a combination of thinning and prescribed fire may be useful in restoration. Nevertheless, only portions of these landscapes may warrant treatment. (5) Restoration plans should systematically incorporate fire to maintain restored forests. Forests are dynamic; therefore, any restoration program must provide for sustained fire management to maintain the desired condition. Low-maintenance forests, which can often be achieved through managed natural fire, are an appropriate restoration goal in many cases; where this is not possible, prescribed fire should mimic the characteristic fire regime as closely as possible. Because fire regimes vary tremendously on a regional scale, managers should allow for a range of fire severities. (6) Species closely associated with late- or early-successional conditions in fire-prone landscapes need special management consideration. For example, managed forests are often fragmented by periodic logging and road-building, or consist only of stands of trees too small or too open to meet the needs of late-successional dependent species, such as the spotted owl (*Strix occidentalis*).

Forest management during wildfire

Fire management policies focus on responses to wildfire, including such basic decisions as whether to suppress it. A generalized policy of fire suppression is inappropriate given the documented negative ecological impacts of fire suppression during the 20th century. Responses to fire must take into consideration many ecological and social factors, beginning with the nature of the forest type and societal goals.

Our findings indicate that allowing fires to serve their natural role is ecologically beneficial. Although fire must be managed when close to human infrastructure, in many wilderness areas, national parks, and large areas of public land there is opportunity to increase the use of wildland fire. Such management benefits species that require the shifting mosaics of post-fire habitats found in natural landscapes (Smucker *et al.* 2005). Furthermore, fire suppression may be ecologically warranted in some cases, particularly where special values are at risk. For example, it may be appropriate where habitat of critically imperiled species could be lost, where uncharacteristic fuel accumu-

© The Ecological Society of America

lations have created the potential for a fire outside the historical range of variability, or where high severity fires are not now viewed as ecologically desirable (eg old-growth forests in the Pacific Northwest). Finally, ecologists should be included on fire management teams to ensure that decisions consider the ecological costs and benefits of management actions.

Figure 3. *A restored ponderosa pine stand, Grand Canyon National Park (North Rim).*

Forest management after wildfire

Forest landscapes that have been affected by a major natural disturbance, such as a severe wildfire or wind storm, are commonly viewed as devastated. Such perspectives are usually far from ecological reality. Overall species diversity, measured as number of species – at least of higher plants and vertebrates – is often highest following a natural stand-replacement disturbance and before redevelopment of closed-canopy forest (Lindenmayer and Franklin 2002). Important reasons for this include an abundance of biological legacies, such as living organisms and dead tree structures, the migration and establishment of additional organisms adapted to the disturbed, early-successional environment, availability of nutrients, and temporary release of other plants from dominance by trees. Currently, early-successional forests (naturally disturbed areas with a full array of legacies, ie not subject to post-fire logging) and forests experiencing natural regeneration (ie not seeded or planted), are among the most scarce habitat conditions in many regions.

Our key findings on post-fire management are as follows. First, post-burn landscapes have substantial capacity for natural recovery. Re-establishment of forest following stand-replacement fire occurs at widely varying rates; this allows ecologically critical, early-successional habitat to persist for various periods of time. Second, post-fire (salvage) logging does not contribute to ecological recovery; rather, it negatively affects recovery processes, with the intensity of impacts depending upon the nature of the logging activity (Lindenmayer *et al.* 2004). Post-fire logging in naturally disturbed forest landscapes generally has no direct ecological benefits and many potential negative impacts (Beschta *et al.* 2004; Donato *et al.* 2006; Lindenmayer and Noss 2006). Trees that survive fire for even a short time are critical as seed sources and as habitat that sustains biodiversity both above- and belowground. Dead wood, including large snags and logs, rivals live trees in ecological importance. Removal of structural legacies, both living and dead, is inconsistent with scientific understanding of natural disturbance regimes and short- and long-term regeneration processes. Third, in forests subjected to severe fire and post-fire logging, streams and other aquatic ecosystems will take longer to return to historical conditions or may switch to a different (and often less desirable) state altogether (Karr *et al.* 2004). Following a severe fire, the biggest impacts on aquatic ecosystems are often excessive sedimentation, caused by runoff from roads, which may continue for years. Fourth, post-fire seeding of non-native plants is often ineffective at reducing soil erosion and generally damages natural ecological values, for example by reducing tree regeneration and the recovery of native plant cover and biodiversity (Beyers 2004). Non-native plants typically compete

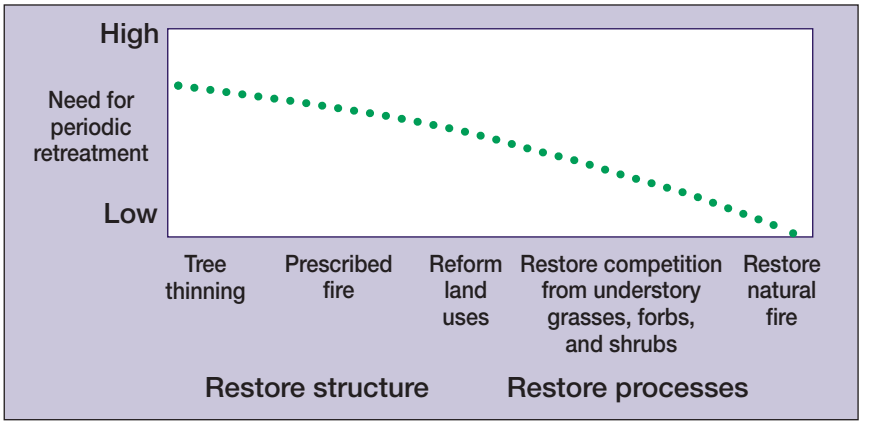

Figure 4. *Forest restoration varies along a continuum from restoring structure (which requires periodic retreatment) to restoring potentially self-sustaining processes.*

© The Ecological Society of America

with native species, reducing both native plant diversity and cover (Keeley *et al.* 2006). Fifth, the ecological importance of biological legacies and of uncommon, structurally complex early-successional stands argues against actions to achieve rapid and complete reforestation. Re-establishing fully stocked stands on sites characterized by low severity fire may actually increase the severity of fire because of fuel loadings outside the historical range of variability. Finally, species dependent on habitat conditions created by high severity fire, with abundant standing dead trees, require substantial areas to be protected from post-fire logging (Hutto 1995).

More ecological science is needed in fire management

Despite the complexity of fire ecology in western forests and uncertainty over the effects of particular management actions, the scientific basis for rational decision-making about fire has improved dramatically in recent years. It is time to systematically incorporate principles of ecological science and existing knowledge of individual forest ecosystems into forest fire and fuel policies.

One barrier to better use of ecological science is that individuals involved in developing fire policies and practices have tended to be specialists in fire and fuel management, not ecologists, conservation biologists, or other broadly trained scientists. It is not surprising, therefore, that current forest law does not adequately incorporate ecological considerations in its implementation and tends to promote a narrow definition of restoration that focuses almost exclusively on fuels (DellaSala *et al.* 2004; Schoennagel *et al.* 2004).

True ecological restoration requires the maintenance of ecological processes, native species composition, and forest structure at both stand and landscape scales. Because forests are highly variable over space and time, few universal principles exist for integrating insights from ecology and conservation biology into fire management policies. Nevertheless, one fundamental principle is that managed forests should not only support the desired fire regime but also viable populations of native species in functional networks of habitat (Hessberg *et al.* 2005). A common-sense conservation goal is to achieve forests that are low maintenance and require minimal repeated treatment. With time, in a landscape of sufficient size, the right end of the restoration continuum (Figure 4) could be reached, where natural fire maintains the system in the desired state. Indeed, wildland fire use is the cheapest and most ecologically appropriate policy for many forests. We envision a future where fire is seen by land managers and the public as the key to healthy forests, but where each forest and each patch of the forest mosaic is recognized for its individuality and managed accordingly. Above all, a guiding principle of forest management should be a precautionary approach that avoids ecological harm.

Abstract. Wildland fire is an important disturbance agent in the western US and globally. However, the natural role of fire has been disrupted in many regions due to the influence of human activities, which have the potential to either exclude or promote fire, resulting in a "fire deficit" or "fire surplus", respectively. In this study, we developed a model of expected area burned for the western US as a function of climate from 1984 to 2012. We then quantified departures from expected area burned to identify geographic regions with fire deficit or surplus. We developed our model of area burned as a function of several climatic variables from reference areas with low human influence; the relationship between climate and fire is strong in these areas. We then quantified the degree of fire deficit or surplus for all areas of the western US as the difference between expected (as predicted with the model) and observed area burned from 1984 to 2012. Results indicate that many forested areas in the western US experienced a fire deficit from 1984 to 2012, likely due to fire exclusion by human activities. We also found that large expanses of non-forested regions experienced a fire surplus, presumably due to introduced annual grasses and the prevalence of anthropogenic ignitions. The heterogeneity in patterns of fire deficit and surplus among ecoregions emphasizes fundamentally different ecosystem sensitivities to human influences and suggests that large-scale adaptation and mitigation strategies will be necessary in order to restore and maintain resilient, healthy, and naturally functioning ecosystems.

Key words: climate; fire deficit; fire departure; fire exclusion; fire occurrence; fire suppression; fire surplus; invasive species; protected areas; wilderness; wildland fire.

INTRODUCTION

The arrival of Euro-American settlers in the late-1800s disrupted the natural ecological role of fire in the western US (Keane et al. 2002), thereby resulting in departures in fire activity compared to earlier periods (Safford and Van de Water 2014). These departures in fire activity have been directly linked to a decoupling of the relationship between climate and fire, which, prior to Euro-American settlement, was fairly strong (Marlon et al. 2012). Consequently, many fire-prone ecosystems in the western US have experienced a reduction in fire activity since Euro-American

settlement compared to earlier periods (e.g., Mallek et al. 2013). Such decreases in fire activity have been attributed to human activities such as fire suppression, livestock grazing, logging, land-type conversion (e.g., to agriculture), and other anthropogenic influences (e.g., roads; Savage and Swetnam 1990, Heyerdahl et al. 2001, Allen et al. 2002, Marlon et al. 2008). Conversely, *increases* in fire activity have also been documented in certain ecosystems or localized areas due to factors such as invasive species that facilitate fire ignition and spread as well as high rates of human-caused ignitions (D'Antonio and Vitousek 1992, Syphard et al. 2007, Balch et al. 2013). Although many of these studies definitively demonstrated that fire activity today is much different in the western US compared to historical conditions (e.g., pre Euro-American settlement), some have questioned the relevance of a past time period in defining reference conditions given that contemporary climate change is altering the biophysical environment (Harris et al. 2006).

At broad spatial scales, climate clearly influences fire activity, although the temporal resolution of analysis can result in different interpretations (Parisien et al. 2014). For example, fire activity has been shown to strongly correlate with climatic normals (e.g., 30 year averages; hereafter "climate;" Krawchuk et al. 2009, Parisien et al. 2011, Moritz et al. 2012). This is likely an indirect influence on fuel conditions via climate's effect on productivity, moisture, and dominant vegetation type (Krawchuk and Moritz 2011, Pausas and Ribeiro 2013, Parks et al. 2014). This climatic effect is in contrast to inter-annual *climatic variability* that also influences fire activity, whereby warm and dry years generally correspond to increased fire activity (Westerling et al. 2006, Heyerdahl et al. 2008, Littell et al. 2009). We suggest that, because climate (i.e., climatic normals) is a strong top-down control on fire activity (although it may be an indirect control), a natural level of fire activity can be defined as that which emerges from the climate. As such, the "expected" amount of fire can be statistically modeled as a function of climate. Indeed, this rationale is often invoked in studies evaluating the effect of climate change on future fire activity (Krawchuk et al. 2009, Moritz et al. 2012, Batllori et al. 2013). This rationale also allows for an evaluation of contemporary departures in fire activity by comparing the expected and observed area burned. Where observed fire activity is less than expected, the result is a "fire deficit" because there is less fire than the climate dictates (Marlon et al. 2012). Where observed fire activity is greater than expected, the result is a "fire surplus."

Because ecosystems with disrupted fire regimes are thought to be less resilient to environmental change (Millar et al. 2007), land managers often cite the need to restore wildland fire as a natural disturbance (NWCG 2001). To accomplish this, land managers need to better understand current departures from natural levels of fire activity, especially considering that restoring wildland fire necessitates that our communities learn to co-exist with fire (Moritz et al. 2014). However, quantifying natural levels of fire activity is challenging for two reasons. First, as climate changes, the natural level of fire activity is a moving target. Second, human activities continue to alter fire regimes (as previously described). Fortunately, protected areas and other lands with little anthropogenic impact can provide a benchmark for quantifying natural levels of fire activity as a function of climate. For example, Parks et al. (2014) found that the relationship between climate and fire activity was reasonably strong in the western US when models were built using samples primarily comprised of protected areas; the relationship was weak when models were built using samples irrespective of the protected area composition (Appendix A). Archibald et al. (2010) had a similar finding in their study of fire and climate variability in southern Africa. A comparison of expected (according to the natural benchmark) to observed fire activity then allows for a formal evaluation of fire deficit and surplus for lands of all management designations.

We sought to quantify departures from contemporary natural levels of expected fire activity and identify areas of fire deficit and surplus in the western US for the 1984–2012 time period. This was achieved by developing a boosted regression tree (BRT) model to predict area burned as a function of several climatic variables for 500 km^2 hexagonal polygons (hereafter "hexels"). The model was built using fire and climate data from a subset of hexels in the western US having substantial area in a protected

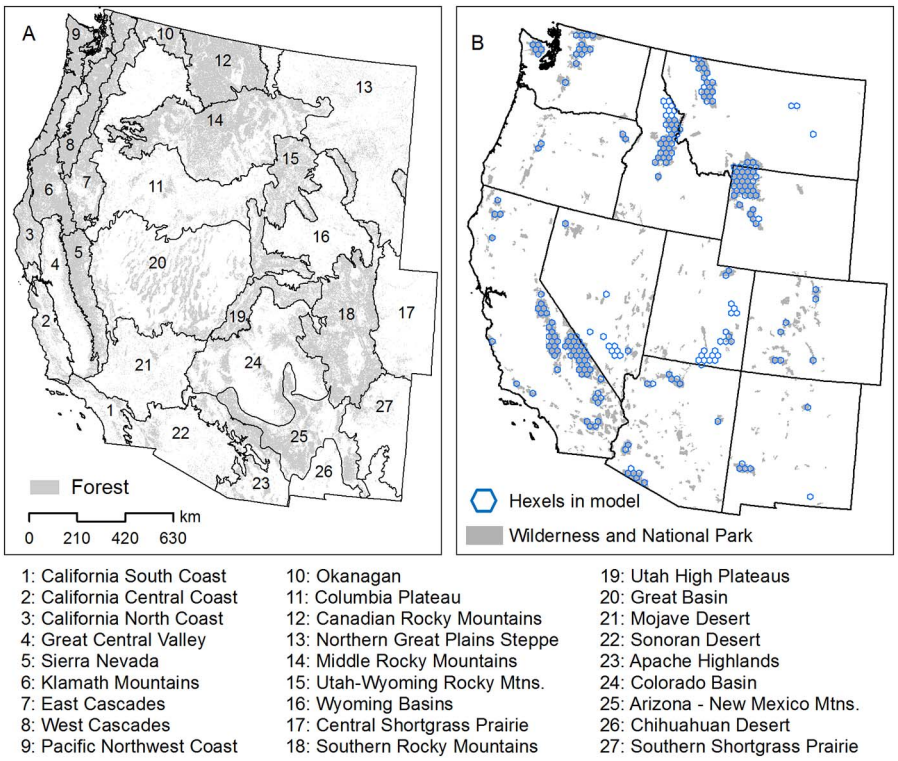

Fig. 1. Study area of the western US for which we quantify departures in expected area burned. Map showing forested areas and ecoregion boundaries (A) and showing designated wilderness areas and national parks as well as the hexels we used to build the model of area burned (B).

status (e.g., wilderness and parks) or otherwise having a low anthropogenic influence. These hexels serve as a natural benchmark (e.g., Appendix A) and are representative of a broad gradient in climate (Appendix B) and include ecosystems such as desert, dry conifer forest, and cold conifer forest. We then quantified the degree of fire deficit or surplus as the difference between expected (as predicted with the BRT model) and observed area burned from 1984 to 2012 for all hexels in the western US and provided ecoregional summaries. Our study is relevant to the contemporary time period (i.e., 1984–2012) and does not reflect prior time periods in which the climate was different or indigenous burning was common.

Methods

We quantified departures in expected area burned from 1984 to 2012 for each 500 km^2 hexagonal polygon (i.e., "hexels") in the western US (Fig. 1). We chose this hexel size based on previous work (Parks et al. 2014), although we acknowledge that the resolution of analysis may influence the relationship between fire and its environment (Parisien et al. 2011, Parks et al. 2011). We built a model of area burned as a function of climate and then used model results to quantify fire departures.

We selected a subset of hexels with low human influence to build the model because the relationship between climate and fire is reasonably strong in areas of low human impact but weakens as anthropogenic influences increase (Archibald et al. 2009, Parks et al. 2014; Appendix A). Consequently, areas of low human impact act as "controls" and therefore characterize the expected relationship between fire and climate were human activities not an overarching influence. We selected hexels comprised of at least 75% designated wilderness and national park or had an average "human footprint" (HFP; Leu et al. 2008) $\leq$1.5 (on a scale of 1–10). We also

Table 1. Climatic variables evaluated as independent variables in the statistical model describing area burned. Only those that had a correlation coefficient <0.9 (bold) to each other were included in the final model ($n = 5$). The coefficient of variation (among years) of the five selected variables were also included in the statistical model for a total of 10 variables. These variables represent climatic conditions from 1984 to 2012.

Variable abbreviation	Description	Units
AET	Actual evapotranspiration (annual average)	mm/year
DMC†	Duff moisture code (annual average)	dimensionless
ERC‡	Energy release component (annual average)	dimensionless
PRECIP	Precipitation (annual average)	mm/year
SWE	Snow water equivalent (monthly average)	mm/month
SMO	Soil moisture (monthly average)	mm/month
TEMP	Temperature (annual average)	°C
VPD	Vapor pressure deficit (monthly average)	kPa
WD	Water deficit (annual average)	mm/year

† ERC is a fire danger index in the National Fire Danger Rating System (NFDRS; Cohen and Deeming 1985).
‡ DMC is a fire danger index in the Canadian Forest Fire Danger Rating System (CFFDRS; van Wagner 1987).

excluded hexels with more than 50% nonfuel (e.g., open water and barren). These selection criteria resulted in 235 hexels for which we built the model of area burned (Fig. 1). Despite representing only a small proportion of the western US (~4%), the hexels span broad climatic gradients ranging from warm deserts to cold forests (Appendix B). Although human-ignited fires may blur the relationship between climate and fire, only about 8% of the area burned from this subset of hexels was due to such fires (for the years 1992–2012; Short 2014).

Area burned (ha) was calculated within each hexel using a fire atlas covering all fires ≥400 ha from 1984 to 2012 (Eidenshink et al. 2007). Area burned was adjusted to account for unburnable areas (e.g., open water) within each hexel by dividing area burned by the proportion of the hexel that was composed of burnable fuel types (Rollins 2009). Several climatic variables known to influence fire activity were evaluated for inclusion into the model as independent variables (e.g., Littell and Gwozdz 2011, Abatzoglou and Kolden 2013, Parks et al. 2014; Table 1). Gridded monthly temperature and precipitation data were obtained from the parameter-elevation regression on independent slopes model (PRISM; Daly et al. 2002) that uses station data and physiographic factors to map climate at a spatial resolution of ~800 m. Abatzoglou (2013) combined monthly data from PRISM and hourly estimates from coarser scale analyses from the North American Land Data Assimilation System Phase 2 (NLDAS-2; Mitchell et al. 2004) to produce daily and sub-daily surface meteorological variables at a ~4-km resolution that captures temperature, humidity, winds, solar radiation, and precipitation, which were subsequently used to estimate the energy release component (ERC; Cohen and Deeming 1985), duff moisture code (DMC; van Wagner 1987), and reference evapotranspiration. These data were collectively used to run the climatic water balance model following Dobrowski et al. (2013) to estimate monthly actual evapotranspiration (AET), snow water equivalent (SWE), soil moisture (SMO), and water deficit (WD). This model operates on a monthly time-step and accounts for atmospheric demand (via the Penman-Monteith equation), soil water storage, and includes the effect of temperature and radiation on snow hydrology via a snow melt model. All variables were characterized by averaging or summing monthly values over each year, then averaging the values over 1984–2012, and finally, averaging within each hexel. Those variables with a correlation coefficient of ≥0.9 (for the 235 hexels used to build the model) were excluded from the model (Table 1). For the five variables that met this correlation criterion, we also included in the model variables representing inter-annual variability (coefficient of variation).

We built our model of area burned as a function of climate using boosted regression trees (BRT) within the R statistical program (R Development Core Team 2007; "gbm" package). BRT is a machine-learning approach that does not require a priori model specification (De'ath 2007). We square-root-transformed area burned to homogenize variance in model residuals and

21508925, 2015, 12, Downloaded from https://esajournals.onlinelibrary.wiley.com/doi/10.1890/ES15-00294.1, Wiley Online Library on [01/02/2024]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

used a Poisson distribution. We followed the recommendations of Elith et al. (2008) for selecting BRT options; we set the bagging fraction to 0.5, learning rate to 0.0025, and tree complexity to 5. We used a custom script from Elith et al. (2008) to determine the necessary number of trees, thereby reducing the potential for overfitting the model. We evaluated model fit using 10-fold cross-validated correlation between predicted and observed values of area burned.

We quantified departures in expected area burned for each hexel in the western US by subtracting predicted from observed area burned for the 1984–2012 time period; negative values indicate less area burned than expected (i.e., a fire deficit), and positive values indicate more area burned (i.e., a fire surplus). We "clamped" predicted area burned to the maximum value in the training hexels to avoid predicting outside of the observed range of area burned. We summarized deficits and surpluses, as well as the expected and observed fire rotation, for each ecoregion (Olsen and Dinerstein 2002; Fig. 1); results for ecoregions with minimal overlap with the study area are not shown (e.g., Black Hills). Hexels on the edge of study area boundary are omitted from the ecoregional summaries if $>50\%$ of its area overlaps with the ocean, Mexico, Canada, or areas east of the study area. Hexels are defined as unburnable if $\geq 50\%$ is characterized as irrigated agriculture, barren, urban, or water (Rollins 2009) and are excluded from the ecoregional summaries.

Results

The BRT performed well; the cross-validated correlation between predicted and observed area burned was 0.80 (see Appendix C for variable importance and response curves for selected variables). Departures from expected area burned from 1984 to 2012 were spatially heterogeneous across the western US (Fig. 2). Some ecoregions exhibited large fire deficits (e.g., California North Coast and Apache Highlands), others a fire surplus (e.g., California South Coast and Columbia Plateau), and others no substantial departure (e.g., West Cascades and Sonoran Desert; Fig. 2, Table 2). Most forested ecoregions experienced a fire deficit, with the notable exception of mesic forested ecoregions in the Pacific Northwest, which showed no substantial departure from expected area burned. Large geographic expanses of fire surplus were apparent in some non-forested regions (e.g., the southern Columbia Plateau and northern Great Basin), although a fire deficit was observed in two non-forested ecoregions (i.e., Central Shortgrass Prairie and Southern Shortgrass Prairie; Fig. 2, Table 2).

Discussion

Our results reveal a striking pattern of departures from expected area burned across the western US from 1984 to 2012. We found that fire deficits were more prevalent in forested ecoregions compared to non-forested ecoregions. In several non-forested ecoregions, large expanses of fire surplus were evident. The contrasting patterns of fire deficit and surplus between forested and non-forested ecoregions emphasize fundamentally different ecosystem sensitivities to human influences. However, there were also large expanses that experienced no substantial departure from expected area burned. Such areas generally corresponded to two types of ecosystems that typically experience little fire: very dry ecosystems that are biomass limited (i.e., warm and cold deserts that have not been invaded by annual grasses) and wet ecosystems (temperate rainforest) that are rarely conducive to burning (Krawchuk and Moritz 2011, Parks et al. 2014).

Most forested areas in the western US experienced a fire deficit from 1984 to 2012. These deficits strongly support the widespread notion that fire activity is reduced by human activities that exclude fire. Although our findings are only relevant to climate and fire over the 1984–2012 time period, they corroborate the findings of Marlon et al. (2012) and multiple fire history studies that indicated a sharp reduction in fire activity since the arrival of Euro-Americans, e.g., in the Sierra Nevada (Taylor 2000, Beaty and Taylor 2008), Klamath Mountains (Taylor and Skinner 2003), California North Coast (Stuart and Salazar 2000), East Cascades (Wright and Agee 2004), Southern Rocky Mountains (Grissino-Mayer et al. 2004), Middle Rocky Mountains (Heyerdahl et al. 2001), Canadian Rocky Mountains (Power et al. 2006), Utah High Plateaus (Stein 1988, Brown et al. 2008), Apache High-

21508925, 2015, 12, Downloaded from https://esajournals.onlinelibrary.wiley.com/doi/10.1890/ES15-00294.1, Wiley Online Library on [01/02/2024]. Fig. 2. Map depicting departures in expected area burned from 1984 to 2012 (A). Blue hexels represent less fire than expected (i.e., a fire deficit); red hexels represent more than expected (i.e., a fire surplus); yellow hexels indicate no substantial departure; dark gray hexels are unburnable. Histograms of each ecoregion (B) correspond to fire departure categories shown in the map legend (A).

lands (Baisan and Swetnam 1990), and Arizona-New Mexico Mountains (Swetnam and Dieterich 1985). Decreased fire activity has resulted in substantial changes to some forested ecosystems. For example, reduced rates of burning have resulted in altered species composition (i.e., increases in shade-tolerant species), increased tree density, and increased landscape homogeneity (Taylor 2000, Naficy et al. 2010, Fry et al. 2014, Stephens et al. 2015). A major concern of these site- and landscape-level ecosystem changes is the increased likelihood of uncharacteristically large and severe wildland fire in future years (Hessburg et al. 2005, Stephens 2005, Calkin et al. 2015). Although such fires may contribute to a reduction in the fire deficit, the uncharacteristic manner in which they burn can exceed ecological thresholds and result in conversion to non-forest types (Savage and Mast 2005). A few forested areas did not experience a fire deficit (i.e., Pacific Northwest Coast and West Cascades ecoregions), which is coherent with our knowledge of the fire regime characteristics of these regions where fires are infrequent (fire return intervals of 200–1000 years; Agee 1993).

The pattern of fire surpluses and deficits in non-forested ecoregions is consistent with our knowledge of the impact of human activities on area burned. For example, in the Columbia Plateau and Great Basin ecoregions, the large expanse of fire surplus is likely the result of cheatgrass invasion (*Bromus tectorum*; Fig. 3; Knapp 1996, Bradley and Mustard 2008), a non-native annual grass that was introduced to North America during the 1800s that is known to increase fire activity (Knick and Rotenberry 1997, Balch et al. 2013). Similarly, the fire surplus in the Mojave Desert ecoregion is likely due to invasion by the annual grass red brome (*Bromus rubens*; Hunter 1991, Salo et al. 2005, Brooks and Matchett 2006), another grass introduced from Europe. In many of these affected areas, there is generally a positive feedback where fire facilitates invasive grass establishment, which in turn

† Hexels are considered unburnable if ≥50% is characterized as irrigated agriculture, barren, urban, or water and are excluded from all calculations.

‡ Negative values indicate a fire deficit and positive values a fire surplus.

§ Fire rotation is defined as the number of years necessary to burn an area the size of the ecoregion and for the 29 year record (1984–2012) is calculated as follows: 29/(expected [or observed] area burned/area of the ecoregion).

increases fire frequency because the invading grass produces a continuous bed of flammable fine fuels (Brooks et al. 2004). Although the Sonoran Desert and Chihuahuan Desert ecoregions exhibited no substantial fire departure from 1984–2012, natural and climate-induced range expansions of invasive annual grasses could put them at risk in the future (Salo 2004, Abatzoglou and Kolden 2011). In addition to the effects from invasive and exotic plant species, the prevalence of human-caused ignitions are implicated in increased fire activity and the associated fire surplus found in the California South Coast ecoregion (Syphard et al. 2007, Keeley et al. 2011, Keeley and Brennan 2012). The fire deficits we found for the Central Shortgrass Prairie and Southern Shortgrass Prairie ecoregions are areas that naturally would support periodic fire, but fire suppression and grazing by domestic cattle has reduced fire activity in these areas (Axelrod 1985, Brockway et al. 2002).

Other studies that also evaluated potential departures in fire activity include Mallek et al. (2013), who used the results of numerous published dendrochronology studies to infer historical annual area burned for several forest types in the Sierra Nevada and made comparisons to contemporary rates of burning. Also, Ager et al. (2014) compared burn probability maps (generated with simulation models) to those of the Landfire "mean fire return interval" product (Rollins 2009) for National Forests in the western US to identify which pixels had higher or lower burn probabilities compared to presumed historical conditions. Similar to our findings, these studies found that contemporary fire activity in forested regions, for the most part, was less than that of the pre-European reference period. However, formal comparisons between our study and these previous studies are not appropriate due to differences in the reference period, spatial resolution, and spatial extent of

21508925, 2015, 12, Downloaded from https://esajournals.onlinelibrary.wiley.com/doi/10.1890/ES15-00294.1, Wiley Online Library on [01/02/2024]. Fig. 3. Departures in expected area burned (km^2) within the Bradley and Mustard (2008) study area (A) and cheatgrass (*Bromus tectorum*) distribution according to Bradley and Mustard (2008) (B). Note the high spatial correspondence between fire surplus and cheatgrass distribution. The large expanse of fire surplus in southeastern Nevada (shown by the dashed circle) is likely due to a different invasive annual grass, red brome (*Bromus rubens*; Salo 2005).

analyses.

Multiple lines of evidence have attributed departures in fire activity between contemporary and historical (i.e., pre-Euro settlement) eras to human activities. Studies using both dendrochronology (i.e., cross-dated fire scar records; e.g., Heyerdahl et al. 2001, Mallek et al. 2013) and charcoal records (e.g., Colombaroli and Gavin 2010) have inferred that humans are at least partly responsible for reductions in rates of burning after about 1900. Our findings suggest that humans continue to influence fire activity today and show how this influence varies among ecosystems. As such, our approach to quantifying departures in fire activity complements earlier research and offers certain advantages. For example, because our model of expected area burned was built from a broad spatial extent, it incorporates all major ecosystems in the western US (e.g., shrub, forest, desert). Specifically, our method is not limited to tree-dominated ecosystems (cf. dendrochronology) or those that have permanent or ephemeral water bodies (cf. charcoal records). Furthermore, because we used contemporary fire and climate data in our study, we defined a contemporary, climatically driven baseline for expected fire activity. As such, in quantifying departures in fire activity, we avoid the use of a past reference period in which climate and indigenous burning practices were quite different (Sheppard et al. 2002, Stephens et al. 2007).

Several factors should be considered when interpreting our results. We assume a space-for-time substitution in calibrating our model; the large sample domain ensures adequate sampling of fires and allows us to infer relationships between fire and climate. Nevertheless, the temporal window of our analysis (1984–2012) is relatively short for many ecosystems (Agee 1993). Consequently, we may not have adequately characterized departures from expected area burned in certain regions, especially in cool/wet forested areas that show an apparent fire surplus only because of large, infrequent fires (sensu Meyn et al. 2007) that have occurred during our study period (e.g., Yellowstone National Park in 1988). For this reason, it is inappropriate to focus

21508925, 2015, 12, Downloaded from https://esajournals.onlinelibrary.wiley.com/doi/10.1890/ES15-00294.1, Wiley Online Library on [01/02/2024]. on any single hexel or small group of hexels to infer departures in expected fire activity. Instead, it is most appropriate to evaluate fire surplus and deficit over large geographical regions, which explains our rational for providing ecoregional summaries (Fig. 2, Table 2). The temporal window we analyzed (i.e., 1984–2012) also coincides with increased fire activity compared to earlier decades (e.g., 1940–1970; Littell et al. 2009). Consequently, had we analyzed fire and climate data from a different time period, our results would certainly be different. Periodic updates to our model and map are clearly warranted to provide a longer-term perspective on departures in expected fire activity, especially given the heterogeneous nature of fire and that negative feedbacks associated with recurring fires will likely limit future burning in some areas (Héon et al. 2014, Parks et al. 2015). Lastly, our study relies heavily on data from protected areas, which, despite representing the majority of climates in the western US, admittedly do not represent the complete range of climatic conditions (Batllori et al. 2014). Nevertheless, the climatic variability encompassed in the data we used to build the model (Appendix B) translates into a broad range of ecosystem and vegetation types, for example, warm desert (Death Valley National Park [NP]), dry conifer forest (Gila Wilderness), and cold forest (Yellowstone NP). As such, we suggest that poorly represented climates have only a marginal effect on our results.

Conclusions

Previous studies conducted at a variety of temporal and spatial scales identified a sharp drop in fire activity with the arrival of Euro-American settlers in forest-dominated landscapes of the western US (e.g., Marlon et al. 2012, Mallek et al. 2013). Our study makes no comparisons to time periods and climates prior to 1984 but demonstrates that most forested regions continue to experience less fire than expected, or a fire deficit. Our study also demonstrates that some non-forested regions experienced more fire than expected, or a fire surplus, over the 1984–2012 time period. The findings of our study, as well as other efforts such as the Landfire "Vegetation departure" (Rollins 2009) product, suggest that multiple large-scale adaptation and mitigation strategies will be necessary in order to restore and maintain resilient, healthy, and naturally functioning ecosystems (cf. Hessburg et al. 2015). For example, forested areas experiencing a fire deficit may be candidates for restoration treatments (e.g., mechanical fuel treatments, prescribed fire, wildland fire use) intended to promote resilience to future disturbances (Stephens and Ruth 2005, Millar et al. 2007). Conversely, areas experiencing a fire surplus may be indicative of highly altered and degraded ecosystems (Bradley and Mustard 2008, Brooks 2012) that are in need of restoration and ignition management (e.g., fire suppression and prevention). Protected areas and other areas with low anthropogenic influence served as a natural benchmark in which fire activity and climate are relatively tightly linked, and as such, are an invaluable data source for assessing perturbations to fire regimes across multiple ecosystem types.

DOES RIPARIAN FOREST RESTORATION THINNING ENHANCE BIODIVERSITY? THE ECOLOGICAL IMPORTANCE OF LARGE WOOD[1]

Michael M. Pollock and Timothy J. Beechie[2]

ABSTRACT: Intact riparian ecosystems are rich in biological diversity, but throughout the world, many have been degraded. Biodiversity declines, particularly of vertebrates, have led to experimental efforts to restore riparian forests by thinning young stands to accelerate creation of large diameter live trees. However, many vertebrates depend on large diameter deadwood that is standing as snags or fallen to the forest floor or fallen into streams. Therefore, we reviewed the sizes of deadwood and live trees used by different vertebrate species to understand which species are likely to benefit from different thinning treatments. We then examined how riparian thinning affects the long-term development of both large diameter live trees and deadwood. To this end, we used a forest growth model to examine how different forest thinning intensities might affect the long-term production and abundance of live trees and deadwood. Our results suggest that there are long-term habitat tradeoffs associated with different thinning intensities. Species that utilize large diameter live trees will benefit most from heavy thinning, whereas species that utilize large diameter deadwood will benefit most from light or no thinning. Because far more vertebrate species utilize large deadwood rather than large live trees, allowing riparian forests to naturally develop may result in the most rapid and sustained development of structural features important to most terrestrial and aquatic vertebrates.

(KEY TERMS: riparian ecology; rivers/streams; restoration; forests; fish; fluvial processes; forest management; forest structure; large wood.)

Pollock, Michael M. and Timothy J. Beechie, 2014. Does Riparian Forest Restoration Thinning Enhance Biodiversity? The Ecological Importance of Large Wood. *Journal of the American Water Resources Association* (JAWRA) 50(3): 543-559. DOI: 10.1111/jawr.12206

INTRODUCTION

Throughout much of the world, old, complex, and biologically diverse forested riparian ecosystems have been cleared and replaced by young, structurally simple forests (Naiman *et al.*, 1993; Sala, 2000; Stromberg *et al.*, 2004). In the Pacific coastal states of North America, extensive degradation of riparian forests has led to the decline of numerous aquatic and terrestrial species that depend upon them, a number of which are now listed under the United States (U.S.) Endangered Species Act (ESA) (Nehlsen *et al.*, 1991; USDA and USDI, 1994). In such forests, much of the decline in biodiversity is due to the loss of four major structural features; large live trees, large snags, large down wood on the forest floor, and large down wood in streams (Bauhus *et al.*, 2010; Bunnell and Houde, 2010; Marcot *et al.*, 2010). Notable among the ESA-listed species that utilize riparian ecosys-

tems are several salmonids of the genera *Oncorhynchus* and *Salvelinus*, which rely on habitat created by large wood falling into streams; northern spotted owls *Strix occidentalis*, which depend on large live and deadwood for nest sites and habitat for their prey; and marbled murrelets *Brachyramphus marmoratus*, which require large live trees for nesting (USDA and USDI, 1994).

Large living trees and deadwood provide important habitat for a range of other species. Diverse epiphytic communities are found in the crowns of large live trees (Muir *et al.*, 2006), while large snags and down wood provide nesting, roosting, denning, and foraging habitat for numerous birds and mammals (Bunnell *et al.*, 1999; Bunnell and Houde, 2010; Marcot *et al.*, 2010). For numerous aquatic organisms, large wood that falls into streams is essential for the maintenance of habitat because it forms pools, traps, and sorts gravels, increases hyporheic exchange, modulates stream temperature, and provides cover and increased habitat complexity (Beechie and Sibley, 1997; Moore *et al.*, 2005). Large wood that falls to the forest floor provides thermal and moisture refugia for amphibians, habitat for small mammals, and establishment sites for numerous plant species (Harmon and Franklin, 1989; Carey *et al.*, 1999; Kluber *et al.*, 2009). Standing and down wood in various stages of decay creates habitat heterogeneity that supports a complex and diverse fungal community (Norden *et al.*, 2004; Berglund *et al.*, 2005). Large wood ultimately decomposes and helps to provide a humic-rich forest floor with high moisture holding capacity and a biologically complex and diverse soil taxa (Harmon *et al.*, 1986; Coleman and Whitman, 2005). Much of the riparian forest structure needed to maintain biologically diverse aquatic and terrestrial communities is provided by large standing and fallen deadwood.

Rapid biodiversity declines in forested ecosystems have led to experimental efforts to accelerate the development of complex forest ecosystem structure, and in particular to more rapidly create large live and deadwood from young forests (Davis *et al.*, 2006; Puettmann *et al.*, 2009; Bauhus *et al.*, 2010). In the U.S. Pacific Northwest and elsewhere, riparian forest reserves have been established for the primary purpose of recovering species with declining populations (USDA and USDI, 1994). However, many riparian forest reserves are degraded from past land use activities and are now dominated by young, simplified forests. There is an emerging debate as to what types of active and passive management are the best approaches for restoring the structural complexity needed to maintain both terrestrial and aquatic biodiversity as these young forests mature (Beechie *et al.*, 2000; Puettmann *et al.*, 2009; Bauhus *et al.*, 2010; Marcot *et al.*, 2010).

To help resolve this debate, in this article we review and summarize available quantitative data describing the different sizes of large live trees and deadwood that are used by vertebrate species, to better understand which species are likely to benefit from restoration thinning. We then use a forest growth model, Forest Vegetation Simulator (FVS), to simulate how four common restoration thinning intensities (high, medium, low, and no thin) are likely to affect the long-term production of large live trees and large deadwood. We focus our analysis on the sizes of wood important to aquatic and terrestrial vertebrate species found in the Pacific Northwest that are known to use riparian forests, with an emphasis on the structural attributes required by species in population decline.

THE STRUCTURAL HABITAT REQUIREMENTS OF SPECIES THAT UTILIZE RIPARIAN FORESTS

From the perspective of enhancing and maintaining biological diversity in riparian forests, it is helpful to understand the specific structural attributes a given species needs. There has been some effort to understand the specific habitat needs of vertebrate species, while the needs of specific plants, fungi, and invertebrate fauna are not as well known, although data are accumulating (Bunnell *et al.*, 2008; Bunnell and Houde, 2010). However, to date, there has been no synthesis that summarizes how different species utilize specific sizes and types of large wood in riparian forests. To this end, we provide a review of the specific structural components of forests that have been directly linked to usage by vertebrate species. Initially, we used Web of Knowledge, Google, and Google Scholar to search for studies published in peer-review journals examining quantifiable forest structural attributes that are correlated with usage by Pacific Northwest forest vertebrate species. In reviewing the literature, we found that researchers consistently identified one or more of four measurable forest structural attributes that could be related to the habitat requirements of specific species: (1) large down wood in streams, (2) large down wood on the forest floor, (3) large standing snags, and (4) large living trees, often with large limbs and structural irregularities such as cavities and irregular, broken branches, and broken tops. A fifth structural attribute often identified as important for certain species was canopy gaps (e.g., Spies, 1989). However, this attribute was frequently discussed conceptually, and limited quantitative information was available as to the specific size, frequency, and general nature of

canopy gaps that were needed by specific species. Therefore, we limited our review of this attribute to a generalized qualitative discussion, and focused our review effort on identifying studies examining relationships between specific species and the four quantifiable structural attributes of riparian forests previously identified. Many of the studies we examined established relationships between specific forest structural elements and vertebrate species abundance that were not limited to riparian forests, particularly for terrestrial vertebrates, but all of the species we discuss in this review utilize riparian forests.

Table 1 summarizes specific sizes of instream wood, forest floor wood, snags, and live trees associated with certain vertebrate species that we were able to identify in the scientific literature. Each of these attributes and the species associated with them are discussed below.

Trees That Fall into Streams

Salmonids and other aquatic species benefit from the presence of large diameter riparian trees that have fallen into streams. The loss wood inputs from riparian forests is thought to be a major factor in the degradation of freshwater habitat (Gregory *et al.*, 2003; Cluer and Thorne, 2014). Large wood ranging from 15 to 200 cm in diameter and over 2 m in length has been found to structure stream habitat in ways that are beneficial, primarily by forming wood jams, reducing sediment transport, and creating pools (Table 1; Bilby, 1981; Montgomery *et al.*, 1996; Beechie and Sibley, 1997; Fox and Bolton, 2007).

Complex wood jams, that is, the accumulations of many pieces of large wood in streams and rivers, are particularly important because they fundamentally alter transport rates of both sediment and water and in doing so, create complex instream and floodplain habitat (see overview in Cluer and Thorne, 2014). By slowing the flow of water and sediment, complex wood jams help to push water onto floodplains, increasing the dynamic nature of riparian ecosystems and in doing so creating multithreaded channels, mid-channel islands, off-channel habitat, and wetlands which fundamentally enhance riparian species richness by creating a diversity of habitats (Naiman *et al.*, 1993; Walter and Merritts, 2008; Cluer and Thorne, 2014). Thus, arguably, the most important role of riparian forests in terms of enhancing biological diversity is to produce wood of a size distribution and abundance sufficient for large, complex wood jams to form.

Complex wood jams are composed of wood across a wide range of sizes (length and diameter) that is generally commensurate with the size of riparian trees available to fall into streams. Wood jams are composed of a framework of large structural pieces that then serve to trap smaller pieces, which fill in the interstices such that sediment accumulates behind jams and flow is routed around them. However, all wood jams initially require at least one piece which is large enough to be stable during high flows and which forms the initial frame against which other pieces can accumulate (Bilby and Ward, 1989; Fox and Bolton, 2007). The size of such a "key" piece varies with stream characteristics. The size (volume) of the key piece of large wood needed to form stable jams is proportional to the bankfull width for low gradient streams, and wood volume ranges from 1 to 11 m^3 for streams up to 100-m wide or measured by diameter or length ranges from 40 to 70 cm or 8 to 24 m, respectively, for streams up to 20-m wide (WFPB, 1995; Fox and Bolton, 2007) but in high gradient headwater streams, at least one piece of large diameter wood (60-200 cm) is needed to form stable wood jams even if the streams are small (Montgomery *et al.*, 1996). Thus, restoration of riparian forests for the purposes of providing wood to streams such that complex jams can form requires consideration of both the size and abundance of large trees.

Individual riparian trees that fall into streams can also provide important habitat for aquatic organisms, primarily by creating cover and helping to form pools. Similar to key pieces, the minimum size of large wood needed to independently form pools can be predicted from the width of the stream, and ranges from 15 to 75 cm diameter for streams ranging in width from 4 to 23 m (Table 1; Beechie and Sibley, 1997).

Standing Snags and Trees That Fall to the Forest Floor

Numerous terrestrial vertebrates that utilize riparian forests are associated with large trees that have fallen completely or partially to the forest floor (a portion of the tree may have also fallen into a stream or remain standing as a snag). The size of tree utilized by such species ranges from 13 cm to >200 cm diameter, with the average diameter of deadwood used ranging from 53 to 123 cm, depending on the species (Table 1). A number of forest vertebrates are also positively associated with the percent cover of all deadwood on the forest floor, often defined as logs >10 cm or >30 cm diameter (Marcot *et al.*, 2010). Large diameter snags or down wood are used in a number of ways that vary by species (Table 1). Such uses include nesting, denning, resting, foraging, and roosting. For example, the widely distributed wood duck *Aix sponsa* requires large riparian snags with cavities for nesting and the loss of such structures is thought to have resulted in population declines (Soulliere, 1988). Several small

TABLE 1. Examples of Species of Pacific Coastal Forests Use of Large Diameter Deadwood and Live Trees in Aquatic and Terrestrial Habitats, with an Emphasis on ESA-Listed Species (salmonids, the northern spotted owl [and its prey base], and the marbled murrelet). mammals, such as the northern flying squirrel *Glaucomys sabrinus* form the prey base for avian predators with declining populations such as the spotted owl and are among the species utilizing riparian forests that are associated with abundant large dead standing and down wood. This presumably is why such avian predators prefer to forage in stands with abundant standing and fallen deadwood (Table 1; North *et al.*, 1999). The fruiting bodies of hypogeous fungi are a food source of northern flying squirrels and are also associated with down logs, suggesting that there are complex, indirect paths through which trees that fall to the forest floor support biologically diverse ecosystems (Amaranthus *et al.*, 1994; Carey, 2000).

Although species associations with specific sizes of large deadwood are known (Table 1), mechanistically speaking, the reasons why a particular species is associated with a particular size class of deadwood are not always well understood (cf. Bunnell *et al.*, 1999). Potential functions provided by large dead terrestrial wood that would not occur in smaller deadwood includes temperature (hot and cold) and humidity refugia which are particularly important to riparian-dependent taxa such as amphibians (Ruggiero *et al.*, 1998; Kluber *et al.*, 2009), large internal cavity volumes for nests and dens (Bull *et al.*, 2000; Zielinski *et al.*, 2004), cavities between the bark and bole (Bunnell *et al.*, 2002), and sustained structural integrity, particularly during advanced stages of decay (Mannan *et al.*, 1980). For some species, the size of the deadwood may not matter so much as the mechanism by which the tree died and what happened to the tree while it was alive. As an example, the slow death of a tree by heart rot creates a large cavity that is useful as a denning site for several species (e.g., black bear *Ursus americanus*, fisher *Martes pennanti*, and marten *M. americana*), suggesting that variation in the mechanisms of tree death is another consideration for the maintenance of biodiversity (Bunnell and Houde, 2010).

A number of vertebrates utilize snags and down wood >100 cm diameter, suggesting that similar to species found in aquatic environments, terrestrial species will also benefit from wood of this very large size (Table 1). However, many of these species will also utilize deadwood 50-100 cm diameter and some will utilize deadwood as small as 10 cm diameter (Marcot *et al.*, 2010).

Large Live Trees

Large live riparian trees are utilized by numerous raptors, including the bald eagle *Haliaeetus leucocephalus*, osprey *Pandion haliaetus*, and the northern spotted owl for nesting and roosting, by pileated woodpeckers *Dryocopus pileatus* for foraging and nesting, and by marbled murrelets for nesting (Table 1). The marbled murrelet and spotted owl are both ESA listed. These two species prefer to build nests on the limbs or the broken tops of very large diameter live trees (Forsman *et al.*, 1984; Huff *et al.*, 2006). Marble murrelets nest in forests that are dominated by large diameter (>50 cm) live trees, and the diameter of individual trees used as nesting sites averages from 49 cm to >500 cm along the west coast from northern California to Alaska, generally decreasing in size with increasing latitude (Table 1).

Spotted owls also build nests in large diameter live trees, either on the platforms of irregular branches such as those misshapen by mistletoe infections, or in cavities atop the boles of trees with broken tops. Platform nests are found in live trees averaging 106 cm diameter and ranging from 36 to 179 cm diameter, while cavity nests are found in live trees averaging 135 cm diameter and ranging from 74 to 205 cm diameter (Table 1; Forsman *et al.*, 1984). Spotted owls also roost in live trees ranging from 15 to 115 cm diameter, depending on location (Forsman *et al.*, 1984).

Canopy Gaps

Canopy gaps have been identified as a structural attribute important to the maintenance of biodiversity primarily because gaps allow more light to reach the forest floor and this can improve the growth of understory vegetation and increase floristic diversity (Halpern and Spies, 1995; Van Pelt and Franklin, 1999). Trees adjacent to canopy gaps also extend their branches into gaps, resulting in larger diameter branches which should create more sites for the establishment of epiphytes and may benefit species such as the marbled murrelet, which nest on "platforms" created by epiphytes growing on large diameter or irregular branches (Hamer and Nelson, 1995; Naslund *et al.*, 1995). Gap creation in Douglas-fir forests also results in short-term increases in the abundance of some songbirds, but causes declines in others (Hagar, 2009).

The character of canopy gaps is complex and metrics for quantifying the value of different types or sizes of gaps have not been well developed. Although active management may create canopy gaps, it is also noteworthy that canopy gaps naturally develop as trees die and fall and knock down neighboring trees, and that the character of natural gaps may differ from artificial gaps, depending in part on whether tree boles are removed during active management (Van Pelt and Franklin, 1999). If a tree dies naturally and falls over to create a gap, it also creates topographical and substrate heterogeneity (e.g., pit and mound topography) that can help increase floristic diversity (Beatty, 1984; Pollock *et al.*, 1998). When trees die and fall, they also may break tops and branches and scrape the boles of

adjacent trees. This can create irregularly shaped branches and apical and lateral cavities, all of which are habitat features used by a variety of species and are a useful index of biodiversity (Michel and Winter, 2009). Additional research is needed to assess the role of variation in the cause of tree death and tree fall in the creation of canopy gaps essential to the maintenance of biodiversity.

EVALUATION OF FOREST THINNING AS A RESTORATION PRACTICE

In the Pacific Northwest, a commonly applied riparian restoration technique is to thin young forests to help promote the development of complex forest structure. The rationale for such thinning is that it should increase the growth rates of the remaining trees and thus more rapidly develop a forest of large diameter trees (Davis *et al.*, 2006). Thinning young forests may also help to create canopy gaps, another structural attribute of older forests that is often missing in dense young stands (Spies, 1989). If such restoration approaches can accelerate the development of complex riparian forest structure, then the restoration of biologically diverse aquatic and terrestrial communities could also be accelerated (Puettmann *et al.*, 2009; Bauhus *et al.*, 2010).

To demonstrate how the potential effects of such restorative treatments on forest structure could be assessed, we used a forest growth model FVS to examine how the size and abundance of large live and dead trees might be affected over the long term in response to various restoration treatments intended to improve the condition of young, degraded conifer stands typical of Pacific Northwest riparian forests. We projected how these stands would respond to three different levels of active restorative thinning treatments and compared them to a passive, no thin treatment. Details of the forest growth model calibration and parameterization, and initial stand conditions have been previously described by Pollock *et al.* (2012) and are detailed below.

PARAMETERIZATION AND CALIBRATION OF THE FOREST GROWTH MODEL, FOREST VEGETATION SIMULATOR

Site Description of Stands Used in the Simulation

For our analysis, we simulated the growth of planted stands of 30- to 40-year-old Douglas-fir forests in the Coast Range of western Oregon. The geology of the Coast Range consists primarily of marine sandstone and shale, with localized basalt intrusions. The terrain is mountainous and highly dissected. Elevations range from sea level to 1,250 m. The climate is temperate maritime with warm dry summers, and mild wet winters. Most of the peak flows occur in late fall or winter and low flows occur in late summer. The watershed is heavily forested in conifers, with Douglas-fir *Pseudotsuga menziesii* the most abundant species. In these forests, the main successional pathway is characterized by Douglas-fir colonization after fire, Douglas-fir dominance during the first 200-300 years, and then slow succession to a "climax" forest dominated by the shade-tolerant (but fire intolerant) western red cedar *Thuja plicata*, western hemlock *Tsuga heterophylla*, and Sitka spruce *Picea sitchensis* (Munger, 1940). However, because the historic fire return interval in these forests averaged between 180 and 230 years (Long and Whitlock, 2002), many of these stands were continually dominated by Douglas-fir, since stands were often reset by fire prior to succeeding to western hemlock and western red cedar dominance.

Model Parameterization and Calibration

To project long-term changes in stand structure, we used the model FVS and the post-processor Fires and Fuel Extension (FFE) (USFS, 2010c). FVS is a distance-independent, individual tree forest growth model developed by the U.S. Forest Service that has been used to project forest stand development in the Pacific Northwest and most other forested regions of the U.S. (Bragg, 2000; Wilhere, 2001; Crookston and Dixon, 2005). Extensive information concerning FVS, including its development, its use, software downloads, reference documents, and related publications can be found at www.fs.fed.us/fmsc/fvs/. Other forest growth models have been developed to simulate the development of Pacific Northwest forests (e.g., Zelig and Organon), but these have significant shortcomings (Pabst *et al.*, 2008; Hann *et al.*, 2009). Zelig is not publically available, lacks institutional support, and has a complex user interface such that a very small number of scientists understand how to use it. Relative to Zelig, Organon is more widely used, but its growth and mortality parameters are not easily adjusted to calibrate the model to real stand data. On the other hand, most of the growth and mortality parameters in FVS can be adjusted, and this enabled us to calibrate the model against real stand data, as we describe below.

The key parameters affecting the FVS model behavior are tree growth rates and mortality rates.

TABLE 2. Long-Term Annual Mortality Rates for *Pseudotsuga menziesii* in Young, Mature, and Old *P. menziesii*-Dominated Stands in the Pacific Northwest.

Note: TPH, trees per hectare; WNF, Willamette National Forest; RNA, Research Natural Area; nw, northwest; sw, southwest.

We used a maximum stand density index of 1,250, which is typical for the area, to project competition mortality rates in young stands. We set a minimum background mortality rate of 0.7% for all stands, a somewhat conservative estimate relative to Douglas-fir mortality rates in older stands or thinned stands (Table 2, Munger, 1946; Bible, 2001). Maximum tree height was set at 76 m because that is the typical site potential tree height in the study area.

To ensure that simulated changes in diameter, stand density, and height were consistent with local conditions, the model was calibrated against 66 Douglas-fir dominated reference stands from the area ranging from 23 to 139 years in age.

We also wanted to assess the effects of the different treatments on potential understory tree growth, since understory growth over the course of 200 years may produce some large diameter live and dead trees. To ensure opportunities for understory tree growth, we simulated the planting of seedlings of the shade-tolerant species, western red cedar, western hemlock, and Sitka spruce, at densities of 60 trees/ha every 10 years. We anticipated that most of these would not survive, particularly in the young stands, because of a dense overstory canopy, but that some would begin to survive as the overstory trees began to die and the canopy opened up, consistent with typical successional processes. However, we also expected that the heavier thinning treatments would reduce the overstory canopy sufficient to allow growth of the shade-tolerant species in the understory at a relatively young age, consistent with empirical studies (Comfort *et al.*, 2010).

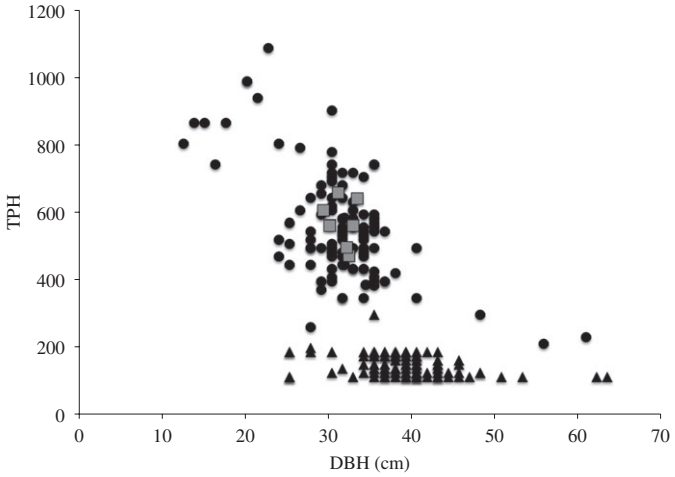

FIGURE 1. Graph Showing Empirical Pre-Treatment Data (black circles) and Proposed (by the USFS, 2010b) Post-Treatment (black triangles) Stand Densities and Average Tree Diameter for the 130 Stands from Which We Modeled Seven for the Purposes of Estimating Long-Term Changes in Large Live Tree and Large Deadwood Production. Gray squares represent the seven stands modeled, and are generally representative of average condition of the larger group of stands, but do not encompass the full range of stand densities.

Initial Stand Conditions

The United States Forest Service (USFS) provided detailed data on seven 30- to 40-year-old Douglas-fir dominated stands in the Siuslaw River basin from a group of 130 stands that will be thinned for the purposes of restoring forest functions (Figure 1). Most of the stands to be thinned originated 30-50 years ago, when Douglas-fir was planted following clear-cut harvest of the original forest. The average stand age proposed for restorative thinning (n = 130) is 35 years (SD = 9.0) and ranges from 14 to 64 years. Stand densities currently average 558 trees/ha (range = 210-1087 trees/ha) and post-treatment will average 147 trees/ha (range = 111-296 trees/ha). The proposed treatment is typical of USFS and Bureau of

Land Management plans to restore biologically diverse forests on riparian reserve lands (e.g., USFS, 2010a; BLM, 2011).

Comparison of our calibrated model outputs with the reference stands showed that our projected changes in diameter, height, and stand density all followed patterns generally consistent with the reference stands, suggesting that the model was appropriately calibrated (Figure 2). The projected changes in average tree height trended toward the higher end of what was observed in the reference stands (Figure 2c) which we attribute to the fact that tree tops in the natural world are often damaged from wind, disease or insects, something that the FVS model does not take into account.

We also compared the thinning treatments with the individual trees in the reference stands used to calibrate the model to verify that all of the treatments produced age-diameter and age-height relationships within the range of natural variation (Figure 3). We found that many trees in the natural environment were growing more rapidly than the trees even in our heaviest thin (Figure 3). This was surprising because the heaviest thin was intended to maximize live tree growth by eliminating any potential for competition.

Caveats

We simulated the growth of stands in the absence of major disturbances. In reality, many stands experience pulses of mortality caused by disturbances such as wind, insect outbreaks, pathogens, and fire. Thus, our mortality estimates are likely lower than what many stands will actually experience. This suggests that recognition of the potential for natural disturbance is important when considering application of restorative treatments. Heavy thins in particular, followed by a disturbance could result in a loss of most of the overstory and delay the creation of a forest with desirable structural attributes (e.g., see Mitchell and Rodney, 2001; Ruel *et al.*, 2001).

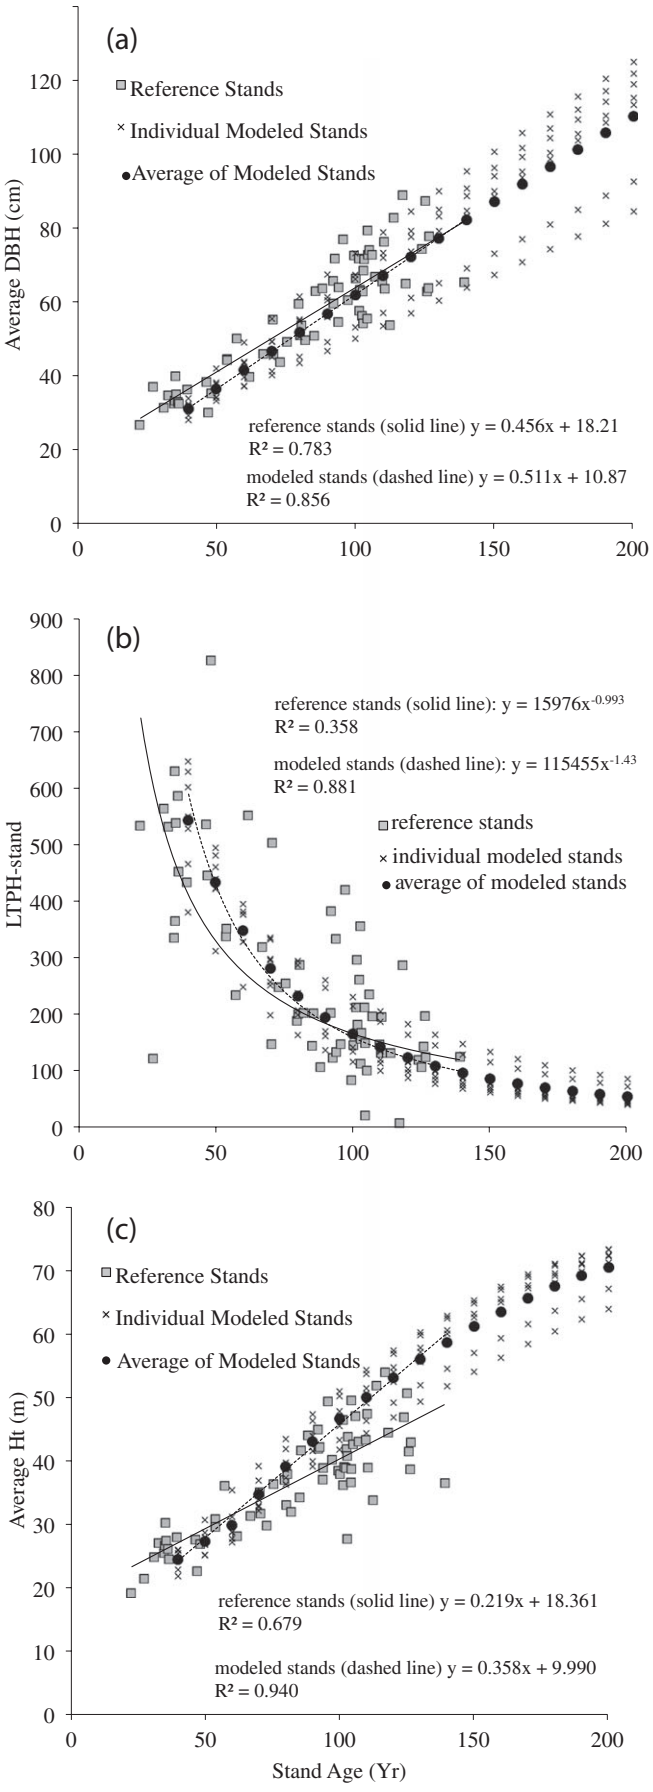

FIGURE 2. Graph Showing Comparison of Forest Vegetation Simulator Model Growth Projection of the Seven Modeled Stands (a) Diameter, (b) Stand Density, and (c) Height, Relative to the Static State of 66 Reference Stands 23-139 Years of Age (see Pollock *et al.*, 2012). The static reference stands are represented by gray diamonds, the crosses represent the modeled trajectory of the seven individual stands described in Figure 1, and the black circles represent the median trajectory of the seven modeled stands. Regression lines help to assess the extent to which the range of modeled stands is representative of the empirically observed range of natural conditions.

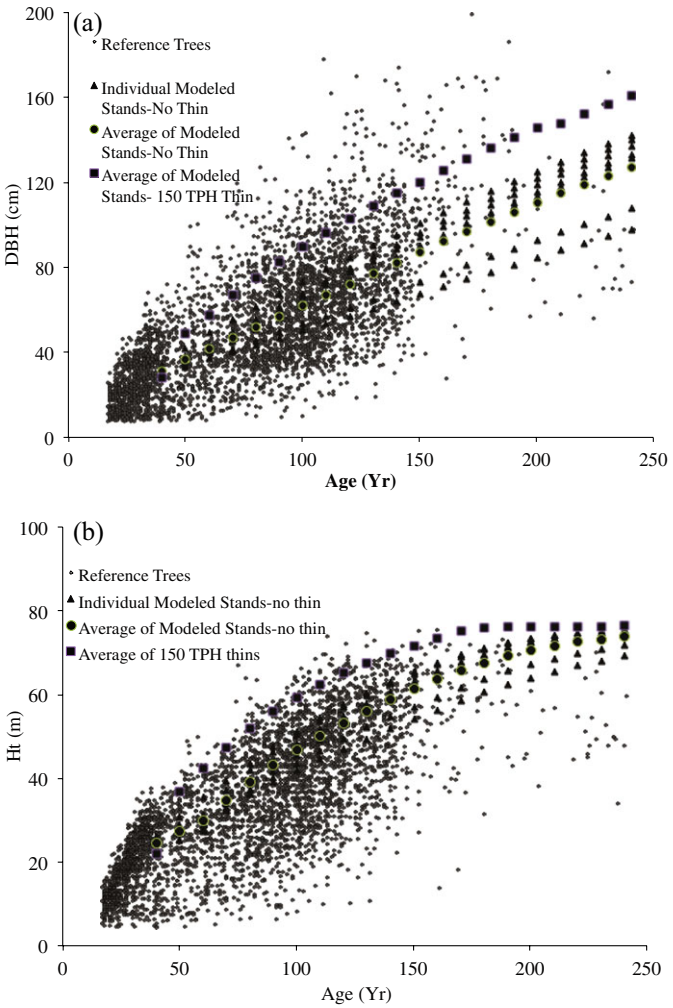

FIGURE 3. Graph Showing the Comparison of the Projected Average Diameter (a) and Height (b) Changes over Time of the Four Simulated Treatments with the Height and Diameter of 3,946 Live Trees in the Area, Ranging in Age from 17 to 250 Years. Tree data were obtained from the USFS Forest Inventory and Analysis database and were limited to productive (site index >120) Douglas-fir-dominated stands that were growing within the coastal region of northwest Oregon. These data help to verify that simulated tree growth in the model was parameterized consistent with growth rates for real live trees.

We found that model projections from the thinning treatments created tree sizes and densities within the natural range of variation. For individual trees, we found that growth rates in the heavy thinning treatment trended toward the upper end of growth rates observed in real stands. This is expected, since the heavy thinning treatments were intended to maximize growth rates of the remaining trees. While such data are reassuring that the model is making reasonable predictions, we note that natural analogues for a stand that has 75% of its overstory removed around age 40 (as was the case for our heaviest thinning treatment) are rare, and forest growth models are not necessarily calibrated for stands that have developed along such a trajectory.

In addition, stochastic events can change stand developmental trajectories and the input data used to parameterize the initial stand conditions do not contain the variation in tree density inherent in any natural stand. As such, using forest growth models (or any models for that matter) in a relative (rather than absolute) context is useful to compare the results of different treatments under controlled conditions where the effects of changing a limited number of variables can be assessed. While forest growth models are no substitute for empirical data, they are currently still the only tool available for predicting the long-term effects of thinning and as such represent our collective best estimate as to how stands will respond to different management scenarios.

Simulated Restoration Treatments

We projected changes in the average mortality, size, and abundance of large diameter live trees, snags, and down wood of seven 30- to 40-year-old stands that averaged about 600 trees/ha, under three restorative treatments; thinning to 400, 250, and 150 trees/ha (light, moderate, and heavy thins). We then compared these to a projection of the stands if left untreated (no thin). Because the restoration thinning is intended to accelerate the development of large diameter trees, all the thinning scenarios removed the smaller diameter trees until the target density was reached, such that the largest trees remained. We assumed that all thinned trees were removed from the site and did not include them in mortality counts. Every 10 years in the simulation, we categorized the live and dead trees by diameter classes; 30-50 cm, 50-100 cm, and >100-cm-diameter breast height. We used these categories because they were representative of size class categorization used to assess live and dead tree habitat value for a variety of taxa (see Table 1).

RESULTS

Deadwood Production

Tree mortality is the number of trees dying in any given decade, and represents the combined production rate of snags and down wood. The thinning treatments minimally affected the timing of the peak in mortality, but substantially affected the magnitude (Figure 4). The peak in mortality rates for trees

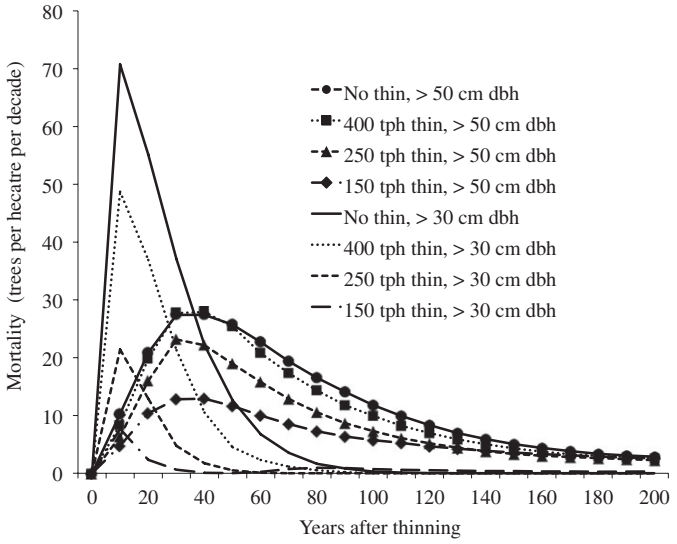

FIGURE 4. Graph Showing Projected Average Mortality Rates (number of trees dying per decade) of Trees >30 cm Diameter and Trees >50 cm Diameter, for each of the Four Simulated Treatments. The 10-year mortality rate of trees >100 cm diameter is low for all treatments throughout the length of the simulation and is not shown in the figure.

>30 cm diameter occurred about 10 years post-treatment and ranged from 8 to 71 trees/ha/decade, with the rate inversely proportional to the intensity of the thin. The peak mortality rate for trees >50 cm occurred about 30 years post-treatment and ranged from 13 to 28 trees/ha/decade, again with the rate inversely proportional to the intensity of the thin. Mortality rates for trees >100 cm were extremely low throughout the simulation (not shown on Figure 4).

The cumulative dead tree production varied considerably among each of the thinning treatments for the >30 cm and >50 cm size classes, while difference in cumulative mortality of trees >100 cm was minimal (Figures 5a and 5b). Over the course of the simulation, the most intensively thinned stands produced a third as many mortality trees >30 cm (145 *vs*. 461) and half as many mortality trees >50 cm (127 *vs*. 250) relative to the unthinned stands (Figures 5a and 5b). In contrast, the heaviest thin produced slightly more mortality trees >100 cm, a cumulative average production of 42 mortality trees >100 cm for the heaviest thin, relative to 37 mortality trees >100 cm for the unthinned stands (Figure 5a).

Relative to the no thin scenario, thinning reduced the mortality peak of boles in the 30-50 cm and 50-100 cm size classes that occurred 10-60 years post-treatment in the passively managed stands, with the reduction in mortality proportional to the intensity of the thin (Figure 4).

In summary, thinning minimally increased the production of large diameter deadwood >100 cm, while causing substantial losses in deadwood 30-

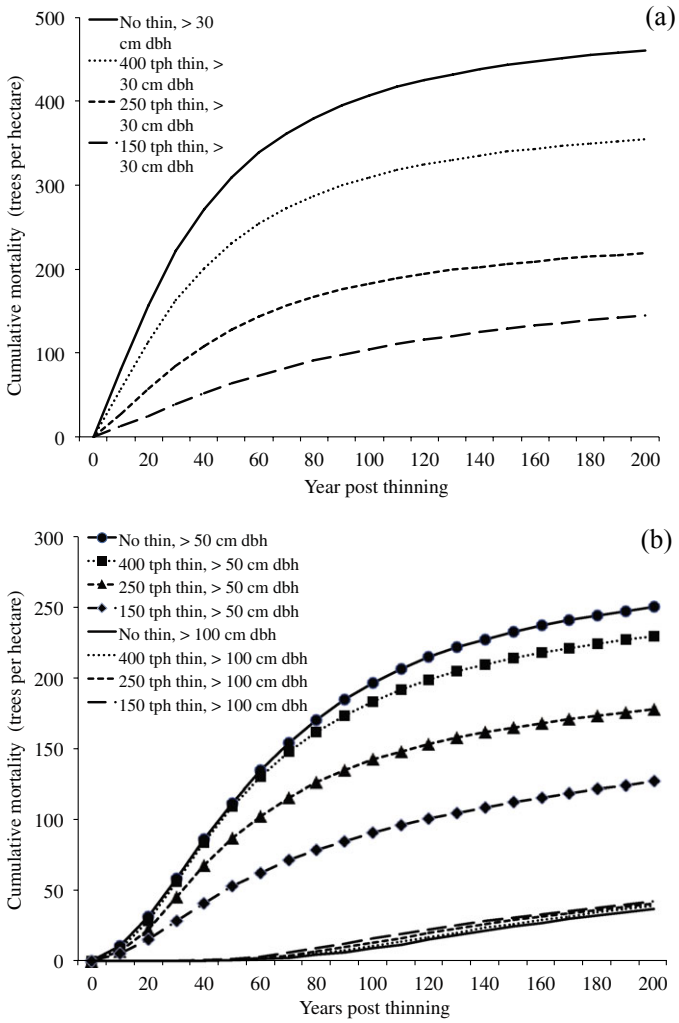

FIGURE 5. Graph Showing Cumulative Mortality over Time for Each of the Four Simulated Treatments. Cumulative mortality provides an index of the total production of deadwood over the course of the simulation and is useful to compare relative production rates of the different treatments for different size classes of wood. Cumulative production of dead trees >150 cm was close to zero for all treatments and is not shown in the figure.

50 cm and 50-100 cm diameter, with no acceleration in the production of these size classes (Figure 5). This suggests that the thinning regimes we examined are not an effective approach for increasing the abundance of ecologically functional deadwood. The no thin scenario produced substantially more deadwood across a wide range of sizes useful to a variety of vertebrate species (Table 1).

Live Trees

Relative to the no thin alternative, thinning initially accelerated the development of large diameter, live trees >100 cm (Figure 6). For example, 100 years post-treatment, the heavily thinned stand contained

34 trees/ha > 100 cm, *vs.* 18 trees/ha for the no thin treatment. However, from 100 to 200 years post-treatment, the number of >100 cm live trees begins to decline in the heavy thinning treatment, such that by year 200, it had the fewest trees >100 cm of all the treatments. Live trees >150 cm begin to show up in the stands 140-160 years post-treatment, but the densities of this size class are very low (9-11 trees/ha) in all the treatments 200 years post-treatment. Heavy thinning caused a 10-year acceleration in the development of live tree densities >50 cm relative to the unthinned stands (Figure 6). However, the higher initial tree densities in the unthinned stand ultimately enabled it to produce more live trees >50 cm than the thinned stands, beginning 30-60 years post-treatment. For trees >30 cm, density generally declined as the intensity of the thinning increased, and this trend was maintained throughout the treatment. The exception was that in the heavy thinning treatment, the growth of understory trees began to produce additional trees in this size class beginning around year 100 (Figure 7a). By year 200, the heavily thinned stand had a broad distribution of tree sizes from 20 to 160 cm, whereas the growth of understory trees in the other treatments was minimal and trees <60 cm diameter were generally absent (Figure 7b).

DISCUSSION

Consideration of the structural attributes that different species utilize and the effect that different restoration treatments have on the abundance of these structural attributes suggests that passive management may often be the treatment that will best enhance biological diversity in degraded riparian forests, but that in some cases thinning may be beneficial. We identified four quantifiable structural attributes of forested riparian ecosystems that are frequently associated with specific habitat needs of vertebrates. Of these structural attributes, three of them (trees that fall into streams, trees that fall onto forest floors and standing snags) are composed of large deadwood, and most species we examined utilize one or more of these structure types. This suggests that the key driver creating biologically diverse forested riparian ecosystems is a steady supply of large deadwood.

We provided examples, using a forest growth model, as to how different restoration efforts might affect the supply of large deadwood and large live

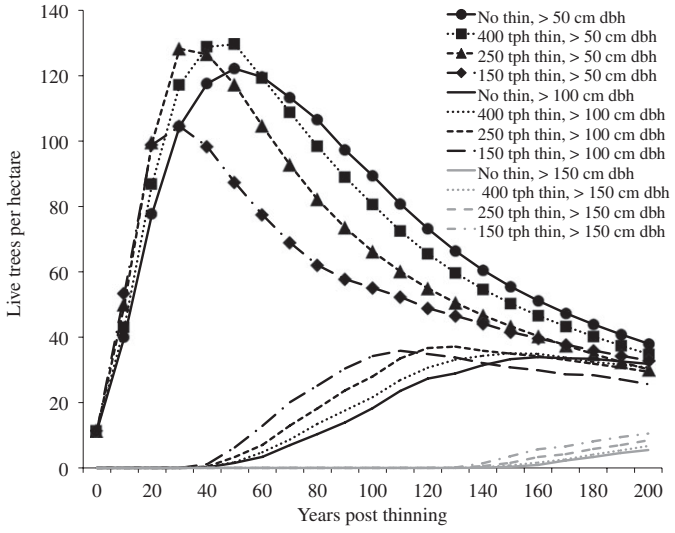

FIGURE 6. Graph Showing the Changes in the Abundance of Large Diameter Live Trees over Time for Each of the Four Simulated Treatments. Relative to deadwood production, the beneficial effect of thinning is more apparent when comparing live trees.

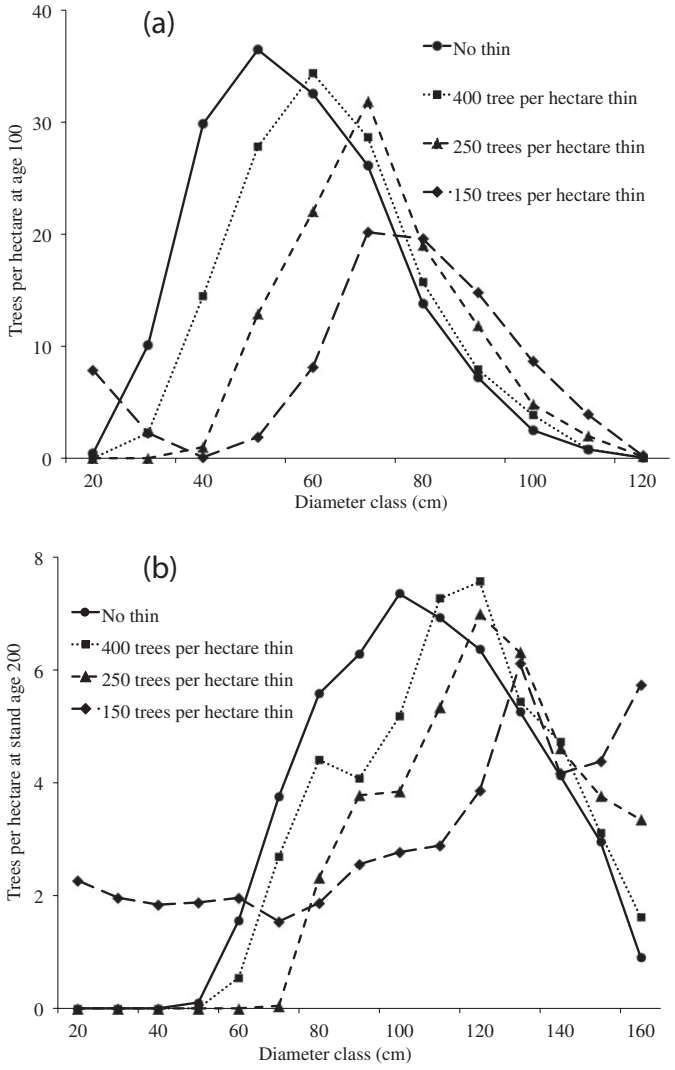

FIGURE 7. Graph Showing the Size Distribution of Live Trees at Age 100 and Age 200 for Each of the Four Simulated Treatments.

trees. Our results suggest that there are tradeoffs associated with both passive and active management, and that different treatments will result in substantial differences in forest structure that will persist over the long term. For the forest stands we examined, as thinning levels increase, forest development predictably trends toward a more open stand with a low number of overstory trees that attain very large sizes, an understory that develops more rapidly, and substantially reduced large diameter deadwood production (Figures 5-7). In contrast, unthinned stands produce abundant large diameter deadwood, but the growth rate of overstory trees and understory development is reduced.

Since different species have a variety of needs in terms of the size and abundance of large live trees and large deadwood (Table 1), we suggest that from a restoration perspective, there is no one "ideal" management regime, but that a range of passive and active management options should be considered for the purposes of creating biologically diverse riparian ecosystems, commensurate with the structural attributes needed by the species of concern. However, we note that for the scenarios examined, more large deadwood that is useful to vertebrates (Table 1) was produced across all size classes when the stands were left unthinned. This suggests that restoration thinning should generally be limited to situations where large deadwood is already abundant, or where the needs of the few species that need very large (>100 cm diameter) live trees outweighs the needs of the many species that utilize large deadwood.

In particular, for providing deadwood to streams, this suggests that for the purposes of facilitating the formation of complex wood jams to benefit the myriad species that utilize the diversity of habitat formed by such jams (e.g., salmonids), a passive management approach that allows for large deadwood production across a range of sizes may be most appropriate.

In contrast, the largest live trees were produced from the heaviest thinning treatment, but this treatment produced the least amount of large deadwood. Thus, such a treatment would be expected to benefit species that utilize very large live riparian trees, but not large deadwood (e.g., marbled murrelets). Examination of Table 1 suggests that deadwood >30 cm diameter creates habitat that is used by many species, but that deadwood >50 cm provides even more habitat benefits, and that maximizing the production of deadwood >50 cm diameter may be a suitable management target if the goal is to benefit the most vertebrates. There were far fewer species that preferred live trees or deadwood >100 cm, but larger diameter dead trees will take longer to decompose, extending the length of time that habitat benefits are provided.

From a restoration perspective, it may also be desirable to directly introduce wood to streams and riparian areas to ensure that there is adequate deadwood in the short term. Even unthinned riparian forests will provide deadwood to forests and streams at a relatively slow rate, and restoration of riparian and instream wood loads to levels that create complex habitat may take decades without active wood placement. Direct placement could also compensate for the loss of instream and riparian wood delivery that will occur if riparian stands are actively thinned.

While our results suggest that passive management will often lead to the most rapid development of large diameter trees and deadwood used by a wide range of species, this interpretation may be limited to the range of stand densities, ages, and forest types that we examined in our study (see Figure 1). Many degraded riparian forests throughout the Pacific Northwest and elsewhere contain stands with smaller and more densely crowded trees that may be dominated by species other than Douglas-fir. The purpose of this study was to assess what structural attributes are used by different species that utilize riparian forests and to provide a simple example of how different management approaches will emphasize the development of different structural attributes important to the maintenance of biological diversity. Future research should examine stands across a wider range of ages, densities, and forest types to develop a more comprehensive understanding as to the conditions where active management can help to restore species-rich riparian forest ecosystems.

Finally, while specific structural attributes of forest ecosystems have been correlated with certain species, it is uncertain how such species will respond to treatments designed to recreate these features. There is always the possibility that in our attempt to create a structural attribute we think is important, we eliminate another attribute that is equally important, but unrecognized. One example is that attempts to restore spotted owl habitat by heavily thinning to accelerate the development of large diameter nesting trees could actually delay spotted owl recovery by reducing production of the large down wood utilized by the species it preys upon (Forsman *et al.*, 1984; Carey, 1995; North *et al.*, 1999). Similarly, heavily thinning stands to accelerate the development of marbled murrelet nesting trees also create open stands with a dense understory that is ideal habitat for a number of corvid species that prey on marbled murrelet nest eggs (USFWS, 2010). Riparian thinning efforts to create long-term supplies of very large diameter instream wood that can initiate complex wood jam formation (e.g., key pieces) are also likely to reduce the supply of large diameter wood that will create pools (Beechie and Sibley, 1997; Beechie *et al.*,

2000; Fox and Bolton, 2007). Thus, we suggest that any efforts to actively restore riparian forests for the benefit of certain species should be treated as scientific experiments and proceed cautiously, skeptically, and with robust pre- and post-treatment data collection efforts. Hypothesized effects of thinning on riparian forest structure and the use of that structure by targeted species should be tested against empirical data.

CONCLUSIONS

The importance of large deadwood as habitat for many aquatic and terrestrial species has been extensively studied over the last three decades, yet there is little comprehensive understanding of how multiple aspects of forest structure contribute to maintaining biologically diverse aquatic, riparian, and upland ecosystems. Our analysis suggests that species rely on different sizes of the key structural attributes of large deadwood in streams, large deadwood on the forest floor, large snags, and large live trees. Different active and passive restoration treatments will have long-term effects on the abundance of these structural elements. For the forests we examined, passive management resulted in the most rapid development of deadwood 30-100 cm diameter, whereas heavy thinning most rapidly developed live trees >100 cm diameter. Other forest types in different climates may produce different results. In the example we provided, passive management created dense forests that produced large volumes of large diameter deadwood over extended time periods as overstory tree densities slowly declined. In contrast, heavy thinning immediately created an open forest that allowed a low-density stand of large diameter overstory trees and an understory of shade-tolerant species to more rapidly develop. Because these size classes of live and deadwood support different biological components of forest ecosystems, tradeoffs in the abundance and production rates of different large diameter live and deadwood size classes should be considered when weighing different management options. Light or medium restoration thins may be an option that provides some increase in diameter growth of live trees, while minimizing production losses of large diameter deadwood. Large deadwood and large live trees are not the only structural attributes needed to maintain biologically diverse riparian ecosystems, but the decline of numerous species has been attributed to the lack of these features. Management strategies that seek to create a range of large live and dead tree densities across the landscape will help to hedge against uncertain outcomes related to unanticipated disturbances, unexpected species needs, and unknown errors in model assumptions. Over the long term, careful monitoring of active and passive treatments can determine if restored riparian ecosystems are being used by the targeted species. Such monitoring will help guide management toward developing biologically diverse riparian ecosystems.

SUPPORTING INFORMATION

Additional Supporting Information may be found in the online version of this article that includes spreadsheets of the forest growth model inputs and outputs necessary to reproduce the results of this study.

Climate change

ABSTRACT

Forests mitigate climate change by sequestering CO_2 from the atmosphere and accumulating it in biomass storage pools. However, in dry conifer forests, fire occasionally returns large quantities of CO_2 to the atmosphere. Both the total amount of carbon stored and its susceptibility to loss may be altered by post-fire land management strategies. Forest managers face a great challenge when asked to manage these lands for C sequestration and simultaneously reduce fire hazard. The objective of our study was to understand how differing post-fire management strategies affect C sequestration and the size of storage pools in the 10 years after a wildfire in a Sierra Nevada mixed-conifer forest. Post-fire management regimes included: (1) salvage-logged, planted, and intensively managed plantation (IM); (2) salvage-logged and planted (SP); (3) no salvage (NS); and (4) green canopy (GC), where fire burned through, but 95% of the overstory trees survived. Carbon sequestration and storage were estimated from measurements of individual ecosystem carbon pools. These pools included: aboveground trees, saplings, snags, stumps, and understory, coarse wood and fine wood, duff, and soil. We found total ecosystem carbon storage was 282 ± 15 Mg ha^{-1} of C in the NS treatment, 206 ± 31 Mg ha^{-1} in the GC, 137 ± 13 Mg ha^{-1} in the SP, and 101 ± 15 Mg ha^{-1} in the IM treatment. There were no significant treatment differences in C storage among the pools that would constitute labile/fine fuels, but there were differences in recalcitrant (coarse fuel) C pools. The greatest C storage in recalcitrant C pools was 258 ± 10 Mg ha^{-1} in the NS and 197 ± 30 Mg ha^{-1} in the GC treatments. Post-fire carbon sequestration rates were 1.6 ± 0.7 Mg ha^{-1} - year^{-1} of C in the GC, 0.7 ± 0.3 Mg ha^{-1} year^{-1} in the SP, 0.5 ± 0.1 Mg ha^{-1} year^{-1} in the NS, and 0.5 ± 0.1 Mg ha^{-1} year^{-1} in the IM treatments, but these differences were not statistically significant. Tree carbon sequestration rates were highest in the GC treatment and lowest in the NS treatment. Overall, our results suggest that a mature green-canopy stand provides most benefit in terms of C sequestration, wildfire resilience, and other ecosystem services at a point 10 years after severe wildfire. For forests that suffer high fire mortality, unsalvaged (NS) stands will retain the most carbon onsite.

Published by Elsevier B.V.

1. Introduction

Forests play an important role in the global C cycle because they sequester large quantities of carbon into storage as biomass. Here we will refer to "sequestration" as the rate of annual transfer between atmosphere and biosphere; "storage" will refer to the size of the carbon pool at a point in time. Summed over the land area of the US, forests sequester 148–204 Tg year^{-1} of C (Birdsey et al., 2006), which would offset 10–19% of the annual fossil fuel emissions in the US (Birdsey et al., 2006; Woodbury et al., 2007; Ryan et al., 2010) However, both storage amount and sequestration vary with climate, ecosystem type, disturbance regime, and land use and management practices (Bonan, 2008). Many of these characteristics are changing. For example, the US sequestration rate has increased by 33% from the 1990s to 2000s as a result of increased forest area and recovery from past disturbance, management, and environmental change (Pan et al., 2011).

Several forest management strategies have been proposed to mitigate C emissions. Silvicultural practices seek to increase the density of C in existing forests by promoting carbon sequestration (Canadell and Raupach, 2008). These strategies include afforestation, reforestation, and other silviculture practices (Fahey et al., 2009; Stephens et al., 2009a,b). Afforestation and reforestation increase the amount of land area covered by forest and the amount of carbon stored in biomass.

Climate mitigation efforts may also be achieved by reducing carbon losses from decomposition, which tends to increase carbon

storage. Carbon storage can be increased through management that favors specific carbon pools that decompose less rapidly (Gaudinski et al., 2000; Kirschbaum, 2000). We will refer to these pools as "recalcitrant." For example, recalcitrant pools include large-diameter trees, coarse wood, and organic matter in mineral soil. In comparison, "labile" C, which decomposes more rapidly, is found in foliage, litter, and understory. Promoting carbon storage in recalcitrant C pools may help managers achieve mitigation goals.

A third way to increase carbon storage is to reduce wildfire occurrence and severity. Managers may achieve these reductions by implementing fuel reduction treatments. Such treatments may seek to reduce surface fuels, increase the height to live crown, decrease crown density, and retain large trees of fire-resistant species (Agee and Skinner, 2005). Fuel reduction may be achieved through prescribed fire, understory removal, tree thinning, whole-tree harvest, or a combination of these approaches (Fule et al., 2001; Peterson et al., 2005; Stephens et al., 2009a,b). These treatments shift carbon storage from pools that favor ignition and increase severity to pools that resist ignition and reduce severity. These pools largely overlap with the ones we have previously termed labile and recalcitrant, because pools that decompose slowly are also less likely to combust. In this study, we will include the following pools as labile/fine fuels: duff, fine wood, and understory. Recalcitrant pools will include coarse wood, stumps, snags, trees, and the portion of soil below the duff layer.

Management of fire-prone forests thus presents a unique challenge. Managers must trade off the promotion of carbon storage against the reduction of fire risk. Managing for carbon storage may increase forest or understory biomass, which may increase fuels (Dore et al., 2008), perhaps propagating crown fires (Agee and Skinner, 2005). On the other hand managing to reduce fire risk often requires a reduction in C storage as fuel loads are reduced (Mitchell et al., 2009). For example, several of our sites have intense post-fire shrub growth (*Ceanothus cordulatus*). This research was initiated in part because, for these shrubs, we did not know the tradeoff between carbon sequestration and their contribution to the labile/fine fuel pool. More generally, we sought to quantify all the major carbon pools and sequestration rates in areas that had been managed differently after fire. The specific objectives of this study were to (1) determine the effects of post-fire management on forest C sequestration, (2) determine how the distribution of C pools varies across management treatments, and (3) compare among treatments the tradeoff between the benefits of C sequestration and the risks of labile/fine fuel accumulation.

2. Materials and methods

2.1. Study site

The study was conducted on the Storrie Fire, which was started at Storrie, CA, USA on August 17, 2000. The fire quickly burned northward through the Sierran mixed-conifer forests of the Plumas and Lassen National Forests in Plumas County, CA. It burned about 21,000 ha on national forest land and 1300 ha on private forest land.

Climate is characterized by hot and dry summers and cold and wet winters. Based on 90-year weather records in Chester, CA, which is located 25 km north of the study plots, annual average maximum temperature was 16.8 °C and minimum temperature was −0.4 °C. Daily extreme high and low temperatures were 40.0 °C and −26.7 °C, respectively. Annual precipitation was 813 mm, with approximately 90% occurring as snow between November and April.

Soils at the study site are loamy, mixed, mesic Ultic Haploxeralfs. They fall within either the Holland family or Holland–Skalan family with volcanic parent materials. The depth to parent material is at least 1.0 m and slope angles range from 0% to 50%. Before the fire, the vegetation was a typical mixed conifer forest dominated by *Abies concolor*, *Abies magnifica*, *Calocedrus decurrens*, *Quercus kelloggii*, *Pinus ponderosa*, *Pinus lambertiana*, and *Pseudotsuga menziesii*; the understory was dominated by *Arctostaphylos*, *Castanopsis*, *Ceanothus*, and *Purshia.* The site index of the tallest trees in this mixed-conifer forest is 23 m at 50 years. The plots are located near latitude 40°5′N and 121°16′W.

2.2. Experimental treatments

The study plots were established with four differing post-fire forest management regimes as our treatments. We selected these treatment areas based on the location of existing forest cover created by the fire and post-fire management regimes. We were able to locate three 300-ha blocks on soils classified as loamy, mixed, mesic Ultic Haploxeralfs; each block included the four treatments. Live tree basal area was between 0 m^2 ha^{-1} on the salvage-logged treatments and 41 ± 6 m^2 ha^{-1} on the green canopy (control) treatment (Table 1). The green canopy experienced a low severity burn with little mortality; the post-fire managed treatments all experienced a high severity burn with nearly 100% tree mortality.

The intensively managed (IM) treatment was established on existing plantations managed by W.M. Beaty and Associates (Redding, California). Following the fire in August of 2000, salvage logging commenced immediately and was completed by the fall of 2001. Total sawlogs and biomass removal averaged 68.8 Mg ha^{-1} C (based on the company's timber sales records). Site preparation began in 2001 and the soil was mechanically altered by ripping. Approximately 740 one-year-old seedlings per hectare were planted between 2001 and 2004. The plantations consisted of either pure *P. ponderosa* or mixed conifer species including *P. ponderosa*, *P. lambertiana*, *P. menziesii*, *A. concolor*, and *C. decurrens*. Competing understory vegetation was controlled with herbicide applied twice within the first 5 years. Our treatment plots were located in pure ponderosa pine plantations planted in 2002 and 2003.

The salvage and planted (SP) treatment plots were selected at three plantations established by the US Forest Service in 2004. After the fire, the Forest Service proposed to salvage and plant some relatively flat areas, but the project was withheld due to an appeal of the project and subsequent reversal of the decision. Three years later, the Forest Service was able to salvage 62.5 Mg ha^{-1} C of equivalent wood materials from four areas for a total of 42 ha (based on records in Lassen National Forest). The salvaged area was planted with *P. ponderosa* at 1000 trees ha^{-1} in 2004. The competing vegetation was removed from circles of 1.5 m radius for the largest 50% of the planted seedlings in 2005. The soil was not mechanically altered by ripping.

The no salvage (NS) treatment plots were naturally regenerating burned stands. These plots were not managed following the fire. They burned at such high severity that the fire killed all of the trees on the plots; the resulting snags were not removed from the site. Snags, down wood, and a dense stand of thorny shrubs

Table 1
Stand characteristics across forest management treatment. Tree parameters included live trees and saplings at least 1.37 m tall.

	Stand characteristic across treatments			
Parameter	GC	NS	SP	IM
Tree basal area (m^2 ha^{-1})	41 ± 6		0.4 ± 0.1	3.8 ± 1.0
Ave. stem diameter (cm)	35 ± 7		3.2 ± 0.3	6.9 ± 0.8
Tree density (stems ha^{-1})	300 ± 59		360 ± 79	840 ± 120
Snag basal area (m^2 ha^{-1})	5.7 ± 1.3	34 ± 5		0.9 ± 0.4

Table 2
Species specific allometric equations used to calculate aboveground tree carbon storage and aboveground tree carbon sequestration. Allometric equation symbols are DBH (diameter at breast height), D (ground level diameter), and variables a, b, and c are constants. Units are biomass units and independent variable units, respectively.

occupied the plots by the time the experimental measurements began.

The green canopy (GC) plots were comprised of mixed conifer stands that experienced a low intensity fire. Following the fire, the dominant and co-dominant trees experienced low or no mortality; we assumed that the understory was consumed by the fire. The stands may have been thinned in the past, but there are no records of such pre-fuel treatment activity. This regime has been considered the managers' model of fire-adapted structure in this forest type. Photographs of the treatments can be obtained upon request to the authors.

Each treatment plot was approximately 2090 m^2 (ca. 150 ft by 150 ft). The plot corners were determined using a rangefinder and compass. We calculated the exact area (S) of each plot as follows:

$$S = 0.5 \times a \times b \times \sin\alpha + 0.5 \times c \times d \times \sin\beta \quad (1)$$

where a, b, c, d were the lengths of the four sides of the plot, α was the angle between a and b, and β was the angle between c and d. We used the exact plot size to calculate C storage and sequestration. Each plot contained five subplots, each 9.29 m^2 (100 ft^2) in area, which were used for some components of forest carbon storage and sequestration. The subplot and plot level data were summed to determine total ecosystem carbon storage and sequestration, as described below.

2.3. Aboveground tree carbon

We estimated the carbon content of all trees in each ~2020 m^2 treatment plot. Total aboveground tree biomass was calculated using species-specific allometric equations (Table 2) that predict aboveground tree biomass from tree diameter at breast height (DBH: 1.37 m above ground line). These allometric equations describe the biomass of live trees above the height of a short stump (~15 cm). Although stump mass of the green trees would have added slightly to the total biomass in the GC treatment, the biomass of these short stumps was neglected in this analysis. We used separate calculations to determine the aboveground portion of C in tall stumps and snags. Additional allometric equations were used to predict aboveground biomass for trees shorter than 1.37 m using tree diameter at ground level and/or tree height. We measured every single tree on each replicate, regardless of size. We assumed that the carbon content of tree biomass was 50% (Table 3) (Woodbury et al., 2007; Campbell et al., 2009) to convert biomass to carbon content and then scaled the tree carbon content to a per hectare basis (Mg ha^{-1} of C).

2.4. Understory carbon

Understory carbon content was defined as the carbon stored in aboveground understory biomass (Mg ha^{-1} of C), which included all annual and perennial plants. It was measured by destructively sampling all non-tree aboveground biomass in three 9.29 m^2 subplots per treatment plot. We measured the fresh weight in the field and subsampled to determine the water content. Subsamples were dried at 60 °C until they reached constant mass, and then weighed. Understory field biomass was converted to carbon content by subtracting the water content from the field fresh weight and assuming that the dry weight of understory biomass was 50% C (Thornton et al., 2002).

2.5. Snag carbon

We measured the carbon content for all snags within each treatment plot. Snags were defined as any standing dead tree at least 1.3 m in height. Snag carbon (Mg ha^{-1} of C) was calculated as:

$$\text{SN} = V \times D \times C \quad (2)$$

where V was volume, D was density, and C was the carbon concentration of the snag. Volume was estimated from an allometric equation that predicts volume from snag diameter measured 1.37 m from the forest floor (Zhang et al., 2005). The volume of the snags with broken tops was estimated as if they were cylinders. We estimated the density of snags by felling and sub-sampling cookies

Table 3
Carbon concentration of ecosystem components used to convert biomass to carbon.

Component	Carbon (%)	Source
Tree	50	Woodbury et al. (2007) and Hurteau and North (2010)

*This study.

from snags of three size classes. Cookie subsamples were dried at 60 °C until they reached constant weight. Density was determined from the dry mass of the subsample and volume as determined by the volume displacement of water (Table 4). After weighing, samples were sprayed with carburetor sealant to minimize water uptake. They were then forced underwater and the apparent increase in mass was used as an estimate of water displacement (Williamson and Wiemann, 2010) and thus volume.

2.6. Stump carbon

The carbon content of aboveground stump biomass was estimated on three subplots per treatment plot. Stumps were defined as the aboveground tree bole biomass remaining after trees were harvested. Stumps were assumed to be cylindrical and stump volume was determined from field measurements of stump diameter and height. Stump carbon content was calculated as:

$$\mathrm{ST} = \pi \times \left(\frac{D_1}{2}\right)^2 \times H \times D_2 \times C \quad (3)$$

where D_1 was the diameter, H was height, D_2 was density, and C was the carbon concentration. We assumed that the carbon concentration of stumps is 50% (Janisch and Harmon, 2002). We assigned a decay class from 1 to 3. Decay class 1 was defined as stumps with greater than 70% of the biomass remaining. Decay class 2 had 30–70% of the biomass remaining. Decay class 3 had up to 30% of the biomass remaining and was characterized by cubical fragments and crumbling chunks. We took four subsamples from each of the decay classes to determine density following the same methods as described in Section 2.5 above (Table 4).

2.7. Coarse wood

We measured the carbon content of all coarse wood (CW) in three subplots per treatment plot. CW was defined as any downed woody debris over 5 cm in diameter (Mattson et al., 1987). The carbon content of CW was calculated as:

$$\mathrm{CW} = \pi \times \left(\frac{D_1}{2}\right)^2 \times L \times D_2 \times C \quad (4)$$

where D_1 was midpoint diameter, L was length within the plot, D_2 was the density of wood determined for each decay class, and C was the carbon concentration. We assumed that the carbon concentration of CW is 50% (Harmon, 2008). We measured the length and diameter of each piece of CW in the 9.29 m^2 subplots. As above, we assigned a decay class from 1 to 3 to determine the density.

2.8. Fine wood

Fine wood was collected on three subplots per treatment plot using a 2500 cm^2 duff sampler. FW was defined as plant biomass 1–5 cm in diameter. FW samples were dried in the oven at 60 °C until the samples reached constant mass and then weighed. To convert FW biomass to carbon, we assumed a carbon concentration of 50% (Prichard et al., 2000).

2.9. Duff

Duff was collected on three subplots per treatment plot using a 2500 cm^2 duff sampler. Duff was defined as plant biomass less than 1 cm in diameter. Samples were oven-dried at 60 °C until they reached constant mass and then weighed. Duff biomass was converted to carbon by assuming that the carbon concentration of duff was 40% (Campbell et al., 2009).

2.10. Soil carbon

Three soil samples per treatment plot were collected to determine soil carbon storage at 0–10 cm, 10–20 cm, and 20–30 cm depths. The samples were collected with a soil auger at a randomly selected corner of each of three subplots on each plot. Soil samples were oven dried at 60 °C until they reached constant mass and then separated into rock, coarse fragment (CF), and mineral soil components using a 2 mm mesh sieve. CF was defined as any organic material that would not pass a 2-mm mesh sieve (Page-Dumroese and Jurgensen, 2006). The dry weight of each component was determined and an Elemental Analyzer (CE Instruments, Milan, Italy) connected to a Delta^{plus} isotope ratio mass spectrometer (Finnigan-MAT, Bremen, Germany) was used to determine the carbon concentration for a subset of coarse fraction and mineral soil samples. One set of bulk density samples per treatment plot was taken using a 52.5-mm diameter slide hammer. Bulk density samples were taken at 1–6 cm, 11–16 cm, and 21–26 cm depths. These samples were assumed to represent 0–10, 10–20, and 20–30 cm depths, respectively. The soil coarse fraction and mineral soil carbon pools were estimated from the dry mass and bulk density of soil samples: the product of dry mass carbon concentration, divided by the bulk density at each depth.

$$\text{Soil C pool} = \frac{M}{V} \times D \times \frac{C}{100} \quad (5)$$

where Soil C pool (g cm^{-2} of C) represented either soil coarse fraction (SCF) or mineral soil C in a 10-cm soil layer, M was the component mass (g), V was the soil corer volume (cm^{-3}), D was the soil depth (10 cm), and C was the carbon concentration (%) of the component. The resultant volumetric C content was summed over the appropriate depths, and then scaled up to Mg ha^{-1}.

2.11. Total ecosystem carbon storage

Total ecosystem carbon storage was estimated by summing the individual carbon pools on each treatment plot. Total ecosystem carbon storage (TEC) was defined as:

$$TEC = TC + UC + SN + ST + CW + FW + D + SCF + MS \quad (6)$$

where TEC was the sum of carbon content of individual ecosystem carbon pools (Mg ha^{-1} of C), TC was aboveground live tree, UC was aboveground understory, SN was snag, ST was stump, CW was coarse wood, FW was fine wood, D was duff, SCF was soil coarse fraction, and MS was mineral soil.

2.12. Aboveground carbon sequestration

For mature trees in the GC treatment, aboveground carbon sequestration was estimated for total carbon accumulated since the fire. Aboveground carbon sequestration (CS) was defined as:

$$CS = TS + US \quad (7)$$

(in Mg ha^{-1}year^{-1} of C) where TS was aboveground tree carbon sequestration, US was aboveground understory carbon sequestration. Aboveground tree carbon sequestration (TS) was calculated as the average annual change in live aboveground tree carbon (TC) for individual trees (Jenkins et al., 2001).

$$TS_m = \frac{(TC)_{t_1} - (TC)_{t_0}}{(t_1 - t_0)} \quad (8)$$

where TS_m was tree carbon sequestration of mature trees on the GC treatment, TC was the aboveground tree carbon (Mg tree^{-1} of C) and $t_1 - t_0$ was the 10 year increment (Hudiberg et al., 2009) between 2001 and 2010. We calculated the average annual change in diameter from the 10 year tree ring width between 2001 and 2010 because we wanted to represent the growth of trees as it recovered from disturbance. We expected that growth patterns in the first few years immediately following the fire and management installation would be low as the trees recovered from the initial disturbance, so the average annual growth would be more representative of the tree response in the 10 years following the fire. TC was calculated using the same species-specific allometric equations that were used to calculate aboveground tree carbon from the tree bole diameter (D) measurements (Table 2). The 2010 diameter, $D_{(t1)}$, was measured in the field as described in the section labeled aboveground tree carbon.

The 2001 diameter, $D_{(t0)}$, was determined from radial tree cores. The radial tree core increment was determined by sampling tree cores from three GC treatment plots. We selected 30 trees from each plot to represent the range of tree size and species. We measured the diameter and took two tree core samples at perpendicular directions at 1.37 m from the forest floor. We also measured the 10-year radial increments (or fresh length, L_w) of the 2001–2010 rings using a caliper to 0.1 mm in the field. The cores were dried and the total dry length (L_d) of the 2001 to 2010 tree rings was measured using a caliper. The shrinkage rate (S) was determined using samples that had been measured outdoors as follows:

$$S = \frac{L_w - L_d}{L_w} \quad (9)$$

The shrinkage was determined to be 3.02%. The 10 year radial increment (r) was calculated using the dry tree ring length measurements for tree ring lengths that were not measured in the field:

$$r = L_w = \frac{L_d}{(1 - S)} \quad (10)$$

Finally, the 2001 diameter on the subsampled trees, $D_{(t0)}$, was calculated as:

$$D_{(t0)} = D_{(t1)} - [2 \times k \times r] \quad (11)$$

where k was the bark correction factor (Wykoff et al., 1982).

In order to estimate the annual tree carbon sequestration for all of the trees in each plot, we developed a regression equation using the 2010 diameter measurements and tree rings from the subsampled trees to predict 2001 tree diameter from the 2010 measured diameter:

$$D_{(t0)} = -4.172 + 0.998 \times D_{(t1)} \quad (12)$$

where the $R^2 = 0.996$.

We used a separate TS calculation for the seedlings planted on the IM and SP treatments because they were planted up to 4 years after the fire:

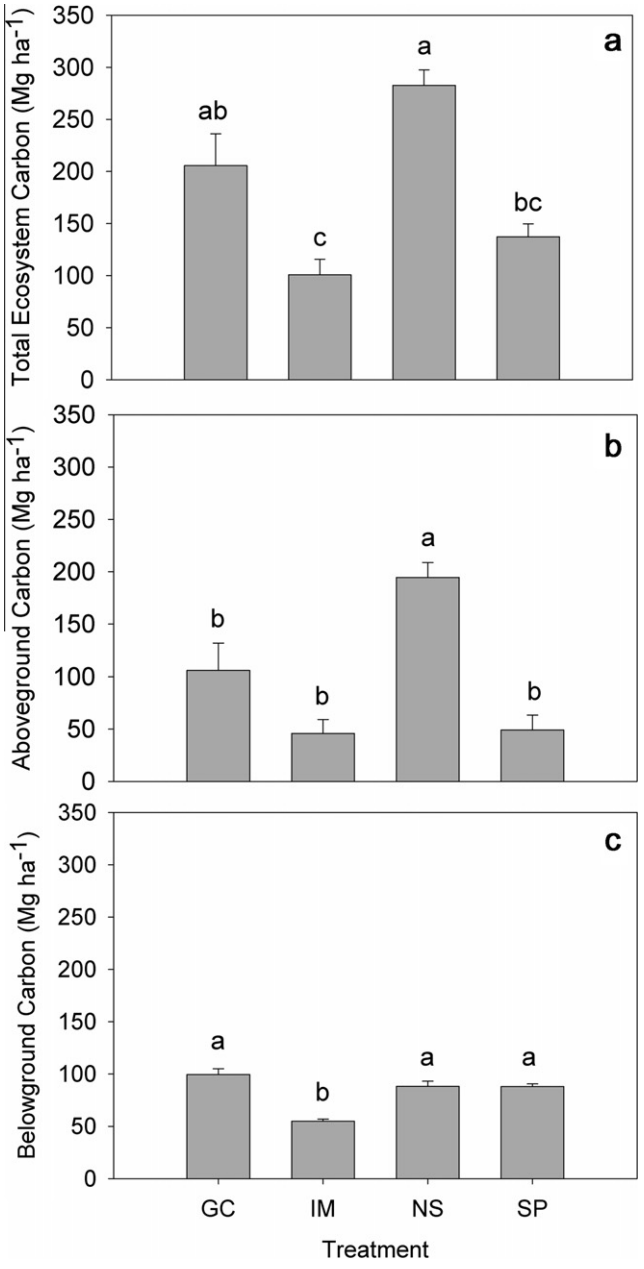

Fig. 1. Carbon storage across management treatment (Mg ha^{-1}) for (a) total ecosystem carbon (aboveground and belowground C storage); (b) total aboveground C (tree, sapling, snag, understory, FW, CW); (c) soil carbon (soil coarse fraction and MS C from 0 to 30 cm depth). Forest management treatments include: green canopy (GC), intensive management (IM), no salvage (NS), and salvage and planted (SP). Bars that are not connected by the same letter are significantly different ($\alpha = 0.05$).

Table 5
Aboveground carbon storage (Mg ha^{-1} of C) for each component across forest management treatments. Letters not connected by the same letter horizontally are significantly different ($\alpha = 0.05$).

Component	Carbon pool (Mg ha^{-1})			
	GC	IM	NS	SP
Tree	81 ± 30*a*	4.1 ± 1.2*b*	0*b*	0.4 ± 0.1*b*
Snag	6.5 ± 1.8*a*	0.5 ± 0.2*a*	82 ± 14*b*	0*a*
Stump	0.6 ± 0.4*a*	11 ± 3*a*	8.2 ± 4.9*a*	2.8 ± 0.7*a*
Understory	1.3 ± 0.6*a*	0.2 ± 0.1*a*	5.2 ± 1.3*a*	5.6 ± 2.4*a*
Coarse wood	9.9 ± 5.7*a*	19 ± 11*a*	81 ± 8*b*	23 ± 9*a*
Fine wood	1.4 ± 0.2*a*	9.5 ± 1.2*a*	13 ± 3*a*	13 ± 5*a*
Duff	5.5 ± 0.2*a*	1.8 ± 0.5*a*	5.7 ± 2.6*a*	4.6 ± 0.9*a*

$$TS_s = \frac{TC_{(t1)}}{(t_1 - t_0)} \quad (13)$$

where TS_s was seedling tree carbon sequestration (Mg ha^{-1} year^{-1}), $TC_{(t1)}$ was the seedling carbon (Mg ha^{-1}) in 2010, t_1 was the year 2010, and t_0 was the year of the start of the growth interval. On the IM and SP treatments, t_0 was the year when the seedlings were planted (see Section 2.2). The individual TS estimates from seedlings and trees were summed on each plot and scaled to an area basis to determine annual tree carbon sequestration.

Aboveground understory carbon sequestration was determined as:

$$US = \frac{UC}{(t_{2010} - t_{2001})} \quad (14)$$

where US was understory carbon sequestration (Mg ha^{-1} year^{-1}), UC was understory carbon storage (Mg ha^{-1}), and t was the year, on the GC, IM, and NS treatments. On the SP treatment, we accounted for the partial understory removal in 2005. We estimated the proportion of the plot that fell within the treated area, which was comprised of circles of 1.5 m radius around the largest 50% of the planted trees:

$$US = p \times \frac{UC}{(t_{2010} - t_{2001})} + (1 - p) \times \frac{UC}{(t_{2010} - t_{2001})} \quad (15)$$

where t was the year, and p was the proportion of plot area with radial understory removal:

$$p = \pi r^2 \times \frac{t}{a} \times 0.5 \quad (16)$$

where r was the1.5 m radius, t was the number of trees per plot, and a was the plot area (m^2).

2.13. Data analysis

Treatment differences in TEC, aboveground C storage, and soil C storage were evaluated using the Tukey–Kramer honest significant difference (HSD) test to make multiple comparisons among treatment means. The HSD was also used to determine treatment differences in less combustible coarse fuels, fine fuels, and individual C storage pools. Statistical analysis was performed using JMP 9 statistical software (SAS, Cary, NC, USA).

To scale plot level estimates of TEC to a land area basis, carbon pool estimates were required for each plot. Due to errors in sample labeling and loss, we were left with 14 missing soil C data points. We used the average of the plot measurements to fill in these missing data. This allowed us to sum each individual ecosystem component of TEC for each replicate. We also excluded one of the coarse wood plots on the NS treatment because satellite imagery (Google earth, http://earth.google.com) showed an anomalously high density of coarse wood when this plot was compared to the surrounding landscape.

3. Results

3.1. Carbon storage across forest management regimes

Total ecosystem carbon storage differed among post-fire management regimes. Total ecosystem carbon storage was 283 ± 15 Mg ha^{-1} in the no salvage (NS) and 206 ± 31 Mg ha^{-1} in the green canopy (GC) treatment (Fig. 1a). These values were significantly higher than those in the plots that were salvaged. The salvage planted (SP) and intensively managed (IM) treatments had values of 137 ± 13 Mg ha^{-1} and 101 ± 15 Mg ha^{-1}, respectively. There were also management differences in aboveground and soil carbon storage (Fig. 1b and c). NS stored significantly more carbon aboveground (194 ± 14 Mg ha^{-1}) than all the other treatments (Fig. 1b); aboveground storage was 106 ± 26 Mg ha^{-1} on the GC, 49 ± 14 Mg ha^{-1} on the SP, and 46 ± 13 Mg ha^{-1} on the IM. The IM treatment stored the least C in the soil (55 ± 2 Mg ha^{-1}); this was significantly lower than the other treatments. The other treatments held 100 ± 6 Mg ha^{-1} in the GC, 88 ± 5 Mg ha^{-1} in NS, and 88 ± 2 Mg ha^{-1} in the SP treatment.

3.2. Distribution of component C storage among treatments

The distribution of carbon among aboveground pools also varied with post-fire management. The largest pool in GC was live tree biomass, with 81 ± 30 Mg ha^{-1} of C (Table 5). The largest pool in IM and SP was coarse wood, which stored 19 ± 11 Mg ha^{-1} and 23 ± 9 Mg ha^{-1}, respectively. The NS treatment stored nearly equal amounts in coarse wood and snag biomass, with 81 ± 7 Mg ha^{-1} and 82 ± 14 Mg ha^{-1}, respectively.

The distribution of carbon among belowground pools was less variable among treatments compared to the aboveground components. The greatest differences in soil C storage were in the top 0–10 cm of soil. In this layer the IM stored 22 ± 1 Mg ha^{-1} in the sieved mineral soil and 1.8 ± 0.8 Mg ha^{-1} in the soil coarse fraction (Table 6). In contrast, the GC stored 47 ± 6 Mg ha^{-1} in the sieved mineral soil from this layer and 1.2 ± 0.7 Mg ha^{-1} in the soil coarse fraction. There were no post-fire management differences in the mineral or soil coarse fraction carbon storage at 10–20 cm and 20–30 cm depths.

There were also shifts in the storage of carbon between labile/fine-fuel and recalcitrant carbon pools with fire and post-fire management. For example, the SP treatment removed all the carbon sequestered in snags and the IM treatment removed over 99% of the snag C compared to the NS treatment. In the NS treatment, fire shifted the carbon stored in large-diameter trees to the snag C pool. The shift in carbon storage among individual ecosystem C pools resulted in treatment differences in carbon storage in fire resistant C pools (Fig. 2a). The NS stored 258 ± 10 Mg ha^{-1} and the IM stored 89 ± 15 Mg ha^{-1} in recalcitrant C pools. There were no significant management differences in labile/fine fuel C storage (Fig. 2b) or individual components of labile/fine fuels, which include the understory, fine wood or duff C pools (Table 5).

3.3. Carbon sequestration

Post-fire management affected components of carbon sequestration, but not total carbon sequestration. Total aboveground carbon sequestration was 1.6 ± 0.7 Mg ha^{-1} year^{-1} of C on the green canopy, 0.7 ± 0.3 Mg ha^{-1} year^{-1} on the SP, 0.5 ± 0.1 Mg ha^{-1} year^{-1} on the NS, and 0.5 ± 0.1 Mg ha^{-1} year^{-1} on the IM treatment (Fig. 3a). There were no treatment differences in understory carbon sequestration. Understory carbon sequestration was 0.1 ± 0.1 Mg ha^{-1} year^{-1} of C on the green canopy, 0.7 ± 0.3 Mg ha^{-1} year^{-1} on the SP, 0.5 ± 0.1 Mg ha^{-1} year^{-1} on the NS, and

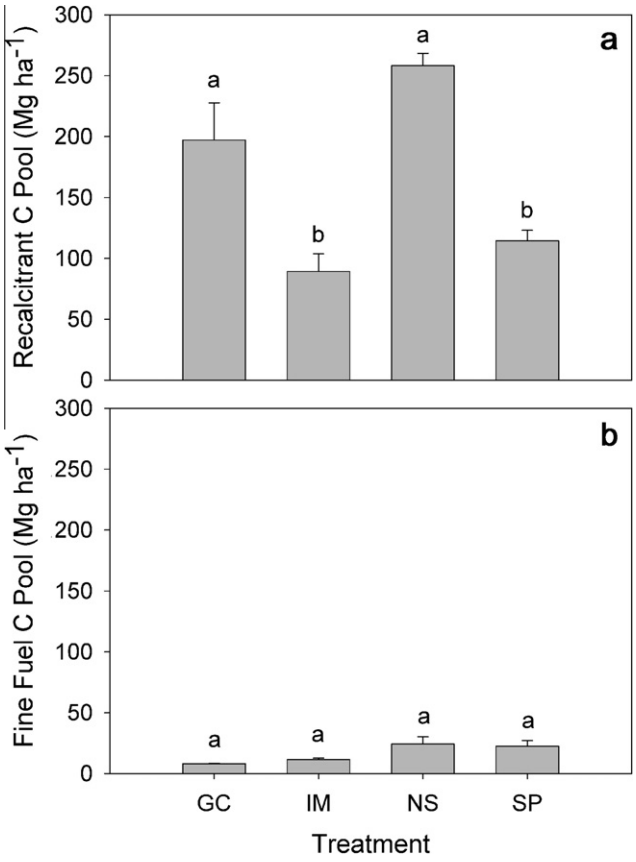

Fig. 2. Ecosystem carbon storage in (a) recalcitrant C pools including tree, snag, stump, coarse wood, and all soil carbon and (b) fine fuels including understory, fine wood, and duff. Forest management treatments include: green canopy (GC), intensive management (IM), no salvage (NS), and salvage and planted (SP). Bars that are not connected by the same letter are significantly different ($\alpha = 0.05$).

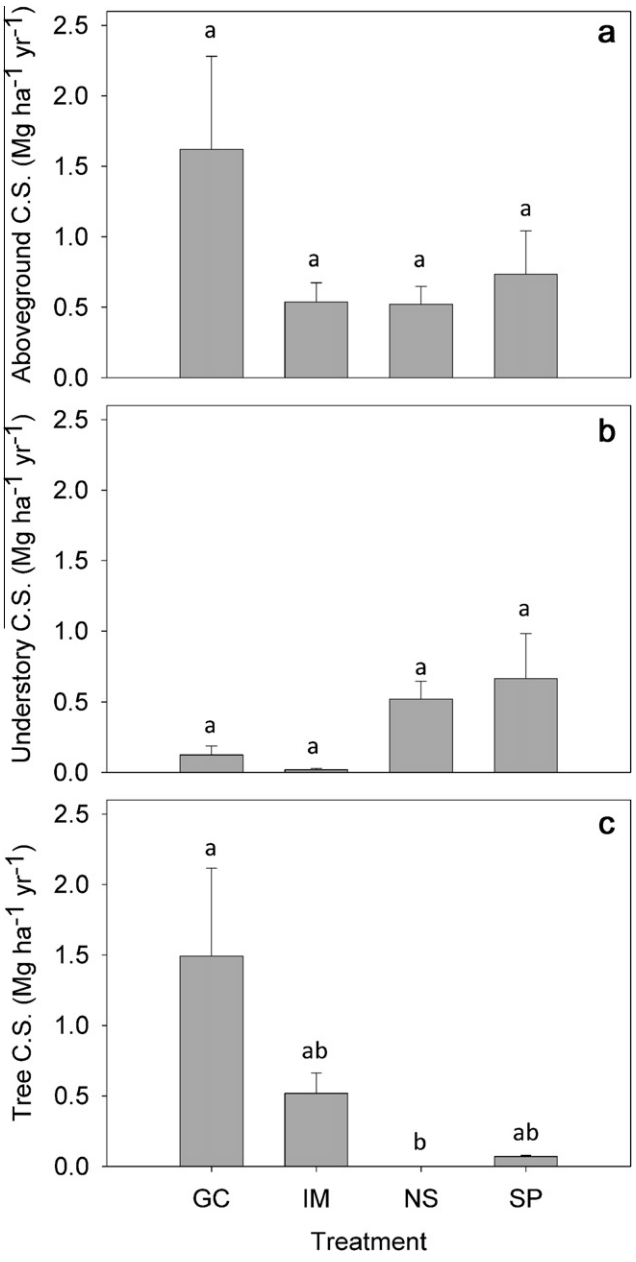

Fig. 3. Carbon sequestration (CS) across forest management treatment averaged over 10 years following fire, (a) total aboveground carbon sequestration (tree and understory), (b) aboveground understory carbon sequestration, and (c) aboveground tree carbon sequestration. Forest management treatments include: green canopy (GC), intensive management (IM), no salvage (NS), and salvage and planted (SP). Bars that are not connected by the same letter are significantly different ($\alpha = 0.05$).

0.02 ± 0.02 Mg ha^{-1} year^{-1} on the IM treatment (Fig. 3b). Aboveground tree carbon sequestration was significantly greater on the GC than the NS treatment; values were 1.5 ± 0.6 Mg ha^{-1} year^{-1} on the GC, 0 Mg ha^{-1} year^{-1} on the NS, 0.07 ± 0.0 Mg ha^{-1} year^{-1} on the SP, and 0.5 ± 0.1 Mg ha^{-1} year^{-1} on the IM (Fig. 3c).

4. Discussion

4.1. Carbon storage and sequestration among treatments

Post-fire management affected total C storage and the distribution of C among ecosystem pools. Of the burned and treated sites, the NS treatment had the highest total C storage due to the large snag and coarse wood pools. The least total ecosystem C was stored in IM and SP treatments due to the reduction of the tree C by the fire and snag C by the logging. The removal of sawlogs and biomass from post-fire salvage logging averaged 68.8 Mg ha^{-1} of C on the IM and 62.5 Mg ha^{-1} of equivalent wood materials on the SP. In addition, soil C was reduced in the 0–10 cm layer on the IM treatment. The IM removed 44. 7 Mg ha^{-1} of soil C from 0 to 30 cm depth compared to the GC (Fig. 1c). Of the 44.7 Mg ha^{-1} removed on the IM, approximately half, 22 Mg ha^{-1}, was lost in the top 0–10 cm of mineral soil (Table 6).

Soil C pools are often incompletely measured or ignored in estimates of carbon storage although soil carbon has been estimated to

represent approximately 40% of terrestrial carbon (Dixon et al., 1994; Kindermann et al., 2008). In our study, soil C contributed between 31% and 64% to total ecosystem carbon storage. Our estimates agree with a previous model of C dynamics throughout the state of California, which estimated that approximately half of total C was in the soil (Turner et al., 1995). The potential change in storage following disturbance is variable (Johnson, 1992). We observed a 45% decrease in total soil C storage in the IM treatment compared to the GC. These reductions were attributed to a decrease in the mineral soil fraction. Two meta-analyses (Johnson, 1992; Johnson and Curtis, 2001) show similar reductions in soil C storage, however the responses were dependent upon disturbance severity and management. For example, soil C storage generally increased after sawlog harvest, decreased following whole tree harvest or prescribed fire, and increased after wildfire (Johnson and Curtis, 2001; Powers et al., 2005). A more recent meta-analysis concluded that harvesting generally reduced soil C by 8%, with the reductions occurring primarily in the forest floor (organic horizon) and not the deeper mineral soil layers (Nave et al., 2010). Other studies observed stable to slight increases in mineral soil C following harvest, however the responses also varied with management intensity and ecosystem type (Sanchez et al., 2006).

Snags also stored a large proportion of total ecosystem carbon in the NS treatment. On the SP and IM treatments, carbon storage had been substantially reduced because the fire-killed trees had been removed during salvage-logging. Snag C and soil C represent large and variable carbon storage pools that should be included in carbon budget estimates.

Carbon sequestration was expected to differ among treatments. However, post-fire management did not affect rates of total aboveground carbon sequestration 10 years after fire. We expected to observe higher total carbon sequestration on the GC treatment resulting from greater stand level tree carbon sequestration rates. In fact, we did observe greater tree carbon sequestration rates on the GC treatment compared to the NS, which had no trees. In contrast, the higher aboveground C in the GC treatment was not different from the IM and SP. This lack of difference may have resulted from the high variability among plots.

It is important to recognize that this storage occurred in the 10 years immediately after the fire. After 10 years, stands have not recovered from disturbance in terms of either site occupation (Pretzsch, 2009) or C sequestration (Fig. 3). We expect that stand sequestration rates will reach GC rates at a later successional stage. The amount of time it takes for the seedlings to recover from disturbance depends upon disturbance type and severity, species composition, post-fire management, and stand density. Intensive management will accelerate this process. For example, it took only 36 years for an intensively managed plantation to carry as much aboveground carbon as pre-fire stands that were approximately 70 years old (Zhang et al., 2008). This leads us to speculate that the C losses on the IM treatment would be offset by the acceleration of stand establishment. It would require a modeling exercise to determine whether and when the offset would occur.

Differences in pre-fire conditions could have influenced our measurements of post-fire C. The study was initiated after the fire, so it was not possible to determine pre-fire carbon stocks. However, our study plots were chosen in similar landscapes with similar soils to minimize pre-fire differences. Further, if we compare live tree basal area on the green canopy treatments to snag basal area on the no salvage treatment, the snag basal area is only a little lower (41 vs. 34 m^2/ha in Table 1). We would not expect them to be exactly the same because the fire may have consumed some of the trees or they may have fallen following fire. Nonetheless, the similarity in these values supports our assumption that the sites were similar before they were treated.

4.2. Error analysis

Sources of error in the carbon measurements include inaccurate and incomplete measurements. One possible source of inaccuracy was the use of inappropriate allometric equations. We minimized inaccuracy by using species-, and where possible, region-specific allometric equations. However, sometimes this was impossible. For example, for *Q. kelloggii*, we applied allometric equations developed for *Quercus velutina* Lam. located in West Virginia. Where possible, we also applied different allometric equations, developed from saplings, to predict C storage in saplings. However, we were forced to use an allometric equation developed for *A. concolor* saplings to estimate C for four individual *P. menziesii* saplings. Error may also have resulted from our snag C estimates, which were derived by assuming that snags are cylinders (Kueppers et al., 2004). This may not be accurate because although broken snags approximate cylinders, they do taper with height and some snags had branches remaining. Future studies could reduce these errors by generating allometric equations for large trees of all species and improving estimates of snag C.

Rates of decomposition were accounted for in our estimates of carbon pools by assigning a decay class to snags and stumps, which we related to wood density and used to reduce our volume to mass conversions. When the sequestration rates were calculated from these pools, the influence of decomposition had thus already been accounted for. Whether this was sufficient is not known. We explored the possibility of further accounting for this flux and concluded that it was too variable to include in the current analysis. Decomposition rates would vary among species, among pools, and probably among treatments given the variable temperature and moisture conditions induced by the treatments. Future work will be needed to address this issue more quantitatively on these sites.

Finally, errors due to incomplete measurements were mostly belowground. We did not, for example, include the carbon in coarse roots or the belowground portions of stumps and snags. We explored the use of coarse-root allometric equations (Jenkins et al., 2003) to live trees and snags and found that coarse root C would increase TEC by 0.4–7% depending upon treatment. We did not include these estimates because the equations were not species–specific. Worse, the coarse roots had probably decayed since the fire and we did not measure the decline in their density; moreover, we would expect that decay rates would differ among treatments. Given these limitations, we decided not to try to estimate coarse root C. Our soil C estimates would also have been more accurate if it had not been necessary to fill in data for the missing samples. Finally, our soil sampling was limited to three soil samples per replicate, which would increase the likelihood of a type II error. We recognize that soil C is often variable (Page-Dumroese et al., 2006) and that we would have benefited from more replication.

4.3. Managing for carbon sequestration and storage

Managing forests for carbon storage and sequestration has become an increasingly important priority to help offset anthropogenic CO_2 emissions. Forest carbon management strategies may include maximizing total ecosystem carbon storage, retaining carbon in recalcitrant pools, or promoting carbon sequestration. The GC and NS treatments had the highest total carbon storage. They also stored the highest proportion of total carbon in recalcitrant C pools. This is important because recalcitrant pools such as large diameter trees, soil, and snags retain C for longer periods of time than labile pools.

This study underlines the importance of soil carbon storage. Previous studies have shown that the reduction of soil C following

forest management is not ubiquitous; the effects vary with time since disturbance, soil type, and forest management (Black and Harden, 1995; Breshears and Allen, 2002; Page-Dumroese and Jurgensen, 2006; Boerner et al., 2008). Because this site underwent mechanical site preparation, some of the reduction may have been due to the mixing of the deep soil materials into the surface horizons. However, the reductions occurred in the 0–20 cm depth without an increase in the 20–30 cm depth, so it is unlikely that downward mixing of organic matter was sufficient to explain the reduction.

4.4. Managing for carbon sequestration and fire

Managing for carbon sequestration may increase fire hazard. Although carbon storage is often favored by climate mitigation efforts, fire hazard reduction often seeks to reduce fuel accumulation by lowering forest carbon density. Managing for both climate mitigation and fire hazard reduction may be achieved by managing to favor recalcitrant carbon storage pools and minimize storage in labile/fine fuels. As noted earlier, recalcitrant pools include large diameter trees, snags, coarse wood, and soil. Labile/fine fuels include understory, fine wood, and duff.

Reducing C storage in labile/fine fuels may be achieved by controlling understory C that burns readily and may propagate crown fires. In this study, the contribution of understory C is relatively low compared to total ecosystem carbon storage, so loss of the understory would have little effect on carbon sequestration. We therefore recommend thinning understory C as a means to reduce labile fuel loading while maximizing C storage. Post-fire strategies favoring recalcitrant carbon may reduce fuels that contribute to increased fire risk and do not contribute a large proportion of C to long term storage. Recalcitrant C is also favored by reducing soil disturbance (Lal, 2004; Page-Dumroese and Jurgensen, 2006).

A complete accounting for C storage would consider forest products (Johnson et al., 2005; Mitchell et al., 2009). For example, partial or complete removal of snags from the forest with post-fire planting could theoretically increase overall long-term carbon storage by promoting forest regeneration and storage of C in recalcitrant forest products offsite. Accounting for off-site storage is beyond the scope of our study. The objectives of our study were to determine C storage and sequestration in previously burned forests, not a full carbon accounting in forest products. An accurate accounting for the carbon removed from the site is complex and would require additional information about the C storage in sawlogs, the post-harvest use, and an accounting of the C required for processing and shipment.

While this study provides management opportunities to balance carbon sequestration efforts with fire, these opportunities should consider management implications besides fire hazard and carbon sequestration. Post-fire salvage should consider the effects on ecosystem function in terms of vegetation regeneration, animal and plant diversity, hydrology, erosion, and nutrient cycling (Serrano-Ortiz et al., 2011; Donato et al., 2006; Castro et al., 2010). For example, fuel reduction treatments that remove shrub cover should consider the ecological significance of *C. cordulatus* as a nitrogen fixer. The presence of nitrogen-fixing shrubs could influence soil C and N dynamics (Boerner et al., 2008) because a significant proportion of N lost from fire disturbance may be offset by nitrogen fixation (Agee, 1993). It remains uncertain how much plant available nitrogen *C. cordulatus* may be adding to the soil and what are its effects on soil fertility and total plant productivity. Managers must also balance management goals with the cost of implementing post-fire treatments at the landscape and regional scale. These management considerations are becoming increasingly important as various lines of evidence suggest that frequency, extent, and – in some cases – the severity of fire is increasing across the western US (Miller et al., 2009; Dillon et al., 2011).

5. Conclusion

Forest managers are faced with complex decisions about how best to manage forest systems for carbon sequestration, fire risk, forest products, and ecosystem processes. Differing management strategies may be implemented depending upon management goals. The results of our study suggest that in fire-prone ecosystems, the green canopy forest and no salvage logging treatments store the most carbon 10 years after a wildfire. Long-term management goals should account for how stand structural changes may shift the distribution of carbon between labile/fine fuels and recalcitrant pools as the stands continue to recover.

To manage for carbon sequestration while still reducing fire hazard, management efforts should maximize carbon storage and carbon sequestration rates in large diameter live trees and other recalcitrant pools, including soils and dead trees, if possible. They should minimize carbon storage in saplings, understory, and surface fuels. The results of our case study provide managers with important background information to make decisions about how to mitigate climate change and reduce future fire risk in a fire-prone Sierra Nevada forest ecosystem.

Acknowledgments

We would like to acknowledge Martin Ritchie and Travis Springer from the Pacific Southwest Research Station, Redding, CA, John Zarlengo from the Almanor Ranger District, Lassen National Forest, CA, and Bob Rynearson from W.M. Beaty and Associates for their contributions. This study was made possible with funding from the USDA Forest Service Lassen National Forest.

ABSTRACT

We examined traditional knowledge of fire use by the Ichishikin (Sahaptin), Kitsht Wasco (Wasco), and Numu (Northern Paiute) peoples (now Confederated Tribes of Warm Springs, CTWS) in the eastside Cascades of Oregon to generate insights for restoring conifer forest landscapes and enhancing culturally-valued resources. We examined qualitative and geospatial data derived from oral history interviews, participatory GIS focus groups, archival records, and historical forest surveys to characterize cultural fire regimes (CFRs) –an element of historical fire regimes– of moist mixed conifer (MMC), dry mixed conifer (DMC), and shrub-grassland (SG) zones. Our ethnohistorical evidence indicated a pronounced cultural fire regime in the MMC zone, but not in the two drier zones. The CFR of the MMC zone was characterized by frequent (few-year recurrence), low-severity burns distributed in a shifting pattern. This regime helped to maintain forest openings created by previous ignitions, resulting from lightning or possibly human-set, that had burned large areas. The CFR was influenced by the CTWS traditional knowledge system, which consisted of four elements: fire use and associated resource tending practices, tribal ecological principles, the seasonal round (the migratory pattern to fulfill resource needs), and culture. Thinleaf huckleberry (*Vaccinium membranaceum*), a cultural keystone species, occurs primarily in the MMC zone and was a principle focus of traditional fire use of the CTWS peoples. Fire was deployed to maintain shrub productivity and site access for harvesting. Cessation of fire use by ~1940 has caused a decline in huckleberry productivity throughout much of the historical harvest zone. Our findings about CFR scale show how a nested, multi-level framework (patch- and landscape-levels) may be employed to reintroduce fire and thereby promote forest restoration and enhance culturally-valued resources. Our findings also highlight the utility of engaging the communities that hold traditional knowledge in the forest management and planning process.

1. Introduction

Millions of hectares of forest in the eastside Cascades of Oregon and Washington have accumulated excessive fuel and undergone stand structural alteration over the past century, priming them for uncharacteristically severe wildfire and insect outbreak (Stine et al., 2014). Public land management agencies and American Indian tribes seek to restore resilience to natural disturbances in these altered forest landscapes given climate change and human development stressors (Lake and Long, 2014; Hessburg et al., 2015). Investigations of historical fire regimes have revealed knowledge to guide forest restoration in Pacific Northwest forests (Cissel et al., 1999; Hessburg et al., 2005; Stine et al., 2014). Historical fire regime metrics including frequency, severity, and patch size, can point to ecological targets for restoration. To date, there is limited understanding of the influence of traditional fire use on historical fire regimes and forest structure of specific ecological zones within a landscape (however, see Boyd, 1999; Turner and Peacock, 2005; Lake, 2007; Turner et al., 2011).

There is growing recognition that American Indians influenced historical fire regimes and forest landscape structure during the Holocene (e.g., Anderson and Moratto, 1996; Agee, 1993; Crawford et al., 2015; Lake et al., 2017). Fire use varied geographically (Crawford et al., 2015), sparking scientific debate about the magnitude of this influence (Denevan, 1992; Vale, 2002). Despite such debate, investigations of traditional fire use have generated restoration applications, such as restoration conceptual models and prescribed fire strategies (Kimmerer and Lake, 2001; Anderson and Barbour, 2003; Senos et al., 2006). In addition, for American Indian tribes, knowledge of fire use can guide restoration practice to promote diverse landscape values, including community identity, intergenerational cohesion, economic benefits, and ecological functions (Lake and Long, 2014; Long et al., 2015; LeCompte, 2018).

Here we focus on the "cultural fire regime" (CFR), meaning the characteristic pattern of managing fuels and ignitions of a particular plant community that a society uses to promote desired natural resources and ecological conditions (Bonnicksen et al., 1999; Lewis and Anderson, 2002; Senos et al., 2006; Lake, 2007; Lake et al., 2017). In combination, the pattern of natural ignitions (e.g., lightning-ignited fires) and that of the

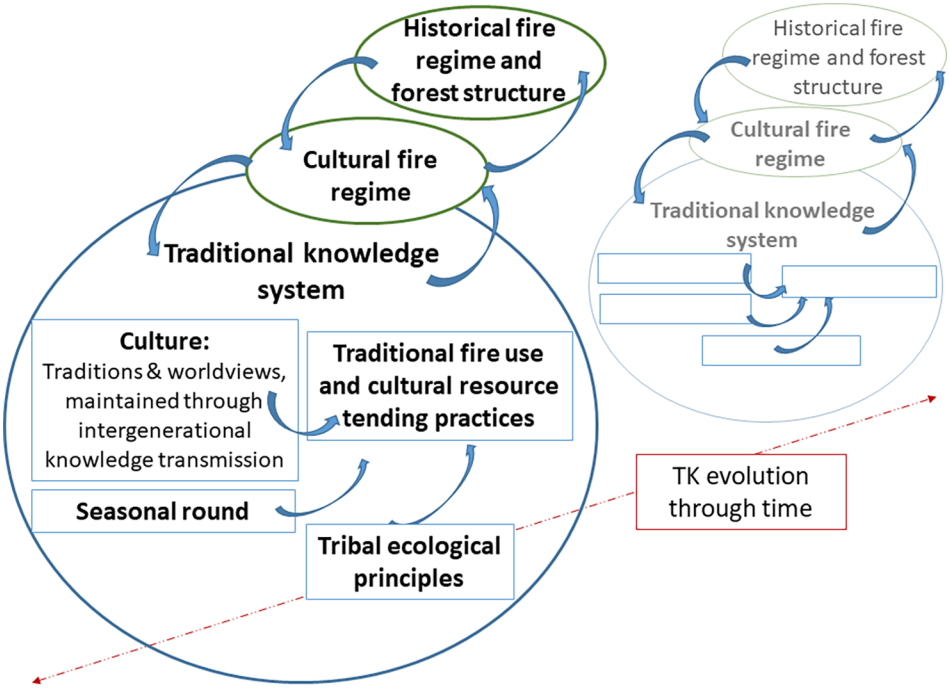

Fig. 1. Conceptual diagram of the traditional knowledge system in relation to the cultural fire regime.

CFR constituted an ecosystem's historical fire regime (Agee 1993; Lake, 2007). This said, the CFR is not necessarily in conjunction with natural fires, e.g., in the eastern U.S., where lightning ignitions are rare (Bonnicksen et al., 1999). CFRs are not well understood, particularly CFR variability across ecological zones, such as those of the eastside Cascades of Oregon (Senos et al., 2006; Lake, 2007; Lake et al., 2017). CFRs are distinct from natural fire regimes in several respects: (1) seasonality; (2) frequency; (3) severity and effects; (4) spatial scale and burn site; (5) ignition strategies; and (6) controls on fire spread, e.g., development of fuel breaks, appropriate timing of fire use (Bonnicksen et al., 1999; Kimmerer and Lake, 2001; Lake, 2007; Lake et al., 2017).

The CFR was structured by the traditional knowledge system of the inhabitant tribal group. In this paper, we use the term traditional knowledge to refer to the body of place-specific knowledge, practices, and beliefs that a society has developed over time to bring about desired ecological conditions, structure, and function (Berkes et al., 1995; Turner et al., 2000). The fire use practices that tribes historically applied to the eastside Cascades landscape were one element of a multi-themed traditional knowledge system (Turner et al., 2000): (1) traditional fire use and associated resource tending practices; (2) tribal ecological principles (understandings about the effects of tending practices on resource productivity and site access); (3) the seasonal round (the migratory pattern to fulfill resource needs); and (4) culture (traditions, ceremonies, and worldviews maintained through intergenerational communication) (Fig. 1). The traditional knowledge system, CFRs, and historical landscape structure were linked through a coevolutionary process of knowledge accumulation and adaptation in response to ecological change (Durham, 1991).

Our focus here is on the CFRs maintained by the Confederated Tribes of Warm Springs (CTWS). The CTWS are three tribal groups who historically inhabited and / or migratorily occupied sites in the eastside Cascades: the Ichishikin- (or Sahaptin) speaking tribes, including the Warm Springs, Tenino, and Dog River bands; the Kitsht Wasco (Wasco); and the Numu (Northern Paiute) peoples (Murdock, 1980; Hunn, 1990; Aguilar, 2005).[1] Our primary research goal was to generate knowledge about traditional fire use and CFRs in the three main ecological zones of the eastside Cascades—the moist mixed conifer (MMC), dry mixed conifer (DMC), and shrub-grassland (SG) zones—and thereby generate applications to forest restoration. Second, we aimed to expand understanding of the CTWS traditional knowledge system and its influence on CFRs. We examined two questions:

(1) How did the CTWS peoples traditionally use fire in the MMC, DMC, and SG zones, and thereby create and maintain CFRs?
(2) How was the CTWS traditional knowledge system structured, and how did fire use fit into this system?

One approach to understanding a society's traditional fire use is to examine which resources it relies on for subsistence and other purposes, including its cultural keystone species – the particular species that "form the contextual underpinnings of a culture" by fulfilling both a key material resource need, and an iconic cultural role as reflected in important ceremonies or narratives (Garibaldi and Turner, 2004; see also, Turner et al., 2011; Long et al., 2015). Western red cedar (*Thuja plicata*) is a cultural keystone species of Northwest coastal peoples of North America, for instance. Keystone species are often intensively managed, as guided by traditional practices and rules. For the CTWS, thinleaf huckleberry (*Vaccinium membranaceum)* (elsewhere, big-leaf huckleberry (Helliwell, 1987), big huckleberry (Minore, 1984; Anzinger, 2002), mountain huckleberry (Richards and Alexander, 2006)) — one of six huckleberry species that grow on the Warm Springs Reservation (Marsh et al., 1987) — is a cultural keystone species because of its importance as a traditional food, for food gatherers, for an annual ceremonial feast, and for wildlife hunted as game (Hunn, 1990; Aguilar, 2005). One CTWS management objective is enhancement of this species, due to its cultural importance (CTWSRO, 1992; Jimenez, 2002). In the broader scope, treaty rights and U.S. government trust responsibility to American Indians (i.e., federal legal obligations to tribes) direct that the area's tribes continue to have access to this species, including on off-reservation sites (primarily on US Forest Service lands), as they have had historically (Goschke 2016; see also, Pitt, 2015). Legal scholarship has advanced the case for co-management of the resource to maintain and/ or restore huckleberry field size and productivity

[1] However historically the Numu people occupied areas outside of the eastside Cascades, in southeastern Oregon (CTWS, 2016).

(Goschke, 2016). We found that traditional knowledge about thinleaf huckleberry (French, 1965; Anzinger, 2002), provided insight into the CFRs of the eastside Cascades.

Lacking in the literature are landscape-level, geographically-explicit analyses of CFR variability across multiple ecological zones of a landscape. This is because much of the research to date has examined fire use of individual ecological zones, resulting in knowledge about CFRs that has been assembled from disparate studies. This situation yields a fragmentary, geographically imprecise understanding of CFR variability across the ecological zones of a tribe's seasonal round and landscape. Moreover, landscape ecological data (e.g., spatial extent, patch size) relevant to our current understanding of historical fire regimes are lacking. Another area that is not well understood is the structure of traditional knowledge systems that maintained CFRs. We address these gaps by conducting a geographical analysis of CTWS burning practices across three ecological zones of the eastside Cascades, and examining the traditional knowledge system in which these practices were rooted. Knowledge about historical fire use may highlight priority zones where reintroducing traditional knowledge-based restoration strategies may have the most impact.

After describing the study area, we review the literature pertaining to historical natural resource use by the CTWS, and traditional fire use in the eastside Cascades. We then describe the mix of qualitative and geospatial methods used in this study. Our presentation of results associated with the research questions is followed by a discussion of their contributions to the literature and application to forest restoration, particularly thinleaf huckleberry restoration. We conclude by summarizing our key findings.

1.1. Study landscape and community

The Greater Warm Springs Reservation Area (GWSRA), the study landscape, spans MMC, DMC, and SG zones in the eastside Cascades (Fig. 2). We primarily employed ecological subregions (ESRs), (Hessburg et al., 2000) to delineate the three zones. In addition, in response to emergent data about resource sites, we expanded the initial MMC zone to include the area along the Cascades crest (Kuchler, 1964; USDA Forest Service ECOMAP Team, 2017).

The GWSRA consists of the Warm Springs Reservation and adjacent forest and shrub-grassland areas within which the CTWS tribes traditionally harvested culturally-valued resources (Hunn, 1990; Aguilar, 2005), including “cultural foods” – foods harvested or gathered by tribal members that have social and historical significance—as defined by the tribes’ Integrated Resources Management Plan (CTWSRO, 1992). The CTWS lands currently include the Warm Springs Reservation (259,000 ha), and treaty-ceded lands (approximately 4 million ha) where the CTWS have reserved rights (WSGVCRD, n.d.). Reserved rights sites in this study were limited to those that lie within the eastside Cascades and adjoining Cascades crest. The Ichishikin-speaking (Sahaptin) people fulfilled their food, household, and cultural needs by harvesting plant and wildlife resources found in the eastside Cascades (Hunn, 1990). The Kitsht Wasco (Wasco) also developed traditional knowledge about the area, as did the Numu (Northern Paiute), who were resettled to the Warm Springs Reservation in 1879 (Aguilar, 2005; CTWS, 2016). After reservation establishment (1855), the knowledge systems of the three tribal groups intermingled (tribal elder informants, personal communication).

2. Seasonal rounds, traditional fire use, and cultural fire regimes of the eastside Cascades

2.1. Seasonal rounds of the CTWS

At the landscape-level, the seasonal round of American Indians set the fundamental migratory spatial and temporal pattern of fire use (Turner et al., 2000), and in turn CFRs (Lake et al., 2017). “Seasonal round” means the pattern of annual migration across an area’s ecological zones to secure the variety of food and household goods that fulfill social-economic and cultural needs. Traditional fire use, as a seasonal round practice, was applied on a consistent return interval at the landscape-level (Hunn, 1990; Senos et al., 2006; Turner et al., 2011). Fire use was also applied at smaller, nested scales, specifically the habitat-scale (e.g., creating canopy openings to maintain productivity of species associated with a specific seral stage), and the population-scale (e.g., practices to maintain a particular patch) (Turner et al., 2000). Fire use was one of a variety of horticultural techniques American Indians used to maintain the composition, distribution, and spatial extent of plant communities (Anderson and Moratto, 1996; Bonnicksen et al., 1999). Others included tree girdling, pruning plants of unproductive branches, and weeding. In combination, these techniques encouraged site conditions that promoted culturally-valued resources.

Since at least 9000 years ago, when fishing settlements were inhabited near present-day The Dalles, Oregon along the Columbia River (Hunn, 1990), eastside Cascades tribes sustained themselves through a migratory seasonal round of gathering and fishing, supplemented by hunting. In addition to their dependence on the abundant salmon runs of the Columbia River system, tribes tended and gathered hundreds (or more) of forest plant species, spanning four plant categories: trees, shrubs, forbs and ferns, and grasses and grass-like plants (Marsh et al., 1987; Helliwell, 1987). The sequence of resource ripening and availability, influenced by phenological, wildlife ecological, and other seasonal factors, as well as annual climatic variability, structured the burning and tending pattern. Each of the three CTWS tribes had its own seasonal round, as structured by their territory and the distribution of culturally-valued resources (Murdock, 1980; Hunn, 1990; Aguilar, 2005).

For the Ichishkin- (Sahaptin) speaking bands, such as the Warm Springs band, dietary staples consisted of roots, especially of the *Lomatium* genus (Hunn and French, 1981), and fish, particularly salmon (Hunn, 1990). Beginning in the early spring, harvesters dug the roots and stems of plants that occur on low elevation, dry sites, particularly on dry rocky hillsides and flats, especially bitterroot (*Lewisia rediviva*), Canby’s biscuitroot (*Lomatium canbyi*), and Indian celery (*Lomatium grayi*). The round proceeded upslope as spring progressed (Hunn, 1990; Aguilar, 2005). Harvest of montane roots such as western springbeauty (*Claytonia lanceolatata* pursh) began soon after snowmelt (French, 1965). During the summer, the harvest focused on foothill species, including chokecherry (*Prunus virginiana*) and serviceberry *(Amelanchier alnifolia)*. In summer and early fall, the harvest transitioned to higher elevation forest sites, often based from encampments (French, 1965; Murdock, 1980; Hunn, 1990; Williams, 2000). For dietary and cultural reasons, thinleaf huckleberry (“We woo no Wash”), the focus of an annual ceremonial feast, was particularly important (Hunn, 1990; Pitt, 2015). The Sahaptin social-economic system also featured fibrous plants, which were used to make mats, clothing, and baskets for food gathering (Hunn, 1990).

The Wasco resided along a stretch of the Columbia River that was prime for trading, near The Dalles (Aguilar, 2005; CTWS, 2016). Celilo Village, located near the now-submerged Celilo Falls, was a main settlement. This Chinookan tribe developed a culture that resembled the Northwest Coast people. The Wasco seasonal round focused on fish (trout, pike, sturgeon, salmon, smelt, and eels)—the staple food and a trade good—, which was supplemented by roots, berries, game, and materials for household goods (Knudson, 1980; Aguilar, 2005). Gathered foods included wild potatoes, onions, hazelnuts, acorns, and huckleberries. Baskets were made of bark or grass; spoons, ladles and bowls were carved of wood.

The Numu (Northern Paiute) people inhabited the western part of the Great Basin (Fowler, 2000). Their territory extended from northern California and western Nevada into south-central and southeastern Oregon, particularly the area between the eastern Cascades and the southern Blue Mountains (Voegelin, 1955; Zucker, 1983; Couture et al.,

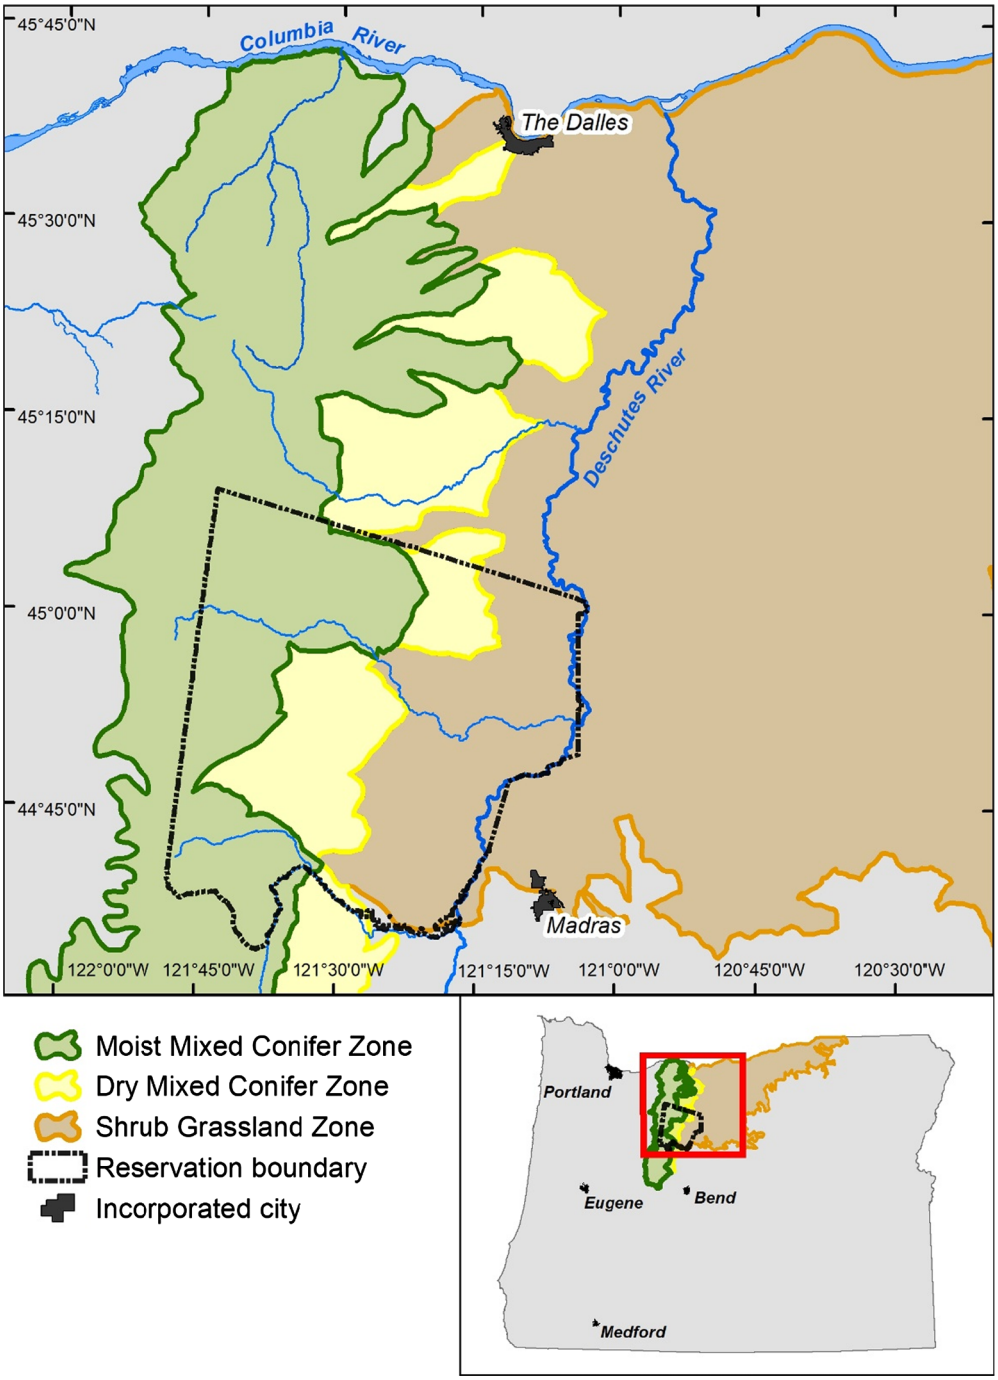

Fig. 2. Greater Warm Springs Reservation Area of the eastside Cascades of Oregon. Ecological zones are delineated mainly from ecological subregions (ESRs, Hessburg et al., 2000), with supplementation of potential natural vegetation geography (USDA Forest Service ECOMAP Team, 2017). MMC zone: ESR 4, ESR 5, and Cascades Crest (Kuchler). DMC zone: ESR 11, ESR 41, and ESR 46. SG zone: ESR 7, ESR 9, ESR 10, and ESR 45.

1986). The Numu seasonal round was adapted to the arid, drought-prone, sparsely vegetated Great Basin environment through its expansive area and "broad-spectrum" hunting and gathering (Fowler, 2000) of a large diversity of plants and animals. The family foraging group resided in temporary camps that moved in response to resource availability. Key plant resources included seed-bearing grasses for consumption, including Idaho fescue (*Festuca idahoensis*) and bluebunch wheatgrass (*Agropryon spicatum*) (Marsh et al., 1987), and at least for tribes of northern California, grasses for basketry construction and herbs for cordage (Anderson and Moratto, 1996; see also, Fowler, 2000).

2.2. Cultural fire regimes of the eastside Cascades of Oregon

In the U.S. Pacific Northwest, CFRs fall into three broad categories, generally spanning a west-to-east geography (Agee, 1993; see also Kimmerer and Lake, 2001). (1) West of the Cascade Range, the Kalapuya Indians frequently burned prairies, e.g., the Willamette Valley, and adjacent dry Douglas-fir forest. (2) In drier coastal and montane areas, including the eastside Cascades, tribal burning maintained meadow openings to promote desired plant resources and game. (3) In the inland Pacific Northwest, tribes broadcast burned grasslands and shrub-steppe regions (Shinn, 1980). Fire use varied ecologically and culturally (Boyd, 1999). In the wet conifer zone of the northern

Table 1
Ecological characteristics of ecological zones of the Greater Warm Springs Study Area, in the eastside Cascades of Oregon.

	Moist mixed conifer zone	Dry mixed conifer zone	Shrub-grassland zone
Key forest/woodland species	Grand fir (*Abies grandis*) White fir (*Abies concolor*) Douglas fir (*Pseudotsuga menziesii*) Western hemlock (*Tsuga heterophylla)* Lodgepole pine (*Pinus contorta*)	Ponderosa pine (*Pinus ponderosa*) Douglas fir (*Pseudotsuga menziesii*)	Western juniper (*Juniperus occidentalis*)
Elevation (m)[1]	820–2100	640–1100	300–700
Physiography	Deep U-shaped valleys, steep to gentle slopes, dissected ridges	Gentle to moderate slopes	Low-elevation plateau, level to gentle slopes, broken by steep V-shaped valleys
Historical fire regime	Variable regimes[2]: Mixed-severity fire/Frequent to moderately frequent intervals (< 20–50 years) Mixed severity, 50–100 year-interval High severity fire (rare)	Variable regimes[3]: PP: Low severity/1–10 year interval DF-OR: Mixed severity/ 10–25 year interval (approximately)	Variable regimes[4]: Grasslands: Low severity/very frequent (< 10 year) Shrublands: Mixed- and high-severity (25–35 year- (occasionally 50 year-) interval

[1] Marsh et al. (1987). Elevation data are approximate. Elevation ranges of zones are not mutually exclusive, due to variability in aspect and other ecological factors.

[2] "Mixed-severity": both low- and high-severity patches occur. Sources: Perry et al. (2011); Stine et al. (2014). "Low severity" = < 20% overstory trees or basal area affected. "Mixed severity" = 20–70% overstory trees or basal area affected.

[3] Sources: Hessburg et al. (2007); Perry et al. (2011); Stine et al. (2014). PP = ponderosa pine; DF-OR = Douglas fir-Oregon.

[4] The confidence of the estimated fire return interval is lower for this ecological zone than forest zones, due to limited fire scar data. Fire interval estimate based primarily on shrub and grassland species, which were historically predominant in the GWSRA; present-day prevalence of western juniper has expanded since the mid-19th century (Miller, 2005). Sources: Morgan et al. (1996); Baker and Shinneman (2004); Stine et al. (2014).

Cascades, fires were typically large and severe, potentially displacing tribes and damaging valued resources, suggesting less prevalent burning, if at all (Agee, 1993). There is evidence of Indian burning in the Oregon coast range, however (Zybach, 2003). The traditional fire use and CFRs of the eastside Oregon Cascades, where the CTWS reside today, lie within this regional context. Below, we present what is known about fire use and CFRs of the MMC, DMC, and SG zones. Table 1 presents the historical fire regimes and related ecological characteristics of these zones.

2.2.1. Moist mixed conifer zone

The CFR of the MMC zone of the eastside Cascades was characterized by small patch, low-severity burns, which maintained meadows and glades (Hunn, 1990; Agee, 1993; Williams, 2000; see also, Kimmerer and Lake, 2001). These openings dotted the matrix and edges of the true fir, Douglas fir, and other conifer communities (Agee, 1993). These openings improved the productivity of berry-producing shrub fields, including thinleaf huckleberry, grouseberry (*V. scoparium*) and blueberry (*V. caepitosum*) (Hunn, 1990; French, 1999), and increased populations of game species, such as deer and elk (Agee, 1993; Williams, 2000). Similarly, on mountain slopes of British Columbia, Canada, tribes burned to enhance berry-producing shrubs (e.g., thinleaf huckleberry, blackcap raspberry [*Rubus leucodermis*]), starch-rich roots (e.g., avalanche lily, *Erythronium grandiflorum*), and nuts (e.g., hazelnut, *Corylus cornuta*) (Gottesfeld, 1994; Turner, 1999; Turner et al., 2011).

Two factors, burn frequency and timing, controlled burn patch size and severity. Ignitions were applied to berry patches every several years. This interval is the sweet spot in which there is adequate fuel to carry a light surface burn, yet not so much fuel that the fire burns hot and creates a large patch. One Oregon Cascades settler observed, "The Indian method was to burn the old burns about every three years or as soon as there was growth enough to make a good fire" (Pioneer of 1847, in Williams, 2000:15). In general however, the burn interval may have been longer than that noted in the settler's account, due to the > 7-year period required for abundant berry production (Minore, 1984; Anzinger, 2002). Burns were timed to coincide with early autumn rain events, or in the early summer before forest fuels became dry, which moderated flammability (Hunn, 1990; Williams, 2000).

2.2.2. Dry mixed conifer zone

Forest characteristics relevant to the historical fire regime of the DMC zone are the historical presence of grasses; a well-developed understory vegetation component; and in ponderosa pine-dominant forests, a diverse age class structure due to susceptibility of older and/or scorched trees to native bark beetle-caused mortality (*Dendroctonus ponderosae; D. brevicomus*) (Agee, 1993). A frequent (approx. 10–25 year), low-severity historical fire regime promoted these vegetation and forest structural characteristics (Agee, 1993; Hessburg et al., 2007; Stine et al., 2014). Evidence of traditional fire use in the DMC zone in the eastside Cascades is sparse. For the northern Rockies however, there is suggestive evidence of widespread Indian burning of DMC forests and grasslands (Barrett and Arno, 1982).

2.2.3. Shrub-grassland zone

Tribal groups may have applied broadcast, low-severity fire to the SG zone, though the paucity of historical ecological records (e.g., fire scars) limits the certainty of conclusions (Agee, 1993). Immediately to east of the SG zone of this study, in the east-central rangelands of Oregon, the Paiute burned in late summer and early fall (Shinn, 1980). For instance, in September 1826, a Hudson's Bay Company explorer traveling east of the Deschutes River noted recently burned-over land, consistent with practices elsewhere, such as the Snake River (Shinn, 1980; Agee, 1993). In less remote places, there is suggestive evidence that tribes broadcast burned large areas frequently (perhaps even annually) (Shinn, 1980). Fire use frequency probably varied widely in association with human population density, as well as social-cultural motivations, specifically signal fires, insect gathering, and hunting (Agee, 1993).

3. Materials and methods

3.1. Approach

To answer our research questions we undertook three main steps. First, we identified culturally-valued resources for the Warm Springs Reservation and located their occurrence by ecological zone. Second, we investigated whether and how fire was used to manage these resources. We sought to understand fire use within the context of the CTWS traditional knowledge system. Third, we sought evidence of how CFRs affected historical fire regimes.

As noted, a major challenge of conducting research on CFRs is the fragmentary record and sparse geospatial data regarding traditional fire use by specific tribes (Turner, 1999; Williams, 2000). We addressed this challenge by developing an anthropological-landscape ecological GIS

framework and a traditional knowledge database. We constructed the integrative GIS framework in steps. (1) We delineated the seasonal round area of the CTWS peoples, based on secondary literature (e.g., French, 1965; Murdock, 1980; Hunn, 1990). (2) We divided this area into its constituent ecological zones (MMC, DMC, SG) constructed from biophysically modeled ecological subregions (Hessburg et al., 2000) and potential natural vegetation (Kuchler, 1964; USDA Forest Service ECOMAP Team, 2017). (3) Historical resource use sites and migration features (trails, settlements) were entered into the GIS. (4) We analyzed the elements of the traditional knowledge database by ecological zone. This approach revealed insights into geographical variation of traditional fire use and CFRs.

3.2. Materials and data processing

3.2.1. Qualitative analysis of traditional knowledge

We constructed a traditional knowledge database, featuring qualitative data, from three sources: oral history interviews, a participatory GIS (PGIS)-based workshop, and archival records (McBride et al., 2017). Where needed, CTWS ethnobotanical and forest ecological sources served as a data cross-reference (e.g., French, 1965; Marsh et al., 1987; Helliwell, 1987; Jimenez, 2002). The oral history interviews (n = 14), conducted with key informants in 2014–2015, employed a semi-structured protocol (Patton, 2002). Interview guide topics were traditional fire use of various ecological zones and influences on fire use. The PGIS workshop, conducted in November 2017, generated focus group-based oral histories (3 focus groups, 32 participants) and geographical data about the interview guide topics. Standard PGIS techniques consist of participant mapping of features relevant to community knowledge and/or values (Besser et al., 2014; McBride et al., 2016). We developed a novel PGIS technique that was adapted to the CTWS community. We supplemented maps with ethnohistorical photographs that depicted activities, places, and people familiar to CTWS participants. We also used base map features that included historical village sites and trail networks derived from a federal survey conducted in 1922–1926, and botanical zones containing culturally-important resources derived from primary and secondary sources (Marsh et al., 1987; Helliwell, 1987; Jimenez, 2002; UWLSC, 2008). These photographs and base map features elicited interactive oral histories associated with each ecological zone. To protect sensitive cultural data, all place-specific data were aggregated by ecological zone. We also extracted data from archival resources (ethnographic records, survey maps) collected from the David H. and Kathrine S. French Papers and the Eugene Hunn Papers, held by the University of Washington and Reed College.

Interviews and the PGIS workshop were recorded and the recordings transcribed. We analyzed the qualitative data using a coding scheme developed through a grounded theory approach (Patton, 2002). We identified emergent themes from the data, which we related to *a priori* themes from the literature. This process generated the four traditional knowledge system elements (Fig. 1) that structured the coding scheme and was applied to the transcribed data. Inter-coder reliability procedures consisted of examining data examples as a team to assess and refine the coding scheme.

3.2.2. Geographical characterization of traditional fire use and burn land-cover

Geographical characterization of traditional fire use and burn land-cover was derived from the Cascade Range Forest Reserve inventory conducted by the U.S. Geological Survey, in 1901 (Langille et al., 1903); ethnohistorical slide imagery of cultural food harvest sites, 1952–1954 (UWLSC, 2008); and oral history interviews. We also quantified the historical village site and trail network data from the PGIS base maps by ecological zone to improve understanding of where human activity was concentrated.

Historical burn land-cover polygons, acquired from the Cascade Range Forest Reserve inventory, were processed using ArcMap 10.3.1. The purpose was to develop baseline data of historical burn geography as a potential influence on subsequent fire use, regardless of ignition source (lightning vs. anthropogenic). We derived data for two variables, burn land-cover area and patch size, from this inventory. Limitations are noted: (i) DMC forest burns are potentially under-represented because surveyors tended to focus on high-severity fire (Langille et al., 1903); (ii) paucity of ignition source information (natural vs. anthropogenic); and (iii) an absence of data for the SG zone, which was outside the inventory area.

The ecological conditions of cultural food sites were derived from the ethnohistorical imagery of D.H. and K.S. French. These anthropologists conducted field work on the CTWS peoples in the mid-20th century, particularly 1949–1956 (UWLSC, 2008). Site locations of the images were identified and entered into the project GIS using U.S. Geographical Survey (USGS) 7.5 min topo-quadrangle maps in consultation with forest managers (CTWS Branch of Natural Resources, Mt. Hood National Forest) and tribal informants.

Spatial data about fire use were gleaned from the PGIS workshop-based oral histories (conducted in 2017) and oral history interviews (2014–2015). Our interview protocol elicited information about the location, timing, severity, and patch size of anthropogenic fire. We elicited data about reference forest structure conditions using imagery from two sources: historical photographs of the study area showing forest type and successional stage, and stand simulations of forest type and successional stage, constructed from Visual Nature Studio software (USDA Forest Service, n.d.).

4. Results

4.1. CFRs among ecological zones of the GWSRA

Evidence from the oral history interviews, participatory GIS, archival data, and spatial analysis revealed that the CTWS peoples deployed fire to increase the ecological productivity of, and access to, certain disturbance-dependent culturally-valued resources in the east-side Cascades. However, fire use varied among ecological zones (Table 2). We found evidence of traditional fire use in the MMC zone, and an absence of such evidence in the DMC and SG zones, which we interpreted to mean that the CTWS peoples maintained a CFR in the MMC zone only. Diverse cultural foods of the seasonal round were tended historically in all three zones (Fig. 3). The ecological utility of burning apparently varied, however, which contributed to fire use variability among ecological zones. In addition, analysis of the historical travel network revealed that trail length was concentrated in the MMC zone (59.0%), compared to the DMC zone (31.8%) and SG zone (9.2%). Settlements were primarily located in the SG zone (80%) and DMC zone (20%). The dense trail network into MMC forests from lower-elevation SG zone settlements supported an overall picture of migratory burning and tending in this zone (e.g., based from encampments).

In the MMC zone, the CFR consisted of low severity, frequent (every few years), small-scale ignitions applied to existing huckleberry shrub sites according to most, but not all, informants. The main reasons to burn were to clear away competing vegetation from the thinleaf huckleberry shrubs and maintain access. If left unchecked, competing vegetation would likely have reduced huckleberry productivity owing to the combination of moist growing conditions and fire recurrence interval variability. Besides burning, other practices to maintain productivity were harvesting and girdling trees, which maintained canopy openings, and possibly weeding out competing shrubs.

In the DMC zone, culturally-important resources included roots (e.g., wild carrot (“saw-wickt”, *Peridérida gairdneri*)); bulbs (e.g., blue camas (“wa-ka-mo”, *Camassia quamash*), which occurred in meadows); and chokecherry, a berry-producing shrub. Thinleaf huckleberry also occurred in the DMC zone of the GWSRA, though with lower productivity than in the MMC zone (Jimenez, 2002; USDA Forest Service,

Table 2
Cultural fire regime and traditional knowledge across ecological zones of the Greater Warm Springs Study Area.

	Moist mixed conifer zone	Dry mixed conifer zone	Shrub-grassland zone
Cultural fire regime	Low severity, frequent ignitions applied to specific plant resources	Fire use not reported	Fire use not reported; natural ignitions perceived as beneficial
Tribal ecological principles	Burning promotes ecological functions that maintain huckleberry productivity (control of competing vegetation and insects, soil replenishment) and resource access	None reported	Fire replenishes productivity of edible roots
Key resources	– Bear grass – Mountain ash berries – Pine nuts[1] – Thin-leaf huckleberry – Western red cedar	– Black lichen – Blue camas – Chokecherry – Thin-leaf huckleberry[2] – Wild carrot	– Biscuitroot – Bitterroot – Desert parsley – Indian celery
Cultural relevance	Huckleberry feast ceremony	None reported	Root feast ceremony
Seasonal round mode[3]	Large, extended family group, long duration	None reported	Individual/small group, short duration
Trail distribution (% length in zone)	59.0	31.8	9.2
Village distribution (% in zone)	0.0	20.0	80.0

[1] White bark pine (*Pinus albicaulis*) may be the species of the pine nuts historically gathered in the MMC zone, as indicated by several sources: Keane, R.E., Tomback, D.F., Aubry, C.A., Bower, A.D., Campbell, E.M., Cripps, C.L., Jenkins, M.B., Mahalovich, M.F., Manning, M., McKinney, S.T. and Murray, M.P., 2012, A range-wide restoration strategy for whitebark pine (Pinus albicaulis), Gen. 	Ecological subregion 46	0.0	0.0
Shrub-grassland zone	n.a.	no data	no data

[1] Names corresponding with ESR numbers are of the form: ESR number = Bailey's ecoregion – Dominant Precipitation Class(es) – Dominant Potential Vegetation Group(s) – Dominant Solar Radiation Class(es) (Hessburg et al., 2000). 4 = M242C – Wet – Warm – MFCF – Low Solar; 5 = M242C – Moist – Warm – MF/CF – Mod Solar; 11 = 200/300 – Dry Moist – Warm – MF/DF – Mod Solar; 41 = M242C – Moist – Warm – MF/DF/CF – High Solar; 46 = M242C – Moist – Warm – DF – High Solar. M242C = Eastern Cascades Section. 200/300 = Okanogan Highlands - Eastern Cascades Sections.

[2] The area of this ecological unit lies outside the geographical extent of the ESR framework (Hessburg et al., 2000). Thus, this unit is derived from the potential natural vegetation framework (Kuchler, 1964; USDA Forest Service ECOMAP Team, 2017).

2010). Our informants reported an absence of burning in this drier zone—a surprising result, given evidence elsewhere that demonstrates burning to promote geophytes (Anderson, 1997, Anderson and Lake, 2016). Lower precipitation and a comparatively frequent natural fire return interval may have constituted an ecological combination that posed less need for fire use in the eastside Cascades.

Edible roots were (and are) the primary cultural food of the SG zone. Staple roots included biscuitroot ("coush", *Lomatium cous*) and bitterroot ("Piyati", *Lewisia rediviva*). The cultural importance of these starch-rich foods was manifested in the root feast, an annual ceremony. These foods were tended through digging practices of the seasonal round. Apparently, fire was not employed by the CTWS to promote resource productivity in this zone, according to tribal informants. However, informants noted increased resource productivity in the years after a natural fire burned over gathering sites; such ignitions were spoken of as a positive event. In this arid zone, the need to control competing vegetation and improve resource access may have been minimal.

Our analysis of historical burn land-cover data provided a landscape-scale context for assessing the role of CFRs in historical fire regimes. The burn area distribution was disproportionately high in the MMC zone (12.3% of zone area) compared to the DMC zone (1.7% of zone area); (SG: no data), (Table 3, Fig. 4). Variability in burn severity, persistence, and cumulative fire scar area may have contributed to the magnitude of difference in burn area among zones, however. The forest inventory (Langille et al., 1903) indicates that burn openings were prevalent in the MMC zone, regardless of initial ignition source (e.g., lightning, settler burns), which traditional fire use appears to have subsequently maintained. Within the MMC zone, burn land-cover was prevalent in the ecological subregions where huckleberry fields were maintained, particularly the Cascades Crest Forest (12.8%). Burn patch size was comparatively large in the MMC zone (406.7 ha) relative to the DMC zone (107.0 ha).

The CFR of MMC forests contributed to the maintenance of openings in mid- and high-elevation montane sites according to ethnohistorical slide imagery and oral history data (Fig. 5). The CTWS applied frequent, low-severity burns on an as-needed basis to maintain openings apparently initially created by large conflagrations. Ignitions were applied to targeted shrub patches, thereby tending to maintain and/ or expand existing openings, estimated at tens to hundreds of hectares (based on historical inventory data), rather than create new openings. This practice resulted in a shifting anthropogenic disturbance pattern across an area that spanned an estimated 220,000 ha across 24 cultural food resource sites on the mid- and upper-elevations of mountain slopes (Mt. Hood, Mt. Jefferson) and buttes of the eastside Cascades and Cascades crest.

4.2. Traditional fire use of thinleaf huckleberry in the CTWS traditional knowledge system

Traditional fire use by the CTWS focused on thinleaf huckleberry. Further analysis revealed that fire use was maintained by a traditional knowledge system composed of four interconnected elements: (i) resource tending practices; (ii) tribal ecological principles; (iii) the seasonal round; and (iv) culture (see Appendix A).

4.2.1. Resource tending practices

Most informants were told by their elders, or had seen as a child, that burning was intentionally used to manage huckleberries. However, one participant reported that tribal members relied on lightning-ignited fires, yet indicated that humans promoted ignitions by preparing site conditions, such as concentrating flammable material (e.g., conifer needles), then praying for lightning strikes. Ignition sites occurred in the MMC zone on Mount Hood and Mount Jefferson, particularly along the Cascades crest. Huckleberry patches were described as having sparsely distributed, small-diameter, short trees, a dense field structure of huckleberry shrubs, and few other understory plants. Huckleberries were also harvested at lower elevation DMC sites. However, informants reported that fire was not used to manage berry patches in the DMC zone. Fire does not appear to have been used extensively, if at all, to manage other resources, such as edible roots, lichen, and medicinal plants in this zone. This said, one interviewee reported that the Paiute used fire to manage roots and possibly oak in lower elevations east of the reservation. All other informants reported that fire was not used to manage roots, although several had observed an increase in root productivity on some sites after burn exposure.

Participants described a rotational system in which different areas were burned each year. One informant reported a 7-year rotation interval. Fires were typically set in the fall at the end of the berry season when temperatures were lower, at precipitation onset, thereby promoting low-severity burns. Occasionally fires were set in late spring but not in the summer because they would be too difficult to control. Small (e.g., < 1 ha), low-intensity burns were designed to control competing underbrush (e.g., snowbrush (*Ceanothus velutinus*)) while not damaging the berry bushes. Fire control practices consisted of clearing flammable material (needles, small branches) from the target area and stationing fire guards. Rather than burn one large area simultaneously, a series of micro-fires (~1 m in diameter) were set. Several informants reported that rituals and prayers were used to bring rain to control the burns.

Fire specialists determined when ecological conditions were appropriate for burning. Fire specialists were older males who had been trained from an early age and had accrued knowledge to determine

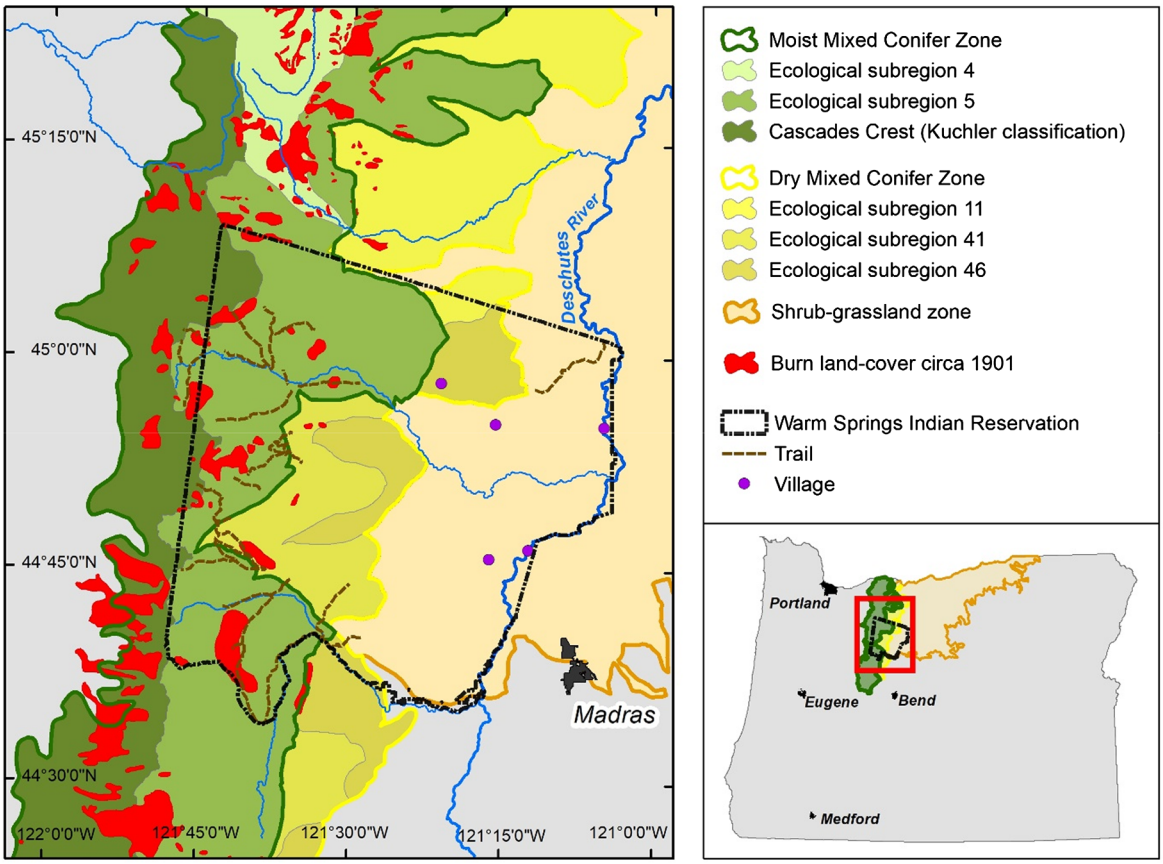

Fig. 4. Historical (1901) landscape pattern of burn land-cover, Greater Warm Springs Study Area. Land-cover data: Langille et al. 1903. Trail and village data: federal survey of Warm Springs Reservation, 1922–1926. For ecological zone details, see Table 3.

when weather conditions were conducive to controlled burns. Internal regulation of fire use by the community has been observed elsewhere (Huffman 2013). Huckleberry resource management was a collective endeavor rather than an individually-organized practice, as described by tribal informants.

4.2.2. Tribal ecological principles

Controlled burns were based on a set of tribal ecological principles and aimed to fulfill several purposes: insect control, reduction of understory vegetation and downed debris, control of tree encroachment, huckleberry patch expansion, stimulation of new plant growth, and soil fertility replenishment. Burn practices were designed to produce stand structure conditions that promoted huckleberry productivity, consistent with previous findings (French, 1999). Target conditions included open sites with scatterings of small diameter trees within the berry fields, relatively little underbrush, few downed logs, and large, densely concentrated huckleberry bushes. Removal of competing understory vegetation improved ecological productivity (e.g., of berries) and facilitated traversing of the fields by harvesters. These cultural site characteristics are also important to beargrass (*Xerophyllum tenax*), which sometimes occurs intermixed with huckleberry shrubs (Hummel and Lake, 2014).

4.2.3. Seasonal round

Fire use was integrated into the seasonal round. In late summer and early fall, tribal members traveled from villages, primarily located in the low elevation SG zone up into the MMC zone to access high country berry fields, deer and elk hunting grounds, and other resources. Base camps near the berry fields, where multiple extended families camped, functioned as an important social structure of the seasonal round. Women and children did most of the berry picking; men handled the packhorses and hunted for deer and elk. The volume of annual huckleberry harvest was substantial (2.5–8 gallons (estimated)/harvester/day).

4.2.4. Culture

The use of fire for huckleberry management was strongly associated with CTWS culture, particularly prayers and rituals. The huckleberry feast, held in early August, was (and remains) an important annual ritual in honor of the huckleberries. A number of participants attributed the poor present-day condition of berry fields to failure by tribal members to properly honor the huckleberries. They highlighted the importance of treating the plants that sustain the tribes with respect; otherwise, ecological productivity would be reduced.

Community cohesion embodied in the intergenerational and interfamilial gifting of huckleberries was a primary tending motivation. A rite of passage for CTWS adolescent girls—a counterpart to a hunting rite for adolescent boys—was a girl's first harvest, which culminated in gifting.[2] Similarly, the huckleberry feast functioned as a ceremonial expression of the longhouse religion, and included ritualized food songs, speeches, and reciprocal gifting. The ceremony brought together the community in sacred thanksgiving.

A worldview of human-nature interdependence also governed fire use and associated practices among the CTWS: if people take care of nature, nature will provide. Linked to this worldview is the belief that plants will reduce productivity if people neglect to tend them. Harvesting berries and edible roots was viewed also as benefitting and thereby honoring these cultural foods.

Fig. 5. Historical reference conditions of sites traditionally tended for big-leaf huckleberry, in the moist mixed conifer zone, Greater Warm Springs Study Area. Fire use was applied into the late 1920s-/early 1940s. Mt. Hood area resource site, 1953, depicting upslope and downslope views (A, B). Multorpor Mountain berry picking area, western slope, 1952; Multorpor Mountain is a small volcanic cone on the southern slope of Mt. Hood (C, UW negative 38660). Mt. Hood area from Multorpor Mountain berry picking area, 1952 (D, UW negative 38662). *Wasquapam satas*, loosely translated as "site where the Wasco harvest", Warm Springs Reservation, 1954 (E, F). Images are derived from the University of Washington Libraries, Special Collections, David H. and Kathrine S. French Papers, Accession 5496-001, Box 54. (Slide images not assigned a UW negative number unless otherwise stated.)

The intergenerational transmission of traditional knowledge was largely field-based and informal, with children expected to learn by watching and imitating their elders. For specialized knowledge such as fire prayers and practices, knowledge was passed on to someone who was recognized by the elders as having a gift for being a "seer". The longhouse ceremonies, such as the huckleberry feast, were key occasions during which cultural knowledge was transmitted to tribal youth.

4.3. Social and ecological ramifications of the disruption of traditional fire use

Traditional fire use on the GWSRA continued on some sites into the late 1920s/early 1940s, according to most tribal participants, although one informant observed that burning had stopped by the late 1800 s. It may be that burning continued into the 20th century on sites where enforcement was limited. The cessation of traditional burning was due in part to the emergence of fire suppression policies of forest land management agencies, as occurred for the Karuk of northern California (Norgaard, 2014), and the Klamath (Turner, 2011). One example policy may have been the US Forest Service – state Cooperative Forest Fire Prevention Campaign of the early 1940s to protect wartime timber supply (Williams, 2009). Another potential factor in fire use disruption may have been escaped burns. One participant noted a large fire that took place in 1938 near Mount Hood—attributed to tribal members burning their huckleberry fields—as a key turning point in burning prohibition. This fire burned the same year that a fire (40,000 ha) occurred in the SG zone of the Warm Springs Reservation (Logan, 1982). Finally, fire use cessation was attributed to the younger generation of men not acquiring the necessary knowledge or skills during the post-World War II era, when they began shifting into new occupations. This combination of change in forest policy, social conditions, and fire events may have increased pressure on CTWS members to curtail burning practices.

The disruption of traditional fire use has contributed to an array of social ramifications (Table 4). One, tribal youth reportedly have experienced a loss of traditional knowledge of burning techniques, a diminished interest in food gathering, and an erosion of tribal language fluency. In response, the Warm Springs community—as one of thirteen tribes operating within the U.S. Fire Learning Network—has worked to recover and rejuvenate this traditional knowledge, including tribal languages, by engaging tribal youth in traditional burning practices (Huffman, 2013). Two, the overall community has reportedly experienced a weakening of traditional beliefs, the traditional relationship with the natural world, and community cohesion.

Fire use disruption also brought about ecological change (Table 4). All of the study participants described the present-day montane huckleberry fields where they had picked as youth as "overgrown," resulting in decreased patch area and productivity, and impeding access due to dense undergrowth. Key ecological changes included an increase in competing vegetation and tree size, resulting in more shade, smaller berry shrubs, and smaller patches. An implication of the understory vegetation accumulation is an increase in fuel loading and potential fire risk and severity if and when wildfires burn after a long absence. Additionally, informants reported the incursion of "non-traditional" plants and willows and more downed wood, further inhibiting access.

Table 4
Social and ecological changes and ramifications of disruption of traditional fire use.

Category	Changes	Ramifications
Social	Loss of ecological knowledge of traditional fire use practices and gathering site locations	– Diminished interest among youth in traditional food gathering and tending – Reduced fluency of language associated with traditional food gathering
	Weakening of traditional beliefs	– Huckleberry plants no longer honored; consequently, the resource is making itself less available for harvest, as perceived by traditional food gatherers – Harvest for huckleberry feast sometimes occurs outside the tribes' traditional territory – Huckleberry fields neglected, due to lack of harvest (harvest perceived by traditional gatherers as a fundamental mechanism of resource tending) – Some tribal members sell huckleberries –a departure from the traditional view that surplus berries should be given to elders and others who aren't physically able to gather them
	Weakening of community cohesion	– Fewer tribal members respect traditional beliefs, behaviors, and spiritual practices
Ecological	Forest encroachment into huckleberry patches	– Decline in huckleberry productivity and area
	Increased density of understory species other than huckleberry plants	– Increased competition for sunlight and soil nutrients, decreased size and productivity of berry bushes, and impeded access to and within berry fields
	Increased fuel loading of downed woody debris	– Impeded access to and within berry fields – Increased fire risk and susceptibility to higher severity, more damaging fires, especially under extreme conditions (e.g., summer drought)

5. Discussion

5.1. Fire use in the eastside Cascades in relation to CTWS traditional knowledge

Our analysis revealed that the distribution of fire use across ecological zones of the eastside Cascades was maintained by the CTWS traditional knowledge system, which was comprised of four interrelated elements: resource tending practices, tribal ecological principles, the seasonal round, and culture. These findings expand upon the existing understanding that fire use is a part of the traditional knowledge system (Turner et al., 2000; Lewis and Anderson, 2002; Stewart, 2009; Huffman, 2013; Lake and Long, 2014) in that we relate fire use to a landscape ecological framework. The seasonal round provided valuable insight into the spatial and temporal pattern of fire use. This factor is associated with data about the biogeographical distribution of culturally-valued plant resources, and by extension the spatial pattern of practices to enhance and access such resources. In addition, the seasonal round denoted data about an array of factors influential to fire use (e.g., encampment duration, encampment group size, harvest volume, preservation techniques). For instance during dry, windy periods, the escaped embers of fires set to dry and preserve the harvest may have augmented intentional burning (Minore et al., 1979). Finally, an aspect of the seasonal round that provided insight into the spatial pattern of fire use was quantification of the trail network. We found that the zone with the highest density of trails, indicating prevalent tribal activity, was associated with fire use. Similarly in the western Klamath Mountains, a relationship has been detected between the spatial patterns of the trail network and settlements and traditional fire use (Lake, 2013). These findings demonstrate how the seasonal round —a type of cultural geographical variable— can reveal historical linkages between tribal societies and landscapes, thereby guiding current restoration.

Our data also highlighted the role of culture in fire use pattern. Culture includes the traditions (e.g., ritualized ceremonies) and social roles (fire specialists; determinants of the start of the huckleberry harvest) through which fire use and other tending knowledge was maintained over generations. For instance, huckleberry traditional knowledge was stewarded by small, designated groups of men and women; in time, these groups transmitted this knowledge to the next generation through a deliberate process of designating specific tribal youth to learn and steward the traditional knowledge. Huckleberry ("We woo no Wash") drew together the tribal community through intergenerational and interfamilial gift-giving, the longhouse religion, as well as gathering by family groups at seasonal encampments, making it a cultural keystone species. When considered in light of previous studies (Berkes et al., 1995; French, 1999; Turner, 1999; Stewart, 2009; Long et al., 2015), we conclude that CTWS traditional burning in MMC forests of the eastside Cascades was purposeful, systematically deployed, intergenerationally maintained, guided by a highly valued knowledge system, and understood as a spiritual obligation and a stewardship responsibility.

Our results also highlight the ramifications of the disruption of traditional fire use on the CTWS community and resources, as has been documented elsewhere in the Pacific Northwest (Turner, 1999; Senos et al., 2006; LeCompte, 2018, and the Inland Northwest (Carroll et al., 2010)). By the late 1920s/early 1940s—about eight decades after the 1855 Treaty with the Tribes of Middle Oregon and roughly contemporaneous with the onset of commercial forestry on the Warm Springs Reservation (Logan, 1982) –fire use had been largely discontinued. Traditional knowledge must be applied if it is to persist and flourish (Charnley et al., 2007; Huffman, 2013; Lake et al., 2017). We found that traditional knowledge has a community basis. An implication of this finding is that unless the community is engaged, traditional knowledge risks deterioration (LeCompte, 2018).

5.2. CFRs of eastside Cascades ecological zones

Our analysis of the MMC zone of the eastside Cascades revealed a CFR characterized by a shifting rotation of frequent, low-severity, small-scale burns at targeted huckleberry patch sites. These results correspond with those of montane areas elsewhere in the Pacific Northwest, including of the Stl'atl'imx (Lillooet) peoples of the Pemberton Valley, B.C., Canada who deployed fire to tend berries and montane roots (*Erythronium, Lilium*) (Turner, 1999), and the Gitksan and Wet-suwet'en peoples of northwestern B.C., who tended mid-elevation *Vaccinium* berry patches (Gottesfeld, 1994). Oral histories have produced evidence of a several-year, rotational fire use pattern in montane areas of B.C. and ecological reasoning that corresponds with the results of this study: "when it got [too] bushy" (Turner, 1999:189), individuals burned one hillside area, then redirected harvesting to an unburnt area. In combination, these findings provide evidence that tribal peoples maintained a CFR in MMC forests of the Pacific Northwest.

Our findings also provide insight into how the CFR of MMC forests may have influenced the zone's historical fire regime and landscape structure. Our results correspond with the evolving picture of MMC zone dynamics that large fires accounted for the most area burned, yet small and medium fires were the most numerous (Stine et al., 2014). The CTWS apparently contributed to fire frequency by applying frequent, low-severity burns on an as-needed basis to maintain openings initially created by large conflagrations, as indicated in the 1901 forest inventory. This finding also expands upon previous research (French,

1999) by identifying geographical evidence that sites traditionally maintained for huckleberry tended to occur on or near large burn scars. This result suggests that the CFR may have contributed to the variability of the mixed severity fire regime, as occurs in the Pacific Northwest (Perry et al., 2011). That is, CTWS ignitions may have intermixed frequent, low-severity fire with the comparatively infrequent, natural ignitions that initially created large openings. The resulting patchwork of burn openings and fuels distribution may have increased historical forest resilience to wildfire (Stine et al., 2014; Hessburg et al., 2015).

At the landscape level, our results show evidence of variability in the eastside Cascades CFRs. We found that traditional fire use was pronounced in mid- to high-elevation MMC forests, but unpronounced for the DMC and SG zones. This result suggests that the CTWS varied ignitions in response to the practical need and appropriateness in different ecological zones and associated natural fire regimes. For certain roots harvested by the CTWS in the SG zone, our results differ from existing studies. For geophyte food plants such as Indian carrot, CTWS informants reported that fire was not purposefully applied, although natural ignitions were perceived to be beneficial. This result contrasts with that of many Sierra Nevada tribes (e.g., Sierra Miwok , North Fork Mono, and others), who reported burning, along with tilling, to promote this species (Anderson, 1997; Anderson and Lake, 2016). For the CTWS, this species tends to grow on low elevation meadows (Marsh et al., 1987), which may be slightly drier and less prone to competing vegetation than those of the Sierra Nevada. Similarly, the absence of CTWS fire use to promote camas contrasts with that reported for the Salish of southern Vancouver Island (Turner, 1999; Turner and Peacock, 2005). Camas harvested by the CTWS tends to grow in meadows (Marsh et al., 1987), whereas that harvested by the Salish occurred on Gerry Oak savannah within the Western Hemlock Biogeoclimatic zone, which is thought to be prone to afforestation. These contrasting findings may be due to regional differences in fire utility. We conclude that fire use variability in the eastside Cascades was driven by its relative ecological appropriateness for maintaining culturally-important resources, as has been shown in Pacific coastal North America (Turner et al., 2011).

5.3. Applications

5.3.1. Applications to thinleaf huckleberry enhancement and forest restoration

Our analysis revealed that the cessation of fire use (by the 1920s-1940s) contributed to reduced productivity and trail navigability of thinleaf huckleberry patches, despite the persistence of this understory shrub (USDA Forest Service, 2010). Informants cite two main causes of this ecological change. First, little sunlight reaches the shrub patches, due to canopy closure and encroachment by trees and competing undesired shrubs—a finding that corresponds with other studies of the eastside Cascades (Senos et al., 2006; USDA Forest Service, 2010; LeCompte, 2018), and B.C., Canada (Turner, 1999). Second, on commercial forest management units, trampling by equipment, vehicles, and yarding can damage shrub patches in the short-term; in addition, logging appears to promote weedy annuals and biennials (Anzinger, 2002). However, foresters note that these impacts subside over time. Soil moisture loss is a compounding factor on sites prone to evaporation and drainage (CTWS Branch of Natural Resources, personal communication). These findings highlight the need for huckleberry restoration prescriptions.

In response, natural resource managers of the GWSRA have adopted huckleberry enhancement prescriptions (Jimenez, 2002; USDA Forest Service, 2010). These prescriptions address objectives to enhance cultural foods for use by tribal members while fulfilling forest stand growth and yield targets, as directed by the agency's forest plan (CTWSRO, 1992). Huckleberry treatments strive to balance appropriate levels of sunlight and shade by retaining a partial overstory (canopy closure target: 30–50% (CTWS personal communication)). CTWS managers are implementing a variety of treatments, which range from commercial thin (70–110 trees per acre (tpa)), to "landscape" intermediate thin (50–70 tpa), to shelterwood (15–25 tpa), and "shelterwood – light" (10–15 tpa) on selected commercial harvest units in the MMC zone (management groups: grand fir; western hemlock-beargrass; mountain hemlock-lodgepole pine, and Pacific silver fir). These harvest modifications constitute an initial transition away from the intensive timber management of the 1960s-1970s, which featured even-aged harvests (clear-cut and plantation) (Logan, 1982). Such harvest modifications are notable, given the constraints posed by long-term management plan harvest commitments (CTWSRO, 1992; CTWSRO, 2012), forest operations, and restoration funding limitations. Managers report that huckleberry treatments allow sunlight to reach understory vegetation and reduce soil water loss, resulting in improved huckleberry productivity. In addition, a snowpack logging prescription (snowpack minimum: 0.9 m to 1.5 m) protects understory vegetation. Finally, CTWS managers have adopted road-edge vegetation retention, which reduces the deposition of detrimental roadbed dust onto huckleberry shrubs.

Although silviculture proxy fire treatments reportedly promote the objectives of forest growth and resource enhancement, such proxy treatments fall short of replicating the ecological benefits of traditional fire use. At the Big Huckleberry Summit (2007), Muckleshoot, Nisqually, Umatilla, and Warm Springs participants reported that fire performs many ecological functions, including nutrient cycling, reinvigoration of plant sprouting, and control of detrimental insects and diseases (LeCompte, 2018). This finding highlights the utility of fire reintroduction on sites where silvicultural objectives allow.

Our results about CFR scale suggest how a nested, multi-level framework, spanning patch- ("landscapes within landscapes") and landscape-levels (Hessburg et al., 2015:1089; see also, Stine et al., 2014) may be employed to reintroduce fire. At the finer-scale, our analysis revealed that the CTWS historically used fire in a rotational pattern to maintain patch openings in the MMC zone (Fig. 5). This finding suggests that one approach to restoration is a multi-stage fire reintroduction process. First, low severity fire initially could expand (or create) forest openings. Second, on-going, shifting application of frequent fire or proxy treatments around the management unit could maintain openings.

At the landscape-level, our analysis revealed that the spatial extent of the CFR (~220,000 ha) spanned an area that currently includes multiple ownerships—the Warm Springs Reservation and the Mt. Hood National Forest. This finding suggests that coordinated planning across ownerships is important to manager capacity to restore forest resilience and enhance cultural food resources. Incident management teams could allow wildfire use in areas that promote desired resources, provided that they do not pose a threat to life and property (Wildland Fire Decision Support System, 2018). However, many reservations, as well as private owners, have tended to favor fire suppression to protect timber resources, due to an array of social-economic and cultural constraints (Steen-Adams et al., 2017). Thus, efforts toward landscape-level, coordinated restoration may require dialogue both within tribal communities and across tribal and nontribal communities about acceptable trade-offs of reintroducing traditional fire as a management tool.

5.3.2. Applications to community engagement

Our research has applications for engaging communities who hold traditional knowledge. Our team's interactions with the CTWS revealed protocols that can promote productive collaboration between forest scientists, tribal communities, and tribal natural resource managers. Traditional knowledge is sacred knowledge (Berkes et al., 1995), some of which may be appropriately known only within the tribal community (Lake et al., 2017). Also, holders of traditional knowledge are unlikely to engage with scientists and managers unless they perceive an opportunity to advance their goals (Charnley et al., 2007) and the

research framework accommodates both traditional and western knowledge (Lake et al., 2017). This said, many tribal elders, young adults, and managers are eager to participate in traditional knowledge documentation activities (e.g., PGIS workshops, interviews). Our team found that the following research design elements promoted successful collaboration: (i) dialogue to elicit tribal community goals and potential concerns about proposed forest science research; (ii) a protocol for protecting culturally-sensitive data (e.g., a non-disclosure agreement); (iii) an oral history approach to knowledge sharing, particularly featuring visual aids (e.g., archival photographs, maps); (iv) opportunities to engage tribal youth in the transmission and documentation of traditional knowledge (e.g., PGIS trainings). Such protocols can promote the revitalization of traditional knowledge, engagement of knowledge holders, and restoration of forests and culturally-important resources in and beyond the eastside Cascades of the Pacific Northwest.

6. Conclusion

This study was motivated by calls for research that integrates traditional knowledge into the understanding of forest ecology and restoration (Turner et al., 2000; Hessburg and Agee, 2003; Charnley et al., 2007; Lake et al., 2017). Eastside Cascades forests, which have been altered by utilitarian forestry practices and the interruption of historical fire regimes (Stine et al., 2014; Hessburg et al., 2015), have been our focus. We endeavored to generate insights by examining traditional knowledge of fire use from a perspective that integrated anthropology and landscape ecology. This approach revealed a pronounced CFR in the MMC zone, but not in the drier DMC and SG zones. This approach also highlighted the interrelated influences of culture, tribal ecological principles, the seasonal round, and fire use practices on the CFR. Our results suggest that the CTWS used fire in the zone that was appropriate to this combination of factors, but not in the drier zones due to comparatively less vegetative competition with cultural foods, and generally more frequent fire recurrence intervals. Another conclusion generated by our integrative approach is that the role of the CFR in the MMC zone was to maintain openings initially created by large conflagrations and that this regime operated at the landscape-level, spanning multiple mountains and buttes of the eastside Cascades. An application of this finding is that the MMC zone may be a priority area for traditional knowledge-based restoration, owing to the disruption of the CFR, in combination with wildfire suppression policies of the past century.

Acknowledgements

We thank the Confederated Tribes of Warm Springs Natural Resources Branch, the Culture and Heritage Committee, the Culture and Heritage Program, and CTWS tribal elders for enabling data collection (oral history interviews, PGIS workshop, huckleberry enhancement field observations) and for feedback to the research design and preliminary findings. We thank Paul Hessburg, Keala Hagmann, Bob Gray, Brion Salter, and James Dickenson for suggestions regarding the landscape ecological component of the research design and for contributing to development of the instruments about reference forest conditions. We appreciate the insightful comments of an anonymous reviewer, which strengthened this manuscript. Finally, we appreciate the Special Collections of the libraries of the University of Washington and Reed College for access to the ethnobotanical documents of this study.

Funding

This work was supported by the USDA Forest Service, Pacific Northwest Research Station, USA. Key Forest Service sources included a grant from the Civil Rights Action Group (CRAG) Research with Underserved Communities fund and the National Fire Plan.

Appendix A. CTWS traditional knowledge (TK) regarding thin-leaf huckleberry resource

TK major category	TK specific category	Data
Traditional fire use	Spatial extent of cultural fire regime (CFR) in moist mixed conifer zone	~220,000 hectares (estimated)
		CFR area spanned 2 Cascade Range mountains (Mt. Hood, Mt. Jefferson) and several buttes
		24 (at least) huckleberry resource sites
	Historical forest structure, as influenced by CFR	Forest matrix included sizable openings
		Openings characterized by minimal canopy cover, minimal competing understory vegetation, and scattered, small-diameter conifers
	Burn timing and frequency	Early fall (generally)
		Several-year recurrence interval: ignitions rotated around resource area
	Burn severity	Low severity
	Burn patch	Small, controllable patch size (a "section" of resource area), < 1 hectare (estimated)
	Fire control techniques	Burning timed to occur with precipitation events
		Clearance of flammable litter, collected in part to dry huckleberries, thereby controlling fuel load
		Fire guards encircled burn area
		Sparks extinguished by wet materials (e.g., gunnysacks)
		Belief in seers' ability to forecast precipitation onset
		Belief that the Creator would control fire spread
	TK practices other than fire use	Tree girdling
		Rotational harvest of huckleberry sites across resource area
		Respect for appropriate harvest start time: wait until berries are mature
		Exercise attention in traversing resource area to avoid damaging plants
	Demographic characteristics of designated fire specialists	"Scouts" or "seers" (older men) determined appropriate ignition conditions and timing
		Men primarily responsible for fire control; women assisted
	Recentness of fire use	Late 1920s to early 1940s
Tribal ecological principles	Target conditions	Relatively open sites with scattered, small-diameter conifers
		Traversable harvest areas: sparse downed woody debris, due to fuel gathering to dry huckleberries
		Minimal competing understory vegetation
		Field structure: Dense occurrence of huckleberry plants
	Reasons for burning	Control competing understory vegetation
		Maintain and/ or expand canopy openings
		Removal of debris to facilitate navigability for harvesters
		Stimulate sprouting of new huckleberry plant growth
		Replenish soil fertility; "cleanse soil"
		Control insect populations

Seasonal round	Socio-economic and cultural utility of huckleberries	Important dietary resource Tea ingredient (huckleberry leaves) Trade good Focus of ceremonial feast Interfamilial and intergenerational ceremonial gifting
	Harvest volume	2.5 - 8 gallons (estimated) / harvester/ day
	Preservation techniques	Air drying Fire /smoke augmented air drying, when cold or cloudy Canning (after 1940s)
	Encampment group size and demographics	Variable group size Multi-family groups, often spanning the three CTWS tribes Intergenerational group composition Mixed gender group composition (women and men)
	Mode of travel to encampment site	Horseback and horse-drawn wagons (until 1940s) Truck or car (post-World War II)
	Encampment duration	Variable encampment duration: some families stayed at a single base camp for the entire harvest season; others migrated among multiple sites Duration of entire harvest season: Several days to several weeks
	Encampment activities	Men handled pack horses and hunted game (deer, elk) Women and children harvested and processed berries Resources harvested other than huckleberries: other berry species, medicinal plants, basketry materials, game
	Land tenure	Harvest and encampment rights not exclusive to specific groups Cultural/language groups intermixed and circulated among gathering sites
Culture	Ceremonial huckleberry feast and associated multi-day festival	Event involved ritualistic blessings, songs, and festivities Ceremony honored the huckleberry plant and women gatherers Prior to the feast, designated women scouted the berry fields to assess ripeness; their return signaled the start of the feast Ceremony signaled the start of the harvest season
	Worldview and beliefs	Worldview of human-earth interdependence Harvest activities benefit the plants (e.g., resource productivity)
	Gender and generational aspects of TK	Older, designated men determined when and where to burn Women determined when to begin harvest Grandparents key to transmitting traditional knowledge to youth
	Intergenerational transmission of TK	Informal mode of transmission largely employed Children learned by watching and imitating their elders Elders sought and identified youth with a gift for TK, as basis for transmitting fire prayers and related knowledge Fasting rituals believed to be a mechanism for the Creator to reveal TK

Abstract. With the potential for worsening fire conditions, discussion is escalating over how to best reduce effects on urban communities. A widely supported strategy is the creation of defensible space immediately surrounding homes and other structures. Although state and local governments publish specific guidelines and requirements, there is little empirical evidence to suggest how much vegetation modification is needed to provide significant benefits. We analysed the role of defensible space by mapping and measuring a suite of variables on modern pre-fire aerial photography for 1000 destroyed and 1000 surviving structures for all fires where homes burned from 2001 to 2010 in San Diego County, CA, USA. Structures were more likely to survive a fire with defensible space immediately adjacent to them. The most effective treatment distance varied between 5 and 20 m (16–58 ft) from the structure, but distances larger than 30 m (100 ft) did not provide additional protection, even for structures located on steep slopes. The most effective actions were reducing woody cover up to 40% immediately adjacent to structures and ensuring that vegetation does not overhang or touch the structure. Multiple-regression models showed landscape-scale factors, including low housing density and distances to major roads, were more important in explaining structure destruction. The best long-term solution will involve a suite of prevention measures that include defensible space as well as building design approach, community education and proactive land use planning that limits exposure to fire.

Received 16 September 2013, accepted 30 May 2014, published online 14 October 2014

Introduction

Across the globe and over recent decades, homes have been destroyed in wildfires at an unprecedented rate. In the last decade, large wildfires across Australia, southern Europe, Russia, the US and Canada have resulted in tens of thousands of properties destroyed, in addition to lost lives and enormous social, economic and ecological effects (Filmon 2004; Boschetti *et al.* 2008; Keeley *et al.* 2009; Blanchi *et al.* 2010; Vasquez 2011). The potential for climate change to worsen fire conditions (Hessl 2011), and the projection of continued housing growth in fire-prone wildlands (Gude *et al.* 2008) suggest that many more communities will face the threat of catastrophic wildfire in the future.

Concern over increasing fire threat has escalated discussion over how to best prepare for wildfires and reduce their effects. Although ideas such as greater focus on fire hazard in land use planning, using fire-resistant building materials and reducing human-caused ignitions (e.g. Cary *et al.* 2009; Quarles *et al.* 2010; Syphard *et al.* 2012) are gaining traction, the traditional strategy of fuels management continues to receive the most attention. Fuels management in the form of prescribed fires or mechanical treatments has historically occurred in remote, wildland locations (Schoennagel *et al.* 2009), but recent studies suggest that treatments located closer to homes and communities may provide greater protection (Witter and Taylor 2005; Stockmann *et al.* 2010; Gibbons *et al.* 2012). In fact, one of the most commonly recommended strategies in terms of fuels and fire protection is to create defensible space immediately around structures (Cohen 2000; Winter *et al.* 2009). Defensible space is an area around a structure where vegetation has been modified, or 'cleared,' to increase the chance of the structure surviving a wildfire. The idea is to mitigate home loss by minimising direct contact with fire, reducing radiative heating, lowering the probability of ignitions from embers and providing a safer place for fire fighters to defend a structure against fire (Gill and Stephens 2009; Cheney *et al.* 2001). Many jurisdictions provide specific guidelines and practices for creating defensible space, including minimum distances that are required among trees and shrubs as well as minimum total distances from the structure. These distances may be enforced through local ordinances or state-wide laws. In California, for example, a state law in 2005 increased the required total distance from 9 m (30 ft) to 30 m (100 ft).

Despite these specific guidelines on how to create defensible space, there is little scientific evidence to support the amount and location of vegetation modification that is actually effective

Journal compilation © IAWF 2014

at providing significant benefits. Most spacing guidelines and laws are based on 'expert opinion' or recommendations from older publications that lack scientific reference or rationale (e.g. Maire 1979; Smith and Adams 1991; Gilmer 1994). However, one study has provided scientific support for, and forms the basis of, most guidelines, policy and laws requiring a minimum of 30 m (100 ft) of defensible space (Cohen 1999, 2000). The modelling and experimental research in that study showed that flames from forest fires located 10–40 m (33–131 ft) away would not scorch or ignite a wooden home; and case studies showed 90% of homes with non-flammable roofs and vegetation clearance of 10–20 m (33–66 ft) could survive wildfires (Cohen 2000). However, the models and experimental research in that study focussed on crown fires in spruce or jack pine forests, and the primary material of home construction was wood. Therefore, it is unknown how well this guideline applies to regions dominated by other forest types, grasslands, or nonforested woody shrublands and in regions where wooden houses are not the norm.

Some older case studies showed that most homes with non-flammable roofs and 10–18 m (33–ft) of defensible space survived the 1961 Bel Air fire in California (Howard *et al.* 1973); most homes with non-flammable roofs and more than 10 m (33 ft) of defensible space also survived the 1990 Painted Cave fire (Foote and Gilless 1996). Also, several fire-behaviour modelling studies have been conducted in chaparral shrublands. One study showed that reducing vegetative cover to 50% at 9–30 m (30–ft) from structures effectively reduced fireline intensity and flame lengths, and that removal of 80% cover would result in unintended consequences such as exotic grass invasion, loss of habitat and increase in highly flammable flashy fuels (A. Fege and D. Pumphrey, unpubl. data). Another showed that separation distances adequate to protect firefighters varied according to fuel model and that wind speeds greater than 23 km h^{-1} negated the effect of slope, and wind speed above 48 km h^{-1} negated any protective effect of defensible space (F. Bilz, E. McCormick and R. Unkovich, unpubl. data, 2009). Results obtained through modelling equations of thermal radiation also found safety distances to vary as a function of fuel type, type of fire, home construction material and protective garments worn by firefighters (Zárate *et al.* 2008).

Although there is no empirical evidence to support the need for more than 30 m (100 ft) of defensible space, there has been a concerted effort in some areas to increase this distance, particularly on steep slopes. In California, a senate bill was introduced in 2008 (SB 1618) to encourage property owners to clear 91 m (300 ft) through the reduction of environmental regulations and permitting needed at that distance. Although this bill was defeated in committee, many local ordinances do require homeowners to clear 91 m (300 ft) or more, and there are reports that some people are unable to get fire insurance without 91 m (300 ft) of defensible space (F. Sproul, pers. comm.). In contrast, homeowner acceptance of and compliance with defensible space policies can be challenging (Winter *et al.* 2009; Absher and Vaske 2011), and in many cases homeowners do not create any defensible space.

It is critically important to develop empirical research that quantifies the amount, location and distance of defensible space that provides significant fire protection benefits so that guidelines and policies are developed with scientific support. Data that are directly applicable to southern California are especially important, as this region experiences the highest annual rate of wildfire-destroyed homes in the US. Not having sufficient defensible space is obviously undesirable because of the hazard to homeowners. However, there are clear trade-offs involved when vegetation reduction is excessive, as it results in the loss of native habitats, potential for increased erosion and invasive species establishment, and it potentially even increases fire risk because of the high flammability of weedy grasslands (Spittler 1995; Keeley *et al.* 2005; Syphard *et al.* 2006).

It is also important to understand the role of defensible space in residential structure protection relative to other factors that explain why some homes are destroyed in fires and some are not. Recent research shows that landscape-scale factors, such as housing arrangement and location, as well as biophysical variables characterising properties and neighbourhoods such as slope and fuel type, were important in explaining which homes burned in two southern California study areas (Syphard *et al.* 2012; 2013). Understanding the relative importance of different variables at different scales may help to identify which combinations of factors are most critical to consider for fire safety.

Our objective was to provide an empirical analysis of the role of defensible space in protecting structures during wildfires in southern California shrublands. Using recent pre-fire aerial photography, we mapped and measured a suite of variables describing defensible space for burned and unburned structures within the perimeters of major fires from 2001 to 2010 in San Diego County to ask the following questions:

1. How much defensible space is needed to provide significant protection to homes during wildfires, and is it beneficial to have more than the legally required 30 m (100 ft)?
2. Does the amount of defensible space needed for protection depend on slope inclination?
3. What is the role of defensible space relative to other factors that influence structure loss, such as terrain, fuel type and housing density?

Methods

Study area

The properties and structures analysed were located in San Diego County, California, USA (Fig. 1) – a topographically diverse region with a Mediterranean climate characterised by cool, wet winters and long summer droughts. Fire typically is a direct threat to structures adjacent to wildland areas. Native shrublands in southern California are extremely flammable during the late summer and fall (autumn) and when ignited, burn in high-intensity, stand-replacing crown fires. Although 500 homes on average have been lost annually since the mid-1900s (Calfire 2000), that rate has doubled since 2000. Most of these homes have burned during extreme fire weather conditions that accompany the autumn Santa Ana winds. The wildland–urban interface here includes more than 5 million homes, covering more than 28 000 km^2 (Hammer *et al.* 2007).

Property data

The data for properties to analyse came from a complete spatial database of existing residential structures and their

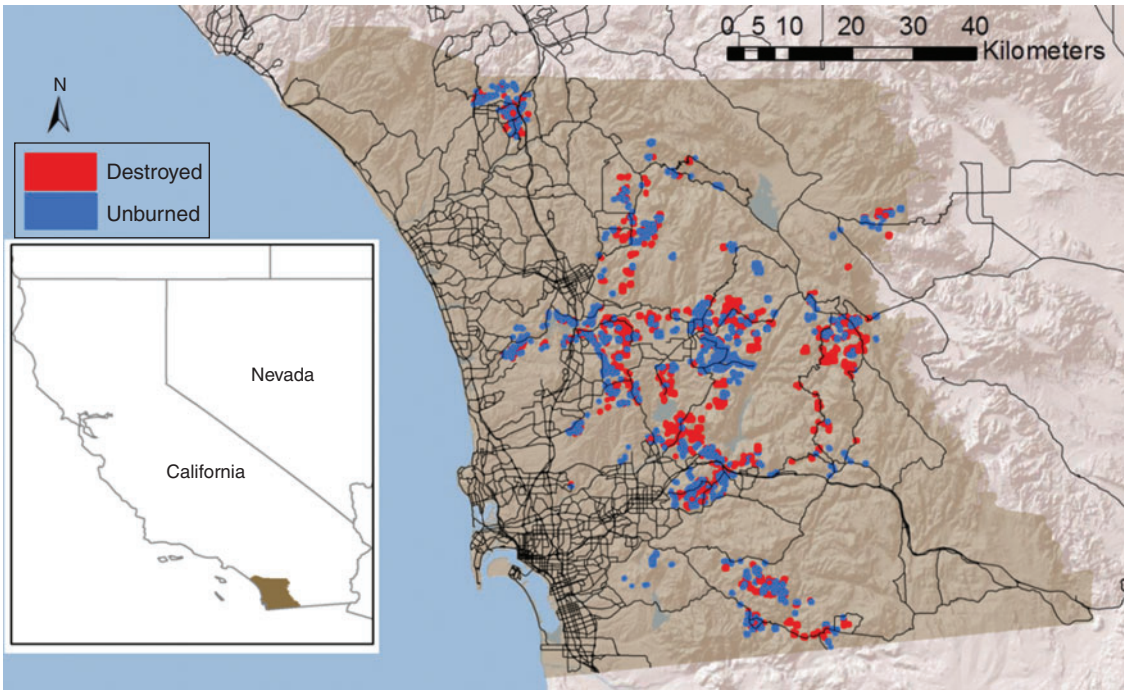

Fig. 1. Location of destroyed and unburned structures within the South Coast ecoregion of San Diego County, California, USA.

corresponding property boundaries developed for San Diego County (Syphard *et al.* 2012). This dataset included 687 869 structures, of which 4315 were completely destroyed by one of 40 major fires that occurred from 2001 to 2010. Our goal was to compare homes that were exposed to wildfire and survived with those that were exposed and destroyed. To determine exposure to fire, we only considered structures located both within a GIS layer of fire perimeters and within areas mapped as having burned at a minimum of low severity through thematic Monitoring Trends in Burn Severity produced by the USA Geological Survey and USDA Forest Service. From these data, we used a random sample algorithm in GIS software to select 1000 destroyed and 1000 unburned homes that were not adjacent to each other, to minimise any potential for spatial autocorrelation. Our final property dataset included structures that burned across eight different fires. More than 97% of these structures burned in Santa Ana wind-driven fire events (Fig. 1).

Calculating defensible space and additional explanatory variables

To estimate defensible space, we developed and explored a suite of variables relative to the distance and amount of defensible space surrounding structures, as well as the proximity of woody vegetation to the structure (Table 1). We measured these variables based on interpretation of Google Earth aerial imagery. We based our measurements on the most recent imagery before the date of the fire. In almost all cases, imagery was available for less than 1 year before the fire.

Our definition of defensible space followed the guidelines published by the California Department of Forestry and Fire Protection (Calfire 2006). 'Clearance' included all areas that were not covered by woody vegetation, including paved areas or grass. Although Google Earth prevents the identification of understorey vegetation, woody trees and shrubs were easily distinguished from grass, and our objective was to measure horizontal distances as required by Calfire rather than assess the relative flammability of different vegetation types. Trees or shrubs were allowed to be within the defensible space zone as long as they were separated by the minimum horizontal required distance, which was 3 m (10 ft) from the edge of one tree canopy to the edge of the next (Fig. 2). Although greater distances between trees or shrubs are recommended on steeper slopes, we followed the same guidelines for all properties. For all structures, we started the distance measurements by drawing lines from the centre of the four orthogonal sides of the structure that ended when they intersected anything that no longer met the requirements in the guidelines. A fair number of structures are not four sided; thus, the start of the centre point was placed at a location that approximated the farthest extent of the structure along each of four orthogonal sides.

We developed two sets of measurements of the distance of defensible space based on what is feasible for homeowners within their properties *v.* the total effective distance of defensible space. We made these two measurements because homeowners are only required to create defensible space within their own property, and this would reflect the effect of individual homeowner compliance. Therefore, even if cleared vegetation extended beyond the property line, the first set of distance measurements ended at the property boundary. The second set of measurements ignored the property boundaries and accounted for the total potential effect of treatment. For all measurements, we recorded the cover types (e.g. structure >3 m (10 ft) long, property boundary, or vegetation type) at which the distance measurements stopped (Table 1). Because property

Table 1. Defensible space variables measured for every structure

Urban veg, landscaping vegetation that was not in compliance with regulations within urban matrix; wildland veg, wildland vegetation that was not in compliance with regulations; orchard, shrub to tree-sized vegetation in rows; urban to wildland, landscaping vegetation that leads into wildland vegetation; structure, any building longer than 3 m (10 ft)

Variable	Definition
Distance defensible space within property	Measure of clearance from side of structure to property boundary calculated for four orthogonal directions from structure and averaged
Total distance defensible space	Measure of clearance from side of structure to end of clearance calculated for four orthogonal directions from structure and averaged
Cover type at end of defensible space	Type of cover encountered at end of measurement (urban veg, wildland veg, orchard, urban to wildland, structure)
Percentage clearance	Percentage of clearance calculated across the entire property
Neighbours' vegetation	Binary indicator of whether neighbours' uncleared vegetation was located within 30 m (100 ft) of the main structure
Vegetation touching structure	Number of sides on which woody vegetation touches main structure (1–4) Structure with more than 4 sides were viewed as a box and given a number between 1 and 4
Vegetation overhanging roof	Was vegetation overhanging the roof? (yes or no)

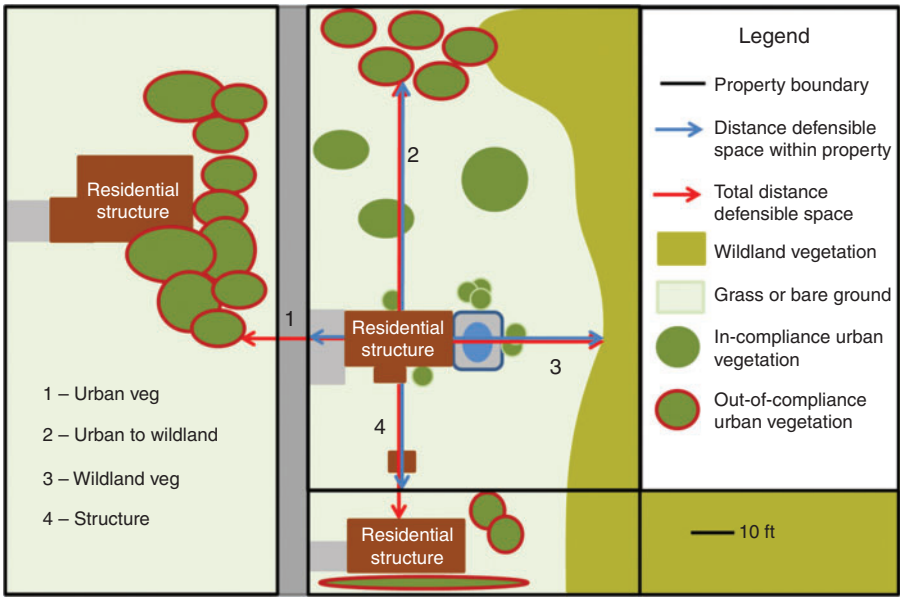

Fig. 2. Illustration of defensible space measurements. See Table 1 for full definition of terms.

owners usually can only clear vegetation on their own land, it is possible that the effectiveness of defensible space partly depends upon the actions of neighbouring homeowners. Therefore, we also recorded whether or not any neighbours' un-cleared vegetation was located within 30 m (100 ft) of the structure.

To assess the total amount of woody vegetation that can safely remain on a property and still receive significant benefits of defensible space, we calculated the total percentage of cleared land, woody vegetation and structure area across every property. This was accomplished by overlaying a grid on each property and determining the proportion of squares falling into each class. Preliminary results showed these three measurements to be highly correlated, so we only retained percentage clearance for further analysis. To evaluate the relative effect of woody vegetation directly adjacent to structures, we also calculated the number of sides of the structure with vegetation touching and recorded whether any trees were overhanging structures' roofs.

In addition to defensible space measurements, we evaluated other factors known to influence the likelihood of housing loss to fire in the region (Syphard *et al.* 2012, 2013). Using the same data as in Syphard *et al.* (2012, 2013), we extracted spatial information from continuous grids of explanatory variables for the locations of all structures in our analysis. Variables included interpolated housing density based on a 1-km search radius; percentage slope derived from a 30-m digital elevation model (DEM); Euclidean distance to nearest major and minor road and fuel type, which was based on a simple classification of US Forest Service data (Syphard *et al.* 2012), including urban, grass, shrubland and forest & woodland.

Analysis

We performed several analyses to determine whether relative differences in home protection are provided by different distances and amounts of defensible space, particularly beyond the legally required 30 m (100 ft), and to identify the effective treatment distance for homes on low and steep slopes.

Categorical analysis

For the first analysis, we divided our data into several groups to identify potential differences among specific categories of defensible space distance around structures located on shallow and steep slopes. We first sorted the full dataset of 2000 structures by slope and then split the data in the middle to create groups of homes with shallow slope and steep slope. We divided the data in half to keep the number of structures even within both groups and to avoid specifying an arbitrary number to define what constitutes shallow or steep slope. The two equal-sized subsets of data ranged from 0 to 9%, with a mean of 8% for shallow slope, and from 9 to 40%, with a mean of 27% for steep slope. Within these data subsets, we next created groups reflecting different mean distances of defensible space around structures. We also performed separate analyses based on whether defensible space measurements were calculated within the property boundary or whether measurements accounted for the total distance of defensible space.

Within all groups, we calculated the proportion of homes that were destroyed by wildfire. We performed Pearson's Chi-square tests of independence to determine whether or not the proportion of destroyed structures within groups was significantly different (Agresti 2007). We based one test on four equal-interval groups within the legally required distance of 30 m (100 ft): 0–7 m (0–25 ft), 8–15 m (26–50 ft), 16–23 m (51–75 ft) and 24–30 m (76–100 ft). A second test was based on three groups (24–30 m (75–100 ft), 31–90 m (101–300 ft) and >90 m (>300 ft) or >60 m (>200 ft)) to evaluate whether groups with mean defensible space distances >30 m (>100 ft) were significantly different from groups with <30 m (<100 ft). When defensible space distances were only measured to the property boundary, few structures had mean defensible space >90 m (>300 ft). Therefore, we used a cut-off of 60 m (200 ft) to increase the sample size in the Chi-square analysis. In addition to the Chi-square analysis, we calculated the relative risk among every successive pair of categories (Sheskin 2004). The relative risk was calculated as the ratio of proportions of burned homes within two groups of homes that had different defensible space distances.

Effective treatment analysis

In addition to comparing the relative effect of defensible space among different groups of mean distances, as described above, we also considered that the protective effect of defensible space for structures exposed to wildfire is conceptually similar to the effect of medication in producing a therapeutic response in people who are sick. In addition to pharmacological applications, treatment–response relationships have been used for radiation, herbicide, drought tolerance and ecotoxicological studies (e.g. Streibig *et al.* 1993; Cedergreen *et al.* 2005; Knezevic *et al.* 2007; Kursar *et al.* 2009). The effect produced by a drug or treatment typically varies according to the concentration or amount, often up to a point at which further increase provides no additional response. The effective treatment (ET50), therefore, is a specific concentration or exposure that produces a therapeutic response or desired effect. Here we considered the treatment to be the distance or amount of defensible space.

Using the software package DRC in R (Knezevic *et al.* 2007; Ritz and Streibig 2013), we evaluated the treatment–response relationship of defensible space in survival of structures during wildfire. To calculate the effective treatment, we fit a log-logistic model with logistic regression because we had a binary dependent variable (burned or unburned). We specified a 2-parameter model where the lower limit was fixed at 0 and the upper limit was fixed at 1. We again performed separate analyses for data subsets reflecting shallow and steep slope, as well as from measurements of defensible space taken within, or regardless of, property boundaries. We also performed analyses to find the effective treatment of percentage clearance of trees and shrubs within the property.

Multiple regression analysis

To evaluate the role of defensible space relative to other variables, we developed multiple generalised linear regression models (GLMs) (Venables and Ripley 1994). We again had a binary dependent variable (burned versus unburned), so we specified a logit link and binomial response. Although the proportion of 0s and 1s in the response may be important to consider for true prediction (King and Zeng 2001; Syphard *et al.* 2008), our objective here was solely to evaluate variable importance. We developed multiple regression models for all possible combinations of the predictor variables and used the corrected Akaike's Information Criterion (AICc) to rank models and select the best ones for each region using package MuMIn in R (R Development Core Team 2012; Burnham and Anderson 2002). We recorded all top-ranked models that had an AICc value within 2 of that of the model with lowest AICc to identify all models with empirical support. To assess variable importance, we calculated the sum of Akaike weights for all models that contained each variable. On a scale of 0–1, this metric represents the weight of evidence that models containing the variable in question are the best model (Burnham and Anderson 2002). The distance of defensible space measured within property boundaries was highly correlated with the distance of defensible space measured beyond property boundaries ($r = 0.82$), so we developed two separate analyses – one using variables measured only within the property boundary and the other using variables that accounted for defensible space outside of the property boundary as well as the potential effect of neighbours having uncleared vegetation within 30 m (100 ft) of the structure. A test to avoid multicollinearity showed all other variables within each multiple regression analysis to be uncorrelated ($r < 0.5$).

Surrounding matrix

To assess whether the proportion of destroyed structures varied according to their surrounding matrix, we summarised the most common cover type at the end of defensible space measurements (descriptions in Table 1) for all structures. These summaries

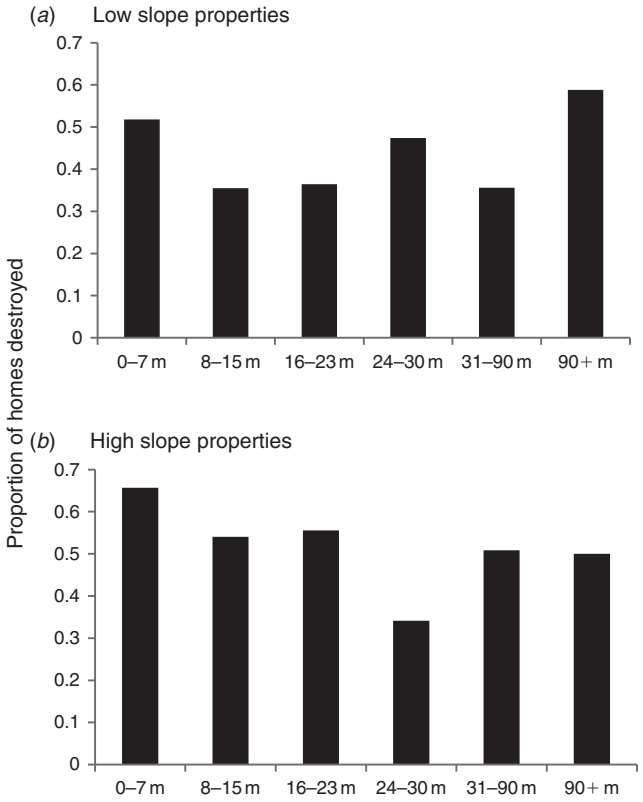

Fig. 3. Proportion of destroyed homes grouped by distances of defensible space based upon total distance of clearance within property boundary, for structures on (*a*) shallow slopes (mean 8%) and (*b*) steep slopes (mean 27%).

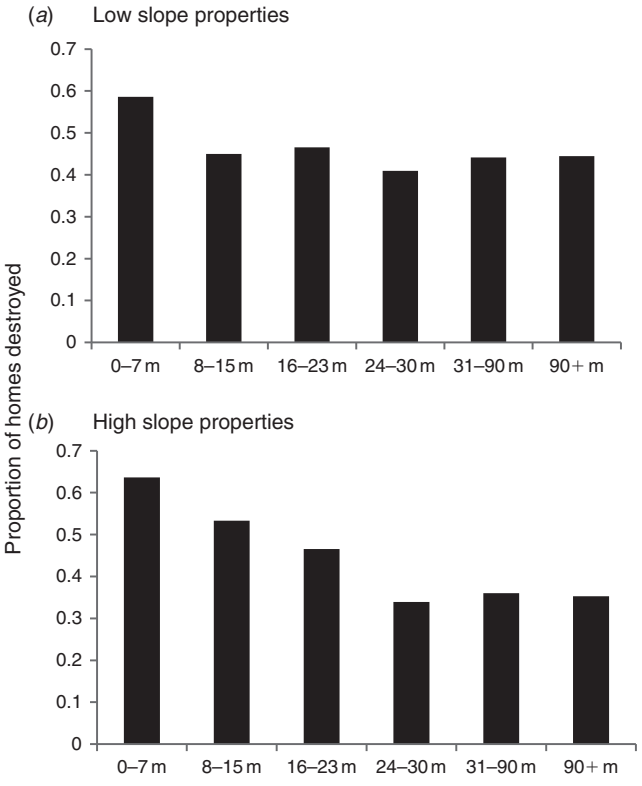

Fig. 4. Proportion of destroyed homes grouped by distances of defensible space based upon total distance of clearance regardless of property boundary, for structures on (*a*) shallow slopes (mean 8%) and (*b*) steep slopes (mean 27%).

were based on the majority surrounding cover type from the four orthogonal sides of the structure. We also noted cases in which there was a tie (e.g. two sides were urban vegetation and two sides were structures).

Results

Categorical analysis

When the distance of defensible space was measured both 'only within property boundaries' (Fig. 3) and 'regardless of property boundaries' (Fig. 4), the Chi-square test showed a significant difference ($P < 0.001$) in the proportion of destroyed structures among the four equal-interval groups of distance ranging from 0 to 30 m (0–100 ft). This relationship was consistent on both shallow-slope and steep-slope properties, although the relative risk analysis showed considerable variation among classes (Table 2) There was a steadily decreasing proportion of destroyed structures at greater distances of defensible space up to 30 m (100 ft) on the steep-slope structures with defensible space measured regardless of property boundaries (Fig. 4*b*). Otherwise, the biggest difference in proportion of destroyed structures occurred between 0 and 7 m (0–25 ft) and 8–15 m (26–50 ft) (Figs 3*a–b*, 4*a*).

When the distance of defensible space was measured in intervals from 24 m (75 ft) and beyond, the Chi-square test showed no significant difference among groups ($P = 0.96$ for shallow-slope properties and $P = 0.74$ for steep-slope properties) (Figs 3, 4), although again, the relative risk analysis showed considerable variation (Table 2).There was a slight increase in the proportion of homes destroyed at longer distance intervals when the defensible space was measured only to the property boundaries (Fig. 3*a–b*). This slight increase is less apparent when distances were measured regardless of boundaries (Fig. 4*a–b*).

The relative risk calculations showed that the ratio of proportions was generally more variable among successive pairs when the distances were measured within property boundaries (Table 2). For these calculations, the risk of a structure being destroyed was significantly lower when the defensible space distance was 8–15 m (25–50 ft) compared to 0–7 m (0–25 ft) on both shallow- and steep-slope properties. On the steep-slope properties, there was an additional reduction of risk when comparing 24–30 m (75–100 ft) to 16–23 m (50–75 ft). However, the risk of a home being destroyed was slightly significantly higher when there was 31–90 m (101–225 ft) compared to 16–23 m (50–75 ft). For distances that were measured regardless of property boundary (total clearance), the only significant differences in risk of burning were a reduction in risk for 8–15 m (25–50 ft) compared to 0–7 m (0–25 ft).

Table 2. Number of burned and unburned structures within defensible space distance categories (m), their relative risk and significance
A relative risk of 1 indicates no difference; <1 means the chance of a structure burning is less than the other group; >1 means the chance is higher than the other group. The relative risk is calculated for pairs that include the existing row and the row above. Confidence intervals are in parentheses

	Distance within property				Total distance			
	Burned	Unburned	Relative risk	*P*	Burned	Unburned	Relative risk	*P*
Shallow slope								
0–7	200	186			162	114		
8–15	109	198	0.69 (0.12)	<0.001	108	132	0.77	0.002
16–23	51	89	1.03 (0.30)	0.850	78	90	1.03	0.770
24–30	36	40	1.30 (0.39)	0.110	50	70	0.90	0.430

Table 3. Effective treatment results reflecting the distance (in metres, with feet in parentheses) and percentage clearance within properties that provided significant improvement in structure survival during wildfires
The property mean is the average distance of defensible space or percentage clearance that was calculated on the properties before the wildfires and provides a means to compare the effective treatment result to the actual amount on the properties

	All parcels effective treatment ($n = 2000$)	Parcel mean	Shallow slope (mean 8%) effective treatment ($n = 1000$)	Parcel mean	Steep slope (mean 27%) effective treatment ($n = 1000$)	Parcel mean
Defensible space within parcel	10 (33)	13 (44)	4 (13)	14 (45)	25 (82)	11 (35)
Total distance defensible space	10 (32)	19 (63)	5 (16)	20 (67)	20 (65)	18 (58)
Mean percentage clearance on property	36	48	31	51	37	35

Effective treatment analysis

Analysis of the treatment–response relationships among defensible space and structures that survived wildfire showed that, when all structures are considered together, the mean actual defensible space that existed around structures before the fires was longer than the calculated effective treatment (Table 3). Regardless of whether the defensible space was measured within or beyond property boundaries, the estimated effective treatment of defensible space was nearly the same at 10 m (32–33 ft).

The effective treatment distance was much shorter for structures on shallow slopes (4–5 m (13–16 ft)) than for structures on steep slopes (20–25 m (65–82 ft)), but in all cases was <30 m (<100 ft). Although longer distances of defensible space were calculated as effective on steeper slopes, these structures actually had shorter mean distances of defensible space around their properties than structures on low slopes (Table 3).

The calculated effective treatment of the mean percentage clearance on properties was 36% for all properties, 31% for structures on shallow slopes and 37% for structures on steep slopes (Table 3). In total, the properties all had higher actual percentage clearance on their property than was calculated to be effective. However, this mainly reflects the shallow-slope properties, as those structures on steep slopes had less clearance than the effective treatment.

Multiple regression analysis

When defensible space was measured only to the property boundaries, it was not included in the best model, according to the all-subsets multiple regression analysis (Table 4). However, it was included in the best model when factoring in the distance of defensible space measured beyond property boundaries (Table 5). In both multiple regression analyses, low housing density and shorter distances to major roads were ranked as the most important variables according to their Akaike weights. Slope and surrounding fuel type were also in both of the best models as well as other measures of defensible space, including the percentage clearance on property and whether vegetation was overhanging the structure's roof. The number of sides in which vegetation was touching the structure was included in the best model when defensible space was only measured to the property boundary. The total explained deviance for the multiple regression models was low (12–13%) for both analyses.

Table 4. Results of multiple regression models of destroyed homes using all possible variable combinations and corrected Akaike's Information Criterion (AICc)

Includes variables measured within property boundary only. Top-ranked models include all those ($n = 12$) with AICc within 2 of the model with the lowest AICc. Relative variable importance is the sum of 'Akaike weights' over all models including the explanatory variable

Variable in order of importance	Relative variable importance	Model-averaged coefficient	Number inclusions in top-ranked models
Housing density	1	−0.003	12
Distance to major road	1	−0.0005	12
Percentage clearance	1	−0.02	12
Slope	1	0.03	12
Vegetation overhang roof	1	0.5	12
Fuel type	0.67	Factor	9
Vegetation touch structure	0.49	0.07	6
Distance defensible space within property	0.45	−0.0002	5
South-westness	0.36	−0.0007	3
Distance to minor road	0.28	−0.0002	1
D^2 of top-ranked model			0.123

Table 5. Results of multiple regression models of destroyed homes using all possible variable combinations and corrected Akaike's Information Criterion (AICc)

Includes variables measured beyond property boundary. Top-ranked models include all those ($n = 6$) with AICc within 2 of the model with the lowest AICc. Relative variable importance is the sum of 'Akaike weights' over all models including the explanatory variable

Variable in order of importance	Relative variable importance	Model-averaged coefficient	Number inclusions in top-ranked models
Housing density	1	−0.003	6
Distance to major road	1	−0.0005	6
Total distance defensible space	1	−0.004	6
Percentage clearance	1	−0.01	6
Vegetation overhang roof	0.99	0.4	6
Slope	0.99	0.03	6
Fuel type	0.86	Factor	4
South-westness	0.42	−0.0009	2
Distance to minor road	0.36	−0.0009	2
Neighbours' vegetation	0.27	0.08	1
Vegetation touch structure	0.27	0.18	1
D^2 of top-ranked model			0.125

Surrounding matrix

The cover type that most frequently surrounded the structures at the end of the defensible space measurements was urban vegetation, followed by urban vegetation leading into wildland vegetation, and wildland vegetation (Fig. 5). Many structures were equally surrounded by different cover types. There were no significant differences in the proportion of structures destroyed depending on the surrounding cover type. However, a disproportionately large proportion of structures burned (28 *v.* 9% unburned) when they were surrounded by urban vegetation that extended straight into wildland vegetation.

Discussion

For homes that burned in southern Californian urban areas adjacent to non-forested ecosystems, most burned in high-intensity Santa Ana wind-driven wildfires and defensible space increased the likelihood of structure survival during wildfire. The most effective treatment distance varied between 5 and 20 m (16–58 ft), depending on slope and how the defensible space was measured, but distances longer than 30 m (100 ft) provided no significant additional benefit. Structures on steeper slopes benefited from more defensible space than structures on shallow slopes, but the effective treatment was still less than 30 m (100 ft). The steepest overall decline in destroyed structures occurred when mean defensible space increased from 0–7 m (0–25 ft) to 8–15 m (26–50 ft). That, along with the multiple regression results showing the significance of vegetation touching or overhanging the structure, suggests it is most critical to modify vegetation immediately adjacent to the house, and to move outward from there. Similarly, vegetation overhanging the structure was also strongly correlated with structure loss in Australia (Leonard *et al.* 2009).

In terms of fuel modification, the multiple regression models also showed that the percentage of clearance was just as, or more important than, the linear distance of defensible space.

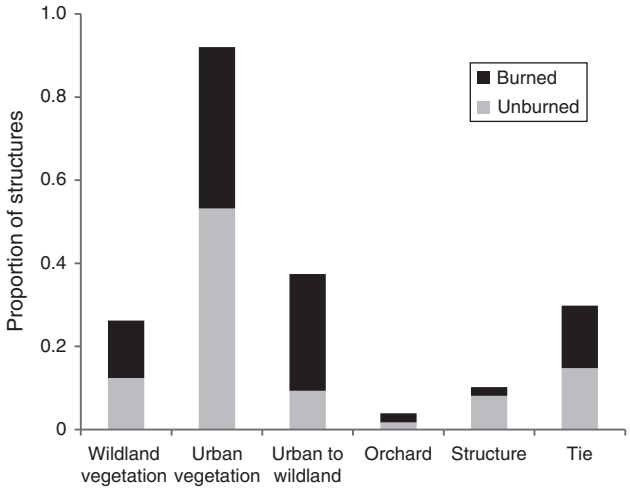

Fig. 5. Proportion of destroyed and unburned structures based on the primary surrounding cover type at the end of defensible space measurements. There were no significant differences in the proportion of burned and unburned structures within cover types ($P = 0.14$). Cover types are defined in Table 1.

However, as with defensible space, percentage clearance did not need to be draconian to be effective. Even on steep slopes, the effective percentage clearance needed on the property was <40%, with no significant advantage beyond that. Although these steep-slope structures benefited more from clearance, they tended to have less clearance than the effective amount, which may be why slope was such an important variable in the multiple regression models. Shallow-slope structures, in contrast, had more clearance on average than was calculated to be effective, suggesting these property owners do not need to modify their behaviours as much relative to people living on steep slopes.

Although the term 'clearance' is often used interchangeably with defensible space, this term is incorrect when misinterpreted to mean clearing all vegetation, and our results underline this difference. The idea behind defensible space is to reduce the continuity of fuels through maintenance of certain distances among trees and shrubs. Although we could not identify the vertical profile of fuels through Google Earth imagery, the fact that at least 60% of the horizontal woody vegetative cover can remain on the property with significant protective effects demonstrates the importance of distinguishing defensible space from complete vegetation removal. Thus, we suggest the term 'clearance' be replaced with 'fuel treatment' as a better way of communicating fire hazard reduction needs to home owners.

The percentage cover of woody shrubs and trees was not evenly distributed across properties, and we did not collect data describing how the cover was distributed. Considering the importance of defensible space and vegetation modification immediately adjacent to the structure, it should follow that actions to reduce cover should also be focussed in close proximity to the structure. The hazard of vegetation near the structure has apparently been recognised for some time (Foote *et al.* 1991; Ramsey and McArthur 1994), but it is not stressed enough, and rarely falls within the scope of defensible space guidelines or ordinances.

In addition to the importance of vegetation overhanging or touching the structure, it is important to understand that ornamental vegetation may be just as, if not more, dangerous than native vegetation in southern California. Although the results showed no significant differences in the cover types in the surrounding matrix, there was a disproportionately large number of structures destroyed (28% burned *v.* 9% unburned) when ornamental vegetation on the property led directly into the wildland. Ornamental vegetation may produce highly flammable litter (Ganteaume *et al.* 2013) or may be particularly dangerous after a drought when it is dry, or has not been maintained, and species of conifer, juniper, cypress, eucalypt, *Acacia* and palm have been present in the properties of many structures that have been destroyed (Franklin 1996). Nevertheless, ornamental vegetation is allowed to be included as defensible space in many codes and ordinances (Haines *et al.* 2008).

One reason that longer defensible space distances did not significantly increase structure protection may be that most homes are not destroyed by the direct ignition of the fire front but rather due to ember-ignited spot fires, sometimes from fire brands carried as far as several km away. Although embers decay with distance, the difference between 30 and 90 m (100 and 300 ft) may be small relative to the distance embers travel under the severe wind conditions that were present at the time of the fires. The ignitability of whatever the embers land on, particularly adjacent to the house, is therefore most critical for propagating the fire within the property or igniting the home (Cohen 1999; Maranghides and Mell 2009).

Aside from roofing or home construction materials and vegetation immediately adjacent to structures (Quarles *et al.* 2010; Keeley *et al.* 2013), the flammability of the vegetation in the property may also play a role. Large, cleared swaths of land are likely occupied at least in part by exotic annual grasses that are highly ignitable for much of the year. Conversion of woody shrubs with higher moisture content into low-fuel-volume grasslands could potentially increase fire risk in some situations by increasing the ignitability of the fuel; and if the vegetation between a structure and a fire is not readily combustible, it could protect the structure by absorbing heat flux and filtering fire brands (Wilson and Ferguson 1986).

The slight increase in proportion of structures destroyed with longer distances of defensible space within parcel boundaries was surprising. However, that increase was not significant in the Chi-square analysis, although there were some significant differences in the pairwise relative risk analysis. Nevertheless, the largest significant effect of defensible space was between the categories of 0–7 m (0–25 ft) to 8–15 m (26–50 ft), and it may be that differences in categories beyond these distances are not highly meaningful or reflect an artefact of the definition of distance categories. These relationships at longer distances are likely also weak compared to the effect of other variables operating at a landscape scale. Although the categorical analysis allowed us to answer questions relative to legal requirements and specific distances, the effective treatment analysis was important for identifying thresholds in the continuous variable.

The multiple regression models showed that landscape factors such as low housing density and longer distances to major roads were more important than distance of defensible space for explaining structure destruction, and the importance of

these variables is consistent with previous studies (Syphard *et al.* 2012, 2013), despite the smaller spatial extent studied here. Whereas this study used an unburned control group exposed to the same fires as the destroyed structures, previous studies accounted for structures across entire landscapes. The likelihood of a fire destroying a home is actually a result of two major components: the first is the likelihood that there will be a fire, and the second is the likelihood that a structure will burn in that fire. In this study, we only focussed on structure loss given the presence of a fire, and the total explained variation for the multiple regression models was quite low at ~12%. However, when the entire landscape was accounted for in the total likelihood of structure destruction, the explained variation of housing density alone was >30% (Syphard *et al.* 2012). One reason for the relationship between low housing density and structure destruction is that structures are embedded within a matrix of wildland fuel that leads to greater overall exposure, which is consistent with Australian research that showed a linear decrease of structure loss with increased distance to forest (Chen and McAneney 2004). That research, however, only focussed on distance to wildland boundaries and did not quantify variability in defensible space or ornamental vegetation immediately surrounding structures. Thus, fire safety is important to consider at multiple scales and for multiple variables, which will ultimately require the cooperation of multiple stakeholders.

Conclusions

Structure loss to wildfire is clearly a complicated function of many biophysical, human and spatial factors (Keeley *et al.* 2009; Syphard *et al.* 2012). For such a large sample size, we were unable to account for home construction materials, but this is also well understood to be a major factor, with older homes and wooden roofs being most vulnerable (Franklin 1996; Cohen 1999, 2000). In terms of actionable measures to reduce fire risk, this study shows a clear role for defensible space up to 30 m (100 ft). Although the effective distances were on average much shorter than 30 m (100 ft), we recognise that additional distance may be necessary to provide sufficient protection to firefighters, which we did not address in this study (Cheney *et al.* 2001). In contrast, the data in this study do not support defensible space beyond 30 m (100 ft), even for structures on steep slopes. In addition to the fact that longer distances did not contribute significant additional benefit, excessive vegetation clearance presents a clear detriment to natural habitat and ecological resources. Results here suggest the best actions a homeowner can take are to reduce percentage cover up to 40% immediately adjacent to the structure and to ensure that vegetation does not overhang or touch the structure.

In addition to defensible space, this study also underlines the potential importance of land use planning to develop communities that are fire safe in the long term, in particular through their reduction to exposure to wildfire in the first place. Localised subdivision decisions emphasising infill-type development patterns may significantly reduce fire risk in the future, in addition to minimising habitat loss and fragmentation (Syphard *et al.* 2013). This study was conducted in southern California, which has some of the worst fire weather in the world and many properties surrounded by large, flammable exotic trees. Therefore, recommendations here should apply to other non-forested ecosystems as well as many forested regions.

ABSTRACT

Prescribed fire is a primary tool used to restore western forests following more than a century of fire exclusion, reducing fire hazard by removing dead and live fuels (small trees and shrubs). It is commonly assumed that the reduced forest density following prescribed fire also reduces competition for resources among the remaining trees, so that the remaining trees are more resistant (more likely to survive) in the face of additional stressors, such as drought. Yet this proposition remains largely untested, so that managers do not have the basic information to evaluate whether prescribed fire may help forests adapt to a future of more frequent and severe drought.

During the third year of drought, in 2014, we surveyed 9950 trees in 38 burned and 18 unburned mixed conifer forest plots at low elevation (<2100 m a.s.l.) in Kings Canyon, Sequoia, and Yosemite national parks in California, USA. Fire had occurred in the burned plots from 6 yr to 28 yr be-

RESUMEN

El fuego prescripto es una herramienta primordial utilizada para restaurar los bosques del oeste de los EEUU luego de más de una centuria de exclusión del fuego, reduciendo el peligro de incendios mediante la remoción de combustibles vivos y muertos (pequeños árboles y arbustos). Se asume comúnmente que la reducción en la densidad del bosque luego de un fuego prescripto también reduce la competencia por los recursos entre los árboles remanentes, de manera tal que éstos son más resistentes (tienen más probabilidad de sobrevivir) frente a un estrés adicional como la sequía. Sin embargo esta suposición permanece aún sin verificar, por lo cual los gestores no tienen información básica para evaluar si el fuego prescripto puede ayudar a los bosques a adaptarse a un futuro con sequías más frecuentes y severas.

Durante el tercer año de sequía, en 2014, relevamos datos de 9950 árboles en 38 parcelas quemadas y 18 parcelas sin quemar en bosques mixtos de coníferas de elevaciones bajas (<2100 msnm) en los parques nacionales de Kings Canyon, Sequoia, y Yosemite en California, EEUU. El fuego había ocurrido en las parcelas quemadas entre 6 años y 28 años antes de

fore our survey. After accounting for differences in individual tree diameter, common conifer species found in the burned plots had significantly reduced probability of mortality compared to unburned plots during the drought. Stand density (stems ha^{-1}) was significantly lower in burned versus unburned sites, supporting the idea that reduced competition may be responsible for the differential drought mortality response. At the time of writing, we are not sure if burned stands will maintain lower tree mortality probabilities in the face of the continued, severe drought of 2015. Future work should aim to better identify drought response mechanisms and how these may vary across other forest types and regions, particularly in other areas experiencing severe drought in the Sierra Nevada and on the Colorado Plateau.

nuestro relevamiento. Después de considerar las diferencias en el diámetro individual de los árboles y durante la sequía, las especies de coníferas encontradas en las parcelas quemadas redujeron significativamente la probabilidad de muerte comparadas con las parcelas no quemadas. La densidad del rodal (fustes ha^{-1}) fue significativamente menor en sitios quemados versus los no quemados, apoyando la idea que una reducción en la competencia puede ser la responsable de la mortalidad diferencial en respuesta a la sequía. En el momento de escribir este artículo, no estamos seguros si los rodales quemados mantendrán una mortalidad baja en vistas a la sequía continua y severa de 2015. El trabajo a futuro debería apuntar a identificar mejor los mecanismos de respuesta a la sequía y como éstos pueden variar en otros tipos de bosques y regiones, particularmente en otras áreas que están experimentando sequías severas en Sierra Nevada y en la meseta de Colorado.

Keywords: drought, fire effects, forest management, prescribed fire, Sierra Nevada, tree mortality

INTRODUCTION

Drought is a major disturbance agent in forest ecosystems, causing tree mortality directly (Adams *et al.* 2009) or by making trees more vulnerable to insects (bark beetles) or pathogens (Weed *et al.* 2013). While reduced precipitation often defines drought, higher temperatures lead to increased evapotranspiration that also causes drought stress. Indeed, chronic drought caused by long-term warming trends is believed to be an underlying cause of increased "background" (non-catastrophic) tree mortality across western North America (van Mantgem *et al.* 2009, Peng *et al.* 2011). Recent observations from the American Southwest have shown that the co-occurrence of reduced precipitation and high temperatures—"hotter drought" (Allen *et al.* 2015)—can lead to massive forest die-back, in which entire stands are lost (Breshears *et al.* 2005, Allen *et al.* 2010).

Fire exclusion has also led to unforeseen changes in many western forests, particularly in those forests that historically experienced high frequency and low severity fire (Allen *et al.* 2002, Brown *et al.* 2004, Agee and Skinner 2005, Noss *et al.* 2006). Fire exclusion in these forests has typically resulted in high fuel accumulations, high densities of trees, and increasing dominance of fire-intolerant species. In response, many public land agencies support large prescribed fire programs aimed at reducing understory fuels and forest density.

Prescribed fire has been generally successful at reducing severe fire hazard (van Wagtendonk 1996, Hurteau and North 2009, Fulé *et al.* 2012) by removing surface fuels, along with shrubs and small trees (ladder fuels). It is commonly assumed that following fire there is less competition among remaining trees so that they have increased resistance (more likely to survive) to additional stressors, such as drought.

Published findings on mechanical thinning and drought response provide mixed results. Thomas and Waring (2014) suggested that mechanical thinning treatments conferred improved forest resistance (remaining unchanged when subjected to disturbance) and resilience (capacity to return to original conditions) to drought. Other work suggests that the influence of mechanical thinning may be conditional on timing of treatments, the size structure of residual trees, and potential threshold responses (D'Amato *et al.* 2013). Moreover, the response of individual trees to drought is likely complex, partially dependent on local competitive environments and cumulative impacts of past drought events (Macalady and Bugmann 2014).

Can prescribed fire create conditions that enhance forest drought resistance? The answer to this question has profound implications for forest management over the coming decades. Drought-induced forest decline was identified as a key emerging threat to US forests in the recent National Climate Assessment (Joyce *et al.* 2014). Indeed, drought is expected to be more frequent and severe in coming decades across the southwestern United States (Garfin *et al.* 2014, Cook *et al.* 2015), underscoring the importance for land management agencies to develop cost-effective adaptation strategies to drought (Millar *et al.* 2007). Prescribed fire may serve as an adaptation tool, helping forests withstand expected warmer and drier future conditions, but this effect remains largely untested. California is currently experiencing its most severe drought in at least the last 120 years, and perhaps as much as a millennium, driven by low precipitation and record high temperatures (Griffin and Anchukaitis 2014). Aerial observations across California suggest that by 2014 forests at lower elevations experienced significant drought stress (Asner *et al.* 2016). We used this drought as a natural experiment, assessing whether or not past prescribed fires were associated with increased drought resistance (reduced tree mortality) in low elevation forests (<2100 m a.s.l.) at three national parks in the southern Sierra Nevada of California, USA.

METHODS

Study Area

We sampled burned and unburned mixed conifer forests in Kings Canyon, Sequoia, and Yosemite national parks (Table 1, Figure 1). Lower elevation forests at these parks were observed to be responding to drought with elevated mortality by 2014 (Figure 2), while forests at higher elevations did not visibly display elevated mortality by 2014. Prior to the initiation of a prescribed burn program or the management of lightning ignited fires by the parks in the late 1960s, these forests generally had not burned since the 1860s or 1870s (Schwilk *et al.* 2006, Swetnam *et al.* 2009). The climate of this area is mediterranean, with wet, snowy winters and long, dry summers. The weather station at Grant Grove (2011 m elevation a.s.l.), near the majority of our plots, reported annual average minimum and maximum air temperatures of 1.9 °C and 13.6 °C, and mean annual precipitation of 109 cm (30 yr average, 1951 to 1980). Compared to these long-term averages, 2013 and 2014 were unusually hot and dry. Average annual minimum and maximum air temperatures for these years were 3.1 °C and 15.8 °C, with mean annual precipitation of 59 cm. The Yosemite Valley weather station (1210 m elevation a.s.l.) reported similar trends.

Table 1. Summary statistics of burned and unburned forest monitoring plots. Average values (±1 standard deviation) are presented for plot elevation, stand density, stand basal area, and quadratic mean stem diameter (QMD). Note that slope measurements were missing for one burned plot and for five unburned plots. Live and dead tree summary statistics in 2014, with species composition presented in terms of proportional basal area.

Data Sources

We used two primary data sources for this project: the US Geological Survey-led Sierra Nevada Forest Dynamics Plot Network (van Mantgem and Stephenson 2007) and the National Park Service fire effects monitoring (FMH) plots for Sequoia and Kings Canyon national parks (NPS 2003). The Sierra Nevada Forest Dynamics Plot Network is a globally unique and ongoing plot-based forest monitoring project that has annually tracked the birth, death, and growth of nearly 30 000 individual trees across all major forest types on the western slope of the Sierra Nevada since the early 1980s. This network includes several plots in low elevation forests with and without a recent history of prescribed fire. The FMH fire effects monitoring data records forest conditions before and after prescribed fire. Sequoia and Kings Canyon national parks were early adopters of these fire-effects monitoring protocols and have maintained an active program since the 1980s. Stand conditions at these sites differ according to pre-fire conditions and variability in fire effects. This plot-based program also tracks individual tree birth, death and growth, but at staggered intervals (typically pre-fire, and post fire at 0-, 1-, 2-, 5-, 10-year intervals, and every 10 yr thereafter).

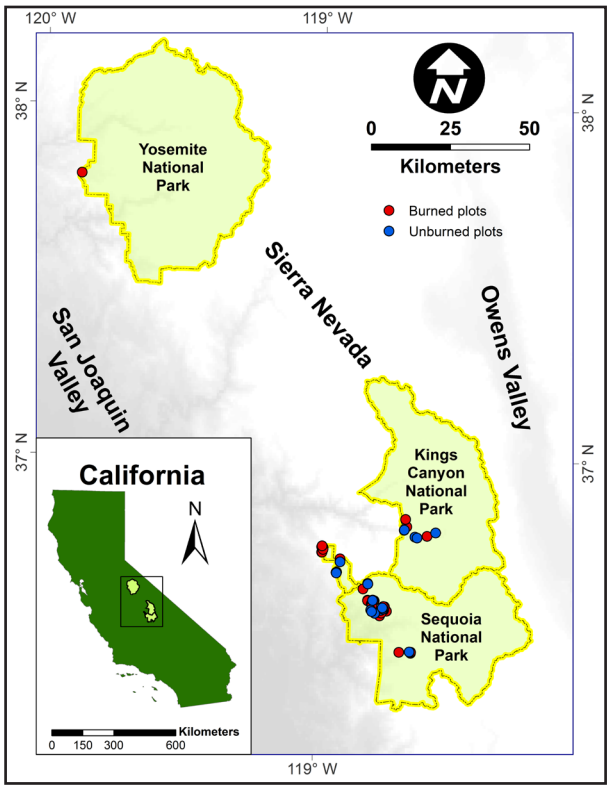

Figure 1. Locations of burned an unburned plots used for analysis at Kings Canyon, Sequoia, and Yosemite national parks, California, USA.

Figure 2. Drought-related tree mortality at a low elevation forest in Sequoia National Park. Photo credit: Nate Stephenson, US Geological Survey.

There are a number of unburned FMH plots, established as unburned reference sites or prior to a prescribed fire that then did not occur. A major difference between these monitoring programs is plot size, with the Sierra Nevada Forest Dynamics plots generally at 1.0 ha, and the FMH plots at 0.1 ha. However, model testing did not provide evidence for systematic differences between individual tree response in the Sierra Nevada Forest Dynamics and FMH plot networks. Similarly, the single large plot at Yosemite National Park was composed of the same vegetation type as the other plots, met our criteria for analysis, and testing did not reveal significant differences in the mortality response in this plot compared to the plots found in Kings Canyon and Sequoia national parks.

In 2014, we conducted mortality assessments of trees that had died in 2013 or 2014 for individually marked trees in mixed conifer forests at all Sierra Nevada Forest Dynamics plots, and all FMH plots at Sequoia and Kings Canyon national parks. We considered only low elevation forests, here defined as <2100 m a.s.l., which is the upper elevation boundary of ponderosa pine forests in the southern Sierra Nevada (Fites-Kaufman *et al.* 2007). We wanted to avoid measuring fire-caused tree mortality, and so excluded plots that had been burned ≤5 yr prior (van Mantgem *et al.* 2011). We focused on tree survivorship as an immediate drought response, noting if individual trees were alive or dead (no green needles). For the Sierra Nevada Forest Dynamics plots, annual assessments of tree mortality allowed observations of the exact year in which tree mortality occurred. Assessing trees that had died in 2013 or 2014 in the FMH plots was less straightforward; we excluded trees that were listed as dead in previous years and counted trees as newly dead within the past two years if they were retaining dead reddish needles and did not have a past history of severe crown scorch (>90% crown volume scorch). Dead trees meeting these criteria in the FMH plots were scarce, so to increase our sample size of dead trees we expanded each side of the FMH plot by 10 m, covering an additional 0.18 ha to search for dead trees only. Our final sample was 9353 live trees and 415 dead trees in 38

burned and 18 unburned plots at Kings Canyon, Sequoia, and Yosemite national parks. Fire had occurred in the burned plots from 6 yr to 28 yr before our survey. For a subset of our plots, prescribed fire had been applied once (14 plots) or twice (4 plots) prior to the most recent prescribed fire. A history of repeated prescribed fire did not appear to influence our results.

Analyses

We compared burned and unburned plots in terms of stem density (trees ha^{-1}), stand basal area (m^2 ha^{-1}), and quadratic mean diameter using randomization tests, creating 1000 samples with replacement (Manly 1997). We compared the proportion of stem density composed of dead versus live trees in burned and unburned stands with logistic regression, using a quasi-binomial response distribution to account for overdispersion. While this analysis shows differences in the observations of tree mortalities between burned and unburned plots, these differences may arise from the unburned plots having greater numbers of small trees that may be at higher risk of mortality. To account for differences across stem sizes, we estimated individual tree mortality probabilities for our most common conifer species, which included white fir (ABCO, *Abies concolor* [Gordon & Glend.] Lindley, n = 3759 live trees and 123 dead trees), incense cedar (CADE, *Calocedrus decurrens* [Torrey] Florin, n = 3021 live trees and 152 dead trees), sugar pine (PILA, *Pinus lambertiana* Douglas, n = 777 live trees and 59 dead trees), and ponderosa pine (PIPO, *P. ponderosa* Laws, n = 428 live trees and 39 dead trees). Other conifers were sparse (generally fewer than 100 individuals) or lacked observations of mortality. We used generalized linear mixed models (GLMM, Gelman and Hill 2007) to estimate individual tree mortality probabilities, which allows us to analyze tree status (0 = live, 1 = dead), considering both individual-level variables (characteristics of individual trees) and plot-level variation. Our base model estimated two-year (2013 and 2014) mortality probability m_{ij} of tree i in plot j as:

$$logit(m_{ij}) = \beta_0 + a_j + (\beta_{logDBH} \times logDBH_{ij}) + (\beta_{CADE} \times Spp_{CADEij}) + (\beta_{PILA} \times Spp_{PILAij}) + (\beta_{PIPO} \times Spp_{PIPOij}), \quad (1)$$

$$a_j \sim N(0,\sigma^2),$$

where *logDBH* is the log-transformed (base 10) DBH (stem diameter at breast height, 1.37 m), and *Spp* is an indicator variable for species identity, with white fir (ABCO) used as the reference species. The variable a_j represents plot-level variations in the regression intercept. We considered varying-intercepts with varying-slope models, but these formulations did not improve model performance. We evaluated improvements to this base model with additional variables, including a term for a history of prescribed burning.

Selection for the GLMMs was done using the Akaike Information Criterion adjusted for sample size (AICc) (Burnham and Anderson 2002), with differences in AICc (ΔAICc) >2 used as evidence of substantial model dissimilarity. We used the area under the receiver operating characteristic curve (AUC, Saveland and Neuenschwander 1990) to characterize candidate model accuracy (predicted proportions of Type I and Type II errors), with values of AUC >0.70 suggesting acceptable model accuracy (Hosmer and Lemeshow 2000). Model fit was checked by binning the data and plotting average predicted mortality probability against the observed proportion of dead trees. The proportion of variation explained using the individual-level variables only (marginal R^2) and the combined individual- and plot-level variables (conditional R^2) of the fitted models were calculated following Nakagawa and Schielzeth (2013). We calculated bootstrapped (1000 realizations) confidence intervals for parameter estimates from the models with the best support according to AICc. Analyses were conducted using the R

statistical language (R Development Core Team 2015) with the lme4 (Bates *et al.* 2015) and MuMIn (Barton 2015) packages.

RESULTS

The burned and unburned plots were different in some dimensions of stand condition in 2014 (Table 1). The average length of time since prescribed fire in the burned plots was 15 yr, while the unburned plots likely had not experienced fire for >100 yr (Schwilk *et al.* 2006, Swetnam *et al.* 2009). The burned plots had lower average stem density in the burned plots compared to the unburned plots (randomization test, $P = 0.001$). In contrast, burned plots had slightly higher average basal area compared to unburned plots, but this difference was non-significant (randomization test, $P = 0.417$). Quadratic mean diameter was greater in the burned plots compared to the unburned plots (randomization test, $P = 0.001$). Logistic regression indicated that the density of recently dead trees was negatively related to a history of prescribed fire ($\beta_{BurnStatus} \pm 1$ SE $= -1.62 \pm 0.44$, $P < 0.001$).

GLMM results showed that the two-year (2013 and 2014) probability of individual tree mortality varied by tree size (*logDBH*), species identity (*Spp*), and history of prescribed burning (*BurnStatus*) (Tables 2 and 3). Common conifer species appeared to respond somewhat individualistically to a history of prescribed burning (i.e., there was support for *Spp* × *BurnStatus* interaction terms), with *Pinus* species having the greatest sensitivity to history of prescribed burning. Individual tree mortality probabilities also varied substantially with size among species. Residual plots did not suggest model misspecifications and AUC = 0.77. Adding an additional term for the years since prescribed burning was not supported (ΔAICc = 0.19). The individual-level effects of the model explained a relatively low amount of variation in tree mortality (marginal $R^2 = 0.11$), although the inclusion of the plot-level effect improved the model performance (conditional $R^2 = 0.37$). Excluding the *BurnStatus* term resulted in a relatively large proportional reduction in the marginal R^2 (marginal $R^2 = 0.05$). Prediction plots show that trees in plots that experienced prescribed fire had lower mortality probabilities (with some overlap in confidence intervals, particularly for white fir), and that these differences were most pronounced in small trees (Figure 3).

DISCUSSION

Our results suggest that a common forest restoration tool, prescribed fire, may increase resistance to drought. After accounting for

Table 2. Model selection for GLMMs of two-year tree mortality probabilities for common conifers, including terms for tree size (*logDBH,* log-transformed stem diameter), species identity (*Spp*), and history of prescribed fire (*BurnStatus,* unburned or past prescribed fire) using AICc. Evidence for substantial model dissimilarity was ΔAICc > 2.

Model class	Model predictors	df	log likelihood	AICc	ΔAICc
Base model	*logDBH* + *Spp*	6	–1381	2773	14.6
	logDBH × *Spp*	9	–1375	2769	10.0
BurnStatus	*logDBH* × *Spp* + *BurnStatus*	10	–1371	2762	3.3
	logDBH × *Spp* + *BurnStatus* × *logDBH*	11	–1371	2764	5.1
	logDBH × *Spp* + *BurnStatus* × *Spp*	13	–1366	2759	0.0
	logDBH × *Spp* × *BurnStatus*	17	–1366	2766	7.3

Table 3. GLMM parameter estimates for individual-level effects of two-year tree mortality probabilities for common conifers. Species differences are shown relative to white fir (ABCO). Species codes follow Table 1 and model terms follow Table 2. Parameter 95% confidence intervals were derived from 1000 bootstrapped samples.

Individual-level effect	Estimate	Standard error	95% CI
logDBH	–0.85	0.16	–1.11 to –0.55
Spp_{CADE}	–0.41	0.20	–0.84 to –0.01
Spp_{PILA}	0.44	0.24	–0.02 to 0.88
Spp_{PIPO}	0.66	0.32	–0.07 to 1.30
$logDBH \times Spp_{CADE}$	0.47	0.21	0.09 to 0.84
$logDBH \times Spp_{PILA}$	0.63	0.25	0.18 to 1.04
$logDBH \times Spp_{PIPO}$	–0.07	0.33	–0.96 to 0.61
BurnStatus	–0.84	0.48	–1.88 to 0.08
$BurnStatus \times Spp_{CADE}$	–0.56	0.42	–2.19 to 0.47
$BurnStatus \times Spp_{PILA}$	–0.83	0.49	–2.47 to 0.26
$BurnStatus \times Spp_{PIPO}$	–2.00	0.84	–9.98 to –0.38

differences in individual tree diameter, common conifer species found in plots with a history of prescribed fire had significantly reduced mortality probabilities compared to trees in unburned plots. Small trees had high mortality probabilities, but the effect of past prescribed fire did not appear to be dependent on tree size (i.e., there was not strong support for an interaction between *logDBH* and *BurnStatus*). The support for the interaction term between species identity and history of prescribed burning suggests that *Pinus* species may be particularly sensitive to changes in stand conditions. Stand density (stems ha^{-1}) was significantly lower in burned versus unburned sites, supporting the idea that reduced competition may be at least partly responsible for the differential drought mortality response. However, basal area (m^2 ha^{-1}) was not significantly lower in burned versus unburned sites, so the role of competition in determining the differential mortality response is not clear.

At the time of writing, we are not sure if burned stands will maintain lower tree mortality probabilities in the face of the continued, severe drought of 2015. Future work should aim to better identify drought response mechanisms. While the causal links among prescribed fire, reduced stand density, and reduced mortality under drought are intuitively appealing, our data were insufficient to test this directly. Plot sizes were generally too small (0.1 ha) to confidently measure individual-level competitive interactions (i.e., many trees will be at the plot margins, with unknown competitive environments outside of the plot boundary) (Das 2012). We also did not collect information on other potentially important mortality predictors, such as individual tree growth history (Das *et al.* 2007), insect and pathogen pressure, and plot-level environmental conditions (e.g., soil depth or water holding capacity). Future work should attempt to combine both direct and indirect influences of tree mortality across a broader geographic area, likely using a more sophisticated analytical framework such as structural equation models (Youngblood *et al.* 2009).

While reconstructing historical forest structure is problematic (Stephenson 1999), recent analyses of inventories of productive ponderosa pine forests conducted in 1911 for trees ≥15.2 cm DBH near our study sites identified average stand densities of 72.7 trees ha^{-1}

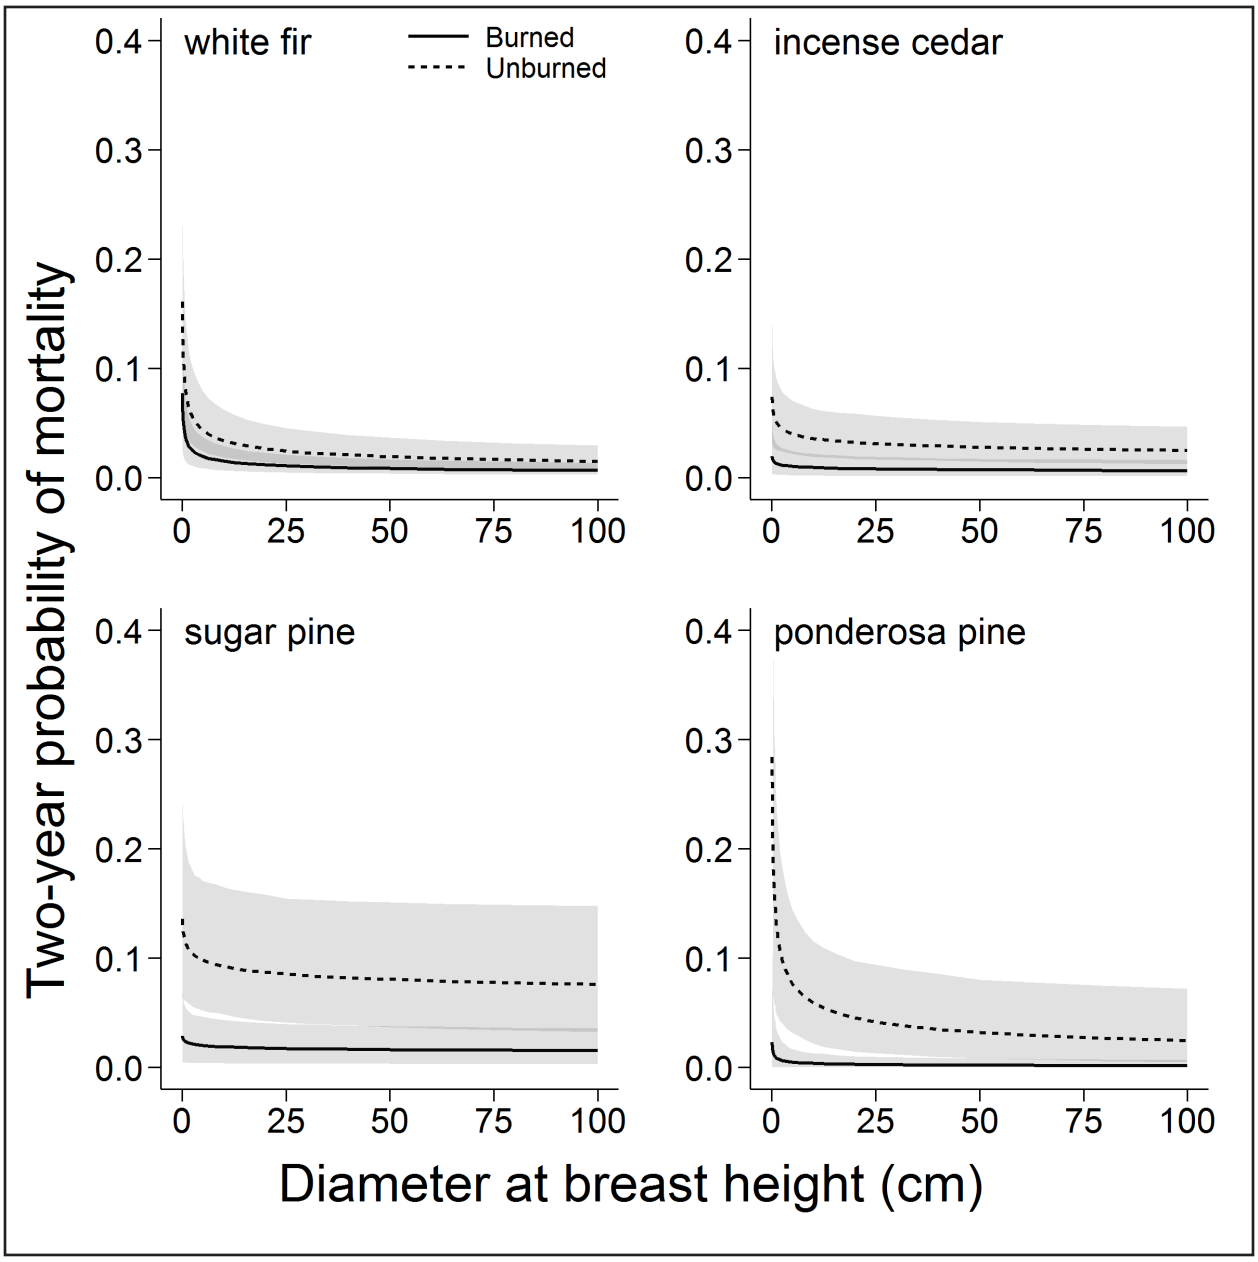

Figure 3. Predicted individual tree mortality probabilities for common conifer species in burned and unburned plots. The heavy lines represent modeled average trends and the shaded band represents 95% bootstrapped confidence intervals from uncertainty in the average mortality probability.

and basal area of 21.5 m^2 ha^{-1} (Collins *et al.* 2015). Using the same stem diameter range, our burned plots had an average stand density of 159 trees ha^{-1} and average basal area of 74.0 m^2 ha^{-1}. These statistics suggest that, even after prescribed burning, our forests contain many more trees relative to estimates of historical averages. It could be that forests with structures more closely approximating these presumed historical conditions may be more resistant and resilient (*sensu* Walker *et al.* 2004) to drought.

It may be possible to eventually manage for drought resistant and resilient forest structures. Such knowledge would provide a target when designing prescriptions using fire (per-

haps in combination with mechanical thinning) under expected future climatic conditions. We currently do not know if prescribed fire prescriptions will need to be more aggressive to promote resistance and resilient to drought. If prescribed prescriptions do need to be more aggressive, how much and under what conditions? These are critical management concerns, as many regions in the western United States are expected to see increased frequency and intensity of both drought and wildfire (Littell *et al.* 2009, Williams *et al.* 2012, Cook *et al.* 2015). It may be possible that prescribed fire can serve as an adaptation tool for both of these threats, using existing resources and human capital. Yet many barriers exist to maintaining, let alone expanding, the deployment of prescribed fire, particularly logistical constraints and air quality concerns (Ryan *et al.* 2013). Our study also underscores the need to maintain plot-based forest monitoring networks, in both treated and untreated stands, to gauge the success of prescribed fire. Overcoming obstacles to the use of prescribed fire may prove crucial to the future integrity of western forests.

ACKNOWLEDGEMENTS

We thank the many field crews who collected and organized the forest plot data. P. Moore, J. Yee, and three anonymous reviewers provided helpful comments on the manuscript. This project was partially supported by the National Park Service and the US Geological Survey Southwest Climate Science Center. Any use of trade names is for descriptive purposes only and does not imply endorsement by the US government.

Northwest Forest Plan Just Futures Collaborative

Recommendations for Tribal Sovereignty and Environmental Justice in the Northwest Forest Plan Amendment Draft Environmental Impact Statement

What: This white paper provides recommendations around Tribal sovereignty and environmental justice that we hope will be useful to organizations and individuals as they comment on the Draft Environmental Impact Statement for the Northwest Forest Plan (NWFP) amendment. We hope that these suggestions reach a diversity of organizations and individuals with divergent visions of federal land management. We encourage organizations and individuals to consider where their values align with Tribal sovereignty and environmental justice.

Who: The Northwest Forest Plan Just Futures Collaborative is a campus-community collaboration out of the University of Oregon. FUSEE has joined University of Oregon and Portland State University faculty, graduate students, and undergraduate students with expertise in Indigenous studies and/or environmental justice in this work. Our purpose is to amplify Tribal sovereignty and environmental justice issues in the lands managed by the US Forest Service (USFS) through the Northwest Forest Plan (NWFP). Ultimately, we envision contributing to paradigm shifts in land management and beyond that prioritize environmental justice, holistic worldviews, reciprocity, and Tribal sovereignty.

Review Process: We consulted with several Tribal, NGO, and academic experts to review this document. We recognize that the Northwest Forest Plan encompasses the territories of 80+ Tribal nations, and our review process does not reflect the diversity of perspectives that exist across these many nations. The consulted Tribal experts reviewed this document as individuals and do not represent Tribal governments or organizations.

Acronyms

CE: Categorical Exclusion
DEIS: Draft Environmental Impact Statement
EA: Environmental Assessment
EIS: Environmental Impact Statement

Tribal Inclusion Measures

The DEIS includes many important measures to expand Tribal inclusion across the NWFP area, through expanded measures for cultural harvesting and access, co-stewardship agreements, fire stewardship, workforce development, and youth education. Alternative B's approach to Tribal inclusion is strongest because it includes concrete requirements that national forests must meet within specified timeframes. When Tribal consultation, collaboration, and co-stewardship is optional, many national forests fail to meaningfully engage Tribes (see NWFP Tribal monitoring reports).

We suggest the following:

- Retain all Tribal inclusion plan components (Goals, Desired Conditions, Objectives, Standards, Guidelines, and potential Management Approaches) in Alternative B. Strengthen Tribal inclusions plan components in Alternatives C and D by including (most or all) approaches from Alternative B.
- Include the FAC's full Tribal Inclusion recommendation preamble (pg. 8-9) into the Record of Decision and any other relevant areas, with special emphasis on the section:

  > *Over a century of fire suppression, coupled with regulatory restrictions, removal of Indigenous practitioners and practices (including cultural fire), as well as assimilationist policies from the boarding school era, have led to today's increased risks from catastrophic wildfire and has also created structural barriers and mechanisms preventing Indigenous peoples from enacting sustainable stewardship. The NWFP amendment must signal a shift in Tribal relations across NWFP forests and include an apology for the exclusion of Tribal communities from the original formulation of the NWFP and call for healing and reparations for over a century of settler colonialism, land dispossession, criminalization and marginalization of Indigenous cultural stewardship practices, and mismanagement of Tribal lands.*

- Add Tribal inclusion measures to Alternative B and C that are included in Alternative D but not in B, which include Tribal involvement in protecting rare and listed plants, post-disturbance management, and first foods management. These plan components are:
  - TRIBAL-FORSTW-ALL-GOAL-08–D
  - TRIBAL-FORSTW-ALL-GOAL-09-D
  - TRIBAL-FORSTW-ALL-PMA-D

- For restoring dry, serpentine, and wet meadow-associated culturally significant species, use TRIBAL-FORSTW-ALL-OBJ-03-D from Alternative D rather than TRIBAL-FORSTW-ALL-OBJ-03 from Alternative B across Alternatives B and C.
  - TRIBAL-FORSTW-ALL-OBJ-03-D uses "10 projects" as the metric rather than 2000 acres, which can better allow for different scales of stewardship as defined by Tribes.
- Change TRIBAL-FORSTW-ALL-DC-05 and TRIBAL-FORSTW-ALL-DC-09 to incorporate stronger language from Federal Advisory Committee Desired Condition 1-16, which reads:

    - "Cultural burning is recognized as an inherent Tribal right and responsibility that has existed for millennia and is rooted in Tribal laws and Indigenous knowledge, practices, and belief systems. The Forest accommodates cultural burning and coordinates, consults, and collaborates with Tribes in order to create conditions conducive for this Tribal sovereign practice."

- National forests should accommodate both cultural fire and Tribally-led prescribed fire, allowing Tribes to define for themselves the management techniques needed to achieve their objectives.
- Change TRIBAL-FORSTW-ALL-STD-06 to remove this sentence: "A closure shall affect the smallest practicable area for the minimum period necessary for activities of the applicable Tribe." This sentence could be used to justify restricting the scope of closure orders desired by Tribes.
- Move Potential Management Approaches to Standards or Guidelines so they are enforceable, especially:
    - TRIBAL-FORSTW-ALL-PMA-A through TRIBAL-FORSTW-ALL-PMA-H

Beneficial Fire Use

Beneficial fire is one of the principal means that Indigenous peoples use to steward the land, protect built dwellings, nurture biological productivity, and sustain vital resources for traditional foods, fibers, medicines, and ceremonies. The Forest Service's fire suppression and fire exclusion policies have significantly altered landscapes and degraded ecosystems and habitats that are nurtured by Native peoples and in turn nourish Native cultures. From its criminalization of Indigenous cultural burning to its militarization of fire management through fire "fighting," the agency's fire exclusion policies represent an insidious form of environmental racism. Alternative B's approach to beneficial fire is strongest because of its support of Indigenous cultural burning and co-stewardship agreements.

Remedying cultural and ecological harms caused by fire exclusion requires fire *inclusion,* in addition to expanding Tribal partnerships as discussed above. Authorizing greater fire use while imposing limits on aggressive firefighting represents an essential step toward environmental justice for Indigenous peoples. In the Pacific Northwest native forests need Native fires, and Tribal inclusion requires fire inclusion. Likewise, fire inclusion requires Tribal inclusion, whether through cultural fire or Indigenous-led prescribed fire with cultural objectives.

The DEIS presents numerous supportive statements on beneficial fire use for cultural and ecological purposes. Indigenous cultural burning is rightfully supported across all action alternatives, and statements favoring prescribed burning and managing wildfires for resource benefits are present in alternatives B and C. These praiseworthy statements signify a necessary change in Forest Service fire policy that better recognizes Tribal sovereignty. The DEIS could go further in incorporating more of the FAC recommendations on Indigenous cultural burning and/or Indigenous-led prescribed fire with cultural objectives, as discussed in the prior section.

Additionally, the DEIS lacks analysis on how existing bureaucratic barriers to fire use will be overcome. And it lacks disclosure of where and how beneficial fire use will be allowed and applied. The fact that the Northwest Forest Plan amendment is tiered to the agency's Wildfire Crisis Strategy is a warning sign that fuels reduction for fire suppression may continue to dominate Forest Service fire management, turning fire use provisions in the Northwest Forest Plan amendment into broken promises.

We suggest the following:

- Expand the discussion of the numerous social, cultural, economic, and ecological benefits of cultural burning and prescribed fire, and contrast these effects with the costs and impacts of mechanical fuels reduction treatments alone and conventional wildfire suppression operations.

- Describe the numerous safety risks, economic costs, and direct environmental impacts of conventional wildfire suppression operations to make the case for alternative fire use practices.

- Tier the authorization of beneficial fire use from Indigenous cultural burning, prescribed fire, and managed wildfire to the Federal Wildland Fire Policy (1995/2001) and the growing literature on Indigenous fire use.

- Provide spatial fire management information on the locations of Potential Operational Delineations (PODs) and fire management zones where wildfires could be managed for resource benefits.

- Require that any/all fuels reduction or fire resilience projects include a fire use component (e.g. prescribed pile burning and/or broadcast understory burning) and specify that the primary objective of these fuels projects is to prepare sites for managing future fire for resource benefit rather than fire suppression.

- Indigenous peoples use fire lighting, not firefighting, and mature/old-growth trees are an outcome, not an objective, of Indigenous fire use. Frequent low intensity burning helps nurture soil, water, and fuel conditions that enabled some trees to grow big and old, with wide range of tree species' diversity, and survive occasional passage of wildfires.

- Follow the Good Fire II Report's Recommendation #3 to identify barriers to the exercise of reserved, retained, and other rights by Tribes and their members, including the right to engage in cultural burning and prescribed fire. Make clear to employees and representatives of that agency that the exercising of these rights is welcome and encouraged.

- Work to remove bureaucratic barriers to beneficial fire inclusion and managed wildfire. This includes following the Good Fire II Report's Recommendation #35 to create concrete policies that allow for managed ignitions under particular conditions.

- Implement recommendations #15, 16, and 92 from the Wildlife Fire Mitigation and Management Commission's "On Fire" report to empower Tribes to plan and implement more beneficial fire

through expansion of the Tribal wildland fire workforce and legal authority to promote cultural burning.

Guide to Avoiding Colonial Environmentalism in Public Comments

Federal land management and wilderness preservation movements have long perpetuated Indigenous erasure and environmental racism. Today, environmental groups still perpetuate harm to Indigenous communities and landscapes when they advocate for a "hands-off" approach that denies/erases the violence that settler land management has enacted to Indigenous ecologies. Here are some considerations for moving past colonial environmentalism in your public comments and forest advocacy:

What's your historical baseline?

- Pacific Northwest forests have been dramatically altered by 150+ years of genocide and the associated shift from Indigenous ecologies to settler colonial land management. Exclusion of Indigenous cultural fire regimes, wildfire suppression, timber management, invasive species introduction and spread, and climate change have led to shifted forest species composition (e.g. loss of oak woodland, expansion of Douglas-fir and other conifers), tree and canopy density, and other altered landscape conditions that are not sustainable now or in the future.
- **Avoid** using a *settler ecological baseline* when describing a "natural" forest and advocating for hands-off approaches that leave colonial forest conditions intact.
    - Understandings of "natural" often ignore long-term, ongoing Indigenous land relations that shape environmental conditions, as well as the changes in forests that have come with genocide as mentioned above.
    - Similarly, the concepts of *wild* and *wilderness* are colonialist and discriminatory as these terms have been used as part of the racial othering of Indigenous peoples to justify the oppression of Indigenous people and the erasure of their legacy and living connections with their homelands.
- **Avoid** rigid understandings of "mature" and "old growth" tree and forests that often represent overly dense forests and altered species compositions that have emerged through colonial management and the exclusion of Indigenous stewardship.
- **Instead, say this:** Draw from specific Tribal climate adaptation plans and Indigenous science syntheses (see resources below) for culturally-informed ecological baseline and stewardship orientations.
- **Instead, say this:** Across the NWFP area, the Forest Service should collaborate with Tribes to identify and manage for desired ecological conditions. Whenever possible, barriers should be removed for Tribes to engage in stewardship that meets their objectives.

- **Instead, say this:** Old growth forests across the Pacific Northwest are not wildernesses, and have always been stewarded and managed by Tribes for a variety of cultural objectives.
- **Resources**
    - Eisenberg et al 2024 "Braiding Indigenous and Western Knowledge for Climate-Adapted Forests"
    - PNW Tribal Climate Change Project – Tribal Climate Change Adaptation Plans database
    - Karuk Climate Adaptation Plan 2019
    - Whyte 2018 "Settler Colonialism, Ecology, and Environmental Injustice"
    - Worl 2022 "Restoring What? And For Whom?"
    - Eichler 2021 "Settler Colonialism and the US Conservation Movement: Contesting Histories, Indigenizing Futures."

Which species matter?

- **Avoid** perpetuating single-species approaches. The 1994 Northwest Forest Plan focused too much on single, charismatic species like the spotted owl and other threatened & endangered species. These species are important, but focusing on single species is a colonial approach to environmental management.
- **Instead, say this:** Across the NWFP area, the Forest Service should manage for a diversity of habitat and ecosystem types, collaborating with Tribes to identify management actions that foster biological diversity and benefit culturally important species to Tribes. This could include prioritizing for ESA or threatened species, but monolithic management for one desired species typically doesn't achieve the desired outcome.
- **Instead, say this:** The Forest Service should also support Tribal management for first foods species, as defined by Tribes.
- **Resources**
    - Eisenberg et al 2024
    - Karuk Climate Adaptation Plan 2019
    - Hoagland and Albert 2023 "Wildlife Stewardship on Tribal Lands"

    - Amelia and Joaquin Marchand 2023 "Rights of Nature, Indigenous, and Advocacy Perspectives" livestream from Gonzaga Climate Center
    - Reed and Norgaard 2021 "Fire is Food"

Whose science are you citing?

- **Avoid** biasing your advocacy by only drawing from western science, which is rooted in European and colonial understandings of the world. Western science presents an incomplete understanding of forest, fire, and landscape ecology. Land management that emerges from only western science perpetuates settler colonial harm to land and people.

- **Avoid** referring to Indigenous knowledge solely in the past tense, which erases present-day Indigenous knowledges that are constantly adapting and evolving.
- **Instead, say this:** Cite Indigenous science in addition to western science in public comments, and call on the Forest Service to engage Indigenous science in updating and implementing the NWFP.
- **Resources**

    - Fisk et al 2024 "Evolving wildlife management cultures of governance through Indigenous Knowledges and perspectives"
    - Medin and Bang 2014 "Who's Asking?"

Are you tokenizing Indigenous knowledges?

- **Avoid** the common settler environmentalist practice of referencing Indigenous knowledge and stewardship only when it fits existing advocacy goals.
- **Avoid** referring to Indigenous knowledge and stewardship in the past-tense, as a static, historical body of knowledge to draw from and inject into settler colonial management frameworks.
- **Avoid** referencing or treating Tribes as stakeholders rather than sovereign nations.
- **Avoid** paternalistic and white savior assumptions that Tribes need help or that you know what they need.
- **Instead, say this:** The USFS should create decision-making structures and share power to honor Tribal sovereignty, including fulfilling governmental trust responsibilities and upholding Tribal Treaty Rights. This includes the expansion of co-stewardship and co-management agreements where Tribal nations (both federally recognized and not federally recognized) have decision-making power over their territories.
- **Instead, say this:** The USFS should include additional language that incorporates empowerment of Tribal decision making, self-defining terminology, and self-autonomy, thus substantiating Tribal sovereignty. For example, the USFS should revise existing plan components to place decision making in Tribal hands, where appropriate (i.e., use language such as "At Tribal request" or "As determined by Tribes" etc.)
- **Instead, say this:** The USFS should promote and incorporate a more holistic worldview consistent with Indigenous concepts of kinship and stewardship toward the ecological world and all species that share our planet. Move away from an anthropocentric approach to "resource" management and more toward ecosystem stewardship where the rights of nature are valued alongside those of humans.

Additional Environmental Justice (EJ) Concerns

Environmental justice matters to assess and address the uneven burdens and benefits created by and/or exacerbated by federal lands management. Tribal inclusion is at the forefront of an environmental justice (EJ) approach to federal lands management because all federal lands are Indigenous lands and because environmental justice centers Tribal sovereignty. However, it is not the only environmental justice concern relevant to the Northwest Forest Plan (NWFP). This section addresses some of these additional environmental justice concerns.

The DEIS fails to offer appropriate landscape level analysis or plan components to address EJ concerns. The EJ appendix focuses on identifying which communities are to be considered as EJ communities in project-level analysis, using race, ethnicity, and income. Addressing predictable EJ concerns should happen on a landscape level across the NWFP management area, not only (but also) in site-specific project design and outreach. In other words, analysis and plan components (including Standards and Guidelines) should be found in the Environmental Impact Statement (EIS), rather than deferring such analysis only to the Environmental Assessment (EA) or Categorical Exclusion (CE) for each individual site-specific project (such as individual timber sales).

We suggest the following:

- Incorporate all management suggestions from Chapter 10-Environmental Justice of the "Synthesis of Science to Inform Land Management Within the Northwest Forest Plan Area" (pages 839-841).
- Consider how the NWFP amendment is consistent with the Presidential Memorandum "Promoting Diversity and Inclusion in Our National Parks, National Forests, and Other Public Lands and Waters" (2017), including the two sections "Enhancing Diversity and Inclusion in the Federal Workforce" and "Enhancing Opportunities for all Americans to Experience Public Lands and Waters."

Toxicities

- Assess the air and water quality impacts of pesticides, herbicides, fire retardants, and other chemicals used in the forest as part of NWPF management. These should be assessed in relation to worker exposure, in relation to nearby communities exposed through drift, and in relation to food, including first foods, and water, including drinking water, upon which many communities rely. Mandate assessing and addressing these concerns within project-specific analysis.

Recreational access and equity

- Provide analysis and discussion of inequities in access to recreational opportunities and different cultural uses of the NWFP area at the landscape scale, not only (but also) in site-specific project design. Include clear plan components in all alternatives that site-specific project analysis should:
    - Assess and protect sites with recreation use by diverse communities and that are disproportionately used by certain underrepresented or historically-excluded communities (by race, ethnicity, income, disability, etc.) following EO 14096's mandate to improve equitable access to public lands as environmental justice praxis.
    - Assess and protect sites in relationship to the economic impact that disruption of recreation will have on local communities, especially given that recreation is the primary economic contributor of NWFP lands to the regional economy.
    - Assess and protect sites for lesser-known recreation values by diverse communities.
    - Survey for and protect culturally or historically sensitive and/or meaningful sites for diverse communities.

Youth education and mentorship

- Maintain and build on ECON-SUST-DC-3 and ECON-SUST-GOAL-1 from the DEIS to promote meaningful youth education and mentorship opportunities on every national forest in the plan area, particularly in the realms of prescribed, cultural, and wildland fire mentorship and training.

Environmental workforce

The DEIS acknowledges that the environmental workforce is largely "composed of low-income Hispanic or Latino immigrants and undocumented workers" (3-145) who travel long distances for work. Similarly, other Communities of Interest, "Nontimber Forest Products Gathering" and "Recreation," also travel frequently to different sites across NWFP locations. Without landscape scale analysis, it is unlikely that these groups will be adequately considered in site-specific project analysis since they are unlikely to be present at the time of Environmental Assessment. Although the DEIS mentions that evaluating for EJ implications within EJ communities and Communities of Interest should include "opportunities for meaningful involvement in the decision-making process" made available (3-141), it does not offer any recommendations to do so.

- Create an additional ECON-SUST-GOAL that aims to remove financial barriers to public participation, invests in communication beyond translation, and uses regional liaisons or trusted channels of communication to form connections with Communities of Interest.

In DEIS Section 3.8.1.12 Environmental Justice, the subsection titled "Environmental Workforce" (3-145) acknowledges some of the inequitable labor practices that this workforce faces. However, this section fails to provide a more in-depth analysis of how the workforce is distributed and quantify the size and scale of this workforce. More discussion is needed on the equity implications of using temporary migrant workers to compensate for labor shortages. Without comprehensive immigration reform, this form of employment is predicated on inequitable power dynamics perpetuated by centuries

of neocolonial practices. Furthermore, the DEIS refers to certain types of labor performed by the environmental workforce as "unskilled" (3-121; 3-151) or "low-skilled" (3-122) labor. This type of language is demeaning to workers that have accumulated decades of experience by doing this type of work and erodes class solidarity by reinforcing a hierarchy of labor.

- Provide mechanisms to consistently inspect for and aggressively enforce federal, state, and local wage and safety regulations for contractors in the NWFP management area, including regarding wage theft, worker intimidation, and heat and catastrophic wildfire smoke exposure.
- Consult regularly with workers and worker-organizations to develop protocols for worker protections in the implementation of NWFP projects. More thoroughly address and assess the over-representation of Indigenous, Black, and other marginalized and racialized communities in certain forms of work and the specific vulnerabilities of that work.
- Create an additional ECON-SUST-DC that incentivizes safe, sustainable, and equitable working conditions for forest workers and fair compensation for this work.
- Use language that elevates the importance of the environmental workforce and does not demean worker labor or reinforce the segmentation and hierarchical arrangement of the workforce.
- Provide landscape level analysis of disproportionate harm to forest and fire workers caused by catastrophic wildfire caused smoke and heat (both of which are exacerbated by climate change).

  - Costa 2021 "Temporary work visa programs and the need for reform"

Economic sustainability objective

The DEIS's ECON-SUST-OBJ-01 focuses exclusively on treatment of acres. This type of framing prioritizes efficiency and incentivizes the use of contracting tools which favor selection of contractors who, in addition to meeting the base selection criteria (which does not include local benefits) can get the most work done, the most quickly, for the lowest price. Efficiency does not always equate to effectiveness; by using acres treated as the sole metric of success, it incentivizes practices that contribute to worker inequity and ignore working conditions and local benefits. As noted by Rural Voices for Conservation Coalition, "Although low-price contracting might appear to save the government money, in reality it costs the American taxpayer more money when poor quality work has to be redone, and when poorly-paid workers have to apply for food stamps and other public assistance, or seek medical care without insurance." Additionally, low-bid contracting perpetuates inequities as Latine contractors tend to attain labor-intensive service contracts (LISCs) while white contractors tend to secure more technical work included in master stewardship agreements and stewardship contracts.

- Create an additional ECON-SUST-DC that incentivizes safe, sustainable, and equitable working conditions for forest workers and fair compensation for this work.
- Create an additional ECON-SUST-GOAL that incentivizes increased communication and collaboration between federal agencies, especially land management agencies, the Department of Labor, and OSHA to enforce wage and safety regulations.

- Add language to ECON-SUST-GOAL-03 to incentivize federal land management agencies to prioritize Best Value contracting practices, such as Stewardship contracting rather than BPAs.

NORTHWEST FOREST PLAN
THE FIRST 25 YEARS (1994–2018)

In accordance with Federal civil rights law and U.S. Department of Agriculture (USDA) civil rights regulations and policies, the USDA, its Agencies, offices, and employees, and institutions participating in or administering USDA programs are prohibited from discriminating based on race, color, national origin, religion, sex, gender identity (including gender expression), sexual orientation, disability, age, marital status, family/parental status, income derived from a public assistance program, political beliefs, or reprisal or retaliation for prior civil rights activity, in any program or activity conducted or funded by USDA (not all bases apply to all programs). Remedies and complaint filing deadlines vary by program or incident.

Persons with disabilities who require alternative means of communication for program information (e.g., Braille, large print, audiotape, American Sign Language, etc.) should contact the responsible Agency or USDA's TARGET Center at (202) 720-2600 (voice and TTY) or contact USDA through the Federal Relay Service at (800) 877-8339. Additionally, program information may be made available in languages other than English.

To file a program discrimination complaint, complete the USDA Program Discrimination Complaint Form, AD-3027, found online at https://www.usda.gov/oascr/complaint-resolution and at any USDA office or write a letter addressed to USDA and provide in the letter all of the information requested in the form. To request a copy of the complaint form, call (866) 632-9992. Submit your completed form or letter to USDA by: (1) mail: U.S. Department of Agriculture, Office of the Assistant Secretary for Civil Rights, 1400 Independence Avenue, SW, Washington, D.C. 20250-9410; (2) fax: (202) 690-7442; or (3) email: program.intake@usda.gov.

USDA is an equal opportunity provider, employer, and lender.

Abstract

Davis, Raymond J.; Lesmeister, Damon B.; Yang, Zhiqiang; Hollen, Bruce; Tuerler, Bridgette; Hobson, Jeremy; Guetterman, John; Stratton, Andrew. 2022. Northwest Forest Plan—the first 25 years (1994–2018): status and trends of northern spotted owl habitats. Gen. Tech. Rep. PNW-GTR-1003. Portland, OR: U.S. Department of Agriculture, Forest Service, Pacific Northwest Research Station. 38 p. https://doi.org/10.2737/PNW-GTR-1003.

This is the fourth in a series of periodic monitoring reports on status and trends of forests used by northern spotted owls (*Strix occidentalis caurina*; NSO) for nesting, roosting, and dispersal on federally administered lands within the Northwest Forest Plan (NWFP) area (NSO range in the United States) since its implementation in 1994. The objective of this monitoring is to determine if federal forest lands are providing sufficient conservation of forests that are important elements of NSO habitat, and thus populations. Here we present models on the amount, distribution, and spatial arrangement of nesting, roosting, and dispersal forest types across the NWFP area, and losses and gains resulting from disturbance and forest succession, respectively. Forests suitable for nesting and roosting are one of the most critical components of NSO habitat, defined as the area with the full range of environmental conditions necessary to support occupancy, survival, and reproduction. Given the importance of habitat to support population recovery, this is the first monitoring report to model habitat using distribution and amount of suitable nesting/roosting forest at multiple spatial scales, and in combination with abiotic environmental covariates. We used estimates of territory occupancy in conjunction with available habitat to estimate changes in population size and distribution of territorial NSOs on federal lands at the start and end of this monitoring cycle (1993 and 2017).

We found a 3 percent net increase (from 8,890,500 to 9,155,700 ac) of nesting/roosting forest on federal lands between 1993 and 2017. This net gain occurred despite gross losses from wildfire of 7.9 percent (703,700 ac), 2.9 percent from timber harvest (257,700 ac), and 0.9 percent from insects or other causes (83,700 ac), indicating that processes of forest succession more than compensated for the losses resulting from disturbance during the first 25 years of the NWFP. Dispersal forest on federal lands increased by 1 percent, but dispersal-capable landscapes decreased by 9 percent because of forest losses on surrounding nonfederal lands and large wildfires on federal lands. The forest landscape that allowed for owl movement between one reserved area to another became more confined and fragmented. Despite net increases in NSO forests on federal lands during the monitoring period, the population of territorial owls on federal lands decreased by an estimated 61.8 percent. A primary cause for population declines on federal lands was displacement from native habitat by the invasive barred owl (*S. varia*), which highlights the increasing threat to NSO persistence.

Keywords: Northwest Forest Plan, effectiveness monitoring, northern spotted owl, territory occupancy, habitat, barred owl.

Preface

Monitoring northern spotted owl (*Strix occidentalis caurina*) populations and the forests used by them within the Northwest Forest Plan (NWFP) area was approved by an Intergovernmental Advisory Committee. The program is consistent with the framework for effectiveness monitoring described in "The Strategy and Design of the Effectiveness Monitoring Program for the Northwest Forest Plan" and follows protocols and guidance in the "Northern Spotted Owl Effectiveness Monitoring Plan for the Northwest Forest Plan," both published in 1999. The interagency effectiveness monitoring framework was implemented to meet requirements for tracking the status and trends of older forests, populations and habitats of northern spotted owls and marbled murrelets (*Brachyramphus marmoratus*), watershed conditions, social and economic conditions, and tribal relationships. Monitoring is conducted in 1- to 5-year intervals and results are documented in a series of technical reports. This report, and the others in the current series, covers the first 25 years of the NWFP.

Introduction

More than a quarter century has passed since the design and implementation of the Northwest Forest Plan (NWFP). The NWFP amended 19 U.S. Department of Agriculture (USDA) Forest Service and 7 U.S. Department of the Interior Bureau of Land Management (BLM) resource management plans across three western states and two Forest Service regions within the range of the northern spotted owl (*Strix occidentalis caurina*; NSO) in the United States. As part of the NWFP, an interagency effectiveness monitoring framework was created to track status and trends of late-successional and old-growth forests, NSO populations and habitat, marbled murrelet (*Brachyramphus marmoratus*) populations and habitat, watershed conditions, social and economic conditions, and tribal relationships (Mulder et al. 1999). In 2016, the BLM in western Oregon revised its resource management plans, which adopted the interagency monitoring framework in its entirety (USDI BLM 2016a, 2016b).

This report is the fourth in the series of NSO habitat monitoring reports outlined in Lint et al. (1999). It covers 1993–2018, which marks the year the NWFP was designed (FEMAT 1993) and the following 25 years of NWFP implementation. The goal of this monitoring is to evaluate the success of the NWFP in arresting the downward trends in NSO habitat and populations that preceded its implementation, and in maintaining and restoring forest types necessary to support future NSO populations on federally administered forest lands throughout its range. Specific monitoring objectives are as follows:

- Assess status and trends in NSO demographic rates or population size and distribution on federal lands.
- Assess status and trends in the amount and distribution of NSO forests and habitat on federal lands.

Addressing objective 1, Franklin et al. (2021) provided information on demographic rates from a population meta-analysis of demographic study areas (1993–2018). Here we focused on objective 2 and combined occupancy rates reported by Franklin et al. (2021) in our models to estimate NSO population size and distribution on federal lands.

There has been a long history of inconsistent use of the term "habitat" to describe forest stands (e.g., a stand of "nesting, roosting, foraging habitat"), including its use in previous NWFP monitoring reports. Forest stands of various types, amounts, and spatial configurations are only part of what constitutes habitat. NSO habitat is more accurately defined as the combination of the environmental biotic and abiotic conditions on the landscape necessary to support owl occupancy, survival, and reproduction (see Lesmeister et al. 2018: 250). Here, forest cover type refers to forest structure and tree species composition associated with use by NSOs (e.g., nesting, roosting, foraging, and dispersal), while habitat refers to the combination of forest cover type and the other relevant environmental conditions.

Each monitoring report has used new or revised data and sometimes new or improved analytical methods. For example, in future efforts, Google Earth Engine™ may become the primary platform for monitoring trends in NSO forests and habitat. Given the improvements in analytical tools, the results in every report supersede, and should not be compared to, prior reports. Here we summarized an assessment of NSO forest types and habitat for 22.1 million ac of federally administered forest lands affected by the NWFP. We also included information on the surrounding 23.8 million ac of nonfederal forest lands to provide a broader landscape context across the 57 million ac that comprise the NSO geographic range in the United States.

Habitat Monitoring Under the NWFP

The status and trends of forests used by NSOs have been estimated every 5 years because it was believed that changes in forest vegetation would not be reliably discernible at more frequent intervals using the Landsat remotely sensed vegetation data that this broadscale monitoring program relies upon (Lint et al. 1999). This has proven to be mostly true for changes that result in gains in suitable forest types and habitat as a result of forest succession; however, our ability to detect losses from forest disturbance has now become very reliable and near-real time, thus future monitoring may entail annual updates.

Effectiveness monitoring evaluates assumptions made during development of the NWFP, which included that "habitat" (e.g., suitable forest) likely would not decline faster than the estimated 5 percent per decade (from wildfire and timber harvest combined) in the NWFP's final environmental impact statement (USDA and USDI 1994).

Assumptions outlined in Lint et al. (1999) were evaluated to determine the following:

- Suitable forest conditions within late-successional reserves (LSRs) would improve over time at a rate controlled by successional processes in forest stands that were not suitable when the NWFP was developed. Given the slow process of old-forest development, these gains were not expected to produce any significant changes in suitable forest conditions for several decades.
- Forest conditions outside of reserved land use allocations (LUAs) were declining because of timber harvest and other habitat-altering disturbances, but many forest stands retained vegetation structure across the landscape to facilitate NSO movements.
- Catastrophic events would likely halt or reverse gains of suitable forest in some reserves, but the repetitive design of reserves would provide resiliency, and not result in isolation of population segments.

Based on these assumptions, we addressed the following questions:

- What proportion of the total forested landscape on federal lands is covered by forest types used for owl nesting, roosting, and dispersal?
- What are the trends in the amount of and changes in distribution of these NSO forest types, particularly in large reserves?
- What are the trends in the amount and distribution of dispersal forest that allow for movement of owls between large reserves?
- What are the primary factors leading to loss and fragmentation of suitable forest types and NSO habitat?
- What are the trends in the estimated number of occupied territories over the duration of the monitoring program?

We evaluated these questions at three broad geographic scales: (1) by physiographic province, (2) by state, and (3) for the geographic range of the NSO. Within these spatial extents, we assessed forest types and habitat conditions inside broad federal LUAs representing reserved and nonreserved landscapes.

Phase II Monitoring Under the NWFP

The NSO monitoring plan was designed to occur in two phases. During phase I, NSO populations have been monitored separately by continuing demographic studies using mark-recapture methods on territorial owls in federal study areas and habitat (e.g., forests used by NSO). Thus, appropriate monitoring indicators for phase I have been population demographic rates (e.g., survival, recruitment, population growth) and changes in amount and distribution of suitable forests. Phase II was envisioned as a monitoring program based on predictive models of regional population dynamics driven by landscape-scale amounts and patterns of habitat. Relevant population-level indicators for phase II would then be population size and distribution (Lint et al. 1999).

For the past two decades, the monitoring program has studied relationships between various measures of NSO occupancy and demographic performance with forest conditions (type, quantity, quality, and distribution) at the home range and at landscape scales (Anthony et al. 2006; Dugger et al. 2005, 2016; Forsman et al. 2011; Franklin et al. 2000; Yackulic et al. 2019). These studies have provided critical information on if and what forest conditions could be used to predict owl occupancy, distribution, and demographic performance at a variety of spatial scales. Combining findings from other efforts, Glenn et al. (2017) developed a method to estimate NSO territory density across broad landscapes based on habitat carrying capacity, territorial spacing, and occupancy rate estimates. Here we report on the first application of phase II monitoring to predict population size and distribution on federal lands.

Data Sources

Many, but not all, of the data sources used in this report were initially developed and used in previous monitoring reports (Davis et al. 2011, 2016; Lint 2005). During each 5-year monitoring cycle, previously used data sources are occasionally updated to incorporate new research findings and other information, or to correct errors. More details of these data sources can be found in previous monitoring reports but are briefly described here.

Physiographic Province Map

The NWFP boundary was based on the geographic range of the NSO in the United States. Because the range is large, it was divided into 12 physiographic provinces (fig. 1) to reduce the complexity and diversity of such an extensive

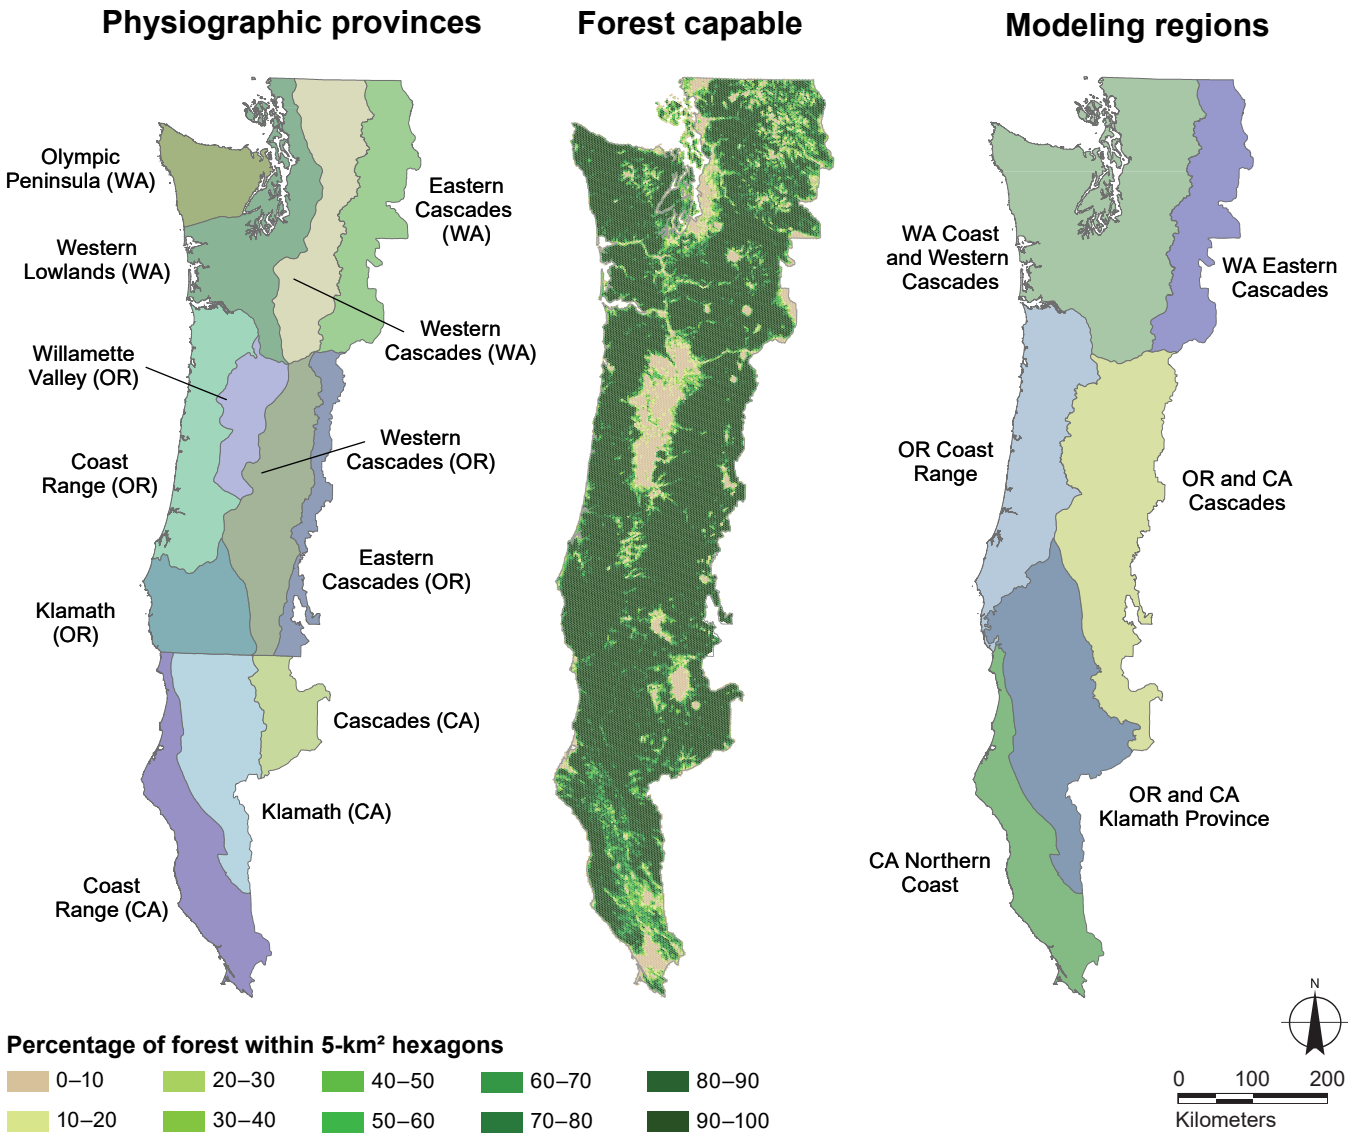

Figure 1—Physiographic provinces, percentage of forest-capable lands within 5-km² hexagons, and modeling regions within the range of the northern spotted owl in the United States.

geography, as well as for analytical purposes (FEMAT 1993; Thomas et al. 1990; USDA and USDI 1994). Physiographic provinces represent different forest zones, plant communities, and disturbance regimes that vary geographically with climate, topography, soils, and geology and were largely based on subdivisions by Franklin and Dyrness (1973).

Forest-Capable Area Map

This data source is a 30-m resolution (pixel size) raster map of areas capable of developing into forests (Davis et al. 2011). It is largely based on the U.S. Geological Survey Gap Analysis Program and the "impervious layer" from the National Land Cover Database (Herold et al. 2003, Vogelmann et al. 2001). It excludes urbanized areas, major roads, agricultural areas, water, lands above tree line, snow, rock, and other nonforested features. We used this map to exclude (mask) these areas for modeling, mapping and analytical purposes (fig. 1).

Modeling Regions

The NSO range was divided into six regions to model forest cover types used by the owl and for habitat modeling. They are a modified version of the physiographic provinces

described above. Boundary modifications were based on (1) ecological similarities between physiographic provinces and (2) balancing the occurrence and distribution of NSO location data used for model training and testing. We used geographic region information from population monitoring work (Anthony et al. 2006: app. A, Forsman et al. 2011) to combine some provinces and Environmental Protection Agency level III ecoregions (Omernik 1987) to guide final delineations of modeling regions (fig. 1).

Land Use Allocation Map

LUAs describe overarching forest management direction. The geographic information system (GIS) layer representing LUAs was originally delineated when the NWFP was developed (USDA and USDI 1994). It has been updated prior to each monitoring cycle to account for LUA changes that occurred in the prior 5 years as well as minor editing to correct mapping errors. Updates include federal surface ownership boundary adjustments, changes in federal land ownership (e.g., land exchanges, land acquisitions and disposals), and changes owing to forest resource management plan amendments or revisions. Since the last monitoring report, the BLM has revised its LUAs in western Oregon (USDI BLM 2016a, 2016b). However, the management objectives and direction for the new LUAs are similar to those in the NWFP (fig. 2). One noteworthy change in the BLM revision is the division of BLM forests into areas characterized as moist (northwestern and coastal Oregon) and dry (southwestern Oregon) to recognize ecological differences between the historical fire regimes of western Oregon, as well as different habitat treatments that are hypothesized to reduce the risk of loss of suitable habitat in the dry forest types.

Federal LUAs have specific management directions, so we classified these allocations into reserved and nonreserved lands. Reserved allocations are areas where the maintenance and restoration of older forests over time are expected under the current land use plans, including the following (GIS layer attribute codes in parentheses):

- Congressionally reserved areas (CR)—lands reserved by the U.S. Congress, such as wilderness areas, wild and scenic rivers, and national parks and monuments.
- Late-successional reserves (LSRs)—lands reserved for the protection and restoration of late-successional/old-growth (LSOG) forest ecosystems and habitat for associated species; this includes marbled murrelet reserves (LSR3) and NSO activity core reserves (LSR4).
- Managed late-successional areas (MLSAs)—areas for the restoration and maintenance of optimal levels of LSOG forest on a landscape scale where regular and frequent wildfires historically occurred. Silvicultural and fire hazard reduction treatments are allowed to help prevent older forest losses from large wildfires or disease and insect epidemics.
- Administratively withdrawn areas (AW)—areas identified in local forest and district plans, including recreation and visual retention areas, backcountry, and other areas where management emphasis does not include scheduled timber harvest.
- Adaptive management area in reserves (AMR)—areas identified to develop and test innovative management to integrate and achieve ecological, economic, and other social and community objectives. Emphasis on restoration of late-successional forests and managed as an LSR.

Nonreserved LUAs were designed for multiple land use objectives, including the following sustained-yield management for timber production:

- Matrix (other)—federal lands outside of reserved allocations where most timber harvest and silvicultural activities were expected to occur.
- Adaptive management area nonreserved (AMA)—identified to develop and test innovative management to integrate and achieve ecological, economic, and other social and community objectives. Commercial timber harvest was expected to occur in these areas, testing alternative approaches to meet NWFP objectives.

Standards and guidelines in the NWFP and revised BLM resource management plans allow for timber harvesting within LSRs that is designed to benefit the development of late-successional conditions. In the moist forests, stands (generally <80 years old) not currently providing nesting/roosting function for NSOs can be managed to speed the development of, or improve, NSO habitat quality in the long term. On BLM lands, these treatments are not to preclude or delay by 20 years or more the nesting/roosting function of a stand compared to development without treatment (USDI BLM 2016a: 64–67). Management direction for dry

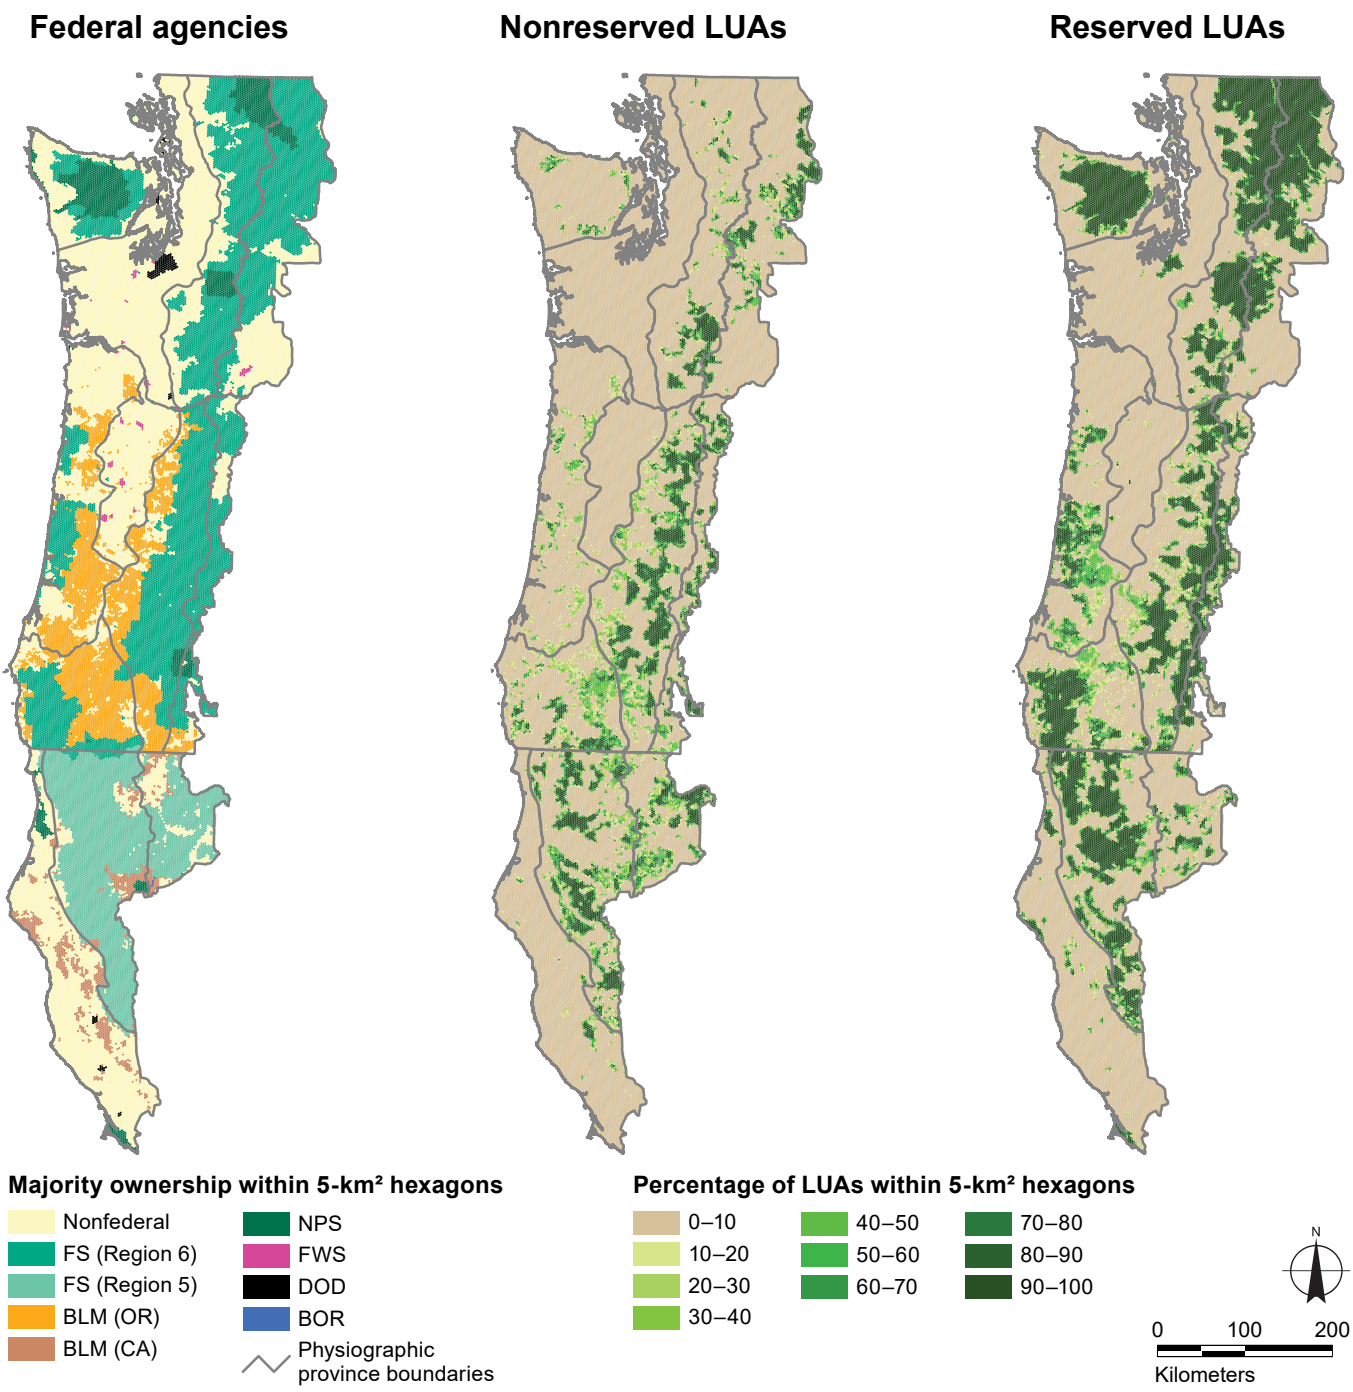

Figure 2—Maps of federal forest management agencies and land use allocations (LAUs) summarized as majority ownership and percentage of area in 5-km^2 hexagons within the range of northern spotted owls in the United States. FS = Forest Service, BLM = Bureau of Land Management, NPS = National Park Service, FWS = Fish and Wildlife Service, DOD = Department of Defense, BOR = Bureau of Reclamation.

forests is reflective of the more frequent, fire-driven stand and landscape dynamics. Focus is therefore on restoring resistance and resilience against fire, insects, and drought through vegetation treatments. Outside of BLM lands, timber harvesting in LSRs is allowed west of the Cascade crest in stands up to 80 years old (110 years in the Northern Coast Range Adaptive Management Area) regardless of stand origin (e.g., plantations or naturally regenerated) if it benefits the creation, hastens the transition to, or maintains late-successional forest conditions. East of the crest and in the Oregon and California Klamath Physiographic Provinces, silvicultural activities aimed at reducing the risk of large, high-severity wildfires are allowed. The focus of these treatments is to make the reserved forests in fire-prone environments less susceptible to losses from large-scale, high-severity fire. Such management activities are encouraged in LSRs even if a portion of the activities must take place in late-successional forests. Such activities in older stands may also be undertaken in LSRs in other provinces if fire risk is particularly high (USDA and USDI 1994: C-12).

We used the updated LUA layer, as of 2017, to frame the status and trend analyses in this report (fig. 2). Since NWFP implementation, there has been a slight overall increase in federal lands (1.8 percent) with an 8 percent increase in reserved LUAs, largely owing to new LSR designations by the BLM in western Oregon. As in previous monitoring reports, riparian reserves, another NWFP LUA, were not delineated because they were supposed to be delineated based on site-specific analyses.

Forest Disturbance Maps

Annual forest disturbance maps (30-m pixel resolution) were produced for forest-capable lands from 1986 to 2017 using an ensemble LandTrendr methodology (Cohen et al. 2018, Healey et al. 2018). These maps (fig. 3) are part of a larger national dataset produced by the USDA Forest Service Rocky Mountain Research Station's Landscape Change Monitoring System program (USDA FS 2021). Three types of annual maps of forest disturbance were produced:

- Year of detection—image taken the year change was detected. This year does not always represent the year of disturbance. Often, vegetation change caused by a disturbance was detected in the following year; but sometimes it was detected >1 year afterward, depending on Landsat image availability and other factors. Usually, disturbance was detected within 2 years of the disturbance event.
- Duration of disturbance—the duration of a disturbance was based on the number of years of consecutive disturbance segments. Short-duration (usually 1 year) disturbances are associated with events that quickly remove or alter forest vegetation cover (e.g., wildfires, timber harvesting, forest clearings, wind, floods, etc.). Disturbances lasting multiple years represent slow forest change and loss of cover caused by insects, disease, or other physiological stressors (Cohen et al. 2016).
- Severity of disturbance—the relativized difference in the normalized burn ratio (RdNBR) (Miller and Thode 2007) was used as our index of disturbance severity. We classified disturbance severity using class thresholds (low, moderate, high) identified by Reilly et al. (2017) that correlated RdNBR with tree mortality (percentage of live tree basal area change) from pre- and postfire forest inventory plots.

The last step in disturbance mapping was to assign a cause agent (wildfire, timber harvest, insect/disease, etc.) for each disturbance signal for each year. This procedure captured multiple disturbances that occurred in the same area (pixel) over time. Assignment of disturbance agent was based on expert rulesets incorporating the duration of the disturbance, its location in relationship to federal LUAs, relationship to aerial detection survey maps for insects and disease (Coleman et al. 2018, Johnson 2016), spatial relationship to mapped wildfire perimeters (e.g., National Interagency Fire Center, Monitoring Trends in Burn Severity), and when inside wildfire perimeters, the year of detection in relationship to the wildfire year. If a disturbance inside a wildfire perimeter predated the wildfire year by >2 years, it was attributed to some other cause (e.g., insects or timber harvest). We classified disturbance cause agents into four general classes using the rules below:

- Timber harvest—including thinning and regeneration. Classified as abrupt disturbances (duration <4 years) outside of CR lands (e.g., wilderness areas) where timber harvesting is not allowed in the reserved area's

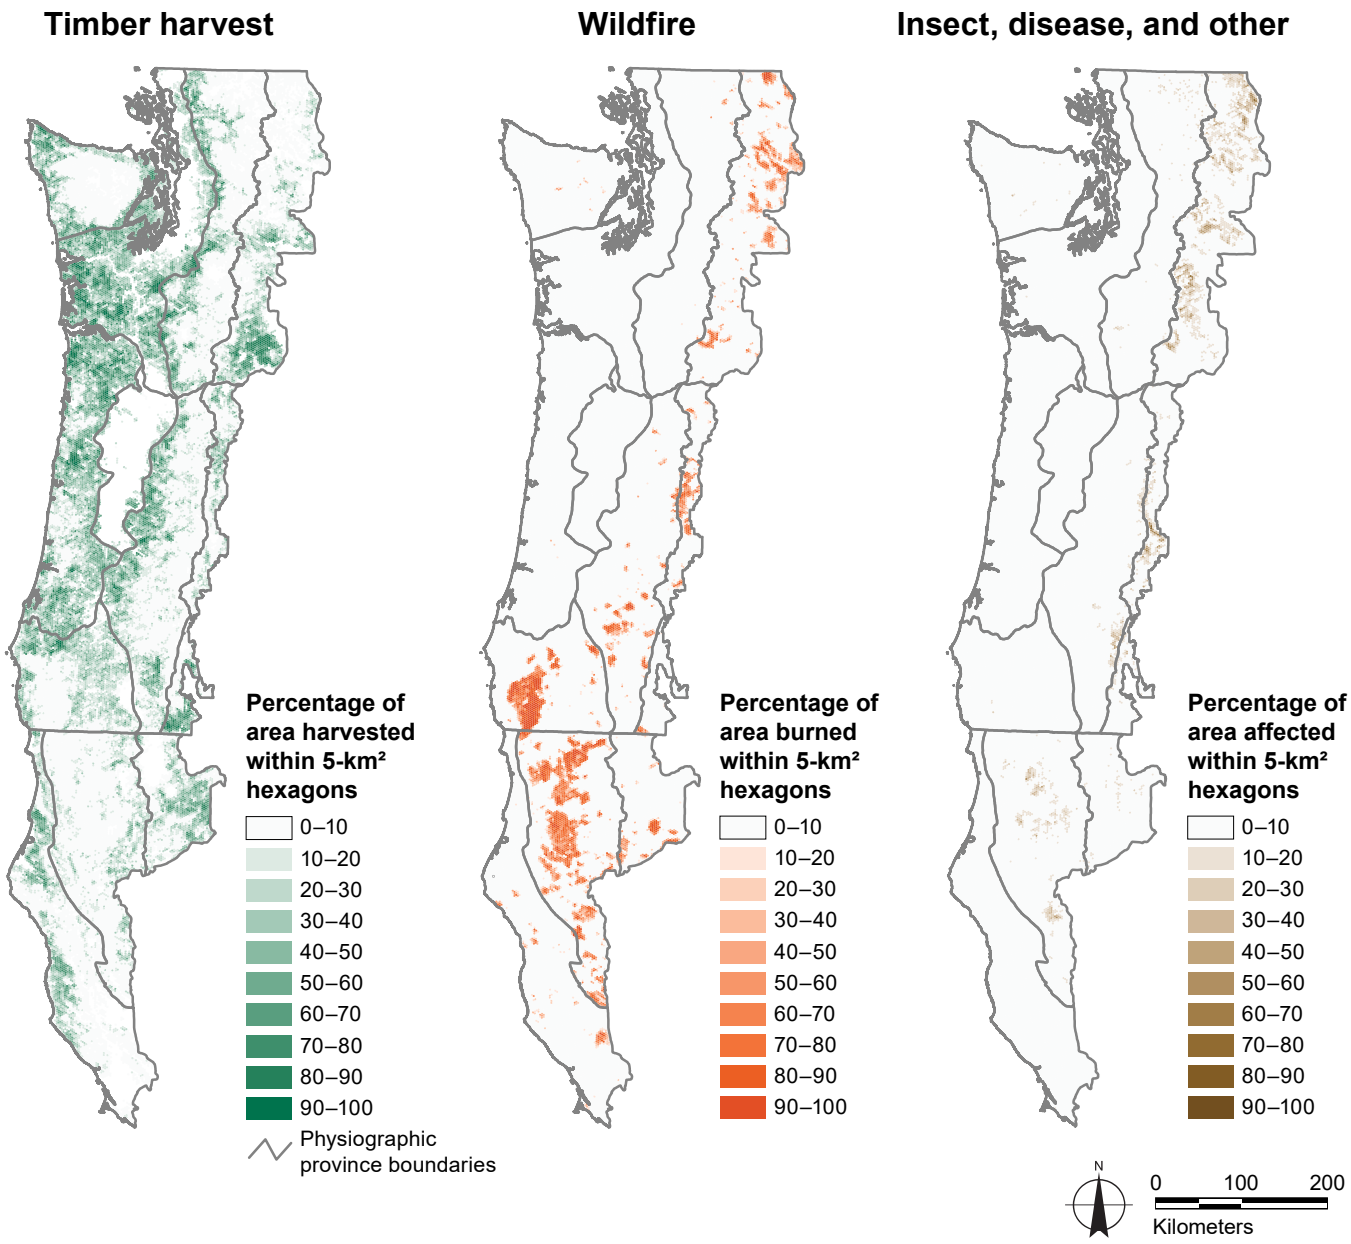

Figure 3—Cumulative forest disturbances over 25 years (1993–2017) summarized as percentage of disturbed area in 5-km² hexagons within the range of northern spotted owls in the United States.

management plan. During our monitoring period, new CRs have been designated; and for these, harvest attribution only applied to disturbances prior to the year of designation. Abrupt disturbances within wildfire perimeters were attributed to harvesting if they occurred prior to the fire year.

- Wildfire—a disturbance with duration of 1 year that occurred the same year, or the year following a fire and within a mapped wildfire perimeter.
- Insect and disease—disturbances with long durations (≥4 years, persistent), or more than four (chronic) disturbances detected. Also, this includes small disturbance patches shorter duration (patch size <9 pixels) when they occurred with a "potential insect/disease area" (PIDA). The PIDA was generated using a focal mean analysis on a binary map of pixels exhibiting persistent or chronic disturbance signals (duration ≥4 years or more than four disturbance events). A focal

mean using a 1-km radius (equivalent to a 776-ac area) was compared against aerial detection survey polygons for the region to identify a mapping threshold to represent PIDAs. We observed that when at least 10 percent of this area contained persistent/chronic disturbance signals, it matched well with aerial detection survey data.

- Other disturbance—All detected disturbances not assigned above.

Forest Structure and Species Composition Maps

Annual forest vegetation structure and composition maps (30-m pixel resolution) for forest-capable lands from 1986 to 2017 were generated using the gradient nearest neighbor (GNN) imputation modeling and mapping methodology developed by Oregon State University Department of Forest Ecosystems and Society's Landscape Ecology, Modeling, Mapping, and Analysis program (LEMMA 2020). GNN is a multivariate, nonparametric modeling and mapping framework that inputs forest inventory plot data to individual map pixels based on Landsat surface reflectance and environmental similarity in the gradient space (Ohmann and Gregory 2002). The version of GNN used in our analysis was based on the composite Landsat images produced to map the forest disturbances above, matching plot measurements to Landsat image years (Bell et al. 2021).

Methodological changes, described in detail in the late-successional and old-growth monitoring report (Davis et al., in press), improved the quality of GNN compared to previous monitoring reports. This included using a consistent type of forest inventory plot for imputations, the ensemble LandTrendr imagery described above, imagery stabilization, and bootstrapped approximations utilizing multiple neighbors ($k = 7$) with weighted means proportional to the probability that a bootstrap sample would result in that plot being the nearest neighbor for a pixel (Davis et al., in press).

NSO Presence Data

NSO pair locations from demographic study areas, supplemented with other location data, were used to train species distribution models used for monitoring. We used the most biologically important pair location based on the following hierarchical ranking: (1) active nest, (2) fledged young, (3) primary roost location, (4) diurnal location, and (5) nocturnal detection from 1993. To reduce sampling bias in relationship to the larger modeling region background (Fourcade et al. 2014, Phillips et al. 2009) we reduced the geographically clumped nature of these data by using only one location per NSO territory. We then filled in the modeling region spaces between demographic study areas with NSO pair presence data from the late 1980s through the 1990s compiled for the 10-year monitoring report (Lint 2005). We limited our data to those collected prior to extensive barred owl invasion that likely affected NSO forest selection. These supplemental locations were geographically thinned out and spaced using nearest neighbor distances to randomly select a subset of these points (as described in Davis et al. 2011: 30, app. B). We did not limit the number of random supplemental locations to match the sample size from the demographic study area. Instead, we used all available location data from the 10-year monitoring report (Lint 2005) that occurred between our study areas. This procedure resulted in a more complete spatial distribution of NSO locations (less clumped) throughout each modeling region. All locations were compiled and checked for spatial accuracy.

Methods

Mapping Nesting/Roosting Forest

Maps of forest types associated with owl nesting and roosting were produced following methods from previous monitoring reports (Davis et al. 2011, 2016), and that methodology is described briefly below. Open-source machine learning software Maxent (Phillips et al. 2006, 2017, 2021) was used to develop a forest cover type model for each modeling region using 10 bootstrapped random samples. We used 75 percent of NSO locations for model training and 25 percent for model testing. Training locations were analyzed against a random sampling of 10,000 background locations from forest-capable pixels within the modeling region.

Based on findings of previous reports and analyses of NSO forest selection (Davis et al. 2011, 2016), we used five GNN forest structure metrics as model predictor variables that co-date the NSO location demography data: density (trees/ha) of large trees >75 cm diameter at breast

height (d.b.h.), percentage of live conifer tree canopy cover, average stand height (meters) of live dominant and codominant trees, mean live conifer diameter (centimeter at d.b.h.), and diameter diversity of live trees as an index of structural diversity based on live conifer tree densities in different diameter classes. Forest species composition GNN variables included proportion of total stand basal area comprising high-elevation tree species, pine species, evergreen hardwood species, oak woodland species, and redwood (*Sequoia sempervirens* (Lamb. ex D. Don) Endl.) (depending on the modeling region). Stand age was also included as a predictor variable.

The relative proportion of training locations were fit to each model predictor variable using linear, product, and hinge response functions. Each model maximized the likelihood ratio of average presence to average background (called the gain function) to best contrast environmental conditions at owl sites from background locations. A regularization multiplier function was applied to penalize high variance in model response functions, where higher variance incurred larger penalties (Merow et al. 2013). Model calibration was accomplished by adjusting the regularization multiplier function setting from 0.25 to 5.0 incrementally by 0.25 and evaluating the difference between the training and testing gain. Maxent is prone to overfitting, resulting in predicted distributions that are clustered around location points. Model overfitting was indicated when training gain was significantly higher than testing gain based on nonoverlapping 95 percent confidence intervals.

We evaluated model predictive performance using the area under the curve (AUC) statistic (Fielding and Bell 1997) based on the held-out test locations and by examining the ratio of the proportion of correctly predicted test locations to the proportion of available area within a moving window of modeled suitability—the predicted-vs-expected (P/E) curve as described in Hirzel et al. (2006). The best model was indicated by having the highest AUC, a monotonically increasing P/E curve with a high Spearman rank statistic, and similar training and testing gain (e.g., overlapping 95 percent confidence intervals).

All replicate model algorithms (Maxent lambda files) from the best model were coded into Google Earth Engine (GEE), where annual model predictor variables were uploaded, to produce a time series of maps based on their mean.[1] This monitoring cycle marks the first use of GEE to demonstrate automated analysis and map production for NSO monitoring. GEE is a cloud platform for massively parallel spatial analyses and computation and has provided many benefits in model development in terms of rapid comparison, visualization, and attribute calculation (Gorelick et al. 2017). Our use of GEE resulted in a considerable savings in time and effort that would normally be required for data management and analyses of such a large quantity of spatial data. Although we produced 31 years of maps (1986–2017) using Landsat 5, 7, and 8 image collections freely available in GEE, the following analyses focused on the years from 1993 to 2017 between which the analyses were bookended.

We used the logistic model output as the relative index of forest suitability for nesting and roosting by NSO pairs. The forest suitability index ranged from 0 to 1.0, where values closer to zero represent forest structure and species composition unsimilar to that found at NSO locations and higher values are more similar. Following procedures from Hirzel et al. (2006), we used the P/E curve to reclassify the continuous suitability index into four biologically meaningful map classes as follows:

- Unsuitable—Maxent logistic output from zero to the mean value between 0 and the P/E = 1 threshold. This map class represents forest types that NSOs normally avoid using for nesting and roosting.
- Marginal—Maxent logistic output from the unsuitable threshold to the P/E = 1 threshold, resulting in a map class that represents forest types approaching what NSOs will nest and roost in.
- Suitable—Maxent logistic output from the P/E = 1 threshold to 0.5. This map class represents forest types where nesting and roosting occurred higher than expected by random chance and up to average conditions associated with nesting and roosting.
- Highly suitable—Maxent logistic output from 0.5 to the highest suitability index value. This map class represents forest types with above-average conditions found at nesting and roosting locations.

[1] The use of trade or firm names in this publication is for reader information and does not imply endorsement by the U.S. Department of Agriculture of any product or service.

To produce rangewide maps of NSO nesting/roosting forest, we applied these mapping thresholds to the Maxent logistic outputs in GEE, producing mosaics of the reclassified maps from each modeling region for each year. The "suitable" and "highly suitable" map classes were combined to analyze trends in nesting/roosting forest.

Pixels can be misclassified as nesting/roosting forest following a high-severity disturbance (e.g., stand-replacing event) because rapid green up of ground vegetation creates surface reflectance in Landsat imagery that is similar to old forest (Bright et al. 2019). These misclassifications can produce errors in the forest vegetation maps used as modeling variables that are transferred to the forest type models and thus cause artificial gains in nesting/roosting forest. To correct for errors in these trends, we used high-severity disturbance maps from the Landscape Change Monitoring System program to mask out unrealistic recruitment of nesting/roosting forest in our time series as it takes decades, not a few years, for a stand-replaced forest to redevelop back into a nesting/roosting forest. Specifically, once a pixel of nesting/roosting forest was lost because of a high-severity disturbance, it was maintained as nonnesting for the remainder of the time series.

Forest Fragmentation Analysis

We used modified methods described by Soille and Vogt (2009) that were coded into GEE to conduct morphological spatial pattern analyses of the time series of nesting/roosting forest maps. These maps were classified into two spatial pattern types (fig. 4):

- Interior—30-m pixels classified as nesting/roosting forest (combined suitable and highly suitable classes) and >1 map pixel from unsuitable or marginal forest. The smallest patch containing interior consisted of a 3-by-3 pixel configuration (2 ac) with the center pixel classified as interior.
- Edge—30-m pixels classified as nesting/roosting forest and directly adjacent to unsuitable or marginal pixels.

Microclimate of interior forest pixels is expected to be similar to intact old forest because patches as small as 2.4 ac have similar microclimates as large intact forest conditions (Heithecker and Halpern 2007). Fragmentation results in lower amounts of interior forest and higher amounts of edge and can occur through two different processes: (1) severe forest disturbances that remove interior forest, or (2) forest succession where a nonnesting forest begins to transition into nesting/roosting forest.

Dispersal-Capable Landscape Analysis

Forest cover types used by dispersing juvenile NSOs moving away from natal areas, or by subadults and adults moving between territories, was mapped following methods in Davis et al. (2011: 40) and is briefly described here. We developed rangewide maps of suitable dispersal forest that included the extent of nesting/roosting forest classes (suitable and highly suitable) and all pixels of GNN data representing mean conifers ≥11 inches d.b.h. and canopy cover ≥40 percent (Thomas et al. 1990). Many of the forests classified as "suitable" dispersal forest may not meet dispersal forest requirements because dispersing juveniles use similar forests as nesting/roosting forests (Sovern et al. 2015) but do serve as an effective measure of landscape forest cover.

NSOs are capable of dispersing long distances, and gene flow from one part of the range to another can occur in a few generations (Forsman et al. 2002, Jenkins et al. 2019). Ninety percent of natal NSO movements from the Forsman et al. (2002) dispersal study occurred within 15.5 mi of the natal site, when the surrounding landscape was covered with ≥40 percent dispersal forest (Davis et al. 2011). Thus, we used a 15.5-mi radius roving circular analysis window to quantify the percentage of dispersal forest for both bookend periods (1993 and 2017), including all forest landownerships. We quantified the percentage of a 15.5-mi radius roving circular window that contained dispersal forest for both bookend periods and considered any pixel with ≥40 percent dispersal forest within the window part of the "dispersal-capable landscape."

Habitat Modeling for Estimating Number of Occupied Territories

Here we followed methods for habitat modeling and estimating density of occupied territories that were developed by Glenn et al. (2017), who reported high predictability based on independent data. Using estimates of occupied territory density, we calculated the likely number of territories occupied (TEROCC) within each demographic study area.

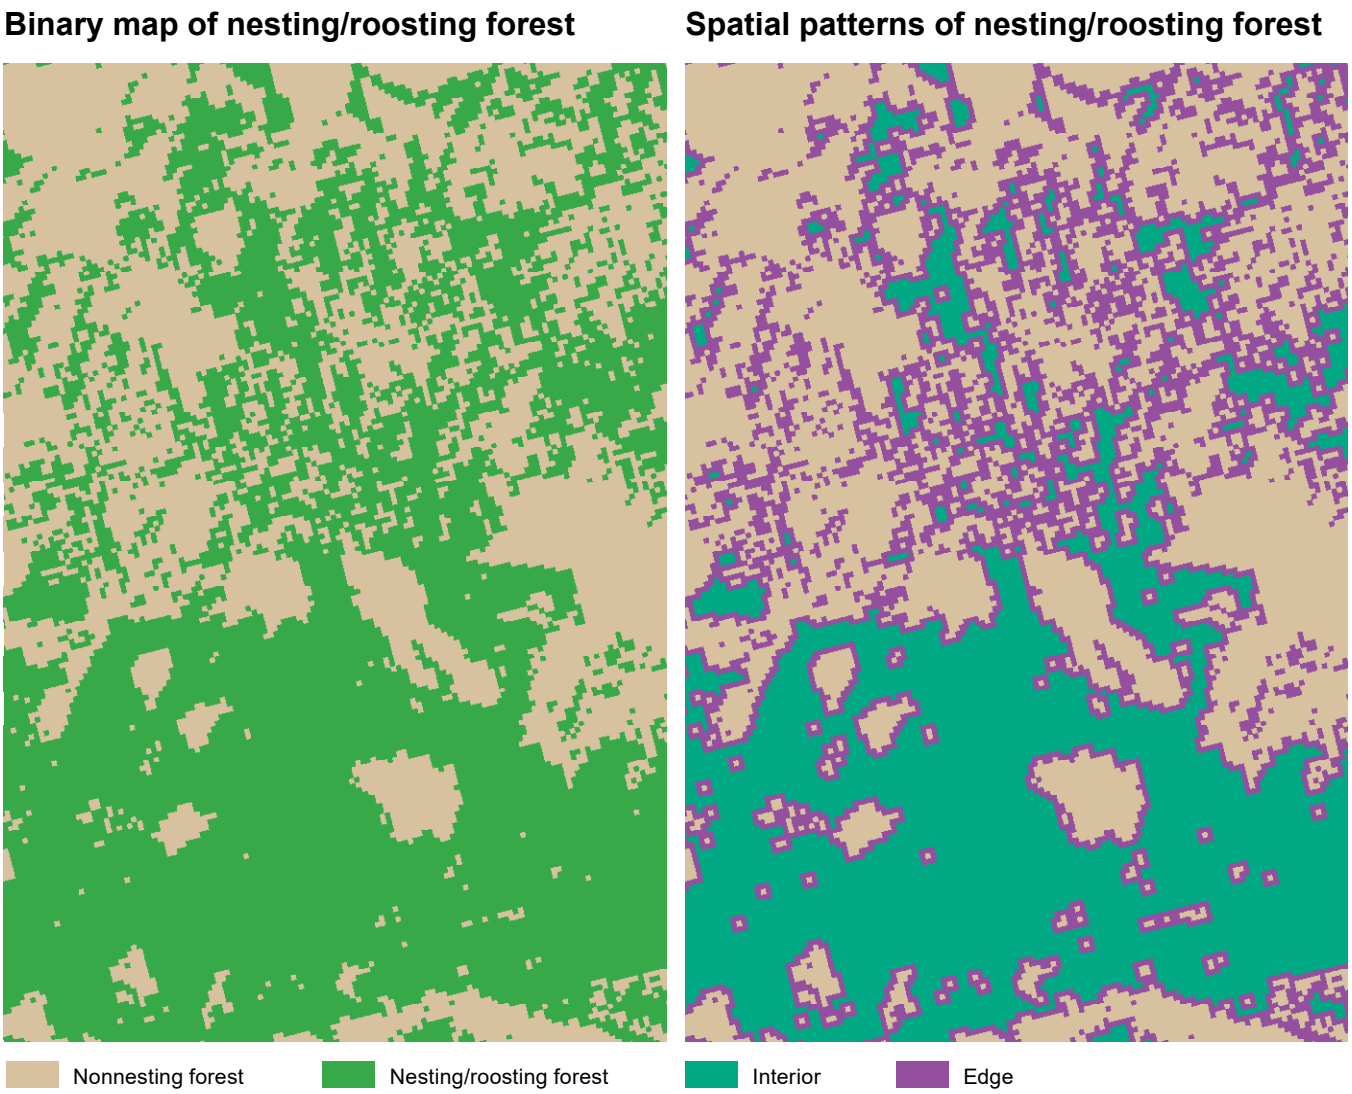

Figure 4—Nesting/roosting forest spatial pattern types produced by the morphological spatial pattern analysis.

We modeled the relationship between territorial owl pair locations and abiotic and biotic environmental conditions at multiple spatial scales (as opposed to the pixel scale used for forest type modeling) using Maxent. Nesting/roosting forest is an essential component of an owl pair's territory, so we used it as the basis for four model predictor variables spatially summarized in four ways: (1) percentage within a nest patch radius (200-m [0.2-mi] radius), (2) percentage within a territory radius (600- to 1900-m [0.4- to 1.2-mi] radii, depending on the modeling region), (3) percentage of edge nesting/roosting forest within a territory radius, and (4) distance (kilometers) from a patch of interior nesting/roosting forest. Abiotic predictor variables included elevation, topographic position index (the difference between a pixel's elevation and mean elevation within a 450-m [0.3-mi]radius), average annual precipitation, average monthly maximum temperature for August, and average monthly minimum temperature for December. All climate variables were based on the 1981–2010 climate normal (PRISM 2015).

Modeling, calibration, evaluation, and reclassification methods were identical to those described above (except that quadratic response functions were used instead of hinge). Model outputs represented a landscape-scale relative suitability index for use by territorial owl pairs and was reclassified into two map classes:

- Unsuitable—Maxent logistic output from 0 to the P/E = 1 threshold. This map class represents the biotic

and abiotic conditions normally avoided for nesting and roosting.

- Suitable—Maxent logistic output from the P/E = 1 threshold to the highest suitability index. This map class represents the biotic and abiotic conditions normally used for nesting and roosting.

We produced habitat maps for the start and end (bookend) years of the monitoring period (1993 and 2017) and estimated habitat carrying capacity and TEROCC by pairs for both years. This method relied on two forms of monitoring information: (1) habitat-based estimates of territory density using median nearest neighbor distance (NND) data, and (2) occupancy rate information provided by the population meta-analyses. We first produced estimates of habitat carrying capacity using 20 random replicates of territory centers within "suitable" habitat and spaced no nearer than the NND. We used a random point generator in open-source software QGIS (QGIS 2021) to fill the suitable habitat footprint for each modeling region until no more centers could be fit, thus an estimate of habitat carrying capacity. We calculated the mean and 95 percent confidence intervals for each point replicate to estimate habitat carrying capacity for each modeling region. To estimate TEROCC, we adjusted the habitat carrying capacity using occupancy rates reported in the latest population meta-analysis (Franklin et al. 2021) that included the effects of other environmental variables that affect occupancy, such as the presence of barred owls. To ensure that our TEROCC estimates were reasonable, we compared them to territory occupancy and realized population change estimates for all eight federal demographic study areas (Franklin et al. 2021).

We calculated change in TEROCC estimates between 1993 and 2017 TEROCC and compared those to realized population change estimates reported by Franklin et al. (2021). For our modeling time period, we calculated change in habitat carrying capacity and TEROCC on all federal lands and within reserved lands.

Results

Mapping Nesting/Roosting Forest

The nesting/roosting forest models had mean testing AUCs ranging from 0.78 to 0.92 and mean Spearman rank correlation coefficients from 0.87 to 0.98 ($P < 0.001$) (table 1).

Nesting/roosting forest was concentrated on federal lands at the beginning of the monitoring period (71.9 percent) and slightly more so at the end (72.5 percent). We estimated a rangewide gross loss of about 1,045,100 ac of nesting/roosting forest on federal lands since the NWFP was implemented (app. 1). This amounted to about 11.8 percent of what was present in 1993. Most of the losses (69.4 percent) occurred within the federally reserved LUAs, roughly in proportion to the amount of nesting/roosting

Table 1—Nesting/roosting forest modeling results for model calibration and testing statistics

Modeling region	Training sample	Testing sample	RM	Training gain	Testing gain	Testing AUC	Spearman rank
Washington coast and Cascades	250	83	0.50	1.15 (±0.03)	1.15 (±0.05)	0.88 (±0.01)	0.97 (±0.01)
Washington eastern Cascades	87	28	1.75	0.90 (± 0.05)	0.93 (±0.13)	0.85 (± 0.02)	0.87 (±0.07)
Oregon Coast Range	247	82	0.75	1.46 (±0.04)	1.48 (±0.07)	0.92 (±0.01)	0.93 (±0.04)
Oregon and California Cascades	596	198	2.75	0.70 (±0.01)	0.73 (±0.03)	0.80 (±0.01)	0.97 (±0.01)
Oregon and California Klamath	757	252	0.75	0.53 (±0.02)	0.52 (±0.03)	0.78 (±0.01)	0.98 (±0.01)

forest that is reserved. Figure 5 shows the spatial pattern of net losses and gains of nesting/roosting forest within the owl's range on all forest lands.

On federal lands, wildfires accounted for 67.3 percent (703,700 ac) of nesting/roosting forest losses. Timber harvesting accounted for 24.7 percent (257,700 ac), while insects, disease, and other disturbances (e.g., blowdown, floods, etc.) accounted for 8 percent (83,700 ac). Considering both losses and gains from forest succession, we estimated a rangewide net increase in nesting/roosting

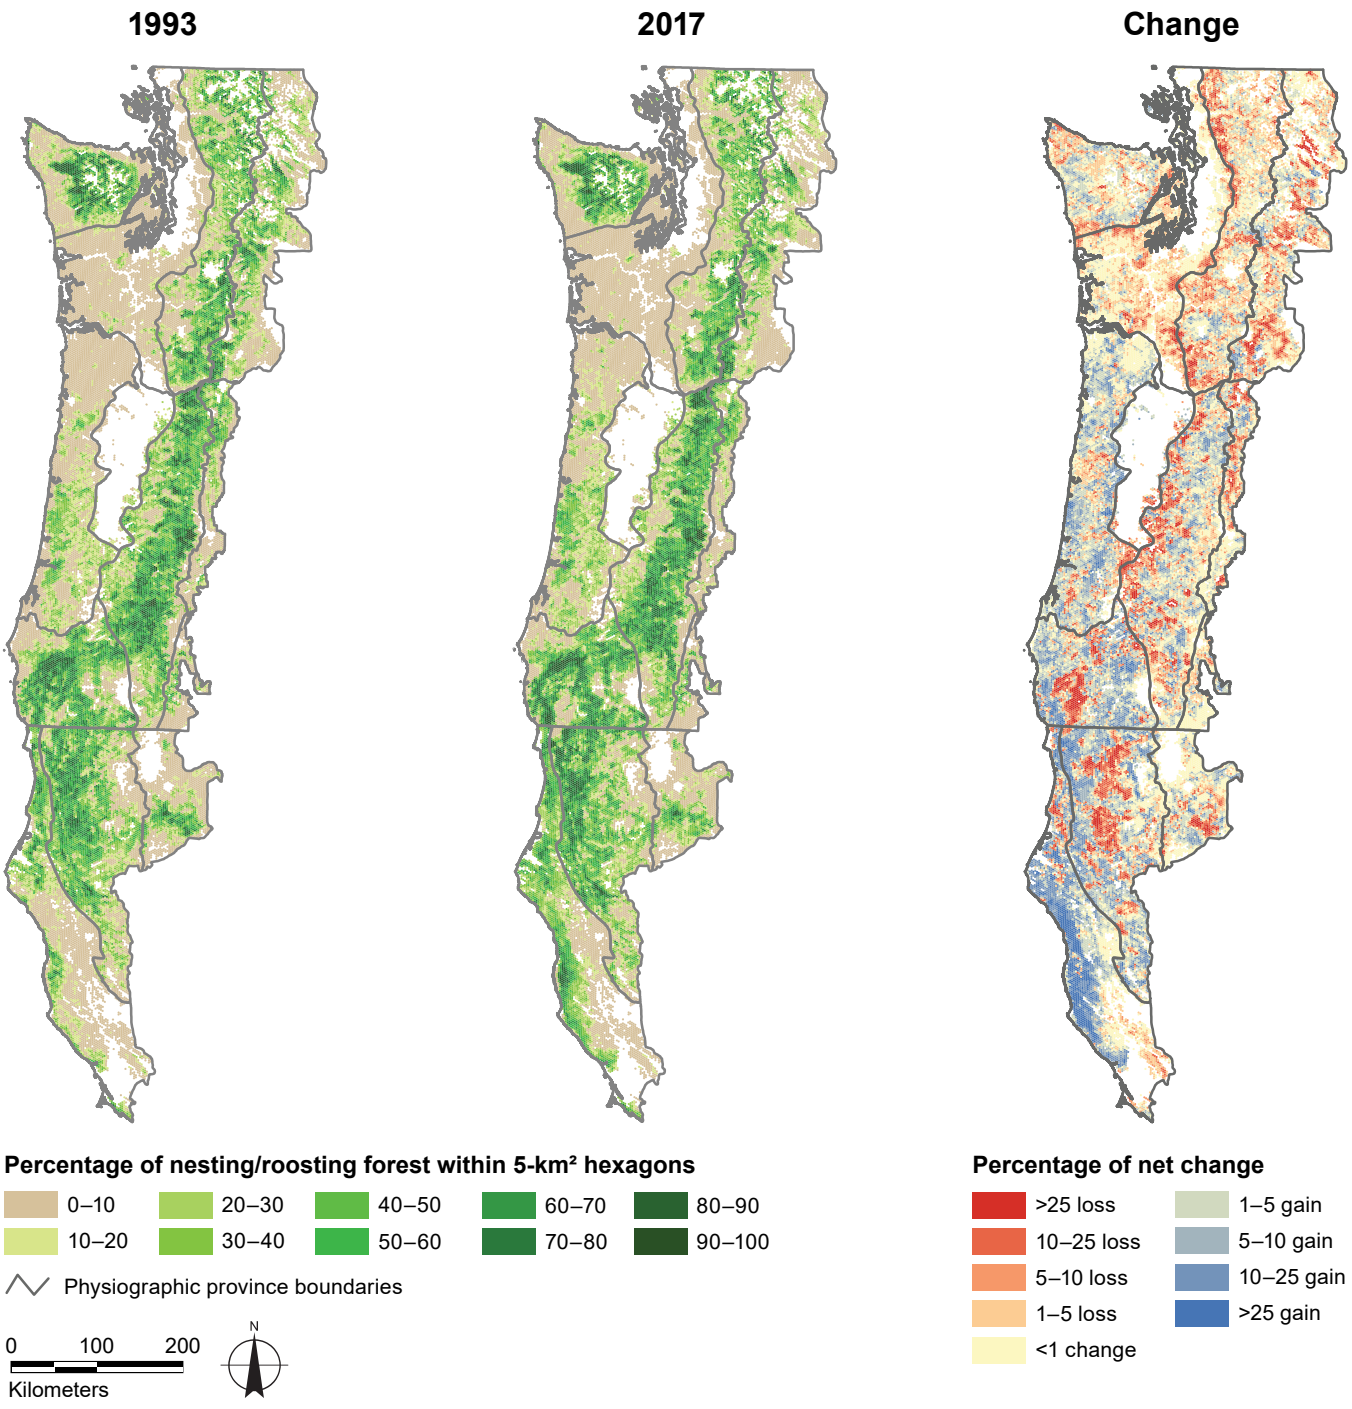

Figure 5—Bookend and change maps of nesting/roosting forest and patterns of change for the first 25 years of Northwest Forest Plan implementation within the range of the northern spotted owl in the United States.

forest of 3 percent on federal lands. The linear trend between bookend years on federal lands was positive, with an average of 12,400 ac (about 0.12 percent) recruited annually. On federally reserved LUAs, the trend was essentially stable with net increase of 0.1 percent (fig. 6).

The 2002 wildfire season caused the largest annual loss of nesting/roosting forest (≈180,000 ac, or ≈1-percent loss), most of this (86 percent) was in reserved LUAs. The period 2009–2012 showed the highest annual gains (about 53,500 ac per year, or 0.6-percent recruitment), with about half of that occurring in reserved LUAs. Most of the gains occurred closer to the Pacific coast and moister physiographic provinces (e.g., coast ranges and western Cascades). Reasons for the net gain were mainly owing to recruitment from old stand-replacing fires that burned in those areas during the mid- to late-1800s.

The physiographic province that experienced the greatest net loss of nesting/roosting forest on federal lands was the Washington Eastern Cascades (fig. 7). The California and Oregon Klamath physiographic provinces experienced the largest gross losses (394,200 and 220,600 ac, respectively) as a result of wildfires, but gains offset losses in both provinces (app. 1). Net gains were seen in 8 of the 12 physiographic provinces with the largest net gains occurring in the Oregon Coast Range and western Cascades (fig. 7). For more details on nesting/roosting forest net change and gross losses, see appendix 1.

Habitat Fragmentation Analysis

Although we estimated a net increase in nesting/roosting forests on federal lands rangewide, these forests have become slightly more fragmented with a rangewide, 2.6-percent increase in the proportion of edge. This varied by physiographic province (fig. 8).

The Oregon western Cascades had the most intact nesting/roosting forest and the western lowlands of Washington had the most fragmented forest. Rangewide, nesting/roosting forest was 5 percent less fragmented on federal reserved LUAs compared to nonreserved forest lands. The most intact reserved allocations were on Washington's Olympic Peninsula, with 30 percent more interior forest on reserved than nonreserved LUAs. The only province with more fragmented nesting/roosting forest on reserved LUAs than nonreserved LUAs was the eastern Cascades of Washington, which increased from 2 to 3.5 percent more fragmented between 1993 and 2017.

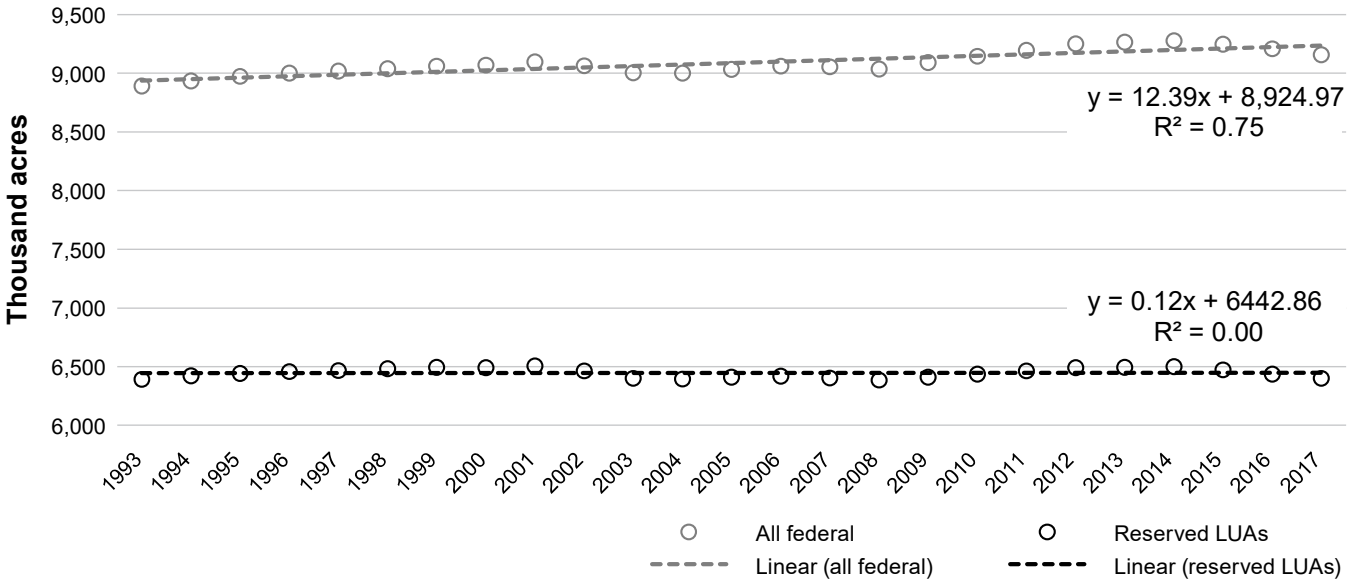

Figure 6—Trends of nesting/roosting forest on federal lands between 1993 and 2017. The *x*-axis values used in the regression are the sequential index of the years starting with 1993 (year 1) and indexed to 2017 (year 25), which represent the first 25 years since the design and implementation of the Northwest Forest Plan. LUAs = land use allocations.

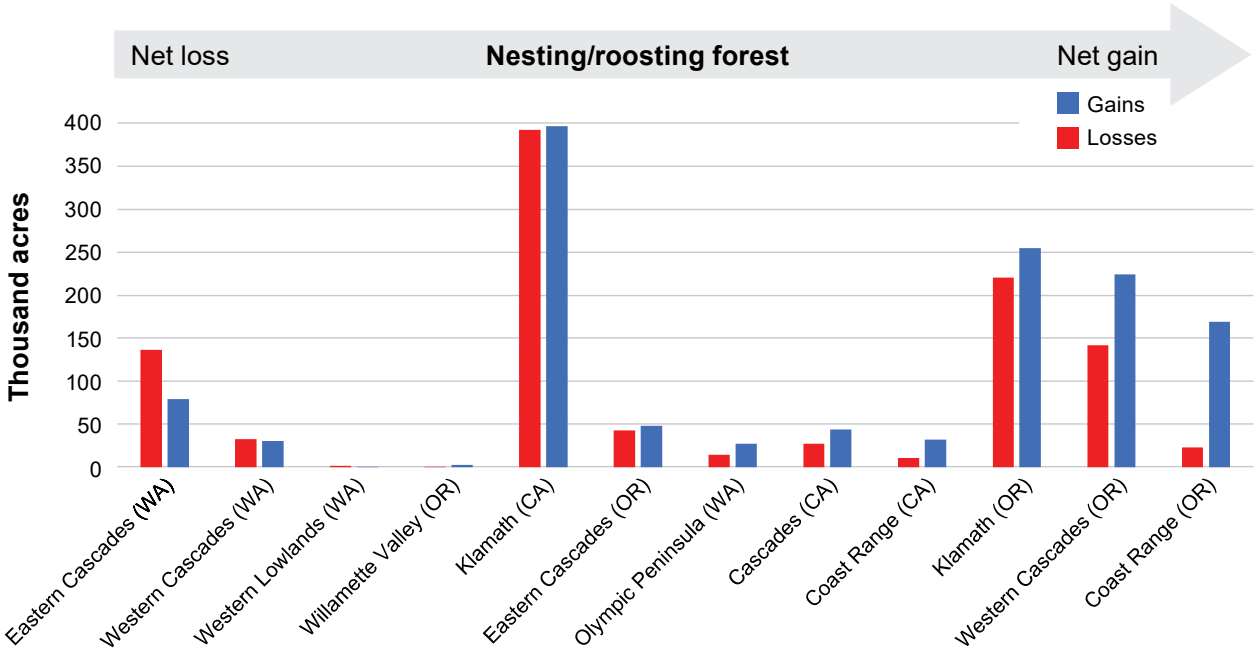

Figure 7—Bookend losses and gains in nesting/roosting forest on federal lands. Physiographic provinces are ordered by net gain (least to most) from left to right.

Figure 8—Bookend changes in nesting/roosting forest spatial patterns by physiographic province.

Dispersal-Capable Landscape Analysis

Rangewide, we report an estimated gross loss of about 1.47 million ac of dispersal forest on federal lands, about 9.4 percent of what was present in 1993 (app. 2). Similar to the pattern of loss for nesting/roosting forest, 69.3 percent of dispersal forest losses occurred on reserved LUAs. On federal lands, wildfires accounted for 67.9 percent (998,300 ac) of dispersal forest losses. Timber harvesting accounted for 23.3 percent (343,200 ac), while insects, disease, and other disturbances accounted for 8.7 percent (128,600 ac). Losses were offset by a 1.63-million-ac gross gain in dispersal forest from forest succession on federal land, resulting in a 1-percent overall net gain; however, a 1.9-percent net decrease remained in the reserved LUAs. The trend in dispersal forest has been positive for all federal lands, with an annual recruitment of about 7,800 ac per year since 1993. The trend on reserved LUAs was negative, with average losses of about 9,700 ac per year (fig. 9).

The physiographic province that experienced the greatest net loss of dispersal forest on federal lands was the Washington Eastern Cascades (fig. 10). All eastern Cascades and Klamath physiographic provinces, which occur in the most fire-prone portions of the range, experienced net losses of dispersal forests largely because of wildfires. Net gains were seen in six physiographic provinces, with the largest net gains occurring in the western Cascade and Coast Ranges (fig. 10). For more details on dispersal forest net change and gross losses, see appendix 2.

Rangewide, we estimated a 15-percent net decrease in dispersal forests on nonfederal lands, and a 5.8-percent net decrease on all lands combined. These losses resulted in a 12.4-percent gross loss in the dispersal-capable landscape, largely because of second-rotation regeneration timber harvesting on bordering nonfederal lands and large wildfires. We detected a 3.4-percent gain caused by forest succession in younger forests along the periphery of some federal forests, but mainly on nonfederal lands within the redwood region of the California Coast Range physiographic province. The result was an overall net decrease of 9 percent of the dispersal-capable landscape since 1993 (fig. 11).

In general, the dispersal-capable landscape continues to recede into federally managed lands in Washington and Oregon. Extremely large wildfires such as the 2002 Biscuit Fire created large internal gaps within federally managed lands. Notable losses of connectivity between physiographic provinces occurred at the pinch point between the Oregon Coast Range and the western Cascades. A connection was also lost within the Oregon Coast Range province, with the northern portion of this province becoming isolated from the southern portions (fig. 11).

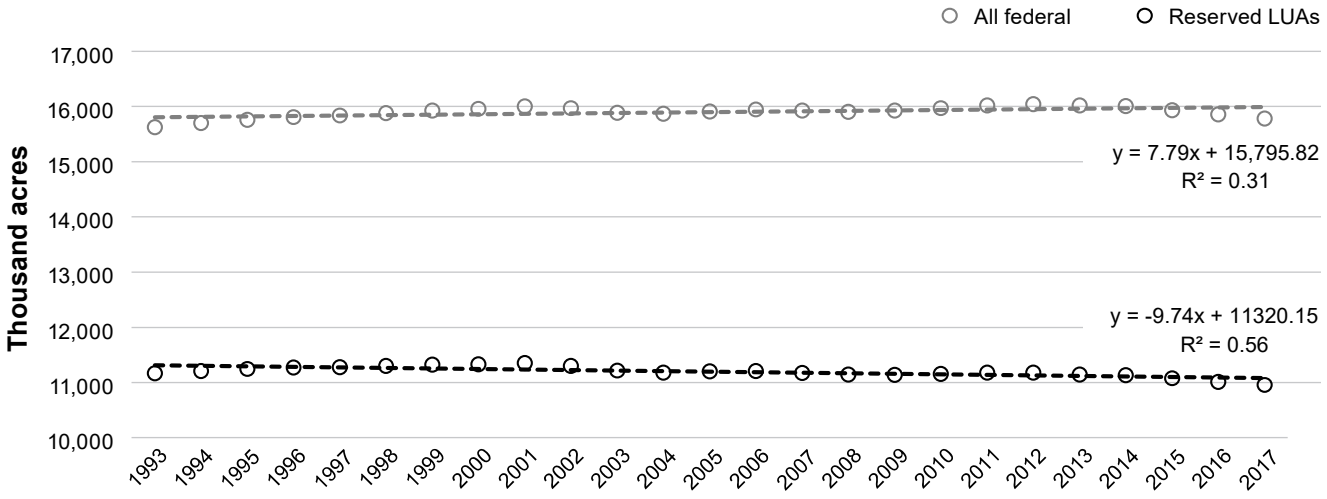

Figure 9—Trends of dispersal forest on federal lands between 1993 and 2017. The *x*-axis values used in the regression are the sequential index of the years starting with 1993 (year 1) and indexed to 2017 (year 25), which represent the first 25 years since the design and implementation of the Northwest Forest Plan. LUAs = land use allocations.

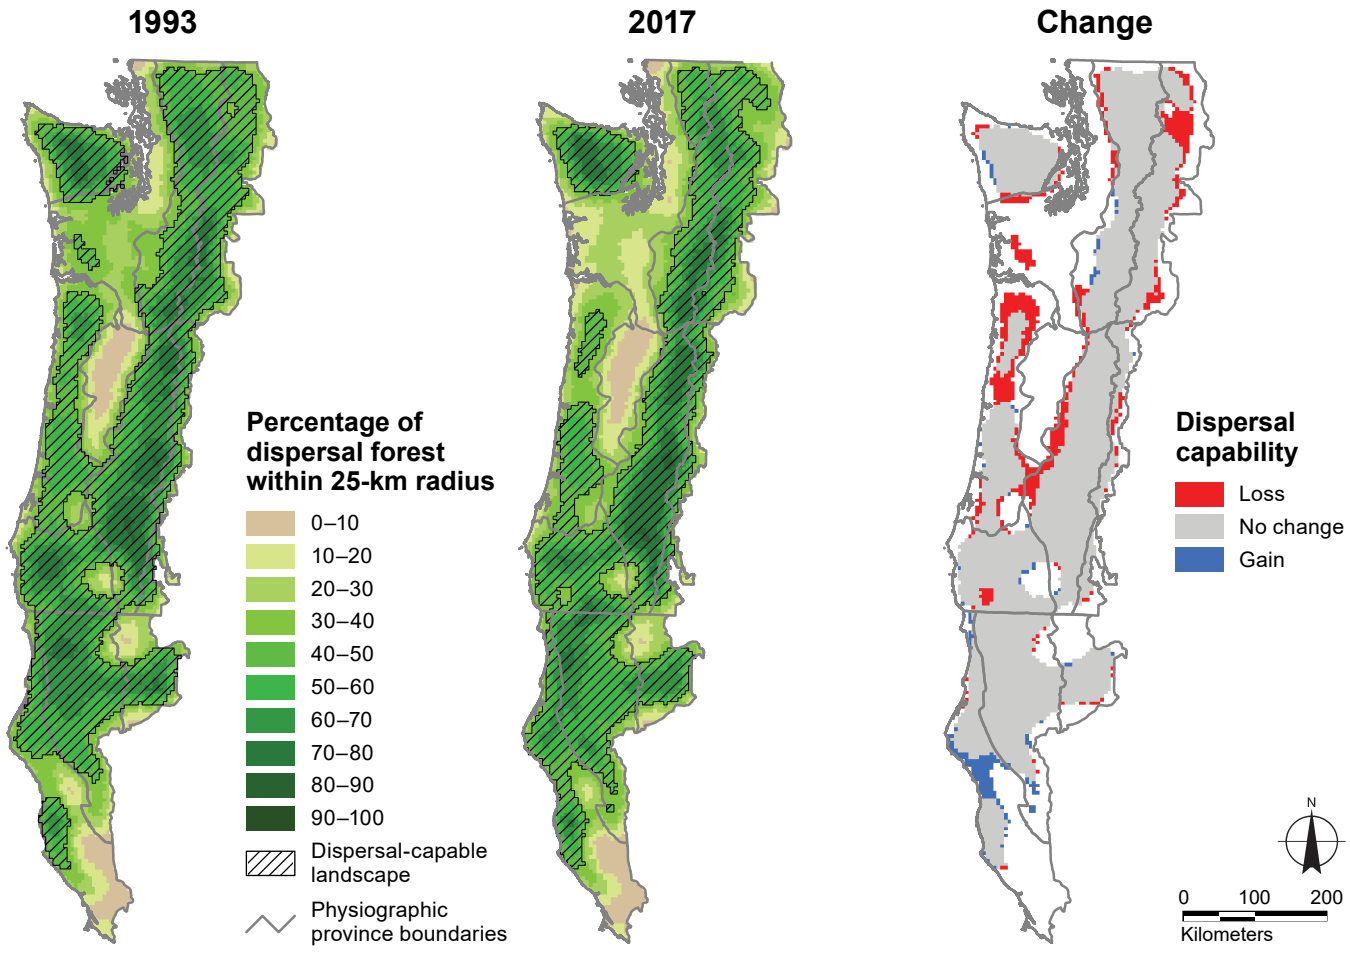

Figure 11—Bookend and change maps of the dispersal-capable landscapes and patterns of change for the first 25 years of Northwest Forest Plan implementation.

Habitat Modeling for Estimating Number of Occupied Territories

Habitat models performed well, with mean testing AUCs ranging from 0.82 to 0.92 and mean Spearman rank correlation coefficients ranging from 0.91 to 0.99 ($P < 0.001$) (table 2).

Our TEROCC point estimates for 1993 and 2017 were generally lower, but with overlapping 95 percent confidence intervals, than those estimated from the most recent meta-analysis (app. 3, Franklin et al. 2021). We suspect that this may be due to the use of an averaged NND based on the NNDs from all study areas within a modeling region for spacing of randomly generated territories. For example, within the Oregon and California Cascades modeling region, the NND for the H.J. Andrews study area is 2 km (1.24 mi) and 3.5 km (2.17 mi) for the southern Cascades study and pair territory estimates for H.J. Andrews were lower for both time periods (app. 3). Changes in TEROCC and Franklin et al. (2021) realized population change estimates had overlapping 95 percent confidence limits (except for the Oregon Klamath study area) and the mean owl pair territory estimates were mostly within the confidence limits of the realized population change (table 3).

On all federal lands at the range scale, habitat carrying capacity increased on federal lands by 3.4 percent, but TEROCC decreased by 61.8 percent (fig. 12). In federal reserved lands, habitat carrying capacity increased by 0.4 percent, but TEROCC decreased by 64.5 percent (fig. 12). On federal lands, the proportion of TEROCC in reserve lands decreased from 70 percent in 1993 to 65 percent in 2017. The opposite trajectories between habitat carrying capacity and TEROCC were mainly due to increased presence of the invasive barred owl. Mean NSO occupancy rates in federal demographic study areas ranged from 46 to 91 percent in 1993 to 7 to 38 percent in 2017 (Franklin et al. 2021). Barred owls displace NSOs from existing and recruited forest habitat. Abundant habitat helps to mitigate the negative effect of barred owls on NSO occupancy but does not reverse it (Franklin et al. 2021, Yackulic et al. 2019).

Discussion

In the early 1970s, the downward trend of old-growth forests resulting from timber harvesting raised concerns for the future of the NSO (Forsman 1975, Gould 1974, Mouat and Schrumpf 1974). Less than two decades later, the owl was listed as threatened under the Endangered Species Act owing to continued chronic habitat loss (USDI FWS 1990). Shortly thereafter, a series of related events led to the design and implementation of the NWFP (FEMAT 1993, Marcot and Thomas 1997), the boundary of which was defined by the NSO geographic range in the United States. A major goal of the NWFP is to stop the downward trend in NSO populations and to maintain and restore forest conditions necessary to support viable populations on federally administered forest lands throughout its range.[2] The recovery of old-forest conditions was anticipated to happen gradually over several decades.

Here we report on monitoring forest structure and composition that are suitable for NSO nesting and roosting; and we demonstrate continued improvements in the process and speed of this monitoring that result in models that performed better than previous monitoring efforts. We expect that future monitoring efforts will improve on our methods to provide near-real-time assessments of status and detailed patterns in annual change. Differing from previous reports, our results indicated a positive trend and net gain in nesting/roosting forest on federal lands that have more than compensated for gross losses caused mainly by wildfires as well as from timber harvesting, insects, disease, and other forest disturbances. Within reserved LUAs, nesting/roosting forest was stable and most of the gains occurred in the nonreserved allocations, contrary to the NWFP assumption that habitat would improve within reserves and decline outside of them. The LSR network was designed (in part) to support NSO metapopulations and dispersal between them across federal lands. As an added measure of assurance for achieving this objective, LSRs were delineated to be large enough to withstand wildfires for up to 50 years (USDA and USDI 1994: apps. J3-8 and 9). In half this time, losses from wildfires have exceeded the anticipated 2.5-percent loss per decade within some LSRs in the fire-prone portions of the range (Davis et al. 2011, Spies et al. 2018). However, some LSRs have remained stable (<1-percent change) and others have shown gains (fig. 13).

There has been a slight increase in the fragmentation of nesting/roosting forests. Not all of it is a result of forest disturbance, it is also owing to the development of younger forests into older forests. These newly recruited nesting/roosting forests tended to occur in small patches, thus increasing the measure of fragmentation. Further, recent studies indicate that interior NSO forest is normally less prone to burning at high severity compared to fragmented (edge) or nonnesting forest types (Lesmeister et al. 2019, 2021b). In addition, it appears to dampen an increasing trend in high-severity wildfire that is occurring in nonnesting forests, and to a lesser extent in edge forests (Lesmeister et al. 2021b). This leads to the conclusion that large patches of interior nesting/roosting forest are

[2] Although the BLM has adopted new resource management plan for BLM land within the range of the NSO, it has retained contributing to the conservation of the NSO as a major objective.

more resilient to wildfires and may serve as fire refugia by normally burning at lower severity than other forest types. Further, these findings highlight the resilience of nesting/roosting forests to wildfire, and these forests are critical in postfire landscapes by providing biological legacies of live and dead large trees as well as logs.

Dispersal forests have increased slightly on federal lands, but losses on nonfederal lands due to timber harvesting

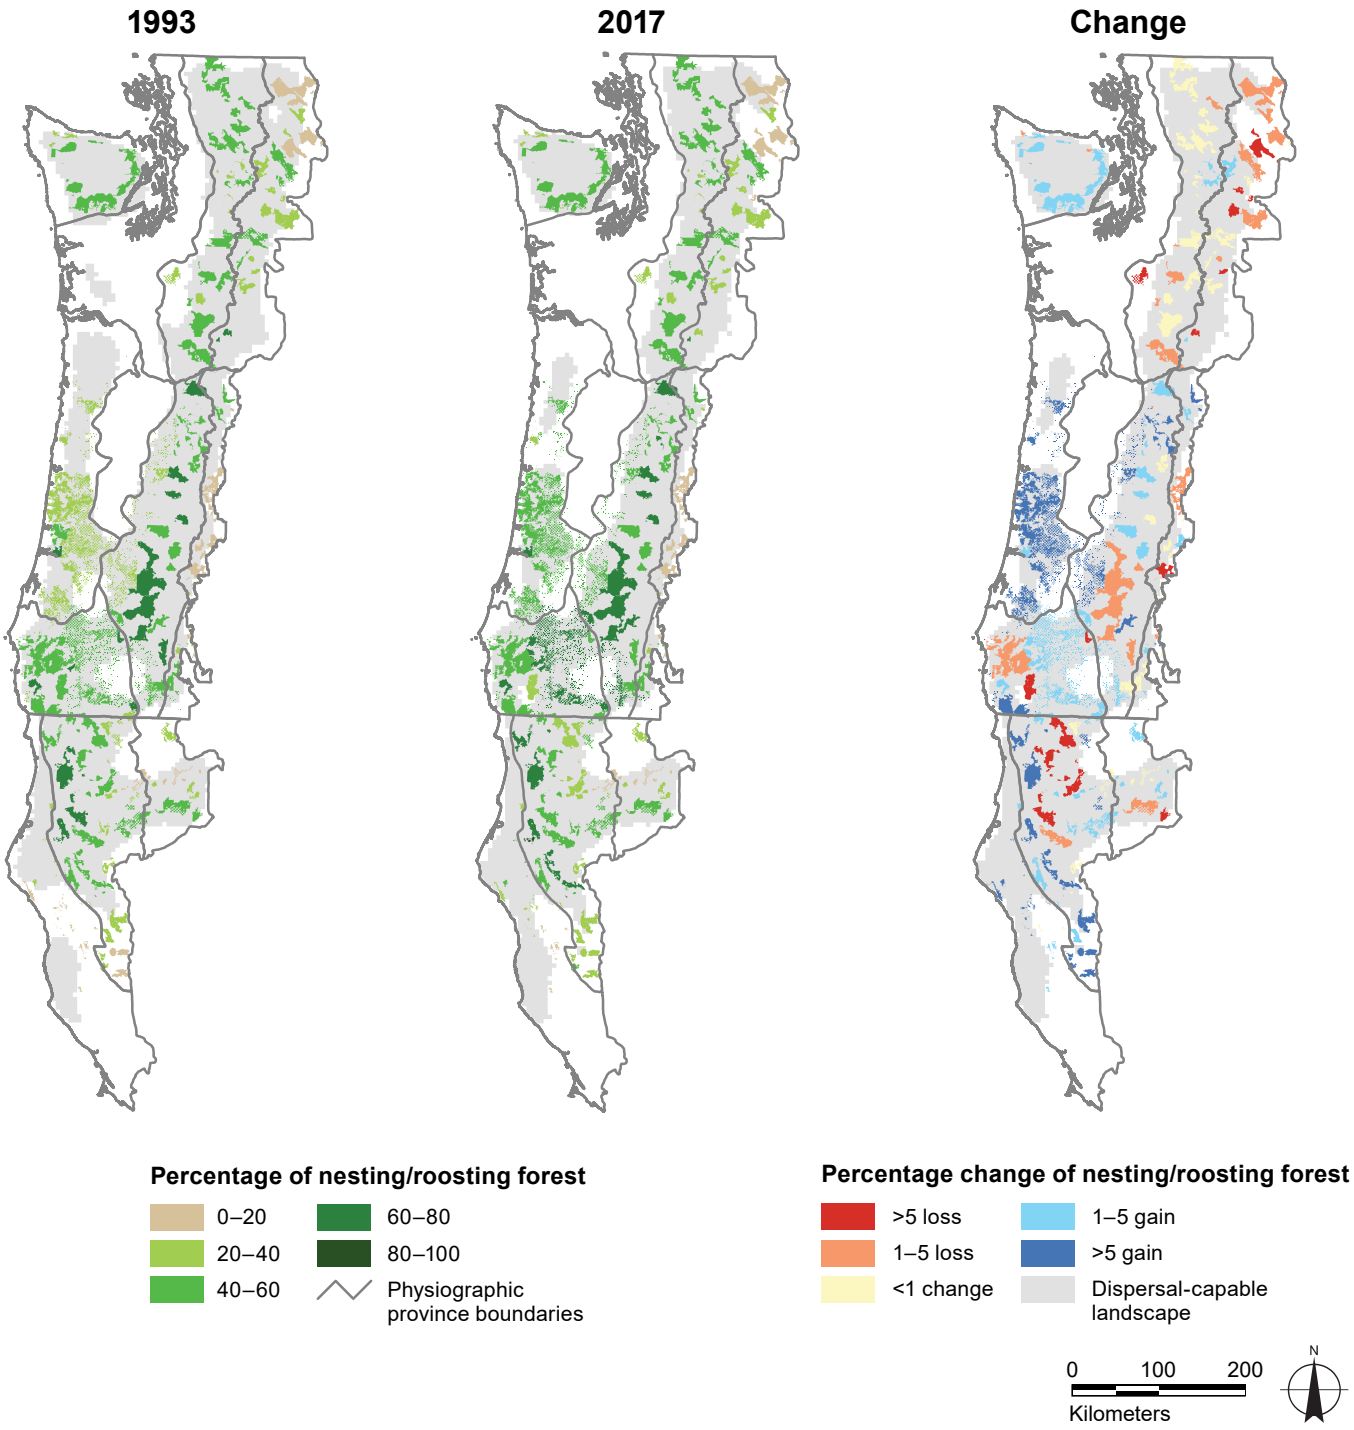

Figure 13—Bookend and change maps of the current large late-successional forest reserve network overlaid on the dispersal-capable landscape maps.

and on federal lands from large wildfires has resulted in a constriction of the dispersal-capable landscape. As a result of past forest management and the ongoing barred owl invasion, NSO populations on federal lands are becoming smaller and more widely dispersed. The decreased, narrowing footprint of dispersal-capable landscapes limits the movement of owls between remnant populations and conceivably makes it harder for recruitment from the floater NSO population (single, nonterritorial birds).

In the previous habitat monitoring report, sufficient time had not yet passed to allow for detectable recruitment of nesting/roosting forest (Davis et al. 2016). Enough time has since passed for old stand-replaced fire patches from the mid- to late-1800s to cross the threshold into suitable nesting/roosting forest conditions. The annual time series maps of nesting/roosting forest allowed us to see this occur as suitable forest pixels began to aggregate as edge-type forest, eventually forming patches of interior forest. More time is needed before we can observe significant recruitment of nesting/roosting forest from the hundreds of thousands of acres of regeneration harvest units that occurred prior to the NSO listing and implementation of the NWFP on federal lands. Given the history of timber harvesting in this region (Gale et al. 2012), this recruitment should begin to peak by around 2040, assuming that setbacks in forest succession do not occur at higher than expected rates as a result of future high-severity wildfires or timber harvest. These assumptions may not fully hold given increased occurrence of wildfires and changes in timber management plans in the region. For example, in 2020, five megafires burned about 812, 977 ac in Oregon and more than 321,236 ac was at high severity.

Despite positive trends in owl forests, NSO populations continue to decline (Franklin et al. 2021), and now the subspecies warrants reclassification to endangered (USDI FWS 2020). The declines have been attributed to continued forest loss and the invasive barred owl that are displacing NSOs from their native habitat. Although increasing amounts of suitable nesting/roosting forest help to mitigate declines in NSO occupancy, it is not expected to reverse the trend by itself (Franklin et al. 2021, Yackulic et al. 2019). The predicted increase in frequency and extent of large wildfires (Davis et al. 2017) will make the NWFP goal of stabilizing NSO habitat and populations more challenging. In addition, the occurrence of large megafires that burn large areas at high severity that results in extensive losses of nesting/roosting forest, as witnessed in 2020, puts isolated populations at risk of rapid extirpation.

Finally, in the short term, climate change is likely to contribute to changes in prey populations and, in the long term, alter future forest species composition, geographic distributions, and extent by the end of the 21st century (Peterson et al. 2014). As the fire-prone footprint expands, fire-susceptible tree species (e.g., *Tsuga heterophylla* (Raf.) Sarg.) may recede and fire-associated species (e.g., *Pinus* spp.) may expand in distribution. Subalpine forests are expected to recede in area, while Douglas-fir forests will likely expand into higher elevations. How these long-term changes unfold remains uncertain, as does the effect on future owl forests.

Conclusion

One of the main goals of the NWFP was to reduce the rate at which owl nesting/roosting forests were being lost on federal lands and to eventually restore them to within a natural range to support viable populations of NSO, especially within the LSR network. A quarter century into the NWFP, the latest monitoring shows that it has been effective at reducing the preceding rate of loss. We also report that recruitment is beginning to occur, but mostly in the nonreserved LUAs.

We estimated rangewide gross losses of nesting/roosting forest on federal lands at 7.9 percent (703,700 ac) from wildfire, 2.9 percent (257,700 ac) from timber harvesting, and 0.9 percent (83,700 ac) from insects, disease, or other natural disturbances. However, we also documented development of about 1.3 million acres through succession, so an overall 3-percent net increase of nesting/roosting forest. All but 0.1 percent of this net gain occurred on nonreserved LUAs. While there was a net gain, a slightly larger proportion of nesting/roosting forest was fragmented, compared to 1993.

Rangewide, the observed rate of loss on federal lands was less than what was anticipated when the NWFP was designed, mostly because of less timber harvest. Losses from wildfire were higher (8.5 vs. 6.25 percent; based on a 2.5-percent loss per decade) than anticipated in federal reserved LUAs at the range scale. Insects and disease

accounted for less than 1 percent of gross losses. Although dispersal forest increased by 1 percent on federal lands, it decreased by 1.9 percent on reserved LUAs. Large losses primarily from timber harvest on surrounding nonfederal lands and large wildfires reduced the footprint of the dispersal-capable landscape by 9 percent. What remains, as of 2017, is more confined to federal forest lands, and the connection between the Oregon Coast Range and the western Cascades through "checkerboard" BLM land has been broken.

Although we observed gains in nesting/roosting forest through mid-2017, there have been four big wildfire seasons (2017, 2018, 2020, and 2021) since the end of this monitoring cycle. Significant challenges remain, as witnessed by the 2020 wildfire season, where decades of forest recruitment can be set back in 1 year by extremely large and severe wildfires—the type that have historically occurred within the infrequent, high-severity fire regime (Spies et al. 2018). Climate change is predicted to increase the extent and frequency of large wildfires, with the largest changes occurring along the western Cascades of Oregon and Washington, which defines the leading front of change (Davis et al. 2017). Changing climates may also cause direct drought-related mortality of large trees that are important nesting/roosting structure (Gutiérrez et al. 2017), as well as large shifts in the forest types that recover (or not) after a stand-replacing event (Halofsky et al. 2020, Peterson et al. 2014). The use of increasing remote sensing and GEE technologies will allow us to monitor NSO forest in near-real time, with annual updates instead of every 5 years. To be successful at managing to maintain and restore nesting/roosting forests into the future, it will be critical for forest managers to track and foresee the "when" and "where" of forest changes that may occur because of climate change. Fire refugia in forested landscapes can be defined as forest stands that remain unburned, burn less frequently, or burn at lower severity than the surrounding landscape (Meddens et al. 2018). Old forest classified as nesting/roosting forest is an important component of fire refugia (Lesmeister et al. 2021b), but further research is needed to identify areas within old forest that could be persistent fire refugia, spatially and temporally, through multiple fires.

Lastly, the long-term goal of the monitoring program to transition to a model-driven, habitat-based approach (phase II) for population monitoring (Lint et al. 1999) is feasible and in progress (Lesmeister et al. 2021a). The gains in nesting/roosting are encouraging, but unfortunately the increases in available forest has not translated into recruitment of new owl pair territories. On the contrary, largely because of the invasion of the barred owl, the number of occupied pair territories has dropped significantly since 1993. A key advantage of phase II monitoring will be the ability to conduct prospective modeling of future change as opposed to being limited to retrospective assessments conducted thus far. As described in the NSO monitoring plan for the NWFP, "the latter leaves us only the option to patch and recover as opposed to the prospective approach, which provides opportunity to set the trajectory for desired outcomes through model-driven insights of the future." (Lint et al. 1999: 21).

Acknowledgments

This report is the result of a large, group effort over many years focused on monitoring the effectiveness of the Northwest Forest Plan. It would not have been possible without the work of many dedicated biologists who annually collected northern spotted owl data used to train and test our forest and habitat models. Wall-to-wall annual time series of forest structure and species composition use maps for model predictor variables would not exist without the hard, dedicated work of Matt Gregory of Oregon State University Department of Forest Ecosystems and Society's Landscape, Ecology, Modeling, Mapping, and Analysis team and Dr. David Bell (USDA Forest Service Pacific Northwest Research Station). The mapping of annual forest disturbances would not have been possible without the USDA Forest Service Rocky Mountain Research Station's Landscape Change and Monitoring System program directed by Dr. Sean Healey.

Appendix 3—Estimating Northern Spotted Owl Pair Territories

Modeling parameters used to estimate owl pair territories following methods in Glenn et al. (2017) relied primarily on demographic data from population meta-analyses information from Dugger et al. (2016) and Franklin et al. (2021). Demographic parameters were averaged when more than one study area occurred within a modeling region (table A3-2).

Table A3-1—Data summary from demographic studies that informed the models

Demographic study areas	½ median nearest neighbor distance[1]	Occupancy rate (1993)[2]	Occupancy rate (2018)[2]	Number of territories (Thiessen polygons)[2,3]
	Kilometers	*Mean (95% CL)*	*Mean (95% CL)*	*1993/2017*

Differences Between Standing and Downed Dead Tree Wood Density Reduction Factors: A Comparison Across Decay Classes and Tree Species

**Mark E. Harmon

Abstract

Woody detritus or dead wood is an important part of forest ecosystems and has now become a routine facet of forest monitoring and inventory. Biomass and carbon estimates of dead wood depend on knowledge of species- and decay class- specific density or density reduction factors. While some progress has been made in determining these parameters for dead and downed trees (DD), there are very few estimates of these key parameters for standing dead trees (SD). In this study we evaluated indicators of decay to relate subjective SD and DD decay classifications then compared SD and DD density and density reduction factors by decay class for a total of 19 tree species at nine sites in the United States and Russia. A set of preliminary decay reduction factors for SD trees by species and decay class was developed for tree species inventoried by the U.S. Department of Agriculture's Forest Inventory and Analysis (FIA) program. Results indicate that SD density declined with decay class for all examined species. For six of the examined species, SD tree density could be assumed equal to that of DD tree density. The most common situation (13 species) was for SD density to be higher than for DD density. The likely cause of these differences was the drier microenvironment of SD which slows decomposition relative to that of DD. By applying these results, a new set of SD density reduction factors was developed for 260 species inventoried by FIA in forests of the United States. Comparison of biomass estimates using this study's proposed SD density reduction factors with existing SD volume estimates based solely on undecayed wood density indicated a possible biomass overestimate of 16.5 percent for Minnesota. Given the size of the potential biases involved and the uncertainty associated with decay reduction factors developed in this study, additional work to develop a multispecies SD decay class system and further empirical sampling of SD tree density is recommended.

INTRODUCTION

Woody detritus or dead wood is an important part of forest ecosystems, providing habitats and food sources, a store of carbon, nutrients, and water, as well as influencing geomorphic processes (Franklin et al. 1987, Harmon et al. 1986, Triska and Cromack 1980). In particular, standing dead trees provide structural complexity and enhance biodiversity in many forest ecosystems (Jonsell et al. 1998, Kruys et al. 1999, Nilsson et al. 2001). Therefore, dead wood is increasingly being included in ecological studies and environmental assessments (Woodall et al. 2009), with the number of publications on this subject rapidly growing. Both downed (DD) and standing dead (SD) wood store carbon and are important components of forest carbon dynamics, but also release carbon via decomposition and combustion in fires. However, given the contrasting microenvironments that SD and DD trees inhabit, their decay dynamics and attributes may vary (Aakala et al. 2008, Aakala 2010, Lee 1998, Vanderwel et al. 2006). Accurate estimates of standing dead tree carbon stocks are important for monitoring carbon flux, for characterizing processes such as respiration and combustion losses, and for validating simulation models that are used to project how carbon dynamics will change in the future.

It is difficult to develop accurate estimates of dead wood biomass for several reasons. First, until recently there have been few systematic, regional-scale dead wood inventories, resulting in highly uncertain dead wood population estimates (Harmon et al. 2001). However, regional-scale inventories of dead wood are becoming more common (Woodall et al. 2009). For example, the Forest Inventory and Analysis (FIA) program of the U.S. Forest Service now conducts a national inventory of woody material including fine woody detritus (FWD) and DD (for more details see Woodall and Monleon 2008). Second, given the size and actively decomposing nature of dead trees, direct measurements of biomass during forest inventories are not possible. Instead, the volume of individual DD pieces is estimated from fixed-area plot or line-intersect transect estimators (Woodall and Monleon 2008). Biomass of DD is then often estimated by multiplying volume by an estimate of density specific to a dead wood piece's individual attributes (e.g., species and stage of decay). Density reduction factors may be defined as the ratio of the decayed density (current mass/volume) of a piece of dead wood compared to its undecayed density (initial live tree mass/volume; Miles and Smith 2009). The development of DD species- and decay class-specific density and decay reduction values for the FIA program has offered the promise of substantially reducing the uncertainty associated with DD mass/carbon population estimates resulting from large-scale inventories (Harmon et al. 2008). Unfortunately, there are very few decay class- or species-

specific estimates of density or decay reduction factors for SD trees. The lack of these estimates is likely due to the danger in felling snags during sampling and the historical lack of emphasis on SD biomass/carbon estimates during traditional forest inventories focused on estimating live tree growing stock volume on timberlands.

Several assumptions regarding wood density influence biomass estimates of SD trees. In the case of the FIA program, it is currently assumed that the density of SD trees is the same as that of live trees. While this seems unlikely, in some situations (e.g., extremely slow decomposition in arid environments) this assumption may be accurate. Alternately, (e.g., Smithwick et al. 2002) the density of SD trees for a given decay class may be assumed to be similar to that of DD wood. While this would seem to be a more realistic assumption, it has yet to be tested across a wide range of tree species and environments. The uncertainty associated with SD tree density is likely to have major impacts on biomass, carbon, and fuel estimates, but without knowledge of how SD tree wood density changes through its decay process, the effect of this uncertainty cannot be quantified.

OBJECTIVES

Given that deadwood inventories are rapidly becoming a common component of forest resource inventories around the world, there is a need to refine the constants used in biomass estimation procedures for both SD and DD. Our objective was to determine SD species- and decay-class specific density and density reduction factors for forest tree species in the United States by linking empirical SD data from a subset of study species with that of DD of those same species to develop constants that can then be applied to other SD species. The broad concept was to use SD:DD density relationships to utilize currently available DD density information to provide an initial approximation of SD density attributes for forest tree species in the United States.

Harmon et al. (2008) developed a set of density reduction factors, including estimates of uncertainty, for DD and FWD based on a thorough literature review and unpublished data. Our approach for this study was to sample SD and DD for 19 tree species in temperate forests of the northern hemisphere. As the decay classification system for both SD and DD trees are qualitative (i.e., visual assessments of wood condition and structure) and separate, the two classification systems need to be linked in order to propose SD to DD wood density relationships by decay class. First, indicators of decay were evaluated for SD and DD decay classes to ensure decay classification system compatibility. Second, the density of SD and DD was compared for the same decay classes and species. These ratios were then used to estimate SD density and density reduction factors for species that have not been sampled across the United States. Finally, to initially assess the impact of wood density decay reduction factors on SD population estimates, a SD tree inventory in Minnesota was used to calculate state SD biomass using no decay reduction factor and using factors developed in previous objectives.

MATERIALS AND METHODS

Study Areas

To ensure our study acquired a robust estimate of SD to DD, we sampled five study sites in the United States and four in Russia representing a range of species and climates in North America and Russia (Table 1). Given the similarity between the temperate and boreal forests of North America and Russia, it was felt that the additional statistical rigor resulting from the combination of data outweighed the loss of some regional specificity. As study objectives focus on tree species in the United States along with greater diversity among the study sites (e.g., species composition), study site locations in the United States were kept separate and identified by unique abbreviations in subsequent tables, while Russian study sites were pooled with the abbreviation "RUS." Site descriptions for Russian locations are based on information from Yatskov (2000).

Cascade Head Experimental Forest (CHE), Oregon

Cascade Head is located on the north-central coast of Oregon, 8 km north of Lincoln City. It lies entirely within the Hebo Ranger District of the Siuslaw National Forest. The site is in the Oregon Coast Range ecoregion and the forests are representative of the sitka spruce-western hemlock (*Picea sitchensis* (Bong.) Carrière -*Tsuga heterophylla* (Raf.) Sarg.) and Douglas-fir (*Pseudotsuga*

Table 1.—Site name, location, and climate description for areas sampled

Site Name	Climate	Temperature
Cascade Head EF, Oregon (CHE)	Very wet	Moderate
Fraser EF, Colorado (FEF)	Dry	Cool
Chapel Hill, North Carolina (NCB)	Moderate	Moderate
Marcell EF, Minnesota (MEF)	Moderate	Cold
Kenai Peninsula, Alaska (AK)	Dry	Cold
St. Petersburg, Russia (RUS)	Moderate	Cool
Krasnoyarsk, Russia (RUS)	Dry	Cold
Irkutsk, Russia (RUS)	Dry	Cold
Khabarovsk, Russia (RUS)	Moderate	Cold

menziesii (Mirb.) Franco) zones of the region. Soils, derived primarily from tuffaceous siltstones, are fine textured, moderately well drained, and deep (up to 100+ cm). Because of the Pacific Ocean influence, CHE has a moderate and very wet climate. Mean annual temperature is 10 °C with minimal seasonal variation. Average yearly rainfall is 2489 mm, although fog drip through the forest canopy can add 500 mm or more precipitation a year (Greene and Acker 1999).

Fraser Experimental Forest (FEF), Colorado

Fraser Experimental Forest is located in the heart of the central Rocky Mountains, about 80 km from Denver. FEF includes subalpine forests typical of the area, with Engelmann spruce (*Picea engelmannii* Parry x Engelm.) and subalpine fir (*Abies lasiocarpa* (Hook.) Nutt.) predominating at higher elevations, and lodgepole pine (*Pinus contorta* var. *latifolia* (Douglas ex Louden var. latifolia Engelm. ex S. Watson)) predominating at lower elevations and on drier upper slopes. Soils are generally derived from gneiss and schist and typically contain angular gravel and stone with very little silt or clay. These soils are very permeable and can store considerable water during snowmelt. Climate varies strongly with elevation. Overall, the climate is cool and dry with long, cold winters and short, cool summers. Mean annual temperature at the Fraser Forest headquarters is 0.5 °C and mean annual precipitation over the entire FEF is 737 mm. (Adams et al. 2004).

Chapel Hill (NCB), North Carolina

The study was conducted at the North Carolina Botanical Garden, a 242-ha tract of oak-hickory-pine forest in Chapel Hill, North Carolina. The area sampled in this project was dominated by mixed hardwoods including *Liriodendron tulipifera* L. on the moist lower slopes and mixed hardwoods with pine (*Pinus taeda* L. and *Pinus echinata* Mill.) on the dryer mid and upper slopes. It is an area defined by undulating topography, soils of poor to good quality, and a temperate climate. Soils of the study area include Wedowee sandy loam and Goldston slaty silt loam (Dunn 1977). The average annual temperature is 14.6 °C and the average annual precipitation is 1220 mm. Precipitation is uniformly distributed throughout the year. The elevation ranges from 103 to 150 m (Fasth et al., in press).

Marcell Experimental Forest (MEF), Minnesota

The Marcell Experimental Forest is an 890-ha tract of land in the Chippewa National Forest, located 40 km north of Grand Rapids, Minnesota. Vegetation in the upland topography includes jack pine (*Pinus banksiana* Lamb.) and trembling aspen (*Populus tremuloides* Michx.) among other species. Mineral soils of the area are derived from glacial processes that occurred during and after the Wisconsinan glaciation. Soils are mainly loamy sands covered with fine sandy loam derived from eolean loess after glacial melt. The climate is subhumid continental, with wide and rapid diurnal and seasonal temperature fluctuations. The average annual temperature is 3 °C and the average annual precipitation is 785 mm with 75 percent occurring in the snow-free period (mid-April to early November) (Adams et al. 2004).

Kenai Peninsula (AK), Alaska

The study was conducted on the Kenai Peninsula of Alaska on Federal lands including the Chugach National Forest as well as on State owned lands. The maritime

climate of this study site supports temperate, coniferous rainforest. The drier and colder climate inland from the coastal mountains supports forests dominated by white spruce (*Picea glauca* (Moench) Voss), black spruce (*Picea mariana* (Miller) Britt), and paper birch (*Betula papyrifera* Marsh). A fertile hybrid between white spruce and Sitka spruce (Lutz spruce, *Picea x lutzii* Little) is a common tree in maritime and mountainous areas of the Kenai Peninsula. The topography of the study area varies from lowlands to foothills. The lowlands of the Kenai Peninsula are a glaciated surface with gentle relief and a mean elevation of approximately 300 m. Throughout most of this lowland glacial till of Wisconsin age is overlain by deep glacial lake and fluvial sediments and is mantled with loess. The Alaska Climate Research Center (ACRC) climatic summaries indicate the study area has a mean annual temperature of approximately 1.1 °C and annual precipitation of 630 mm (Harmon et al. 2005).

St. Petersburg, Russia (RUS)

The region of northwestern Russia has a cool maritime climate with cool wet summers and long cold winters. Major forest tree species include silver birch (*Betula pendula* Roth.), Norway spruce (*Picea abies* (L.) Karst.), and Eurasian aspen (*Populus tremula* L.). The mean annual temperature of July is 16.5 °C, while the mean temperature of January is 8.5 °C with an annual mean of 3.4 °C. The mean annual precipitation is 708 mm.

Krasnoyarsk, Russia (RUS)

This region of central Siberia has a moderately cold and continental climate. It belongs to the Angara province of the southern taiga and is dominated by Russian larch-Scots pine (*Larix siberica* Ledeb. and *Pinus sylvestris* L.) forests. The vegetation period lasts 126 days with a frost-free period of 110 days. The mean temperature of July is 16 °C, while the mean temperature of January is -25 °C, and the overall mean annual temperature is -3.2 °C. The mean annual precipitation is 361 mm.

Irkutsk, Russia (RUS)

This region of Eastern Siberia has sites located in the area of strictly continental climate with permafrost. Forests were primarily comprised of Scots pine (*Pinus sylvestris*). In mountainous areas Siberian larch (*Larix siberica*), Siberian white pine (*Pinus siberica* Ledeb.), and Siberian spruce (*Picea obovata* Ledeb.) were common, and were associated with small amounts of Siberian fir (*Abies siberica* Ledeb.). The mean temperature of July is 17 °C and mean temperature of January is -20 °C with an overall mean annual temperature of -0.6 °C and a mean annual precipitation of 216 mm.

Khabarovsk, Russia (RUS)

This region is part of the Far East and has a continental climate that promotes the growth of a wide range of plant species, including Korean white pine (*Pinus koraiensis* Sieb. et Zucc.), Dahurian larch (*Larix dahurica* Turcz.) spruce (*Picea obovata* and *Picea ajanensis* Fisch.), true fir (*Abies siberica*), and yellow birch (*Betula costata* Trautv.). The vegetation period lasts 174 days in lowlands and 158 days in mountainous areas. The mean temperature of July is 17 °C, while mean temperature of January is -24 °C, with an overall annual mean of -1.9 °C. The mean annual precipitation is 909 mm.

Linking SD and DD Decay Classifications through Indicators of Decay

To accurately estimate DD and SD population attributes such as biomass or carbon, the FIA program assigns each sampled DD and SD individual to a decay class. To facilitate linkage of DD and SD decay classes, indicators of decay were developed in this study that were assessed for each study dead wood piece. For both DD and SD, there were five decay classes that span a spectrum of decay from fresh mortality to nearly complete decay. Decay classes are largely qualitative based on the physical appearance and structural integrity of individual dead wood pieces (USDA 2007, Woundenberg et al. 2010). For SD trees the five decay classes were defined as:

Class 1: All limbs and branches are present; the top of the crown is still present; all bark remains; sapwood is intact, with minimal decay; heartwood is sound and hard.

Class 2: There are few limbs and no fine branches; the top may be broken; a variable amount of bark remains; sapwood is sloughing with advanced decay; heartwood is sound at base but beginning to decay in the outer part of the upper bole.

Class 3: Only limb stubs exist; the top is broken; a variable amount of bark remains; sapwood is sloughing; heartwood has advanced decay in upper bole and is beginning at the base.

Class 4: Few or no limb stubs remain; the top is broken; a variable amount of bark remains; sapwood is sloughing; heartwood has advanced decay at the base and is sloughing in the upper bole.

Class 5: No evidence of branches remains; the top is broken; <20 percent of the bark remains; sapwood is gone; heartwood is sloughing throughout.

For DD trees the five decay classes were defined as:

Class 1: Sound, freshly fallen, intact logs with no rot, no conks present indicating a lack of decay, original color of wood, no invading roots, fine twigs attached with tight bark.

Class 2: Sound log sapwood partly soft but can't be pulled apart by hand, original color of wood, no invading roots, many fine twigs are gone and remaining fine twigs have peeling bark.

Class 3: Heartwood is still sound with piece supporting its own weight, sapwood can be pulled apart by hand or is missing, wood color is reddish-brown or original color, roots may be invading sapwood, only branch stubs are remaining which cannot be pulled out of log.

Class 4: Heartwood is rotten with piece unable to support own weight, rotten portions of piece are soft and/or blocky in appearance, a metal pin can be pushed into heartwood, wood color is reddish or light brown, invading roots may be found throughout the log, branch stubs can be pulled out.

Class 5: There is no remaining structural integrity to the piece with a lack of circular shape as rot spreads out across ground, rotten texture is soft and can become powder when dry, wood color is red-brown to dark brown, invading roots are present throughout, branch stubs and pitch pockets have usually rotten down.

Based on decades of research into the ecological role of detritus in forest ecosystems, we hypothesized that the differences between SD and DD would be greatest for intermediate decay classes (i.e., 2 and 3). Given the lack of time in decay class 1, decay reductions are likely minimal for both SD and DD. For decay classes 4 and 5, which are based on structural strength, it is likely that SD and DD are similar given that structural strength of wood is highly dependent on density. We also hypothesized that the wood density of SD and DD would diverge more in dry climates than in humid ones due to moisture limitations in dry climates that inhibit SD decomposition. Since SD falls and becomes DD, the input of decayed SD-related wood might influence the overall density of DD. Since decay classes are largely based on exterior appearances, it is likely that SD in dry climates will be denser than DD for a given decay class because the exterior of SD will continue to degrade (e.g., bark loss, fragmentation of twigs, etc) whereas the interior will remain relatively sound. Conversely, in very wet environments, fragmentation of bark and cover of mosses and other bryophytes are likely to make the exterior of DD look decayed despite the slow rate of decomposition of DD in very wet environments. Based on these hypotheses, a variety of indicators of decay were visually assessed for both SD and DD in this study (Table 2). Similarities in indicators of decay among SD and DD pieces sampled in this study will suggest appropriate linkage between the SD and DD decay classification systems and subsequent development of SD decay reduction factors based on extensive DD woody decay information.

FIELD AND LABORATORY

Decay Classes and Indicators of Decay

At each study site we sampled SD and DD covering the full range of decomposition stages, which necessitated the felling of SD trees. To sample indicators of decay, selected SD or DD pieces were categorized into one of five decay classes based on visual characteristics linked to the degree of decomposition that was noted in the previous section: the presence of leaves, twigs, branches, percent bark cover on branches and bole, sloughing of wood, collapsing and spreading of DD or SD (indicating the transition from intact elliptical forms to degraded

Table 2.—Decay indicators used to determine decay classes for standing and downed dead trees

Code	Indicator question
Foliage	Is foliage present?
Twigs	Are twigs present?
Branches	Are branches present?
Bark_br	Is there bark present on the branches?
Bark_bole	Is there bark present on the bole?
Moss	Is there moss present?
Lichens	Are there lichens present?
Beetles	Is there evidence of beetle presence?
Woodborer	Is there evidence of woodborer presence?
Conks	Are there conks present?
Whiterot	Is there white rot present?
Brownrot	Is there brown rot present?
Casehard	Does the bole exhibit case hardening?

HW_friable	Is the heartwood crushable by hand?
Ants	Is there evidence of ants present?
SW slough	Is the sapwood sloughing?
Collapse	Has the bole shape collapsed?
Scatter	Is the bole scattered in the ground?
Stub_move	Do the branch stubs move in the bole?

shapes), friability or crushability of wood, color of wood, and mobility of branch stubs (Triska and Cromack 1980, Graham and Cromack 1982, Sollins 1982, Harmon and Sexton 1996). In addition to visual and structural indicators of decay used by the FIA program, biological indicators (Table 2) of decomposition, such as moss cover, presence of fungal fruiting bodies, and the presence of insect galleries, were also noted. In addition, at most sites we sampled live trees to determine densities of undecayed wood and bark. Dimensions recorded for each tree sampled included length, base and top diameters, and current d.b.h. The decay classes of both SD and DD used in this study align with the same decay classes used by the FIA program. Please refer to USDA (2010), Woodall et al. (2010), and Woudenberg et al. (2010) for details regarding the SD and DD decay classification systems used by FIA.

Wood Density and Density Reduction Factors

To measure wood density of SD and DD, samples were divided into four sections of similar length. Short pieces (e.g., in more advanced decay classes) were divided into two or three sections. For each section, end diameters and length were recorded. From the end of each section, a disk (a cross section 5 to 10 cm thick) was cut with a chainsaw to determine wood and bark density. To determine disk volume, for each cross-section disk we recorded the outermost diameter, outer wood diameter, mean longitudinal thickness, circumference covered by bark, radial thickness of bark, and mean radial depth of decay. Bark was separated from wood and the total wet weight of each tissue was determined. Lengths of bark and wedge-shaped wood subsamples of ~100 g taken from each disk using a hammer and chisel were weighed. Dry weights were recorded after oven drying at 55 °C to a constant weight (within 0.01 g). For disks that had not been dried and weighed, dry weights of wood and bark were calculated from total wet weights of these tissues and the ratio of dry-to-wet weight determined from subsamples. The density of the bark and wood for each disk was calculated as the ratio of its dry weight to undecayed volume (g/cm^3). Mean bark density and mean wood density for each tree were calculated by averaging the density of all the cross-section values of each tissue for each tree. Recorded values of percent bark cover for the whole tree and bark circumferential length for each disk were used to determine the proportion of total tree volume that was bark. Total density per tree was calculated as the summation of each tissue density multiplied by the proportion of total tree volume applicable to that tissue. An average density for each tree species, decay class, and position (i.e., SD or DD) was calculated using total tree density. Trees were also categorized as either hardwood (i.e., angiosperm) or softwood (i.e., gymnosperm) and total density per tree was averaged across each category for each decay class and position. Finally, an average of total density was calculated for all trees by decay class and position.

The density reduction factor was calculated as the ratio of the average current density to average undecayed density for each species, category, or combination and by each decay class and position (i.e., SD versus DD) to indicate the relative rate that tree density declined for each scenario.

Statistical Analysis

We used analysis of variance (ANOVA) to test how the dependent variable density reduction factor varied by the independent variables taxa (i.e., species or hardwood/softwood), decay class, and position. The following model was fit:

$$Y_{khij} = m + \alpha_k + \beta_h + d_i + a_j + da_{ij} + \varepsilon_{khij}$$

where:

m is the overall mean value of Y_{khij}, the average density reduction factor of the jth decay class in the ith position in region k and stand h

α_k is the random effect of the region k that was sampled, that adds variability to the value of Y, k=region name, $\alpha_{k\,h} \sim N(0, \sigma^2_b)$, α_k and $\alpha_{k'}$ are independent

β_h is the random effect of stand h that was sampled, that adds variability to the value of Y, h=stand name, $\beta_h \sim N(0, \sigma^2_b)$, β_h and $\beta_{h'}$ are independent

d_i is the effect of the ith level of the independent variable position, i=SD or DD

a_j is the effect of the jth level of the independent variable decay, j= 1, 2, 3, 4

da_{ij} is the interaction of position and decay

ε_{khij} is the random error term that adds variability to the value of Y, $\varepsilon_{khij} \sim N(0, \sigma^2)$ and ε_{khij} and $\varepsilon_{khi'j'}$ are independent.

When comparing softwoods and hardwoods, species was added as an additional random variable in the model. In the case of all species combined, the variables species and type (softwood or hardwood) were added as additional random variables. Residuals from the models were fairly symmetric and there was no indication of increasing variance with decreasing mean. Therefore, assumptions of normality and constant variance of residuals appeared to be adequately met. Through ANOVA testing, three results were postulated: 1) No significant difference between DD and SD density reduction factors by decay classes. This would indicate that decay occurred with similar patterns for dead wood in standing or lying positions; 2) The main effects of position and decay class would both be significant when the density reduction diverged early in the decomposition process (i.e., between class 0 and 1). This might suggest that one position started with a lower density than the other; 3) A significant interaction of position and decay class. This would indicate that one position was decaying to a lesser extent than the other and that density reduction factors were diverging. We tested these hypotheses at three separate levels: individual species, softwoods versus hardwoods, and for all species combined.

To examine why DD and SD might have different densities and density reduction factors, we compared indicators of decay (Table 2) between the two positions. We computed the relative frequency that indicators were present for two positions and the three taxonomic levels described above to examine which characteristics might be associated with differences in dependent variables.

All statistical tests based on the model outlined above were performed by the MIXED procedure of SAS (SAS Institute Inc.) using the LSMEANS statement which computes least squares means of fixed effects and corresponding *t* and *F* tests. Statistical tests were significant if $0.05 > P > 0.01$ and highly significant if $P < \text{or} = 0.01$. We emphasize that a minimal amount of replication was conducted within species, study sites, and decay classes. Replication was limited by the difficulty in finding study sites with a full representation of DD and SD decay classes. Furthermore, the felling of SD trees is extremely hazardous to the sawyer. We have expressed the high levels of uncertainty in Appendix C. The results presented in this study should be considered preliminary to guide future research and promote refined SD population estimation (i.e., use of decay reduction factors in biomass/carbon estimates).

Development of Standing Dead (SD) Databases

We used the findings of the current study to estimate decayed density and the density reduction factors of SD for tree species inventoried by the FIA program. For the species that we sampled, we used the observed densities and density reduction factors. For the species that we did not sample, we calculated decayed density and density reduction factors using ratios of the species we sampled and the estimated values for DD from Harmon et al. (2008). Specifically, for decay classes 1 to 3 we multiplied the SD to DD ratio for either hardwoods or softwoods (depending on the species) by the DD density or density reduction factor. For decay class 4, there were few species sampled. We therefore used the average SD to DD ratio of all species sampled. For decay class 5, as no species were sampled given the scarcity of these trees, this study suggests future research or assuming decay class 4 wood density results can be extrapolated to decay class 5.

To provide an estimate of uncertainty, we used one of the following methods:

A. Species that had been sampled for SD density. We used standard error of the observed values of decayed density or the density reduction factor.

B. Species lacking sampling to determine decayed SD density. The uncertainty (U) in the decayed SD density for this set of species was estimated by:

$$U_{\text{Decayed SD}} = \sqrt{(\text{Den}_{DD}^2)(U_{DD}^2) + (R^2)(U_R^2)}$$

where U_{DD} is the uncertainty in DD (Harmon et al. 2008), Den_{DD} is the mean DD density, and U_R is the uncertainty in R, the mean SD to DD density ratio. This formula accounts for the fact that uncertainty for decayed SD density is a function of two uncertainties. Our formula assumed no correlation between the uncertainties. Uncertainty was estimated for each decay class of SD. For decay classes 1 to 3 we used R values associated with either hardwoods or softwoods and applied them to appropriate taxa. For decay class 4 there were few observations, so we used values for all the taxa sampled.

A similar uncertainty estimate was made for density reduction factors using the average density reduction factor and associated uncertainty for DD.

RESULTS

Decay Indicators

All Species

The relative frequency of decay indicators (Table 2) as DD and SD decomposed was surprisingly similar (Figure 1). In terms of physical indicators (presence of parts, shape, friability) prior to reaching decay class 4, DD and SD were quite comparable and go through a similar progression from one decay class to the next. Decay class 4 DD and SD differed in terms of structural integrity indicators. This is a logical result as SD that lacks physical integrity tends to fall and form DD. The nearly entire lack of bark in decay class 4 SD, as compared to DD, is related to vertical orientation, as even loose bark can remain on the surface of DD. Across all species and study sites, the means of SD bark cover (percent of piece covered by bark) were 91.62, 65.55, 38.91, and 21.11 for decay classes 1 through 4, respectively.

In terms of biological indicators (presence of moss, lichens, insects, and fungi), the major difference between SD and DD appeared to be the abundance of moss. DD tended to have higher presence of moss than SD, which would be consistent with the wetter microclimate associated with DD versus SD. Conversely, lichens were slightly more abundant on SD than DD, which is consistent with a drier microclimate associated more with SD than DD. DD also had a greater tendency to support fungal fruiting bodies, whereas SD had a greater tendency to support wood borers. The former may indicate a more favorable decomposition environment; the latter may be an artifact related to greater moss cover and decay state in DD hiding evidence of wood borers. For further evaluation of these moss/lichen results we suggest consulting the abundance of literature regarding lichen substrate preferences.

We observed little bark cover in both class 2 and 3 SD for some species, making the characteristic less useful as an indicator than for DD. Two characteristics proved

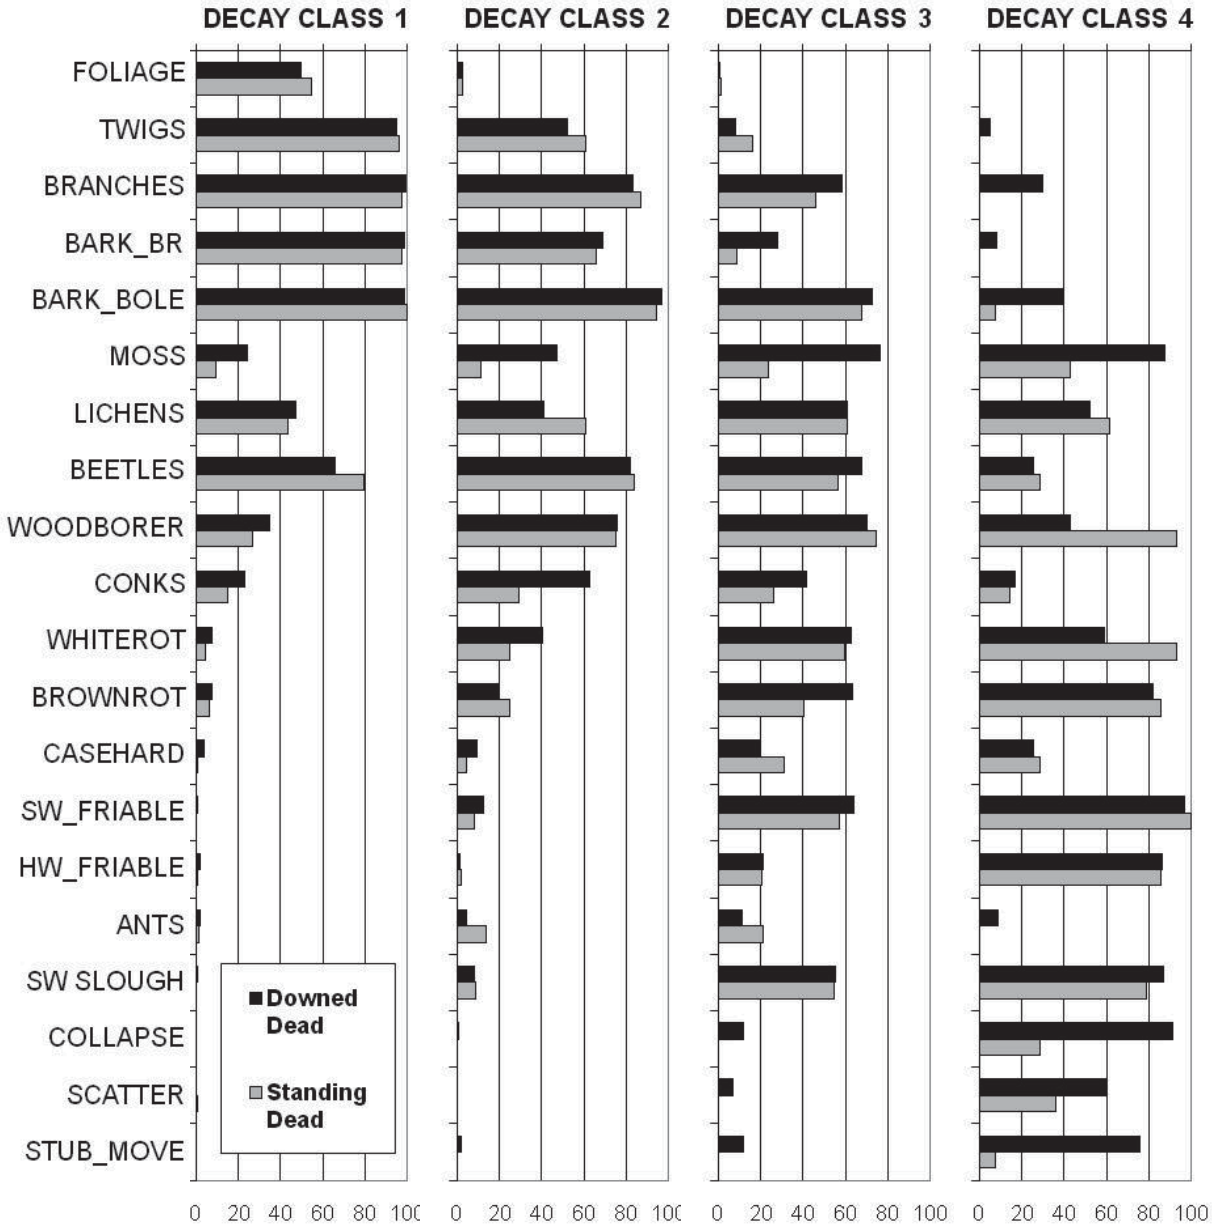

Figure 1.—Percent frequency of abundance for physical indicators of decay class for standing dead and downed dead trees

useful in distinguishing these two decay classes when SD had little bark cover. First, decay class 3 SD tended to have more lichens than decay class 2 SD. This is likely related to the older surface having more time to accumulate lichens. Second, the wood of decay class 3 SD tended to take on what might be described as a "ropey" texture. This is caused by a weakening of the outer wood layers causing cracks that look similar to the strands in a rope often associated with white-rot fungus. Findings by Aakala et al. (2008) indicate that the surface appearance of standing dead trees can remain static for long periods of time, thus the presence/absence of surface biological indicators may not fully indicate internal decay dynamics. Barring destructive sampling, standard forest inventory field crew must continue to rely on qualitative SD appearance to determine decay classification.

Hardwoods versus Softwoods

While the overall relationship between external characteristics and decay classes were similar for hardwoods and softwoods, there were some notable differences (Figure 2). In terms of physical indicators,

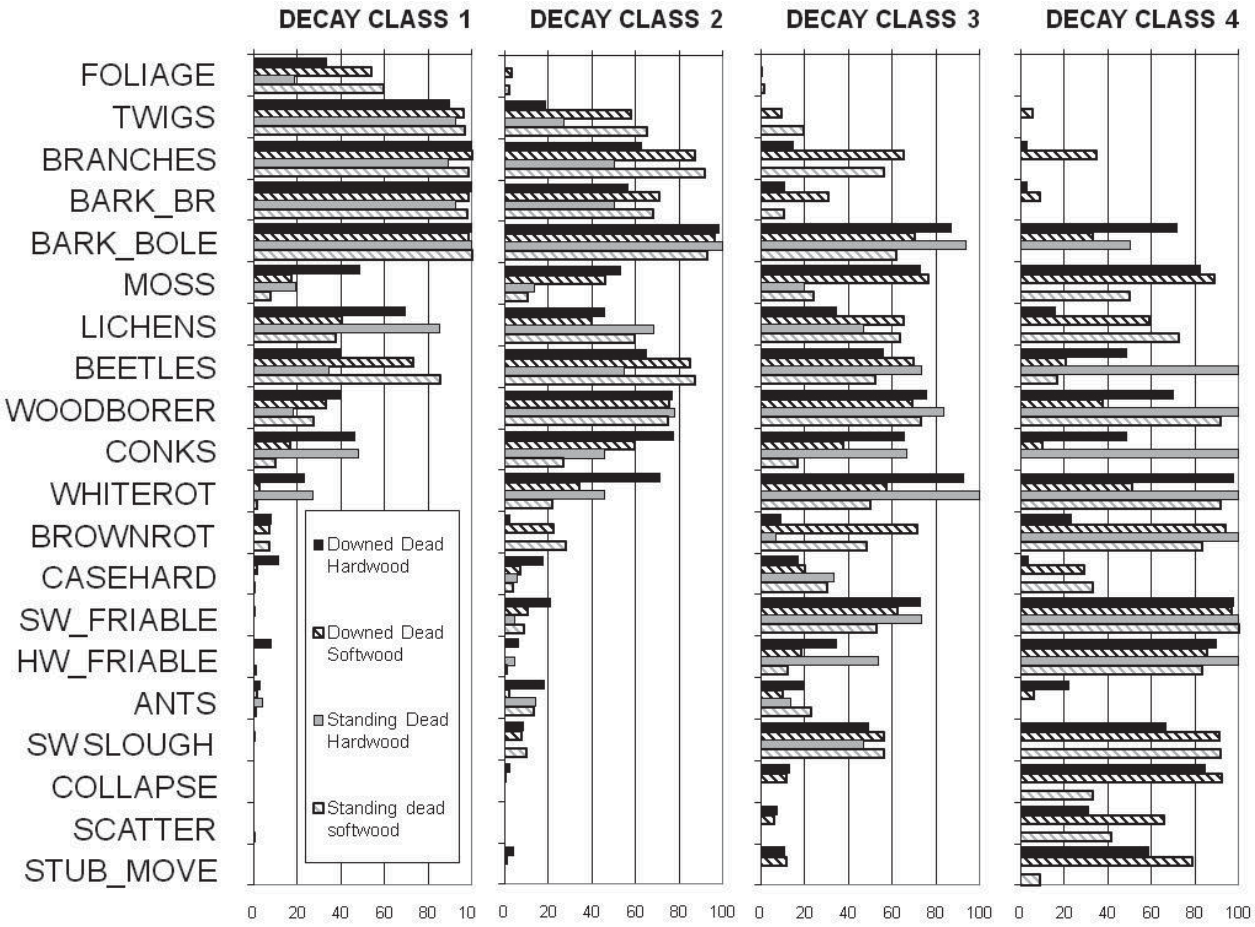

Figure 2.—Percent frequency of abundance for physical indicators of decay class for hardwood and softwood standing and downed dead trees

hardwoods appeared to lose twigs and branches to a higher degree than softwoods as decay class increased. Conversely, softwoods lost bark on the bole to a higher degree than hardwoods, although this was likely related to the presence of birch (*Betula* sp.), a genus well known for bark retention. For the biological indicators, hardwoods were more likely to have white-rot fungus, whereas softwoods were more likely to have brown-rot fungus, at least in decay classes 2 and 3. In decay class 1, hardwood SD were more likely to have lichens and mosses present than softwoods, but this likely stems from the difference of these tree taxa to support epiphytes in general.

Overall, indicators of decay were not evaluated in this study as an in-depth discourse on SD and DD decay dynamics and ecology, rather as a qualitative means to assure differentiation between decay classes and alignment with FIA sampling protocols. Results indicated adequate decay class differentiation, linkage between SD and DD decay classification systems, and FIA sampling protocol alignment allowing subsequent development of wood density estimates for SD tree species in U.S. forests based on relatively extensive DD wood density information.

Wood Density

As expected, SD wood density declined with decay class (Appendix A). The initial, undecayed tree densities for the 19 species studied ranged from 0.31 to 0.54 g/cm^3 (Table 3). The overall mean initial density was 0.39 g/cm^3. Decay class 3, the most advanced decay class common to SD and DD, had densities that ranged from 0.16 to 0.34 g/cm^3 for DD and 0.21 to 0.46 g/cm^3 for SD. Decay class 3 density for all species of DD averaged 0.26 g/cm^3 and averaged 0.35 g/cm^3 for SD indicating that SD contain less decay than logs (Table 4). This is

Decay class	SD (g/cm^3)	n	DD (g/cm^3)	n	SD/DD Ratio
1	0.40 (0.00)	175	0.40 (0.00)	185	1.00
2	0.38 (0.00)	189	0.33 (0.00)	292	1.15
3	0.35 (0.01)	78	0.26 (0.00)	391	1.35
4	0.25 (0.03)	14	0.15 (0.00)	246	1.67
5			0.11 (0.00)	174	

Note: Values are means with standard errors in parentheses. “n” is the number of SD or DD.

consistent with the notion that SD must retain some sound wood to remain upright. Aakala’s (2010) study in *Picea abies* forests in northern Europe found a range of SD decayed density ranging from 0.14 to 0.47 g/cm^3.

Hardwoods tended to have slightly higher initial density than softwoods, but the opposite was true after extensive decay (Table 5). For example, the mean initial, undecayed density for hardwoods and softwoods was 0.40 and 0.38 g/cm^3, respectively. However, decay class 3 hardwood DD and SD had mean densities of 0.23 and 0.24 g/cm^3, whereas softwood DD and SD had mean densities of 0.27 and 0.38 g/cm^3, respectively.

Density Reduction Factors

Individual species

Density reduction factors for decay class 3 ranged from 0.34 to 0.80 and from 0.44 to 1.11 for DD and SD, respectively (Appendix B). Statistical analysis showed five species with highly significant interactions and two with significant interactions between position and decay class (*P*-values: *Larix sibirica* 0.00; *Pinus contorta* 0.00; *Picea lutzii* 0.00; *Pinus* species 0.01; *Pinus sibirica* 0.01; *Pinus banksiana* 0.05; *Pinus koraiensis* 0.05). Of these seven species, four were in the genus *Pinus*. This interaction indicated that SD for these species retained a higher density than DD and that these differences increased as decay proceeded. Aakala (2010) found similar results in *Picea abies* forests of northern Europe, with the wood density of SD significantly higher than DD. Furthermore, in our study three species (two hardwood and one softwood) had highly significant decay class and position main effects, but no significant interaction between the two factors. This result may indicate that early in the decay process, DD and SD diverge, with DD undergoing an initial rapid period of decomposition and SD subject to a lag. Four species (three hardwoods and one softwood) showed only decay class as a highly significant factor in density reduction (*P*-values: *Betula pendula* 0.00; *Tsuga heterophylla* 0.00; *Populus tremula* 0.00; *Populus tremuloides* 0.00). This would indicate that decay progresses similarly in SD and DD for these species. Two species showed only position as a highly significant factor in density reduction, but this was likely an artifact related to the few decay classes sampled for these species.

Hardwoods versus softwoods

Compared to hardwoods, softwoods, on average, are more likely to have a greater divergence in SD and DD decay reduction factors as decay progresses (Table 6). For example, the mean density reduction factors for decay class 3 hardwood DD and SD were 0.51 and 0.54,

Table 5.—Average density (g/cm^3) for standing dead (SD) and downed dead (DD) trees and associated ratio (SD/DD average density) by hardwood/softwood and decay class

Type	Decay class	SD (g/cm^3)	n	DD (g/cm^3)	n	Ratio SD/DD
Hardwood	1	0.46 (0.01)	37	0.43 (0.01)	51	1.07
	2	0.36 (0.01)	31	0.33 (0.01)	58	1.09
	3	0.24 (0.02)	14	0.23 (0.01)	60	1.04
	4	0.20 (0.03)	2	0.13 (0.01)	55	1.54

	3	0.38 (0.01)	64	0.27 (0.00)	331	1.41
	4	0.26 (0.03)	12	0.15 (0.00)	191	1.73
	5			0.11 (0.00)	143	

Note: Values are means with standard errors in parentheses. “n” is the number of SD or DD.

Table 6.—Average density reduction factor (decayed density/undecayed density) for standing dead (SD) and downed dead (DD) trees and associated ratio (SD/DD density reduction factor) by hardwood/softwood and decay class

Type	Decay class	SD	n	DD	n	Ratio SD/DD
Hardwood	1	0.99 (0.01)	37	0.95 (0.01)	51	1.04
	2	0.80 (0.02)	31	0.74 (0.02)	58	1.08
	3	0.54 (0.04)	14	0.51 (0.03)	60	1.06
	4	0.43 (0.05)	2	0.29 (0.02)	55	1.48
	5			0.22 (0.02)	31	
Softwood	1	0.97 (0.01)	138	0.93 (0.01)	134	1.04
	2	1.00 (0.01)	158	0.87 (0.01)	234	1.15
	3	0.92 (0.03)	64	0.70 (0.01)	331	1.33
	4	0.55 (0.06)	12	0.40 (0.01)	191	1.38
	5			0.29 (0.01)	143	

Note: Values are means with standard errors in parentheses. “n” is the number of SD or DD.

respectively. In contrast, the mean density reduction factors for decay class 3 softwood DD and SD were 0.70 and 0.92, respectively. For softwood species collectively, there was a highly significant interaction between position and decay class effects. For hardwood species, decay class was a highly significant factor in density reduction. This indicates that DD density factors could be substituted for SD ones in hardwoods, but not for softwoods.

All species combined

The density reduction factors for all decay class 3 DD and SD was 0.67 and 0.86, respectively (Table 7). There was a highly significant interaction between position and decay class in the reduction factor, which may be due to softwood species being over represented in the data set.

Standing Dead Databases

Of 260 species considered by the FIA inventory, eight (3 percent) have had some SD decay classes sampled. For sampled species, the uncertainty of SD density was approximately 3 to 14 percent of the mean estimate. In contrast for species in which SD density had to be estimated from the DD database produced by Harmon et al. (2008), the uncertainty is approximately 20 to 100

Table 7.—Average density reduction factor for standing dead (SD) and downed dead (DD) trees and associated ratio (SD/DD density reduction factor) for all sites/ species combined by decay class

Decay class	SD	n	DD	n	Ratio SD/ DD
1	0.97 (0.01)	175	0.94 (0.01)	185	1.03
2	0.97 (0.01)	189	0.84 (0.01)	292	1.15
3	0.86 (0.03)	78	0.67 (0.01)	391	1.28
4	0.53 (0.06)	14	0.38 (0.01)	246	1.39
5			0.28 (0.01)	174	

Note: Values are means with standard errors in parentheses. "n" is the number of SD or DD.

percent of the mean estimate, the latter for decay class 4 SD. This indicates that actual sampling of SD density could reduce the uncertainties with this material at least an order of magnitude.

Implications of Density Reduction on Population Estimates

The implications of assumptions of SD density can be potentially profound in terms of biomass estimates. Using FIA's forest inventory of the state of Minnesota (2005-2009), we explored the impact of three plausible scenarios for estimating total SD biomass (i.e., SD wood density assumptions): 1) SD wood density equals live tree wood density; 2) SD and DD wood density are equal; and 3) SD wood density based on this study's newly created SD density reduction factors. To convert that volumetric estimate to one of biomass, the three SD wood density assumptions were evaluated. Assuming that SD wood density was equal to live trees gives a total SD biomass estimate of 32.98 million Mg. By assuming that SD and DD wood density are equal, the estimated biomass was 24.38 million Mg, or 26 percent less. Using the new estimates of SD wood density provided an estimated biomass of 27.52 million Mg or 16.5 percent less than the assumption of undecayed density.

DISCUSSION

SD inhabit a very different environment than DD, with the former usually being drier. Given that the response of decomposition to moisture shows an optimum range (i.e., woody tissues can be too dry or too wet to decompose readily), the position supporting the fastest decomposition can change with macroclimate (Harmon 2009). This might lead to consistent differences in the density of SD versus DD. In very humid environments, DD and SD both may retain moisture and hence the density of SD and DD might remain similar. This may explain our results from Cascade Head, the wettest site examined. In very dry environments SD decay may be limited relative to that of DD and that could lead to an increasing difference as decay class increases. Specific to sites in this study, but possibly not pertinent to all forest conditions across the United States, softwoods tended to grow in drier climates and microsites than hardwoods, which may explain why many softwoods exhibited an increasing difference in density as decay classes increased. In environments with intermediate moisture, SD may be slightly drier than DD. This could lead to a relatively short lag in decomposition that would result in a constant difference between decay classes in terms of density. While our observations are consistent with these hypotheses, other factors could be causing the patterns observed and more SD:DD comparisons in a wider range of environments would be helpful in determining the mechanisms explaining these phenomena. Differences in the density of SD versus DD may also be related to the physical limits of strength of woody tissues. That is, SD have to be fully self supporting, and once their strength decreases past a threshold they will collapse to form DD. In contrast, DD with minimal structural strength can collapse, but remain as DD. This may lead to an apparent abundance of higher wood density SD trees as less sound SD fall to become DD. However, SD do not necessarily have to decompose throughout to fall. For example, SD in dry environments fall after root systems decompose, adding relatively sound wood to the DD pool. When this occurs the density of DD might increase due to this input of relatively sound SD wood. Therefore, the difference in wood density between SD and DD are likely to be controlled by a number of interacting factors. Care should be taken not to infer rates of decay with assigned decay classes. Differences in wood density were quantitively determined between SD and DD qualitative decay classes in this study. Rates of decay are only inferred as initial hypotheses for future research.

There is an emerging abundance of research discussing the dynamics of SD and DD decay and subsequent

effects on biomass/residence times (Aakala et al. 2008, Aakala 2010, Kruys et al. 2002, Vanderwel et al. 2006, Zielonka 2006,). Moving beyond initial characterizations of SD and DD decay dynamics on intensively monitored study sites towards estimates of SD wood density by decay class for all forest tree species in the United States is a tremendous change in study scope. However, the immediate need to develop and document SD decay reduction factors for most forest tree species in the United States to meet mandated carbon stock reports requires a timely assimilation of the best available science. Given the lack of information on SD decayed wood density for hundreds of tree species in the United States, several approaches were considered. First, SD tree density can be assumed to be similar to undecayed tree density. For some environments in which decomposition is very slow, this might be acceptable. However, in our analysis we did not find a single species in which density did not decline with decay class. Second, SD tree density could be assumed equal to that of DD tree density. This would be appropriate for 6 of the 19 species we examined. The most common situation in our study (13 of 19 species) was for either position or a position X decay class interaction to be significant.

To create the needed SD decay reduction factors for all tree species in the United States, decay classes in this study were aligned with those used by FIA using this study's indicators of decay. FIA's SD decay classes 1 and 2 were quite similar to the classes 1 and 2 assessed in this study. Given the more highly decayed nature of SD decay classes 3 and 4, FIA's SD decay classes 3 and 4 seem to span the characteristics of decay class 3 SD trees with some overlap into decay class 4. The FIA SD decay class 5 would seem to be similar to this study's SD decay class 4. Based on this finding, it is suggested that the decay reductions for SD decay class 4 be used as an approximation for SD decay class 5 until such time that empirical information refines SD decay class 5 attributes or a model is suggested to extrapolate decay class 4 attributes to decay class 5 pieces. Furthermore, given the potential safety hazard of felling decay class 5 SD trees, this assumption may be the most practical. In general, these are gross approximations and, given the fact that the FIA system is based on Douglas-fir with unspecified modifications for other species, it would be logical to develop a SD decay class system based on a wider range of species better aligned with the DD system.

While it is important to eventually determine density and density reduction factors for SD and DD of the major species encountered in inventories, in the short-term one is forced to make assumptions when species or positions have not been sampled. Whether considering individual species, hardwoods and softwoods, or all samples combined, the ranges of density reduction factors for SD were consistently higher compared to DD. This indicates generally less reduction in density as decay progresses in SD than DD. Softwood species tended to exhibit this pattern more strongly than hardwood species, sometimes even increasing in density. There were exceptions to this pattern in the statistical analysis (insignificant effect of position), but inspection of the charted data indicated that these cases had samples for only decay classes 1 and 2, were hardwood species, or were located in a warm and wet climate. The assumption with the strongest support at this time is that softwoods tend to have a greater divergence in SD and DD density reduction factors than hardwoods. However, additional sampling of species, hardwoods in particular, is required to confirm if this is actually the case.

Irrespective of the findings of this study, SD wood density at some point in its decay process will become substantially less than that of living trees. The selection of density reduction factors can have a profound effect on resulting population estimates (e.g., SD carbon in a state). This study found substantial variation in SD biomass population estimates for Minnesota when using undecayed density versus reduced wood density values. The differences in estimates depend strongly on the dominance of hardwoods versus softwoods. When only softwood species were considered, the difference between the assumption of live tree wood density and the SD densities that we estimated was 2.5 percent. In contrast, when only hardwood species were considered the difference between these two methods was 22 percent. Therefore, the potential biases contained in current SD estimates are likely to vary substantially. This analysis is considered preliminary for illustrative purposes as structural reductions for decay were not incorporated into the estimation procedures.

CONCLUSIONS

To provide accurate, unbiased estimates of the biomass and carbon stocks of SD trees, it is necessary to have species- and decay class-specific estimates of either density or density reduction factors. Empirically sampling the wood density of SD by species and decay class across the forests of the United States is currently restricted by the inherent costs and felling hazards involved. As an approach to estimate preliminary SD wood density reduction factors, this study established relationships between SD and DD such that extensive DD woody density studies could be used to suggest SD wood density attributes. This study suggests a new set of SD decay specific density and density reduction factors for many tree species in the United States that may be used to refine FIA's SD population estimation procedures. Given the size of the uncertainty involved with the SD wood decay attributes proposed in this study, additional work to develop a multispecies SD decay class system and to better characterize differences between SD and DD trees is recommended.

ACKNOWLEDGMENTS

This work was funded by a joint venture agreement between the U.S. Forest Service Forest Inventory and Analysis and Oregon State University (09-JV-11242305-025).

Special thanks are extended to Shawn Fraver, Ph.D., and Brad Oberle, Ph.D., who provided abundant constructive criticism that improved the quality of this documentation.

The cooperation of numerous experimental forest staff at locations in the United States and Russia were critical to this study's success. In particular, Randy Kolka, Ph.D. and his staff at the Marcell Experimental Forest were especially helpful with facilitating the field work. We would also like to thank Peter White, Ph.D. of the North Carolina Botanical Garden for the use of facilities and his many students whose efforts made this project possible.

Standing Dead Absolute Density Predictions Metadata (Appendix C)

Fieldname	Definition	Code/Units	Method
genus	Sample genus		
species	Sample species		
code	Genus-species code		
den0	Green density (decay class “0”)	g/cm^3	
den1	Density of decay class 1 snag	g/cm^3	
unc1	Uncertainty of den1		
cod1	Uncertainty code for den1 (A, B, C)	A	Species sampled
cod1	Uncertainty code for den1 (A, B, C)	B	Genera sampled
cod1	Uncertainty code for den1 (A, B, C)	C	Species and genus not sampled
den2	Density of decay class 2 snag	g/cm^3	
unc2	Uncertainty of den2		
cod2	Uncertainty code for den2 (A, B, C)	A	Species sampled
cod2	Uncertainty code for den2 (A, B, C)	B	Genera sampled
cod2	Uncertainty code for den2 (A, B, C)	C	Species and genus not sampled
den3	Density of decay class 3 snag	g/cm^3	
unc3	Uncertainty of den3		
cod3	Uncertainty code for den3 (A, B, C)	A	Species sampled
cod3	Uncertainty code for den3 (A, B, C)	B	Genera sampled
cod3	Uncertainty code for den3 (A, B, C)	C	Species and genus not sampled
den4	Density of decay class 4 snag	g/cm^3	
unc4	Uncertainty of den4		
cod4	Uncertainty code for den4 (A, B, C)	A	Species sampled
cod4	Uncertainty code for den4 (A, B, C)	B	Genera sampled
cod4	Uncertainty code for den4 (A, B, C)	C	Species and genus not sampled

Harmon, Mark E.; Woodall, Christopher W.; Fasth, Becky; Sexton, Jay; Yatkov, Misha. 2011. **Differences between standing and downed dead tree wood density reduction factors: A comparison across decay classes and tree species.** Res. Pap. NRS-15. Newtown Square, PA: U.S. Department of Agriculture, Forest Service, Northern Research Station. 40 p.

Woody detritus or dead wood is an important part of forest ecosystems and has become a routine facet of forest monitoring and inventory. Biomass and carbon estimates of dead wood depend on knowledge of species- and decay class-specific density or density reduction factors. While some progress has been made in determining these parameters for dead and downed trees (DD), there are very few estimates of these key parameters for standing dead trees (SD). We evaluated indicators of decay to relate subjective SD and DD decay classifications then compared SD and DD density and density reduction factors by decay class for a total of 19 tree species at nine sites in the United States and Russia. Results indicate that SD density declined with decay class for all examined species. By applying these results, a new set of SD density reduction factors was developed for 260 species inventoried by the U.S. Forest Service's Forest Inventory and Analysis program in forests of the United States.

KEY WORDS: standing dead trees, downed dead trees, carbon, biomass, decay reduction factor

The U.S. Department of Agriculture (USDA) prohibits discrimination in all its programs and activities on the basis of race, color, national origin, age, disability, and where applicable, sex, marital status, familial status, parental status, religion, sexual orientation, genetic information, political beliefs, reprisal, or because all or part of an individual's income is derived from any public assistance program. (Not all prohibited bases apply to all programs.) Persons with disabilities who require alternate means for communication of program information (Braille, large print, audiotape, etc.) should contact USDA's TARGET Center at (202)720-2600 (voice and TDD). To file a complaint of discrimination, write to USDA, Director, Office of Civil Rights, 1400 Independence Avenue, S.W., Washington, DC 20250-9410, or call (800)795-3272 (voice) or (202)720-6382 (TDD). USDA is an equal opportunity provider and employer.

Damon B. Lesmeister, Raymond J. Davis, Peter H. Singleton, and J. David Wiens[1]

Introduction

The northern spotted owl (*Strix occidentalis caurina*) was listed as threatened under the Endangered Species Act in 1990 (USFWS 1990). Providing adequate amounts of suitable forest cover to sustain the subspecies was a major component of the first recovery plan for northern spotted owls (USFWS 1992) and a driver in the basic reserve design and old-forest restoration under the Northwest Forest Plan (NWFP, or Plan) (USDA and USDI 1994). The reserve design included large contiguous blocks of late-successional forest, which was expected to be sufficient to provide habitat for many interacting pairs of northern spotted owls. As such, the selection of reserves generally favored areas with the highest quality old-growth forests, but some areas of younger forest were also included with the expectation that they would eventually develop suitable forest structure characteristics and contribute to spatial patterns that would sustain spotted owl populations.

Northern spotted owls are now one of the most studied birds in the world. Much of the research and interest in spotted owls stem from the economic and ecological implications surrounding management for the subspecies. Courtney et al. (2004) and the U.S. Fish and Wildlife Service (USFWS 2011b) completed comprehensive reviews and syntheses of scientific information regarding the status, ecology, and threats to the northern spotted owl. In the 10-year science synthesis of the NWFP, Raphael (2006) detailed the expectations and observations for northern spotted owl populations and suitable forest types under the Plan. Here we provide a 20-year synthesis of northern spotted owl science and review key information concerning the ecology and expectations for conservation of northern spotted owls under the NWFP. We build upon previous syntheses and address guiding questions by focusing on the scientific understanding accumulated from 2005 to 2016 on the ecology, conservation, and management of northern spotted owls. We also provide an overview of the main scientific debates surrounding conservation and management of northern spotted owls. We discuss the distinction between associated forest cover types and the relative value of habitat in different forest types for the subspecies. Where needed, we review and draw inference from research related to Mexican spotted owls (*S. o. lucida*) and California spotted owls (*S. o. occidentalis*), but keep the focus of this synthesis on published literature specific to northern spotted owls (spotted owl hereafter).

Major threats to spotted owls identified at the time of design and initial implementation of the NWFP and species recovery plan included the effects of past and current timber harvest, loss of old forest to wildfire, and competition with rapidly encroaching barred owls (*Strix varia*) (USDA and USDI 1994, USFWS 1992). Studies of associations between spotted owls and forest cover published since 2005 have reinforced previous work indicating a strong association of nest and roost sites with older forest conditions and a wider range of forest cover types used for foraging and dispersal (Anthony et al. 2006; Carroll and Johnson 2008; Dugger et al. 2005, 2016; Forsman et al. 2011, 2015; Hamer et al. 2007; Irwin et al. 2012, 2013; McDonald et al. 2006; Olson et al. 2005; Sovern et al. 2015). In the southern portions of the range, abiotic environmental factors begin to play larger roles in territorial owl use (Glenn et al. 2017), and at the very southern end of the range (Marin County, California), spotted owls occur at higher densities and tend to nest in a wider variety of forest cover types and ages (Stralberg et al. 2009). The difference in localized spotted owl densities and generalist vegetation associations appear to be driven by the diversity of forest conditions and high prey density prevalent in that landscape.

David Wiens** is a research wildlife biologist, U.S. Department of the Interior, Geological Survey, Forest and Rangeland Ecosystem Science Center, 3200 SW Jefferson Way, Corvallis, OR 97331.

Every study that has assessed rangewide population trends of spotted owls found steady declines since standardized monitoring efforts started in 1985 (Anthony et al. 2006, Dugger et al. 2016, Forsman et al. 2011, Franklin et al. 1996). Loss of suitable forest and competitive interactions with barred owls are the primary threats that have contributed to those declines. In the following sections, we review recent information on the status and trends of spotted owl populations and suitable forest, effects of interactions with barred owls, prey ecology, disturbance impacts, climate change, and other threats. We also review population trends and range expansion of barred owls, their habitat and prey, and identify other sensitive wildlife and ecological processes that may ultimately be affected by the invasion of barred owls. We conclude by outlining considerations for management and research needs for spotted owls and forest types most critical to their persistence.

Guiding Questions

We used the following questions received from forest managers to guide our synthesis and focus on relevant spotted owl literature. Following each question, we provide the section that most effectively addresses the question, or if a question could not be adequately addressed because of a lack of published literature on the subject.

1. What is the current understanding about spotted owl population status? Will continuing to implement the NWFP reverse the downward trend in spotted owl populations?
    - Information can be found in the "Population Status and Trends" and "Conclusions and Management Considerations" sections.
2. Is the NWFP maintaining or restoring forest conditions necessary to support viable populations of spotted owls?
    - Despite old-forest loss to wildfire and timber harvest, implementation of the NWFP has been successful for putting federal lands on a trajectory for restoring forest capable of supporting spotted owls on federal lands. Information can be found in the "Habitat Status and Trends," "Disturbance," and "Conclusions and Management Considerations" sections.
3. What are the effects of various timber management practices and wildfire on forests used by spotted owls?
    - Information can be found in the "Habitat Status and Trends," "Disturbance," and "Research Needs" sections.
4. How is space use by spotted owls affected by timber management? Are there ways to modify management activities (i.e., silvicultural treatments) to benefit spotted owls? How do managed stands compare to untreated forests in terms of use by spotted owls?
    - Information can be found in the "Habitat Status and Trends," "Disturbance," "Research Needs," and "Conclusions and Management Considerations" sections.
5. Do spotted owls use forests following wildfire? If so, how? Do the impacts of treatments that reduce risk of wildfire outweigh the risks of suitable forest loss resulting from wildfire?
    - The short- and long-term response by spotted owls to wildfire remains largely unknown, and scientific debate remains. We were unable to fully address this question, but do provide a synthesis of available literature in the "Habitat Status and Trends," "Disturbance," "Research Needs," and "Scientific Uncertainty" sections.
6. How effective are protections for buffered areas around nest sites in retaining spotted owls across treated landscapes? Are site buffers equally effective as landscape-scale forest management in ensuring species persistence, dispersal, and habitat connectivity?
    - We were unable to address this question fully owing to the lack of published literature, but some information about the effectiveness of buffered management areas can be found in the "Habitat Status and Trends," and "Forest protection effectiveness" sections.

7. Which provides a higher level of spotted owl persistence: the current spotted owl critical habitat or the NWFP late-successional reserve network?
    - Information can be found in the "Habitat Status and Trends," and "Forest protection effectiveness" sections.
8. Does treating late-successional stands improve spotted owl persistence when wildfire, insects, disease, and climate change threaten the ability of these forests to provide habitat for spotted owls?
    - Information can be found throughout the chapter in the "Habitat Status and Trends," "Barred Owls," "Disturbance," "Climate Change," "Other Threats," "Research Needs," "Scientific Uncertainty," and "Conclusions and Management Considerations" sections.
9. What are the effects of barred owls on spotted owls? What is the relationship of wildfires to barred owl encroachment? Can a barred owl management program be effectively implemented at a scale that will have meaningful conservation value for spotted owls?
    - Information about the effects of barred owls is found in "Barred Owls." We were unable to adequately address questions about the relationship between barred owls and wildfire, and barred owl management, because of a paucity of literature. In addition, some of this research was ongoing at the time this synthesis was being prepared. We provide further details in "Research Needs, Uncertainties, Information Gaps, and Limitations."
10. What are the management considerations and research needs for spotted owls?
    - Based on our synthesis of available literature within the context of the guiding management questions we received, we specifically address high-priority information needs in "Research Needs, Uncertainties, Information Gaps, and Limitations." We conclude the chapter with "Conclusions and Management Considerations."

Key Findings

Population Status and Trends

Understanding vital rates (e.g., birth, death) and the factors affecting those parameters over time and space can provide crucial information for management and conservation. Since the listing of the spotted owl, demographic rates have been monitored in up to 14 demographic study areas distributed across the spotted owl's geographic range. Franklin et al. (1996) developed a general framework to estimate demographic parameters and population trends of spotted owls that has been used in subsequent spotted owl population analyses. In the past 10 years, three meta-analyses (Anthony et al. 2006, Dugger et al. 2016, Forsman et al. 2011) documented a continued decline in spotted owl populations throughout their range. Those meta-analyses built upon the Franklin et al. (1996) methods to analyze survival, reproduction, and territory occupancy data that has been collected consistently for nearly three decades.

The number of study areas in which spotted owls have been monitored has changed through time owing to changes in funding and institutional support. Anthony et al. (2006) used data from 14 study areas (1985 to 2003), Forsman et al. (2011) used data from 11 study areas (1985 to 2008), and Dugger et al. (2016) used data from 11 study areas (1985 to 2013) to evaluate survival, fecundity, recruitment, and rate of population change of spotted owls throughout the subspecies' geographic range (fig. 4-1). Dugger et al. (2016) also investigated territory occupancy dynamics (gains and losses of occupied territories; i.e., local colonization and extinction rates). All three meta-analyses investigated relationships between population demography of spotted owls and the distribution of suitable forest cover types, local and regional variation in climatic conditions, and presence of barred owls. Study areas included in these meta-analyses comprised about 9 percent of the spotted owl's range, were distributed throughout the geographic range, and were selected to encompass the broad range of forest conditions used by the subspecies.

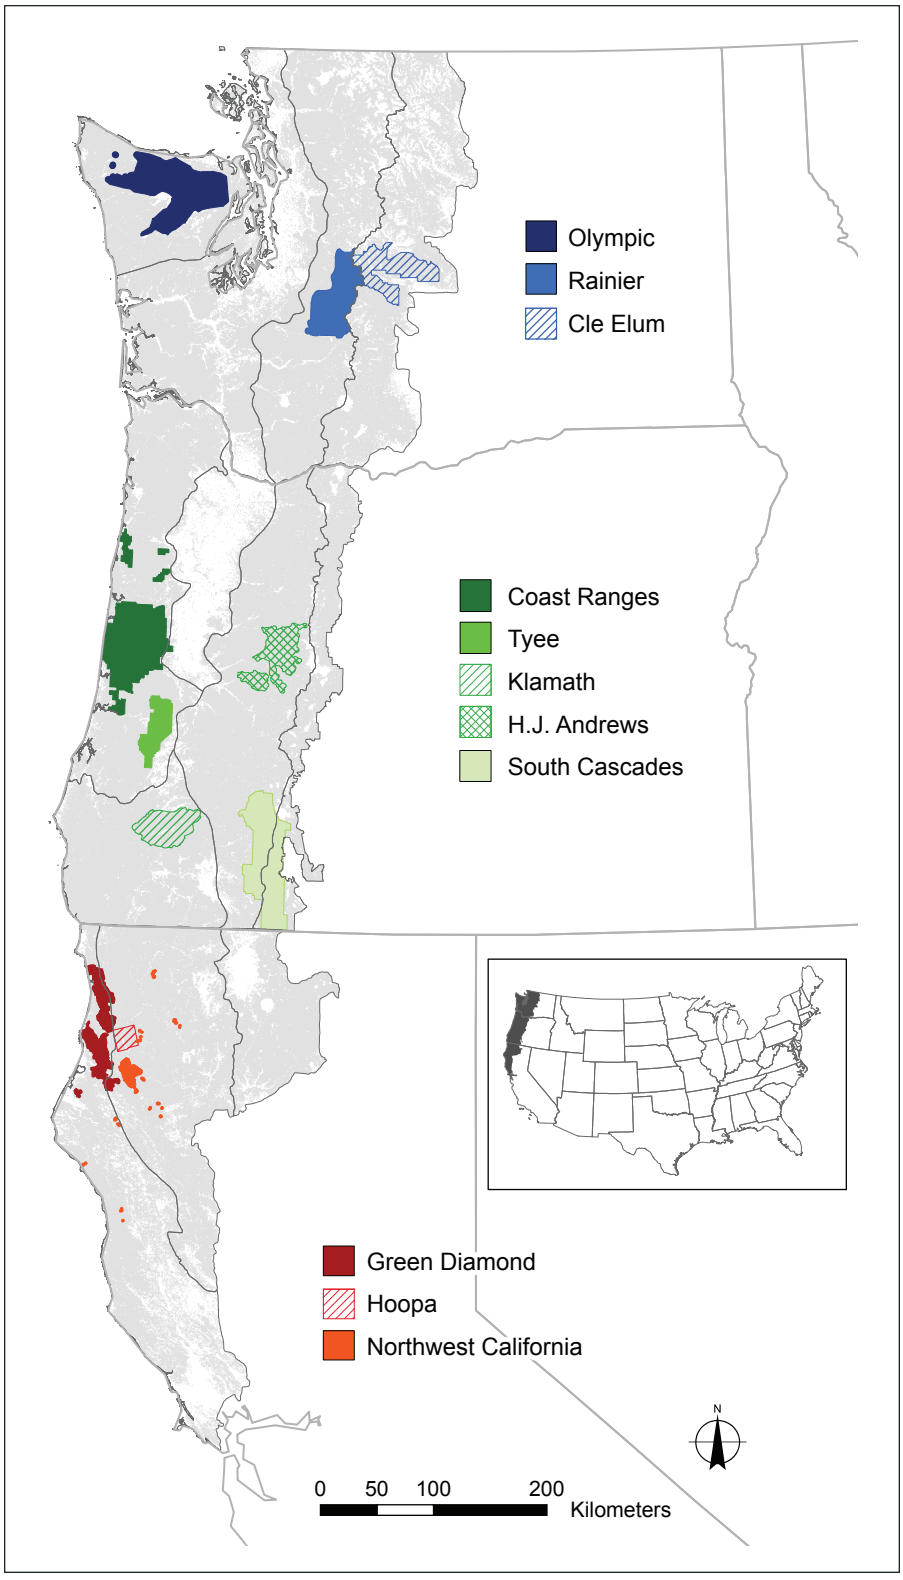

Figure 4-1—Locations of 11 study areas used in the analysis of vital rates and population trends of northern spotted owls, 1985 to 2013 (Dugger et al. 2016).

When the NWFP was developed, populations of spotted owls were estimated to be declining at about 4.5 percent (confidence interval [CI] 1.1 to 7.9) per year (Burnham et al. 1996, USDA and USDI 1994). The population was expected to continue declining for up to 50 years until younger second-growth forest in reserves matured to a point at which it would provide suitable structural conditions for nesting and roosting (Lint 2005, USDA and USDI 1994). During the first 10 years of the NWFP, the overall rate of population decline in Washington was much greater than in Oregon and California (Anthony et al. 2006, Lint 2005). Three study areas in southern Oregon had stable populations during the first decade. Anthony et al. (2006) estimated an annual decline of 3.7 percent (CI = 1.9 to 5.5) across the range, but that analysis included lands outside of the NWFP monitoring area. The eight federal study areas within the boundaries of the NWFP area (i.e., lands under federal management) used for effectiveness monitoring of the NWFP had a decline of 2.4 percent (CI = 1.0 to 3.8) compared to a 5.8 percent (CI = 2.6 to 9.0) decline for study areas composed primarily of nonfederal lands, suggesting that implementation of the NWFP had a positive effect on the demography of spotted owls (Anthony et al. 2006, Raphael 2006). Forsman et al. (2011) estimated an annual decline of 2.9 percent (CI = 1.7 to 4.0) throughout the northern spotted owl's range, and Davis et al. (2011) estimated an annual decline of 2.8 percent (CI = 1.5 to 4.2) within the eight federal study areas. The most recent meta-analysis indicated that spotted owl populations were continuing to decline throughout the range of the subspecies, and that annual rates of decline were accelerating in many areas (Dugger et al. 2016). The population was declining by about 3.8 percent (CI = 0.1 to 7.5) per year and declines ranged from 1.2 percent to 8.4 percent per year depending on the study area (fig. 4-2) (Dugger et al. 2016). For monitored populations, population change was more sensitive to adult survival than to recruitment (Glenn et al. 2010). Other studies have also documented declines in populations throughout the range of the spotted owl (Farber and Kroll 2012, Funk et al. 2010, Kroll et al. 2010).

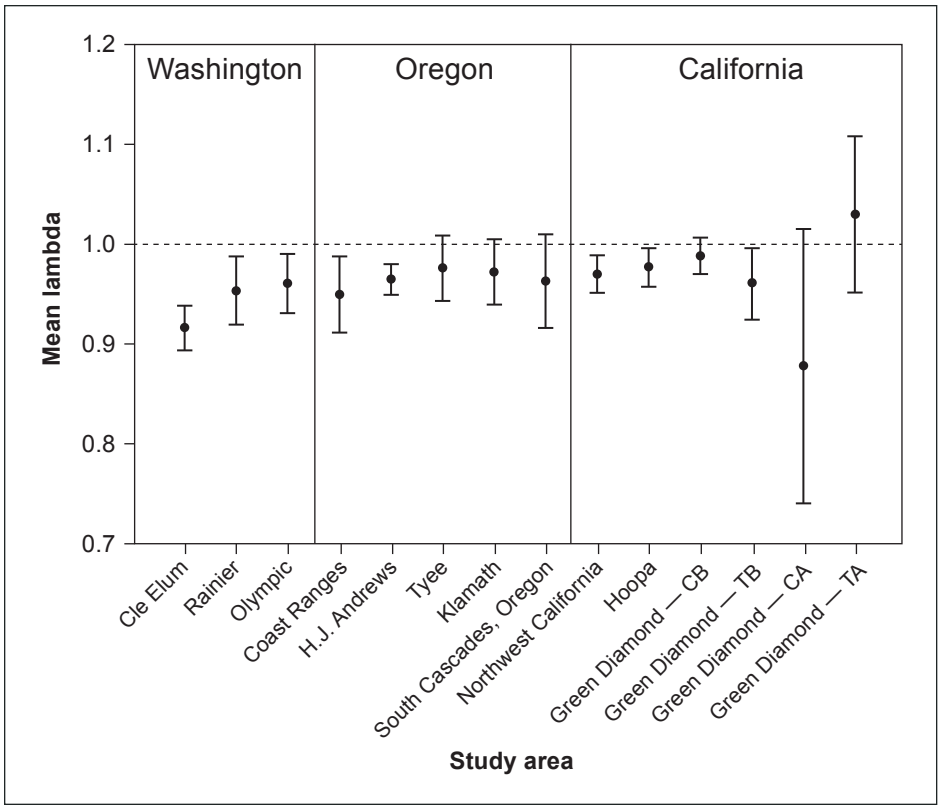

Figure 4-2—Estimated mean rates of population change (mean lambda) and 95 percent confidence limits for spotted owls from 1985 to 2013 at 11 sites: Cle Elum, Rainier, and Olympic, Washington; Coast Range, H.J. Andrews, and Tyee, Klamath, and South Cascades, Oregon; and northwest California, Hoopa, and Green Diamond, California (from Dugger et al. 2016). Estimates for Green Diamond are presented separately for control and treatment areas before (1990 to 2008) and after (2009 to 2013) barred owls were removed on the treatment area (CB = control before removal; TB = treatment before removal; CA = control after removal; TA = treatment after removal) (Diller et al. 2016, Dugger et al. 2016).

Habitat Status and Trends

Background and definitions—

Habitat for a species is an area that encompasses the necessary combination of resources and environmental conditions that promotes occupancy, survival, and reproduction of that species (Morrison et al. 2006). Typical wildlife habitat components include food, water, shelter (including nesting or denning sites), security from predators and competitors, and proper spatial arrangement of those features (Morrison et al. 2006). Although this concept of habitat may seem simple, the ways in which these individual components and animal needs interact in space and time result in very complex relationships (Mathewson and Morrison 2015).

Spotted owl habitat has often been characterized as older forest with large trees and moderate to closed canopy (Courtney et al. 2004, Forsman et al. 1984). Spotted owl site occupancy has repeatedly been shown to be influenced by the presence of these forest conditions (e.g., Dugger et al. 2016), likely because they often provide important habitat components that are suitable for nesting (e.g., cavities or platforms) (Sovern et al. 2011), abundant prey populations (Carey et al. 1992, Forsman et al. 2004, Wilson and Forsman 2013), and security from predators, including other raptors (Forsman et al. 1984, Sovern et al. 2014). An advantage of characterizing spotted owl habitat based on forest structure is that these forest types can be mapped for the entire subspecies' range using remotely sensed data (Davis et al. 2016). Other habitat components like prey abundance, predation risk, and presence of competitors are much more difficult, if not impossible, to map independently. For example, the recent colonization of the range of northern spotted owls by barred owls has confounded efforts to quantify the amount of habitat available for spotted owls because barred owls use similar forest types and can displace spotted owls from those areas (see "Barred Owl" section below).

In addition to availability, the arrangement of habitat components at a variety of scales is also important for understanding spotted owl habitat. Typically, spotted owl habitat is discussed in terms of forest cover types (stand-level forest structure and composition) most suitable for nesting, roosting, foraging, or dispersal (Davis et al. 2016, Lint 2005, Thomas et al. 1990). However, the spatial and temporal dynamics of suitable forest cover types, and how environmental conditions including climate and topography interact with vegetation patterns, are also important for producing and sustaining habitat for spotted owls (USFWS 2012a, 2012b). For example, Glenn et al. (2017) constructed habitat models using forest cover types and abiotic environmental conditions, and estimated the density of spotted owl territories on a landscape before and after barred owl invasion.

In this chapter, we define spotted owl habitat as those areas with the full suite of resources (e.g., abundant prey, available nest structures) and environmental conditions (e.g., appropriate climate, suitable forest structure, and infrequent presence of barred owls) suitable for occupancy, reproduction, and survival of the subspecies. As such, habitat is more analogous to a species' realized niche rather than the fundamental niche because habitat is more constrained than the availability of a vegetation type and a subset of environmental conditions. All published models of spotted owl habitat fall short of this definition because the distribution of spotted owls in relation to abundant prey is not known, and the distribution of an important competitor—barred owls—is not fully known. Throughout this chapter we distinguish between spotted owl habitat and components of that habitat (e.g., forest cover types used for nesting and roosting) regardless of the terms used in published literature.

Differing concepts regarding habitat definitions have long caused confusion and uncertainty in the interpretation of scientific literature (Bamford and Calver 2014, Hall et al. 1997, Morrison et al. 2006). The differences in how spotted owl habitat is defined and modeled has also caused confusion. The NWFP monitoring program estimates trends in forest types used by spotted owls (Davis and Lint 2005). The Fish and Wildlife Service (USFWS 2012a) modeled suitable forest and considered the amount and spatial arrangement of forests associated with specific life history requirements (e.g., forest types used for foraging in relation to forests used for nesting and roosting), as well as abiotic factors (e.g., slope, climate). The resulting models were used for delineation and designation of what was considered critical habitat (USFWS 2011b). The models of potential spotted owl habitat developed by the NWFP monitoring

program and the Fish and Wildlife Service have important differences that result in different amounts of what is considered suitable forest for spotted owls. Estimates of the amount of suitable forest for spotted owls are highly scrutinized because of the conflict caused by the importance of that forest type for the reproduction and survival of spotted owls and because merchantable large timber is important economically for many of the rural areas where old forest occurs. The different estimates of suitable forest cover for spotted owls resulted in litigation filed in relationship to critical habitat designation. Carpenters Industrial Council et al. vs. Ashe and Salazar (District of Columbia District Court case number 1:2012cv00111 filed January 24, 2012) claimed that the USFWS (2012a) estimate of approximately 18 million ac (7.3 million ha) of suitable forest conditions (they used the term habitat) for spotted owls was an overestimate of 5.9 million ac (2.4 million ha) because previous documents produced by the agency had used estimates of approximately 12.1 million ac (4.9 million ha) as found in (Davis et al. 2011). The 2.4 million ha difference can be explained by an examination of how habitat was defined and modeled in the different efforts. For example, estimates from Davis et al. (2011) were based on a stand-level designation of forest cover suitable for nesting and roosting (fig. 4-3A), whereas USFWS (2011b) and USFWS (2012a) delineated critical habitat based on a model that included suitable forest stands (Davis et al. 2011) and other landscape components essential for spotted owls at the core-area scale (200 ha) (fig. 4-3B).

The NWFP defined suitable forest for spotted owls as an area with the species of trees, structure associated most commonly with late-successional forest, sufficient area, and adequate food source to meet some or all of the subspecies' life needs, including nesting, roosting, and foraging (USDA and USDI 1994). This definition relied heavily on the work in the Interagency Scientific Committee report (Thomas et al. 1990), which acknowledged the difficulty in defining habitat and chose to characterize the concept based on relative value or suitability of forest stands for spotted owls. Forest cover can be viewed as supporting different spotted owl life functions (e.g., nesting, roosting, foraging) and a suitability gradient in terms of its influence on individual fitness (Thomas et al. 1990). Partitioning of forest cover

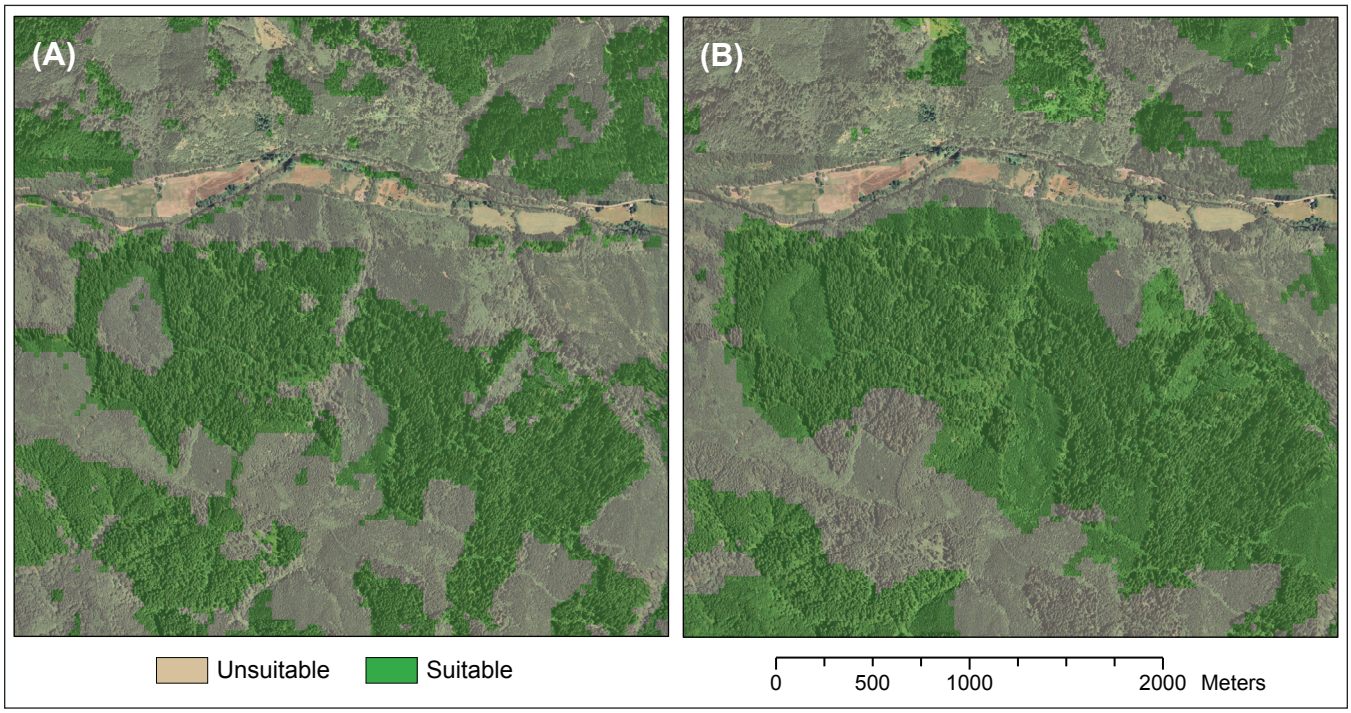

Figure 4-3—Examples of the suitable forest cover at (A) the stand scale developed by the Northwest Forest Plan monitoring program (Davis et al. 2011), and (B) the 200-ha (~250-foot radius) core-area scale used for modeling and delineating critical habitat (USFWS 2012a).

into discrete categories based on established measures of suitability for particular life functions facilitates a common frame of communication and standardization. A monitoring framework to measure relative suitability of forest cover types used by spotted owls was developed as part of a rangewide monitoring program for the subspecies (Davis et al. 2011, 2016; Lint 2005). Monitoring divided a continuous gradient of cover-type suitability into four discrete classes (table 4-1), based on use-versus-availability analyses using documented territorial pair locations. The unsuitable class was used for nesting and roosting by spotted owls less than expected by chance based on availability, the marginal class was used in proportion to its availability, the suitable class was used more often than expected by chance, and the highly suitable class was used much higher than one would expect from chance based on its availability. For monitoring purposes that dates to the life of the NWFP, the suitable and highly suitable classes were combined into a single class to identify forests that were most strongly associated with nesting and roosting locations. Thomas et al. (1990) characterized highly suitable forest cover as forests that include a multilayered, multispecies canopy dominated by large (>30 inch diameter at breast height [d.b.h.]) conifer trees; an understory of shade-tolerant conifers or hardwoods; moderate to high (60 to 80 percent) canopy cover (they used the term closure, but by definition they had described cover) (Jennings et al. 1999); substantial decadence in the form of large, live coniferous trees with deformities (e.g., cavities, broken tops, and dwarf mistletoe infections); numerous large snags; large accumulations of logs; and other woody debris. The unsuitable or marginal classes do not imply unimportance to spotted owls because the classification was restricted to describe only suitability for nesting and roosting activities by spotted owls. The marginal class is likely important for supporting dispersal, foraging, and nonbreeding (i.e., floater) individuals that can replace adult mortality and dispersal at nesting territories. Likewise, unsuitable and marginal classes may be important forest types for many prey species used by spotted owls. Forests that are suitable for nesting and roosting have similar characteristics throughout the range of spotted owls, but the path of development to those conditions typically differ based on the fire regime within the area (chapter 3; table 4-2, fig. 4-4).

Thomas et al. (1990) defined forest suitable for dispersal as having ≥11 inch (28 cm) d.b.h. trees and ≥40 percent canopy cover occurring on ≥50 percent of a 36 mi^2 township; this definition became known as the 50/11/40 rule. Analyses of movement data of spotted owls suggest that most (90 percent) dispersal occurred through landscapes meeting these criteria and are generally considered

Table 4-1—General descriptions of forest cover type classes used to estimate the amount of suitable forest available for nesting and roosting by spotted owls.

Cover type class	General description
Unsuitable	Younger forests or older forests with higher basal area of pine or high-elevation tree species or more open canopies. Usually smaller than average tree diameters, and lacking the presence of residual large trees and multiple canopy layers.
Marginal	Usually mid-seral forests, but can also be older forests lacking large-diameter trees, having simpler stand structure, or primarily composed of pine or high-elevation tree species.
Suitable	Forest stands older than 125 years of age, except in the California redwoods, where younger stands are used. Average tree diameters are usually above 20 inches (50 cm) d.b.h., with the presence of at least a few large trees exceeding 30 inches (75 cm) d.b.h. Canopy cover is usually greater than 60 percent, and the stand has multiple canopy layers.
Highly suitable	Typically forests 150 and 200 years of age or older. Average tree diameters often in excess of 30 inches (75 cm) d.b.h. except in drier portions of the range, where tree ages and sizes are typically smaller (e.g., 120 years and 24 inches). Canopy cover is usually in excess of 70 percent, and the stand has multiple canopy layers with high diversity of tree sizes.

d.b.h. = diameter at breast height.
Source: Davis et al. 2016.

Table 4-2—General descriptions of how forest cover types suitable for nesting and roosting by spotted owls typically develop within four general fire regimes within the Northwest Forest Plan (NWFP) area

Fire regime	Typical development of suitable nesting/roosting forest
Infrequent—high severity (Coast Range, fig. 4-4)	Large contiguous patches that form following infrequent, yet very large, high-severity wildfires. Once established, these large patches persist for long periods until the next large high-severity wildfire. Immediately following a large wildfire, large areas of the landscape are unsuitable for nesting and roosting for decades until closed canopies redevelop in areas that had remnant tree structures that could serve as nest trees. During this period, fine-scale gaps created by root-rot pockets, windstorms, landslides, and other small-scale processes produce complex stand structure. Complex structure sometimes does not develop over large areas for several decades following a wildfire. Produces the largest diameter and tallest nest trees; nests are usually in cavities or broken tops.
Moderately frequent—mixed severity (West Cascades, fig. 4-4)	Abundant to moderately abundant on the landscape, but very well connected across the landscape owing to the lack of extremely large high-severity wildfire patches. High-severity wildfire created smaller patches of complex early-seral forest cover type within an otherwise older forest matrix. Through time, these wildfire-created patches produced complex forest structure at the stand scale and a diverse mosaic of seral stages at the landscape scale.
Frequent—mixed severity (Klamath Mountains, fig. 4-4)	Moderately abundant on the landscape but more confined to topographic positions that functioned as wildfire refugia (e.g., lower slopes, north aspects, etc.). These areas allowed for the development and persistence of large trees required for nesting structures. In the Klamath Mountains and California Coast Range physiographic provinces, evergreen hardwoods (e.g., tanoak) are an important component that increase the suitability of use in these stands. In addition to forest stand structure and species composition, climate, and topography are important predictors of use by spotted owls.
Very frequent—low severity (East Cascades, fig. 4-4)	Not naturally abundant within the NWFP area; primarily restricted to the east side of the Cascade Mountains and eastern parts of northern California. Occurred historically in areas where the topography or soil conditions created a productive environment suitable for the development of large Douglas-fir and grand fir. Once established, these closed-canopy, structurally complex forest cover conditions can be relatively resistant to most fires, but burn with high severity under extreme weather conditions (chapter 3).

capable of supporting dispersal (Davis et al. 2011, 2016; Forsman et al. 2002; Lint 2005). However, the Thomas et al. (1990) 50/11/40 hypothesis was not based on juvenile resource selection data and remains largely untested. Only two studies (Miller et al. 1997, Sovern et al. 2015) have empirically studied forest-type selection during juvenile dispersal. Both studies found that juveniles strongly select for old forest with closed canopy (>70 percent canopy cover) and large-diameter trees (>20 inch d.b.h.), which are similar forest conditions selected by adult spotted owls for nesting and roosting (Miller et al. 1997, Sovern et al. 2015). Given the importance of forest cover classified as suitable for nesting and roosting to juvenile dispersal, the canopy cover recommendations of Thomas et al. (1990) are unlikely to be sufficient to facilitate juvenile movements on the landscape. Sovern et al. (2015) suggested that stands managed for dispersing spotted owls should be at least 80 percent canopy cover and have large average tree diameter.

Both the nesting/roosting and dispersal maps of suitable cover types produced by the NWFP monitoring program were designed to match the conceptual descriptions of forest vegetation components defined by Thomas et al. (1990) and used at the time of the NWFP development. Mapping of forests used by spotted owls is continuing to

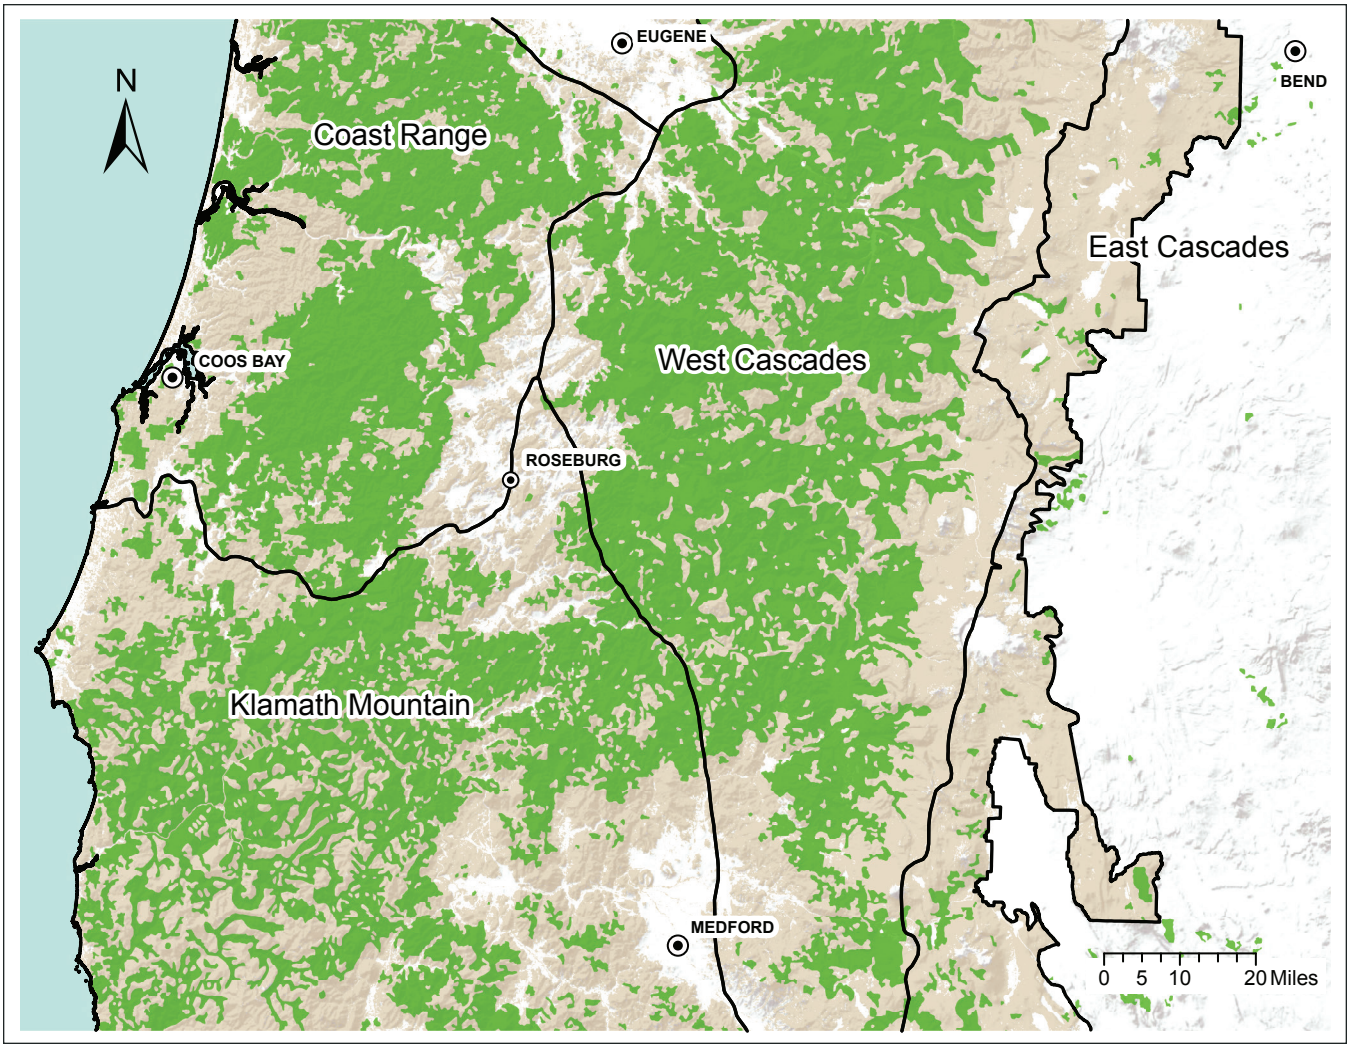

Figure 4-4—Differing historical patterns of old-growth Douglas-fir and mixed-conifer forest (green shaded areas) in west-central Oregon (Andrews and Cowlin 1940) within four areas with different fire regimes (Coast Range, infrequent—high severity; West Cascades, moderately frequent—mixed severity; Klamath Mountains, frequent—mixed severity; East Cascades, very frequent—low severity).

evolve (Ackers et al. 2015). For example, recent maps of suitable forest types (e.g., Glenn et al. 2017; USFWS 2011b, 2012a) differed from the original monitoring maps in that they factored in the spatial arrangement of discrete forest cover types (e.g., nesting, roosting, foraging) as well as abiotic factors (e.g., slope, topographic position, etc.) to produce maps describing a more comprehensive view of suitable forest (i.e., potential habitat). However, even the most recent efforts are not complete models of spotted owl habitat because they lack the impact of prey and barred owls on restricting distribution by limiting access to otherwise suitable forest for spotted owls. An important need is a better understanding and mapping of the differences between the potential and realized habitat for spotted owls. This is discussed in the "Research Needs, Uncertainties, Information Gaps, and Limitations" section below.

Patterns of change—

***Federal vs. nonfederal lands*—**Davis et al. (2016) estimated that there were about 12.6 million ac (5.1 million ha) of suitable nesting and roosting cover type distributed across the spotted owl's geographic range at the time of NWFP development (1993), the majority (73 percent) of which occurred on federal lands. By 2012, suitable nesting/roosting forest

cover decreased to 12.1 million ac (4.9 million ha) (74 percent occurring on federal lands), resulting in an overall net change of -3.4 percent. Net decreases were -1.5 percent on federal lands (primarily caused by wildfire) and -8.3 percent on nonfederal lands (primarily caused by timber harvest). During those two decades, forest cover suitable for dispersal decreased from 26.2 to 25.7 million ac (10.6 to 10.4 million ha) (-2.3 percent net change) on all lands. On federal lands, forest cover suitable for dispersal increased by 2.2 percent, and it decreased by 8.6 percent on nonfederal lands (Davis et al. 2016). Gains occurred because of forest succession, whereas losses were primarily a result of wildfire, disease, and timber harvest (Kennedy et al. 2012).

Timber harvest accounted for the majority (63 percent) of the losses across all lands. The vast majority of losses on nonfederal lands was caused by timber harvest (94 percent), whereas timber harvests accounted for 18 percent of total losses on federal lands (Davis et al. 2016). In Washington alone from 1996 to 2004, most (85 percent) of the timber harvest that resulted in lost forest cover suitable for nesting and roosting of spotted owls occurred on private lands (Kennedy et al. 2012, Pierce et al. 2005). Following timber harvest, wildfire was the next largest cause of loss (31 percent of total losses), which was 73 percent of the losses on federal land and only 3 percent of the losses on nonfederal land.

***Moist vs. dry forests*—**Primary causes of loss differed by ecoregion and forest type. The loss of nesting and roosting forest cover from wildfire occurred primarily in drier, fire-prone portions of the spotted owl's geographic range (i.e., northern California, southern Oregon, and eastern Cascade Range). Losses owing to insects and disease (and other natural disturbances) was the next most significant disturbance and mainly occurred in the eastern Cascades of Washington and Oregon (Davis et al. 2016, Kennedy et al. 2012).

Recruitment of forest cover suitable for nesting and roosting by spotted owls was estimated at 257,591 ac (104 288 ha) from 1993 to 2012 (Davis et al. 2016). Most of the gain occurred on nonfederal lands within the redwood (*Sequoia sempervirens*) zone of coastal California (fig. 4-5). On federal lands, the largest net gain (40,385 ac [16 350 ha]) occurred in the eastern Cascades of Oregon, where fire suppression allowed forest succession of Douglas-fir (*Pseudotsuga menziesii*) and grand fir (*Abies grandis*) to develop in areas that historically had frequent low-severity fires and were formerly dominated by open ponderosa pine-dominated forests (*Pinus ponderosa*) (Davis et al. 2016).

Effects of forest change—
Loss of suitable forest cover for nesting and roosting, especially on nonfederal lands, has been an important contributor to declining populations of spotted owls (Dugger et al. 2016). Those spotted owls that had territories with more forest cover associated with nesting and roosting conditions typically had better survival, fecundity, occupancy dynamics, recruitment, and rate of population change (Dugger 2016; Dugger et al. 2005, 2011; Forsman et al. 2011; Seamans and Gutiérrez 2007). For example, Dugger et al. (2005) found that owl territories with the greatest fitness potential were characterized by >50 percent old-forest habitat within a 412-ac (167-ha) circle centered on used nest locations. Relationships among population parameters of spotted owls and older forests vary over different spatial scales (e.g., individual territory vs. study area), and can be independent of, or interact with, the presence of barred owls. Concentrated areas of older forest suitable for nesting and roosting, or increased amounts of heterogeneity (i.e., mixture of conditions used for foraging), have positive effects on the vital rates of spotted owls (Dugger et al. 2016, Forsman et al. 2011, Franklin et al. 2000, Olson et al. 2004).

In some landscapes, fragmentation of older forest can have negative or positive effects on spotted owl occupancy depending on the scale of fragmentation and edge characteristics. Schilling et al. (2013) found that spotted owls had decreased survival and increased home-range size with increased forest fragmentation in southwestern Oregon. In Washington, territory-level extinction rates decreased with increased amount of late-seral edge, and colonization decreased with more late-seral patches within a territory (Sovern et al. 2014). It is also important to consider spatial scale, and level of contrast between edge, when assessing the influence of forest edges on foraging and space use by spotted owls. Comfort et al. (2016) found that spotted owls radio-marked in southern Oregon were negatively associated with hard edges (high contrast in forest structure and height) at a fine scale (telemetry location), but showed a lack

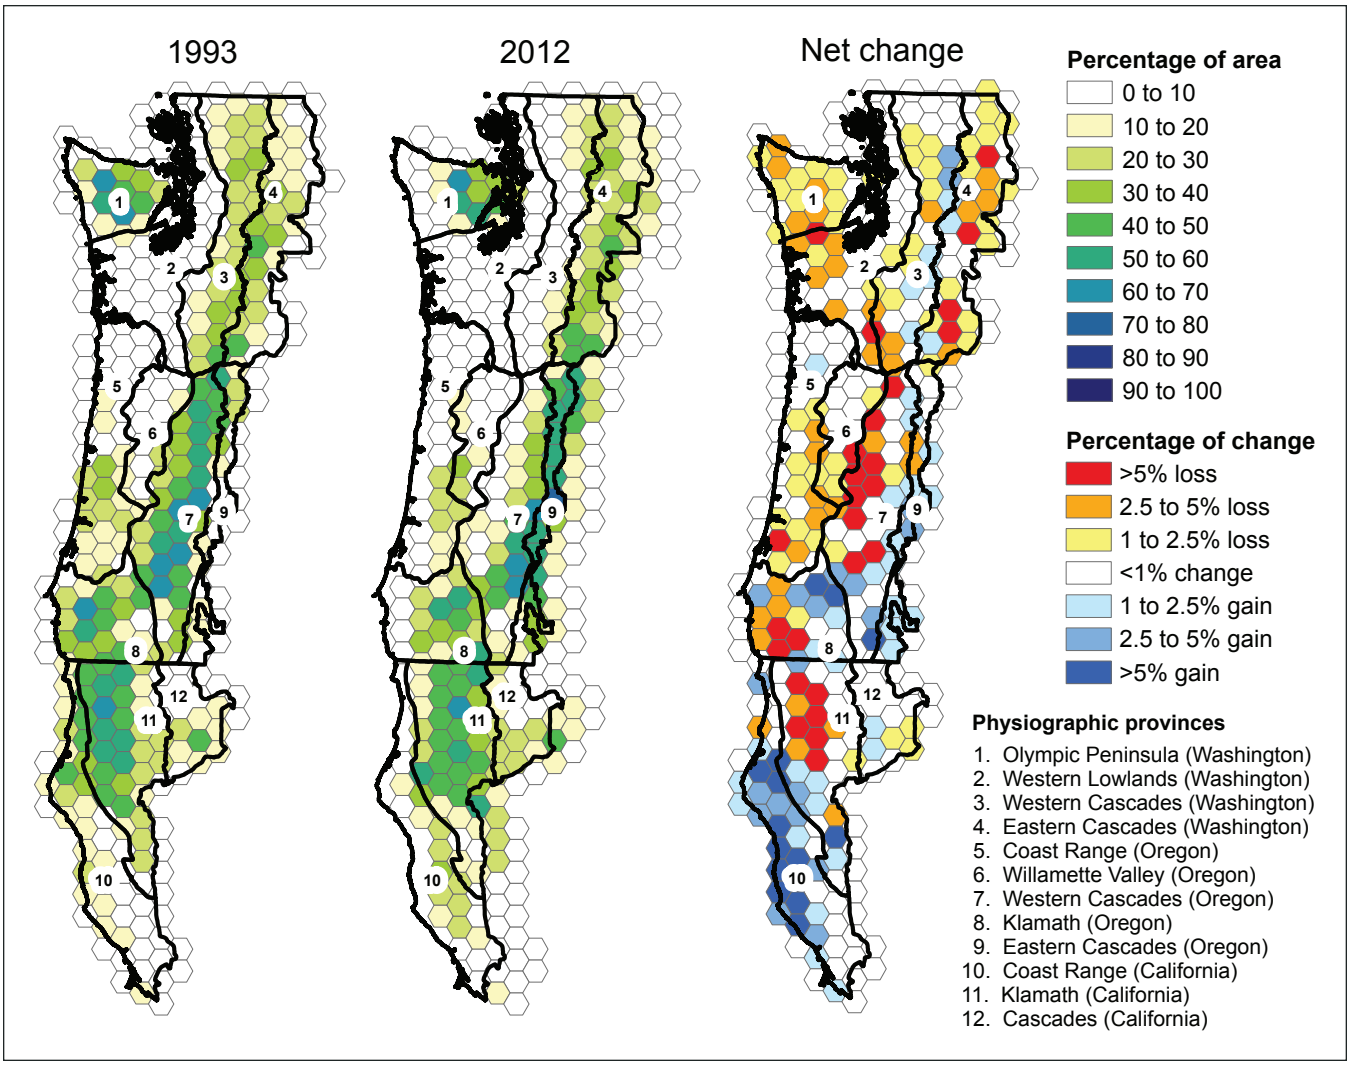

Figure 4-5—Loss and recruitment of forest types suitable for nesting and roosting by spotted owls in 1993 versus 2012, based on change in percentage of cover estimated within 18.6 mi (30 km) (center to center) hexagons across the Northwest Forest Plan area.

of negative response to hard edges at broader scales (territory or home-range scales). At least at the territory scale, heterogeneity can contribute to accessibility to different forest types. Regardless of spatial scale, spotted owls were positively associated with softer, more diffuse edge types created by disturbances such as low- and mixed-severity fire (Comfort et al. 2016). Collectively, these and other studies suggest that spotted owls select for abundant, structurally diverse closed-canopy forest with diffuse late-seral forest edge at the territory scale, and relatively lower fragmentation in nesting areas (Franklin et al. 2000, Olson et al. 2004, Sovern et al. 2014).

Forest protection effectiveness—

The NWFP included a network of large late-successional reserves (LSRs) that were designed to conserve forest for species dependent on older forests (FEMAT 1993). The LSR network was intended to meet the resource needs of many species, but a substantial focus was placed on creating and maintaining forest cover features from a draft recovery plan for the spotted owl (USFWS 1992). LSRs contained enough suitable forest cover to support multiple pairs of spotted owls and were distributed to facilitate movement of spotted owls across their geographic range. Although many of the LSRs contained large areas of older forest, a

significant portion of them were delineated in fragmented landscapes that contained stands of younger forest. Dispersal between LSRs is important for spotted owl conservation, and the NWFP was expected to facilitate that dispersal by designated riparian reserves, retention of green trees in timber harvest units in the matrix, protection of 100 ac (40 ha) areas at known owl sites (managed as LSRs within the matrix), and other administratively withdrawn areas (USDA and USDI 1994). However, these assumptions are largely untested, so it remains unknown if the NWFP is sufficient to facilitate adequate dispersal, which may be a limiting factor of spotted owl populations.

In addition to broad-scale LSRs, forest protections for spotted owls include circles of varying radii centered on used nest locations, within which various amounts of suitable nesting, roosting, and foraging forest cover types are protected. For example, the Fish and Wildlife Service developed guidelines for consultation under section 7 of the Endangered Species Act that included a 2.9-km-radius circle (6,424 ac [2600 ha]) around spotted owl nest locations for evaluating ''incidental take'' for projects affecting suitable habitats (USDA and USDI 1994). The rationale for this circle size was developed based on preliminary analysis of the median home-range size of radio-marked spotted owls. States also developed rules for state and private forestry practices to protect spotted owl nest sites. For example, the 2006 Washington State Forest Practices Board Rules called for protection of 40 percent cover of suitable nesting and roosting forest within a 6,422 ac (2600 ha) circle around nest sites (WAC 222-10-041). Forsman et al. (2015) suggested that level of protection would not be sufficient because spotted owl home ranges contained more suitable forest cover than would be protected under the Washington forest practices rules. Furthermore, new methods for delineating owl territories (e.g., Thiessen polygons) used by Dugger et al. (2016) provide better representations of the territory.

At the time LSRs were delineated, it was estimated that they contained on average 43 percent older forest (USDA and USDI 1994). The expectation was that all LSRs would eventually fill in and achieve the 60-percent-or-greater area threshold needed to support multiple breeding pairs and collectively would facilitate spotted owl population recovery. The success of meeting that threshold depends on the frequency, severity, and spatial extent of disturbance (e.g., wildfire, timber harvests), as well as the rate of forest succession, and interactions among these processes on forest recruitment (chapter 3). As of the most recent monitoring report (Davis et al. 2016), the rangewide estimate for suitable nesting/roosting forest cover in LSRs was an average of 42.4 percent in 1993. As of 2012, this average decreased to 42.0 percent. Larger LSRs (≥10,000 ac) averaged 45.0 percent, decreasing to 44.5 percent by 2012. These losses were due mainly to wildfire and exceeded the regional-scale expected rate of loss (2.5 percent per decade) (FEMAT 1993). Most of the losses of nesting and roosting forest cover have been in the more fire-prone portions of the spotted owl's range (Davis et al. 2011, 2016). For example, within LSRs and other reserves (e.g., administratively withdrawn, wilderness areas, etc.) in the Klamath Mountains physiographic province, losses were as high as 18.9 percent between 1993 and 2012 (fig. 4-5), and largely the result of the 2002 Biscuit Fire, which burned 494,000 ac (>200 000 ha).

Forest cover trends on federal lands during the next two to three decades are expected to benefit spotted owls because significant recruitment of suitable nesting/roosting forest cover is expected to offset many pre-NWFP losses (chapter 3) (Davis et al. 2016). However, this expectation is based on current rates of harvest and wildfire occurrence on federal lands, which may change depending on future forest plan revisions and the predicted increased spatial extent, frequency, and severity of wildfires due to climate change (chapter 2) (Jones et al. 2016, Westerling et al. 2006). In addition, competitive pressure from established barred owls (see below) has raised uncertainties about whether recruitment of suitable forest cover will be enough to conserve spotted owls over the long term. If spotted owls are to persist in LSRs under competitive pressure from barred owls, it will likely be only in localized areas that support few barred owls. However, it remains doubtful if there are any areas where spotted owls hold a competitive advantage over barred owls (Pearson and Livezey 2007, Singleton 2013, Wiens et al. 2014).

The potential effects of climate change add to the uncertainty of how competitive dynamics with barred owls and availability of suitable habitat will affect spotted owls in the future. Carroll et al. (2010) used a climatic niche modeling approach to evaluate the regional system of LSRs for resiliency to climate change for providing necessary resources of species associated with old forest. They developed distribution models integrating climate data with vegetation variables for a large suite of species, including the spotted owl. The LSRs functioned better than expected by chance for capturing all of the species, but community composition and interspecific interactions were also important to consider in evaluating effectiveness of the reserves. A network of fixed reserves with a high level of climatic and topographic heterogeneity (i.e., designed for resilience) has an increased likelihood of retaining the biological diversity of old-forest ecosystems under climate change. Under this scenario, even those species with limited dispersal capability are able to colonize future habitat. Carroll et al. (2010) projected a northward and higher elevation movement of suitable forest for spotted owls; therefore, the current fixed system of LSRs may not have enough climatic and topographic heterogeneity to be adequate for spotted owls into the future. Other reserves designated before the NWFP, such as parks and wilderness areas, may become increasingly important for the subspecies' persistence. LSRs successfully protected areas with greater biological importance for spotted owls when the NWFP was developed, but in the face of climate change, it may be necessary to have another evaluation and planning phase that results in a reserve system designed for more robust resilience (Carroll et al. 2010) (see chapter 3 for more discussion of alternative reserve designs), especially in the dry forest zone where management for ecosystem and spotted owls may not be compatible at stand and small landscape scales (chapter 12). Even with relatively little modification in response to climate change, suitable forest conditions on the east side and southern portions of the range are at risk of losses. Dense, multilayered forests in the dry forest zone are vulnerable to a host of mortality forces, especially wildfire (see chapters 3 and 12).

Barred Owls

Barred owl range expansion and population trends— Competition with established populations of barred owls has emerged as a much more prominent and complex threat to the long-term persistence of the spotted owl than was anticipated during the development of the NWFP. Once confined to forests of eastern North America, the barred owl is a medium-size, ecologically similar species whose newly extended geographic range now completely overlaps that of the northern spotted owl (Gutiérrez et al. 2007, Livezey 2009). Newly colonizing barred owls in the Pacific Northwest have been classified as native invaders—species that, under the influence of events such as climate change or human modifications to the landscape, have become invasive by expanding their populations into new areas (Carey et al. 2012, Valéry et al. 2009, Wiens et al. 2014). The range expansion of barred owls in western North America is well documented (Dark et al. 1998, Dunbar et al. 1991, Kelly et al. 2003, Livezey 2009, Taylor and Forsman 1976). Initial colonization of different regions by barred owls was variable, but barred owls now appear to co-occupy and outnumber spotted owls throughout the entire range of the threatened subspecies (Dugger et al. 2016, Pearson and Livezey 2003, Singleton et al. 2010, Wiens et al. 2011, Yackulic et al. 2012). Barred owls have also invaded the range of the California spotted owl in the Sierra Nevada (Seamans et al. 2004). The cause of this range expansion is unknown, but landscape changes facilitated by European settlement or historical changes in climate are factors that may have enabled barred owls to expand their range from eastern to western North America (Livezey 2009, Monahan and Hijmans 2007).

With few exceptions, barred owls have not been systematically surveyed in the Pacific Northwest, and the majority of information on their distribution and population trends is limited to incidental observations during surveys of spotted owls (Dugger et al. 1991, 2016; Gutiérrez et al. 2007; Wiens et al. 2011). Despite this shortcoming, incidental field data show a rapid increase in barred owls as they expanded their populations westward and southward into the range of the spotted owl (fig. 4-6) (Dugger et al. 2016). Studies focused on barred owls found much higher densities than estimates based on incidental field observations

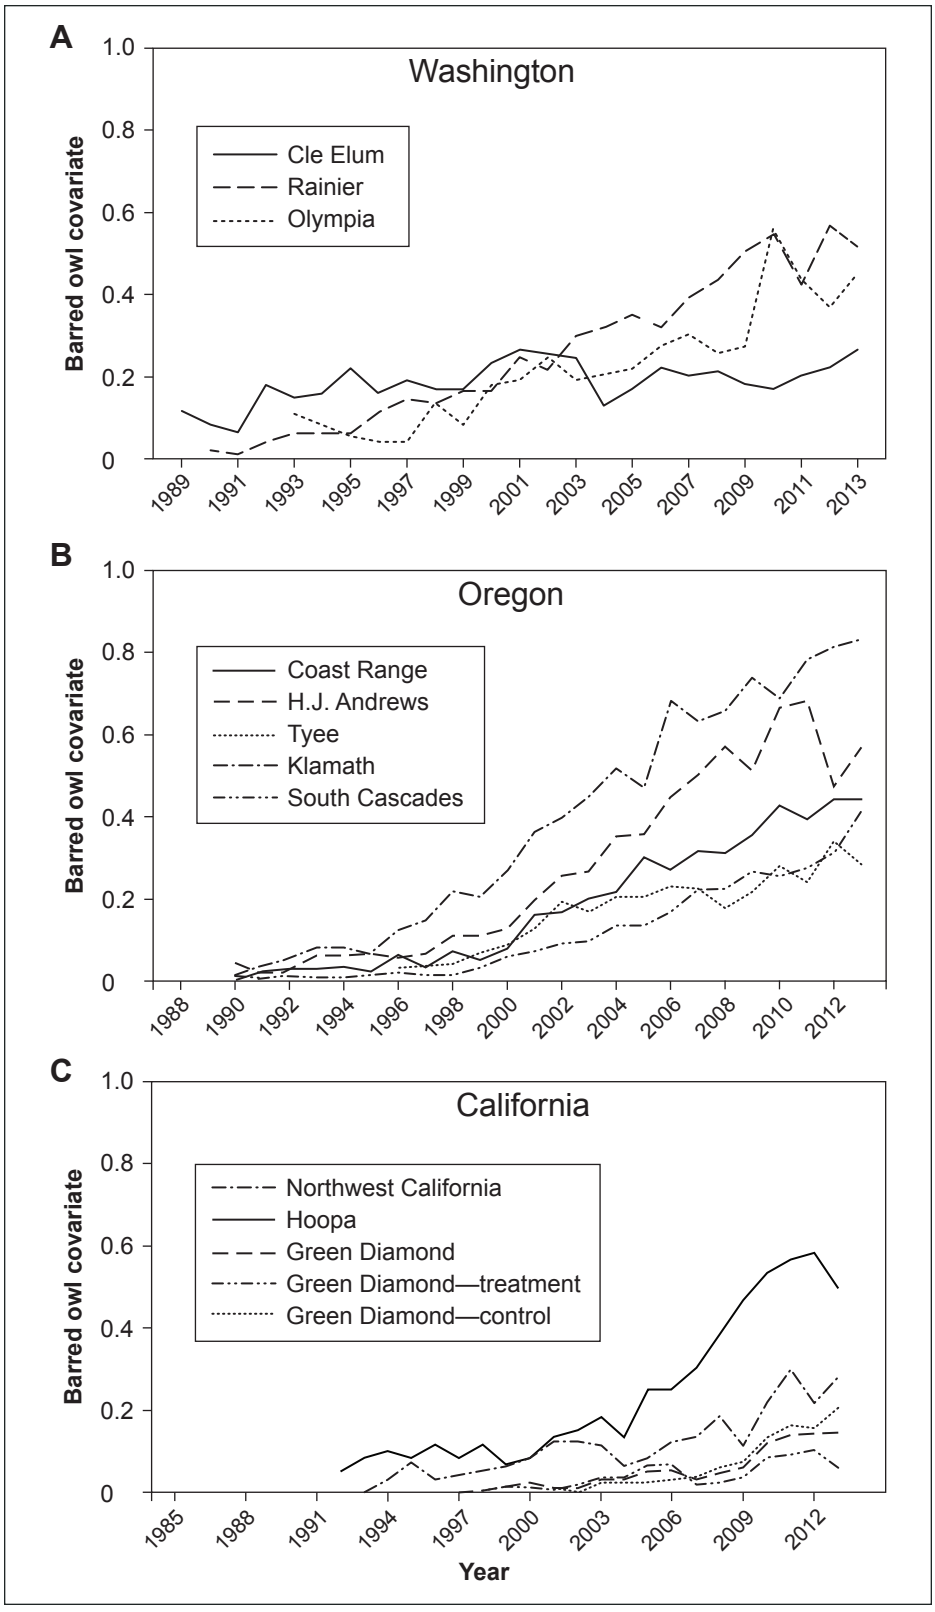

Figure 4-6—Annual increase in the proportion of spotted owl territories with detections of barred owls at (A) three sites in Washington, (B) five sites in Oregon, and (C) three sites in California from 1985 to 2013 (Dugger et al. 2016). Estimates for Green Diamond are presented separately for control and treatment areas and after (2009 to 2013) barred owls were removed from the treatment area from 2009 to 2013.

(Hamer et al. 2007; Singleton et al. 2010; Wiens et al. 2011, 2014; Yackulic et al. 2012, 2014). For example, Wiens et al. (2011) conducted surveys of barred owls during 2009 in the Oregon Coast Range and identified approximately 11 territorial pairs of barred owls per 100 km^2 (39 mi^2; 3 to 8 times higher density than spotted owls) with 89 percent of the landscape occupied, which peaked on publicly owned lands with greater amounts of mature and old coniferous forest. More recent (2015–2016) surveys of barred owls indicate an even greater probability of landscape occupancy in the Oregon Coast Range (~0.94) (Wiens et al. 2017). The degree to which the colonizing population of barred owls has reached carrying capacity within the geographic range of the spotted owl is currently unknown, but studies are underway that can help address this uncertainty (e.g., Wiens et al. 2017). Barred owl populations may continue to increase depending on the capacity of available habitat and food resources, which varies regionally with forest composition and latitudinal changes in prey communities and climate.

Barred owl effects on spotted owls— Compared to spotted owls, barred owls are slightly larger (Gutiérrez et al. 2007), have more diverse diets (Hamer et al. 2001, Wiens et al. 2014), and use a broader range of forest conditions for nesting (Herter and Hicks 2000, Livezey 2007, Pearson and Livezey 2003) and foraging (Hamer et al. 2007, Singleton 2015, Singleton et al. 2010, Weisel 2015, Wiens et al. 2014). Barred owls also have higher annual survival (fig. 4-7), higher reproductive output, and, in most areas, use much smaller home ranges than spotted owls (Hamer et al. 2007, Singleton et al. 2010, Wiens et al. 2014). The exception is in northern California,

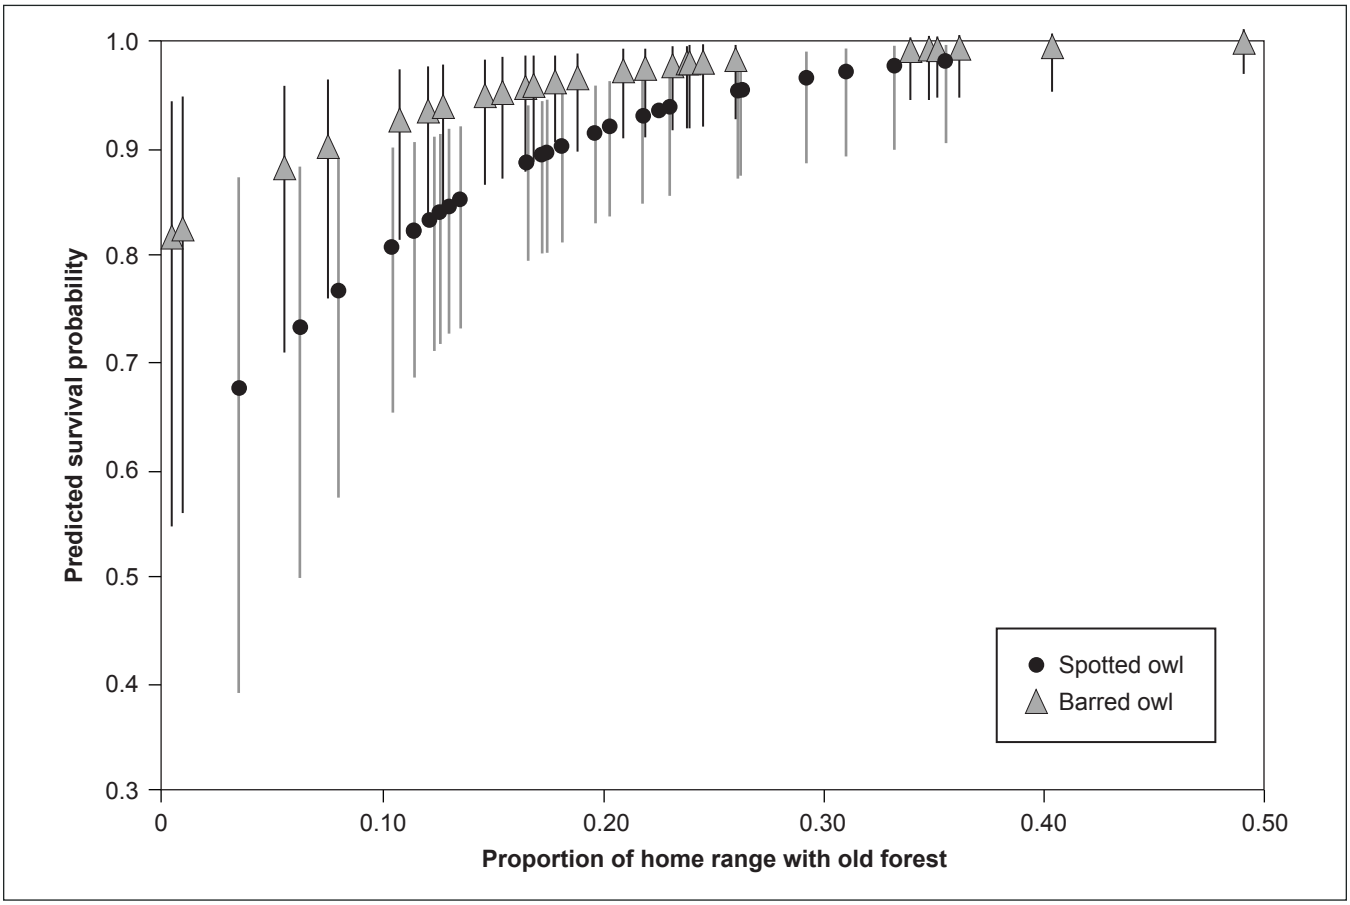

Figure 4-7—Survival (with 95-percent confidence limits) of individual adult barred owls and spotted owls increased with increasing amount of old forest (≥120 years) conifer forest within their home ranges in the Oregon Coast Range (Wiens et al. 2014).

where the two species used relatively small home ranges of similar size (Weisel 2015). Barred owls also defend their territories more aggressively than spotted owls (Van Lanen et al. 2011), which can result in increased mortality of spotted owls from agonistic interactions and direct killing of spotted owls by barred owls (Leskiwand Gutiérrez 1998, Wiens et al. 2014).

The dramatic increase in populations of barred owls since implementation of the NWFP has significant implications for management of forests inhabited by spotted owls. Several lines of evidence indicate that increases in the abundance of barred owls has had a strong and negative impact on spotted owls. Increasing abundance of barred owls has been documented to have the following effects on spotted owl populations:

1. Occupancy of historical spotted owl territories is lower (fig. 4-8) (Bailey et al. 2009, Dugger 2016, Dugger et al. 2011, Kelly et al. 2003, Kroll et al. 2010, Olson et al. 2005, Sovern et al. 2014; Yackulic et al. 2014).
2. Apparent survival is lower (Anthony et al. 2006, Diller et al. 2016, Dugger et al. 2016, Forsman et al. 2011, Glenn et al. 2011a).
3. Reproduction is lower (Dugger et al. 2016, Forsman et al. 2011, Olson et al. 2004).
4. Population size declines more rapidly (Anthony et al. 2006, Dugger et al. 2016, Forsman et al. 2011).
5. Hybridization between the species is increased (Barrowclough et al. 2005, Dark et al. 1998, Gutiérrez et al. 2007, Haig et al. 2004, Hamer et al. 1994, Kelly and Forsman 2004).
6. Detection rates during surveys are lower (Bailey et al. 2009, Crozier et al. 2006, Dugger et al. 2011, Dugger et al. 2016, Kroll et al. 2010, Olson et al. 2005, Sovern et al. 2014, Yackulic et al. 2014).

Moreover, studies of competitive interactions and resource partitioning showed that barred owls can directly alter the movements, resource use, and reproduction of spotted owls (Wiens et al. 2014). Barred owls also display demographic superiority over spotted owls; annual rate of

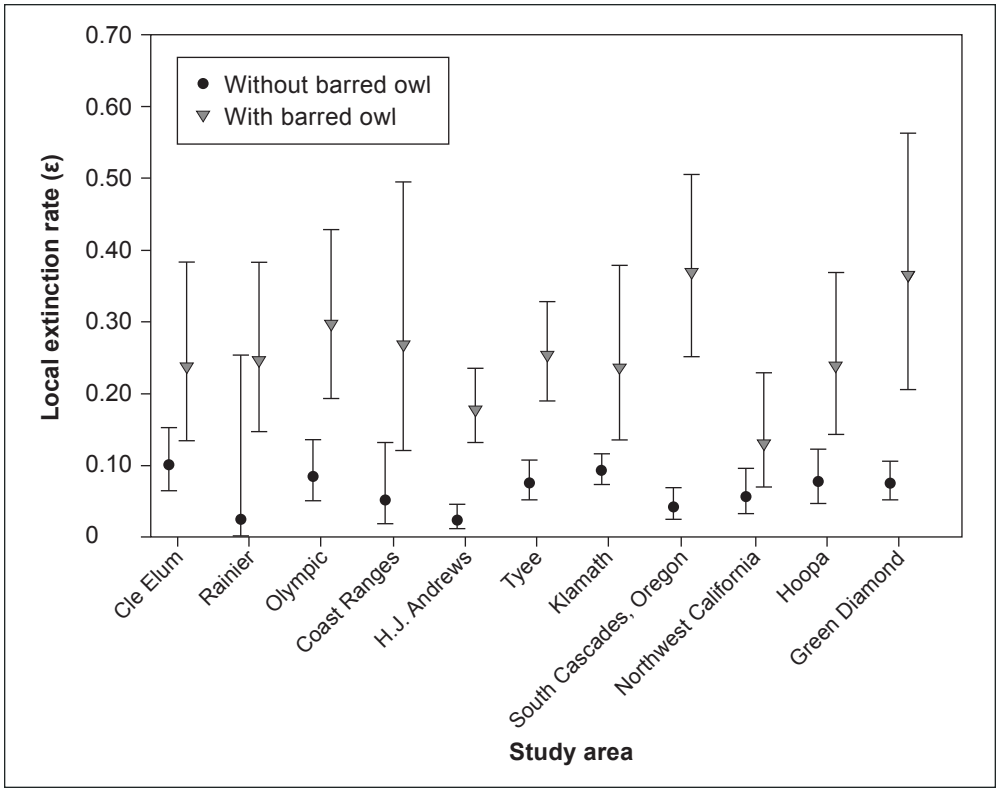

Figure 4-8—Mean annual local extinction rates (with 95 percent confidence limits) for northern spotted owls on 11 study areas in Washington, Oregon, and California relative to with (gray triangles) and without (black circles) the presence of barred owls (Dugger et al. 2016).

survival was greater for barred owls (0.92 ± 0.04) than for spotted owls (0.81 ± 0.05), and mean reproductive output of barred owl pairs was 4.4 times greater than that observed for spotted owls over 3 years in western Oregon (Wiens et al. 2014). More recently, studies in California have demonstrated a positive association between removal of barred owls and population trends of spotted owls (fig. 4-2) (Diller et al. 2016, Dugger et al. 2016). Collectively, these studies provide strong evidence that interspecific competition with an increasing number of barred owls, combined with continued loss of potentially suitable forest cover, is contributing to population declines of spotted owls despite widespread conservation of old forest under the NWFP.

Barred owl densities are now thought to be high enough across the range of the spotted owl that, despite the continued management and conservation of suitable forest cover on federal lands, the long-term persistence of spotted owls is in question without additional management intervention (Buchanan et al. 2007, Diller et al. 2016, Dugger et al. 2016, USFWS 2013). In a few cases, populations of spotted owls have responded positively to the removal of barred owls during pilot removal experiments; supporting the hypothesis that along with forest conservation and management, removal of barred owls might slow or reverse local declines in spotted owl populations in some areas (Diller et al. 2016, Dugger et al. 2016). However, the effectiveness and moreover the feasibility of large-scale barred owl removal for conservation of spotted owls remain to be demonstrated, and barred owl removal activities would likely need to be continued for the foreseeable future to maintain low barred owl densities in control areas.

Barred owl habitat and prey—

Barred owls occupy a broader range of forest types and consume a wider variety of prey than northern spotted owls (Livezey 2007), and use a variety of different forest types in the Pacific Northwest, including fragmented mixed-deciduous forest in rural and urban landscapes (Rullman and Marzluff 2014). Hamer et al. (2007) reported that, in the northern Cascade Range of Washington, barred owls tended to use old forest more than expected, but used most cover types in proportion to availability. Compared to spotted owls, barred owls occupied areas at lower elevations (Hamer et al. 2007). In the eastern Cascades of Washington, Singleton et al. (2010) reported that barred owls typically established their home ranges in areas that had canopy cover more than 72 percent, medium to large trees (tree crown diameter >21 ft [>6.5 m]), low topographic position (<25 percent), and gentle slopes (<11 degrees). Within those home ranges, barred owls used structurally diverse mixed grand fir forest more intensively than open ponderosa pine or Douglas-fir (Singleton 2015). In the Oregon Coast Range, foraging barred owls most often used patches of old (>120 years) conifer forest in addition to riparian-hardwood forests in relatively flat areas (Wiens et al. 2014). In the redwood region of coastal California, barred owls most often used sites with greater understory vegetation height and more hardwood trees, perhaps in response to greater densities of woodrats (*Neotoma* spp.) in these conditions (Weisel 2015). Collectively, these studies showed that barred owls, in areas where they were sympatric with spotted owls, were most commonly associated with relatively gentle slopes in structurally diverse, mature and old-conifer forests or lowland riparian areas containing large hardwood trees. Use of older forest in combination with moist, valley-bottom forest was also consistent with forest associations described for barred owl nesting areas (Buchanan et al. 2004, Herter and Hicks 2000, Pearson and Livezey 2003). Barred owls use the full range of forest types used by spotted owls, and a broader range of forest cover types outside of areas historically occupied by spotted owls. However, systematic studies have yet to quantify the full range of forest conditions that support barred owls in the Pacific Northwest. There are currently no known forest management actions that would benefit spotted owls more than barred owls.

Dietary studies are lacking for barred owls in California, but their diets in Washington and Oregon included a broad variety of small- to medium-size mammals, birds, frogs, salamanders, lizards, snakes, crayfish, snails, fish, and insects (Graham 2012, Hamer et al. 2001, Wiens et al. 2014). Mammalian prey of barred owls primarily included northern flying squirrels (*Glaucomys sabrinus*), woodrats, brush rabbits (*Sylvilagus bachmani*), snowshoe hares (*Lepus americanus*), moles (*Scapanus* spp.), Douglas squirrels (*Tamiasciurus douglasii*), red tree voles (*Arborimus longicaudus*),

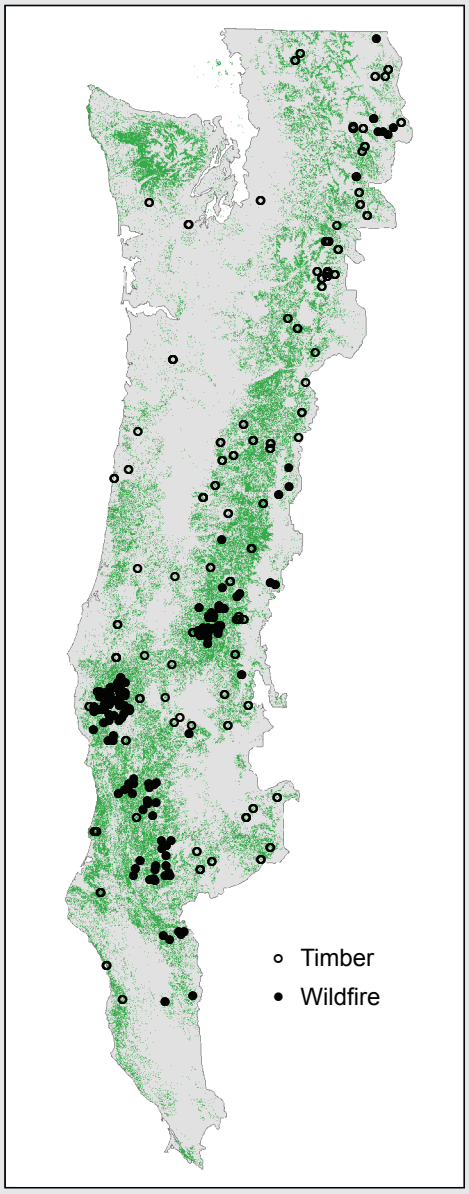
red-backed voles (*Myodes californicus*), shrews (*Sorex* spp.), and deer mice (*Peromyscus maniculatus*) (Hamer et al. 2001, Wiens et al. 2014). Although there is substantial geographic variation in diets of barred owls corresponding with differences in prey distributions, northern flying squirrels appear to be a primary contributor to diets in Oregon and Washington (Graham 2012, Hamer et al. 2001, Wiens et al. 2014).

Although there is some evidence that barred owls were more strongly associated with riparian areas than spotted owls, studies clearly indicate a high degree of ecological overlap between the two species, especially in their use of old-growth forests and associated prey species (Hamer et al. 2001, 2007; Singleton et al. 2010; Weisel 2015; Wiens et al. 2014). In the eastern Cascades of Washington, spotted owls used drier midslope areas less likely to be occupied by barred owls, possibly as a mechanism to minimize interactions with barred owls, at least in the near term (Singleton 2013). This pattern reflects displacement of spotted owls by barred owls from highly suitable forest into conditions less favorable to long-term reproduction and survival of spotted owls, a finding consistent with long-term demographic studies of spotted owls throughout the range of the subspecies (Dugger et al. 2016, Forsman et al. 2011, Singleton 2013, Wiens et al. 2014).

In addition to impacts on spotted owls, changes in the abundance and distribution of an apex predator like the barred owl can have cascading effects on prey populations and food web dynamics (Holm et al. 2016, Wiens et al. 2014), as well as populations of other small sympatric owls (Acker 2012, Elliot 2006). Differences in space use, abundance, demography, suitable forest, diets, and behavior collectively suggest that the barred owl is not a direct functional replacement of the spotted owl in old-growth forest ecosystems (Holm et al. 2016, Wiens et al. 2014). As a consequence, additional changes in community structure and ecosystem processes are anticipated as a result of barred owl encroachment into areas managed under the NWFP.

Spotted Owl Prey

Like all predators, spotted owls are dependent on abundant and vulnerable prey. Much is known about the ecology and population demography of spotted owls, but little information exists on how fluctuations in populations of prey species influence behavior, space use, reproduction, or population growth of spotted owls. Spotted owls in some areas during some periods have had a strong 2-year cycle of high reproduction one year followed by a year of low reproduction (Anthony et al. 2006). One hypothesis for the cycle in reproductive output is variation in prey abundance. However, simple prey relationship models do not explain the highly synchronous and temporally dynamic patterns of spotted owl reproductive performance (Rosenberg et al. 2003). Northern flying squirrels, woodrats, red-backed voles, and red tree voles are the primary prey of spotted owls throughout different regions of the spotted owl's geographic range (Barrows 1980; Bevis et al. 1997; Forsman et al. 1984, 2004, 2005; Hamer et al. 2001; Rosenberg et al. 2003; Wiens et al. 2014; Zabel et al. 1995). None of these studies had data that could be used to examine relationships between annual variation in prey abundance and annual variation in survival or fecundity of spotted owls. Although deer mice are not a primary prey species (<2 percent biomass consumed), one study (Rosenberg et al. 2003) found a positive correlation ($r^2 = 0.68$) between abundance of deer mice and reproductive success of spotted owls.



Abundance and distribution of primary prey species can influence space use by spotted owls. For example, spotted owls more frequently use riparian areas within their home ranges (Wiens et al. 2014), perhaps because the cool microclimates associated with stream drainages may be favorable for thermoregulatory purposes during summer months (Barrows 1981), or more importantly, riparian areas are likely to support a rich diversity of prey (primarily small mammals) used by spotted owls (Anthony et al. 2003, Carey et al. 1999, Forsman et al. 2004). Home ranges of spotted owls tend to be smaller in the southern portion of the subspecies range, where woodrats are the primary prey, as compared to the northern portion of the geographic range, where woodrats are uncommon and northern flying squirrels are the primary prey (Forsman et al. 2005, Zabel et al. 1995). In northern California, southwestern Oregon, and the eastern Cascades, woodrats occur in fairly open forests and at much greater densities compared to northern flying squirrels (Carey et al. 1992; Lehmkuhl et al. 2006a, 2006b; Wilson and Forsman 2013; Zabel et al. 1995). Differences

in space use by spotted owls in different portions of their range also relate to regional differences in the availability of prey species. Northern flying squirrels and red tree voles, for example, occur at highest densities in the complex structure of mature Douglas-fir stands with old-growth characteristics, whereas woodrats have greater densities in young stands, along edges, or in brushy areas (Carey et al. 1992, Price et al. 2015, Sakai and Noon 1993, Swingle and Forsman 2009, Walters and Zabel 1995, Zabel et al. 1995). Spotted owls used forest edges to a greater degree when forage consisted primarily of woodrats (Diller et al. 2012), but preferred forest interiors, where they foraged on red tree voles and northern flying squirrels. Timber harvest activities, including thinning of dense plantations, reduce the abundance of northern flying squirrels and red tree voles for several decades, contributing to a reduction in use by spotted owls (Carey 2000, Dunk and Hawley 2009, Gomez and Anthony 1998, Manning et al. 2012, Price et al. 2015, Waters and Zabel 1995, Wilson and Forsman 2013).

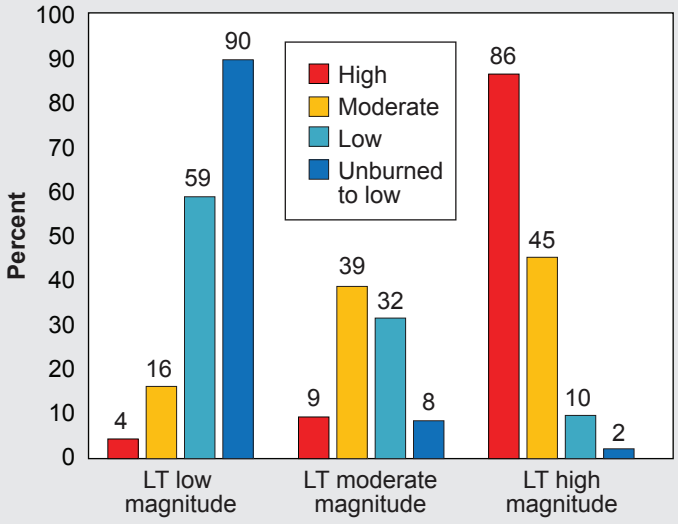
Disturbance

In this section, we define disturbances as modifiers of the structural characteristics, species composition, and landscape patterns of forest cover types used by spotted owls. The range of the northern spotted owl encompasses a variety of historical disturbance regimes that are fundamental to the health and diversity of these ecosystems (chapter 3). Important forest disturbances result from wildfire, forest management (e.g., thinning), timber harvests, extreme weather events, or forest insect and disease processes (Davis et al. 2016). Effects that forest disturbances have on spotted owls depends on spatial scale, severity, and season (McKelvey 2015). Biogeographic variation across the large range of spotted owls also results in very different levels of disturbance type, frequency, and severity (see "Wildfire" below). Major disturbance events influence forest cover types that have been used by spotted owls for many decades, and have different effects depending on the magnitude of change and the time since disturbance. For example, in the short term, a disturbance that creates open canopy conditions could reduce value for spotted owl roosting, but have long-term benefits by enhancing understory vegetation diversity and conditions for spotted owl prey. Further, disturbances can stimulate the development of large-tree, complex-structure stand conditions over time (Lehmkuhl et al. 2015). An important secondary effect of forest disturbances for spotted owls are changes in prey abundance or vulnerability. These effects can be positive by creating conditions that increase abundance or vulnerability for some prey species, or negative by removing critical forest structure required by primary prey populations (e.g., northern flying squirrel, red tree vole) (Manning et al. 2012, Wilson and Forsman 2013). Some disturbances have a neutral affect, particularly when limited in severity or spatial extent, and ample suitable forest remains available at core and home-range scales.

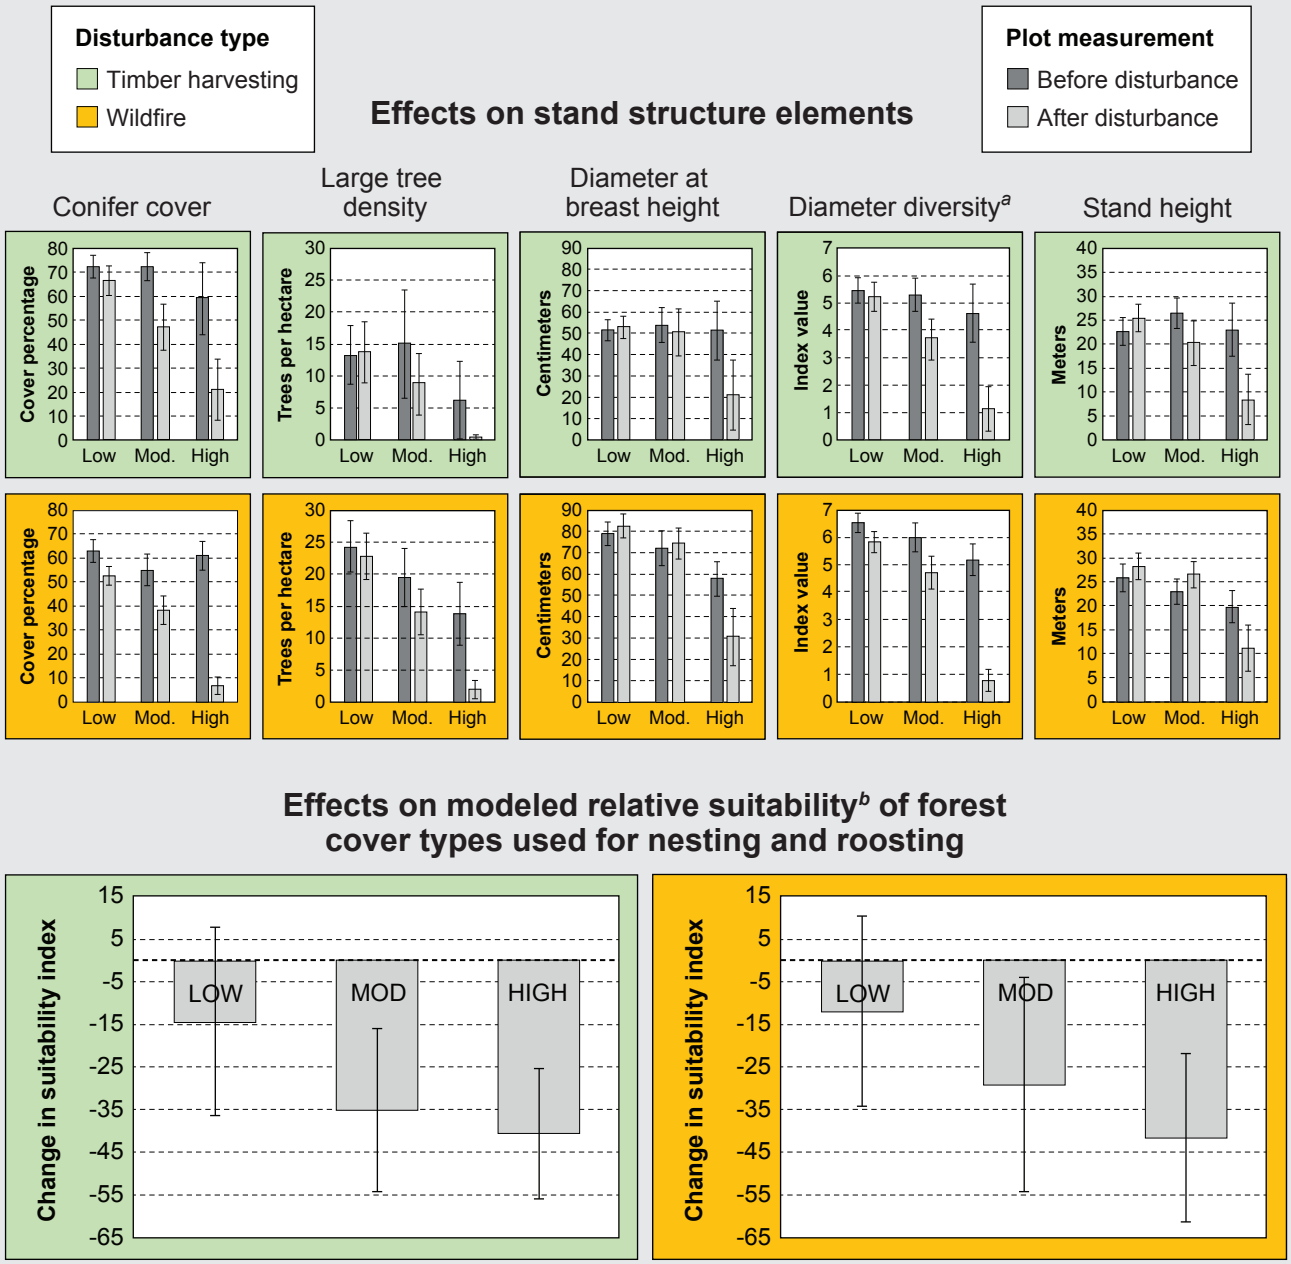
Spotted owls were listed as a threatened species under the Endangered Species Act largely because of concerns regarding loss of old forest resulting from commercial timber harvest (Thomas et al. 2006, USFWS 2011b). Subsequent to reductions in harvest of old forest, high-severity wildfire has become the leading cause of suitable forest loss for spotted owls on federal lands, especially in fire-prone landscapes. However, commercial timber harvest still contributes substantially to the loss of suitable forest cover in some areas, especially on nonfederal lands (Davis et al. 2016, Pierce et al. 2005). Recent research on disturbance effects on spotted owls indicates that disturbances such as mixed-severity fires that generate heterogeneity at landscape and stand scales are not necessarily adverse, provided that adequate nesting and roosting structural conditions remain after the disturbance (Clark et al. 2013, Comfort et al. 2016). High-severity disturbances that broadly alter stands and landscapes within nesting territories can remove critical components of forest structure (e.g., high canopy cover and density of large live trees) required for spotted owl survival and reproduction (Dugger et al. 2005, Franklin et al. 2000, Olson et al. 2004). Timber harvesting and wildfire can both reduce the living tree components of a stand and reduce the overall suitability for spotted owls (see sidebars on pages 265 and 266). An important difference between timber harvest and wildfire is the removal of trees and ground disturbance in a timber harvest. For most wildfires, there is limited physical soil disturbance (although fire

The graph to the right is from Davis et al. (2015) and shows the relationship between these classes and monitoring trends in burn severity classes.

Effects of Forest Disturbances on Nesting/Roosting Forest Cover



Map data from the most recent northern spotted owl habitat monitoring report (Davis et al. 2016) and Forest Inventory Analysis and Current Vegetation Survey plots were used to assess changes resulting from forest disturbances on stand structure elements used in the Davis et al. (2011, 2016) nesting/roosting cover type modeling and mapping procedure.



Plots used in this analysis occurred in mapped suitable nesting/roosting cover type in 1993 that experienced a disturbance between 1994 and 2012 from either timber harvesting or wildfire, which occurred between the initial plot measurement and remeasurement dates.

Changes in the mapped nesting/roosting relative suitability index were also analyzed by differencing the 2012 and 1993 relative suitability maps.

LandTrendr (LT) data (Kennedy et al. 2012) of forest disturbance magnitude are satellite-based measurements of loss of vegetation cover. We divided them into three classes:

- Low (<33 percent cover loss)
- Moderate (33 to 66 percent cover loss)
- High (>66 percent cover loss

[a] The diameter diversity index is a measure of the stuctural diversity of a forest stand based on live tree densities in diameter at breast height classes. An index value of 1 represents a single-story stand. Higher index values represent more complex multistoried stand structure.

[b] Modeled relative suitability from Davis et al. (2016). The index for suitable nesting/roosting forest cover type ranges from 31 to 40, depending on the modeling region.

can have substantial impacts on soil chemistry and organic matter composition), and patches of live trees, snags, and logs remain in situ, which contributes to enhanced biodiversity, future quality of complex forest, and forest succession (Swanson et al. 2011).

Wildfire—

Wildfires occur throughout the entire range of the spotted owl. Some physiographic provinces are more environmentally suitable for wildfire occurrence at a decadal scale, while other provinces have wildfire-return intervals of several centuries (see chapter 3) (Agee 1993). Beyond frequency, the severity and spatial extent of wildfires differ across the NWFP area (Davis et al. 2011). The physiographic provinces of the eastern Cascades, southern portions of the western Cascades, and the Klamath Mountains are characterized by frequent low- and mixed-severity fire regimes (Baker 2015, Hessburg et al. 2007, Perry et al. 2011). Owing to more than a century of fire exclusion (e.g., from grazing, fire suppression, and historical forest management practices), many of these fire-prone landscapes have experienced significant increases in stand density and loss of large trees, threatening forest health and biodiversity (Hagmann et al. 2013, 2014; Hessburg et al. 2007; Perry et al. 2011). The historical extent of forest cover types suitable for nesting and roosting by spotted owls in dry and mesic mixed-conifer forests in the eastern Cascades and other fire-frequent forests was likely historically limited but has increased substantially in recent decades (Hagmann et al. 2013, 2014; Hessburg et al. 2007; Merschel et al. 2014). Moreover, in this fire-prone landscape, forest structure conditions that are more resilient to low- and mixed-severity fires (i.e., single-story old forests with large ponderosa pines) are not suitable for nesting and roosting by spotted owls. Areas occupied by spotted owls in the fire-prone landscapes of the eastern Cascade Range are often dense, closed-canopy, medium-size tree forests with a substantial true fir (*Abies* spp.) component and structural diversity enhanced by a variety of insect and disease processes, including dwarf mistletoe (Stine et al. 2014). These are the conditions that have been promoted through fire suppression and removal of fire-resilient large Douglas-fir and ponderosa pine trees. Compared to forest structure conditions that are more resilient to wildfire, areas occupied by spotted owls in these fire-prone landscapes are at higher risk to high-severity wildfire (Dennison et al. 2014, Stine et al. 2014). All forest types in these landscapes are vulnerable to substantial impacts from high-severity wildfire under extreme weather conditions, which are likely to be more common with climate change (Kennedy and Wimberly 2009, Reilly et al. 2017).

West of these fire-prone areas to the Pacific coastline, the forests become progressively moister and less prone to frequent large wildfire. In these moist forests, large wildfires tend to be infrequent to moderately frequent, and fire severity trends from mixed to high severity (see chapter 3). In less fire-prone landscapes, old and complex forest with large trees—compared to other forest types—has higher moisture retention and cooler microclimates compared to other forest types, and may enhance biodiversity under a changing climate (Frey et al. 2016). In these mixed- and low-frequency fire regime landscapes, old forest may be more resistant to wildfire than young forest with closed canopy under normal fire weather conditions (Thompson and Spies 2009).

Throughout the NWFP area, the fundamental association between spotted owls and multilayer forests with large trees and closed canopies is well established (Dugger et al. 2016, Forsman et al. 1984, Franklin et al. 2000, Olson et al. 2005, Wiens et al. 2014). The severity of the wildfire has a strong influence on the degree to which these forest cover types are altered by wildfire (see sidebar on page 265). Low-severity wildfire can have very little effect on the suitability of nesting and roosting cover types, and can even increase it. Moderate-severity wildfire can change stand structure and species composition, resulting in moderate decreases in cover-type suitability. High-severity wildfire can alter forest cover to the point at which the area is no longer be suitable for nesting, roosting, or dispersal. Multiple lines of research have confirmed the effects of wildfire on stand structure and composition, but much less is understood about the short- and long-term response of spotted owls to wildfire.

Most studies focused on wildfire effects evaluated the short-term response of spotted owls to wildfire, but in one of the few studies of the long-term effects of wildfire

on spotted owls Rockweit et al. (2017) used 26 years of demographic data in a landscape with several wildfires and found that moderate and high burn severities negatively affected spotted owl apparent survival. They also found that burned territories functioned as ecological sinks where recruitment was high, but survival was lower than in nearby unburned territories. Several shorter post-wildfire studies have seemingly contradictory results regarding spotted owls and wildfire. For example, in an occupancy analysis, Jones et al. (2016) found high site extirpation rates of California spotted owls following a large, high-severity wildfire, but in a telemetry study, Bond et al. (2016) observed that burned forests were generally used in proportion to their availability. Other studies of California spotted owls and Mexican spotted owls have shown that wildfire does not necessarily decrease short-term occupancy in low- or moderate-severity burned areas (Bond et al. 2009, Ganey et al. 2011, Lee and Bond 2015, Lee et al. 2013, Roberts et al. 2011). Spotted owls can persist, at least for short periods, in landscapes that have experienced recent wildfires, as long as adequate moderate to closed-canopy nesting/roosting forest cover is retained at nesting core and home range scales. Even with high-severity wildfire, the effects can be insignificant or positive (e.g., increase vulnerability of prey) at larger spatial scales, especially if the forest cover changes caused by high-severity fire comprise only a small portion of a spotted owl's territory (Comfort et al. 2016).

Effects of wildfire interact in complex ways with other historic and current disturbances. Clark et al. (2013) found that local spotted owl site extinction probability was higher for sites with more combined area of past timber harvest, high-severity fire, and salvage logging. They also found evidence that colonization and occupancy rates were higher for sites with older forest burned at low severity (Clark et al. 2013). Coupling wildfire and salvage logging results in a high probability that a site becomes unoccupied after the first year postfire, especially if the core area burns at high severity and is subsequently logged (Bond 2016, Ganey et al. 2011, Lee et al. 2013). Beyond the effects on spotted owls, a human disturbance that directly follows a high-severity natural disturbance can have significant negative consequences to a forest ecosystem by disrupting abiotic and biotic processes, reducing or eliminating biological legacies, simplifying post-disturbance structural complexity, altering vegetation recovery, diminishing natural patterns of landscape heterogeneity, facilitating invasion of nonnative species, decreasing native biodiversity, increasing susceptibility to erosion and repeated high-severity disturbances, and eliminating restorative benefits of disturbance events (Lindenmayer- and Noss 2006, Thorn et al. 2017).

Overall, studies suggest that spotted owls are adapted to a forest landscape with a mosaic of successional stages shaped by historical disturbance regimes, accompanied by abundant prey resources, few barred owls, and structurally diverse closed-canopy forest with diffuse late-seral edge at the territory scale, and limited fragmentation occur within nesting areas (Dugger et al. 2011, Forsman et al. 1984, Franklin et al. 2000, Olson et al. 2004, Sovern et al. 2014). Research supports the premise that some spatial heterogeneity in forest conditions can have a positive effect on demography of spotted owls. At the territory scale (~500 to 1500 ha), a mosaic of older forest interspersed with other vegetation types, including early-seral and riparian forests, can promote high survival and reproduction of spotted owls (Comfort et al. 2016, Franklin and Gutiérrez 2002, Franklin et al. 2000). In terms of the effects of wildfire on spotted owls, we emphasize that most available research on impacts to spotted owls has been based to some degree on short-term responses and primarily focused on the other two spotted owl subspecies. The long-term (>5 years) effects of wildfire on spotted owl survival, reproduction, recruitment, and interactions with barred owls are not well documented.

Forest restoration and silvicultural treatments— To meet management objectives of the NWFP, the spotted owl recovery plan, and critical habitat requirements, researchers and federal land managers have focused on ecosystem function (e.g., fire as an ecological process) in developing silvicultural practices that provide ecologically sustainable alternatives to clearcutting and old-growth harvest while still providing for timber production (chapter 3). As a result, alternative thinning methods, including variable-density thinning, have replaced clearcutting as the predominant form of active management on federal

lands, whether for restoration or timber production goals or both (Anderson and Ronnenberg 2013, Lehmkuhl et al. 2015). Ecological objectives for forest management differ by region, forest type, and historic disturbance regime (Franklin and Johnson 2012) (chapter 3).

Moist forest—The focus of silvicultural treatments in moist forests of the western Cascades and Coast Ranges (historically infrequent, high-severity fire regimes) has been an attempt to accelerate development of old-forest conditions in plantations or younger closed-canopy stands (Anderson and Ronnenberg 2013). Typical thinning treatments that create canopy gaps in moist forests west of the Cascade crest can create relatively rapid increases in understory vegetation diversity and productivity (Johnson and Franklin 2013) (chapter 3). The intensity and pattern of retained trees in forest thinning can have dramatic influence on microclimate and ecological response in the short term (Aubry et al. 2009, Heithecker and Halpern 2006). Stand conditions can be either too open or too dense for foraging because spotted owls are adapted to old forest with closed canopies, and the understory must be open enough to fly and access prey (Irwin et al. 2015). In areas where dusky-footed woodrats are primary prey (e.g., southern Oregon, northern California), thinning of young dense stands may increase spotted owl use for foraging, but still not create preferred forest conditions for other life history needs such as nesting and roosting (Irwin et al. 2015). Wilson and Forsman (2013) found that the abundance of mice, terrestrial voles, and shrews increased immediately following thinning, but that northern flying squirrels and red tree voles—important prey species for spotted owls—decreased dramatically in abundance in treated areas for up to 11 years after treatment (Wilson 2010). Thus, spotted owls respond to silvicultural treatments differently where the primary prey are northern flying squirrels, which includes most of the northern and western portions of their range in Oregon, Washington, and British Columbia.

When assessing the potential effects of thinning on prey species, the landscape context should be considered. For example, the effects of thinning within heterogeneous landscapes with well-connected, intact old-forest cover may be less detrimental to northern flying squirrels than if thinning occurs within a highly fragmented forest landscape (Sollmann et al. 2016). Some degree of landscape heterogeneity resulting from forest restoration activities in west-side forests does not adversely impact spotted owls, provided that sufficient large-tree, closed-canopy forest for nesting and roosting is available at core and home range scales (Andrews et al. 2005). For example, in northern California, Franklin et al. (2000) found that territories with the highest fitness (survival and reproduction) were those with a mixture of old forest and about 40 percent of other vegetation types. Diller et al. (2012) reported that forest cover heterogeneity (i.e., juxtaposition of young and older stands) had positive effects on survival and reproduction of spotted owls on commercial timberlands in northern California, where disturbance regimes were historically of mixed severity. Highly productive growing conditions and abundant hardwoods contribute to structural complexity in these managed forests. However, survival of spotted owls decreased in southern Oregon when the amount of nesting/roosting forest cover within the territory center was less than 50 percent (Dugger et al. 2005), and a similar relationship was found in other studies (Franklin et al. 2000, Olson et al. 2004, Wiens et al. 2014).

Dry forest—In the drier forests of the eastern Cascades, southern Oregon, and northern California, wildfire was historically more frequent and burned with mixed- and low-severity effects. In these areas, forest management treatments have focused on accelerating the development of old-forest conditions, but also have focused more on restoring or promoting fire-resilient forest structure, species composition, and landscape pattern (Hessburg et al. 2016, Lehmkuhl et al. 2015, Stine et al. 2014). Landscape managers implementing forest restoration treatments in drier, mixed- and low-severity fire regime forests face substantial challenges in balancing the tradeoffs between known short-term forest cover impacts on spotted owls from restoration and fuel reduction treatments versus potential benefits of reducing losses of forests with larger trees from high-severity, large-scale wildfire (Hessburg et al. 2015, 2016; Lehmkuhl et al. 2015; Stine et al. 2014). Management emphasis on wildfire suppression combined with historical harvest of large trees in these landscapes over the past 100 years has contributed to the recruitment of small-tree, closed-canopy forest

(Hessburg et al. 2016). In these regions, the moderate- to closed-canopy forest with multilayer canopy structure enhanced by dwarf mistletoe infestations are used by spotted owls for nesting and roosting areas, and appear to have increased over the latter part of the 20th century into the 21st century (Davis et al. 2016, Lint 2005). Large tree, multistory canopy typical of forest cover types used for nesting and roosting by spotted owls across their range make them less flammable under most fire conditions, but, like most cover types, these are susceptible to burning intensely in extreme weather. Standard treatments focused on increasing stand-level resilience to wildfire by using prescribed fire and removing ladder fuels (e.g., Cochrane et al. 2012, Safford et al. 2012, Stephens et al. 2009), and reducing canopy connectivity (Agee and Skinner 2005) can reduce the risk of stand-replacement high-severity wildfires, but the practices also remove important forest cover elements for spotted owls and their prey (Lehmkuhl et al. 2006a, 2006b, 2015). Prescribed fire treatments as part of fuel reduction projects can further reduce under- and mid-story canopy complexity, and burn up logs and snags, potentially causing additional negative impacts to suitable forest for spotted owls and their prey (Lehmkuhl et al. 2015). Silvicultural practices that promote spatial and structural complexity have been proposed for retaining suitable foraging conditions for spotted owls while also reducing fuel loads (Churchill et al. 2013, Gaines et al. 2010, Hessburg et al. 2016, Johnson and Franklin 2013, Lehmkuhl et al. 2015). However, the effectiveness of these management practices to restore ecological resilience and reduce risk of loss to high-severity wildfire, while maintaining components of suitable forest for spotted owls, remains to be tested in dry forest landscapes (see chapters 3 and 12 for more discussion of this issue).

Several simulation studies have used coupled wildfire and forest growth models to investigate the relative effects of wildfire and forest restoration treatments on recruitment and retention of forest cover types used by spotted owls in fire-prone landscapes. Some of these studies suggest that certain fuel treatment scenarios (i.e., active management) can reduce wildfire-caused losses of forest cover types used by spotted owls (Ager et al. 2007, Roloff et al. 2012). Other modeling efforts found that active management reduced forest cover used by spotted owls more than simulations with no management, (Roloff et al. 2005, Spies et al. 2017). As with any modeling exercise, outcomes of these studies reflect the assumptions incorporated into the simulations. Assumptions regarding wildfire severity, return intervals, and effects of treatments are particularly influential. One general theme from these simulations is that benefits of fuel treatments to forest types used by spotted owls depend on what probability of occurrence is assumed for future high-severity wildfires. If the likelihood and impacts of high-severity wildfire are assumed to be high, thinning treatments are more likely to have a positive outcome for spotted owls (e.g., Roloff et al. 2012). If the likelihood of high-severity wildfire is assumed to be low, however, then thinning treatments are more likely to produce only declines in the amount of suitable forest cover types used by spotted owls.

Climate Change

Climate change will affect spotted owl populations through changes in weather, forest cover, disturbance processes, prey availability, and other ecological interactions. Population growth of spotted owls appears to be positively associated with wetter than normal conditions during the growing season (May–October), which likely increases prey populations and thus availability (Glenn et al. 2010). Population growth and reproduction were also negatively associated with cold, wet winters (pre-nesting) and the number of hot summer days (July–August) (Diller et al. 2012, Glenn et al. 2011b). Annual survival was more closely related to regional climate conditions (Southern Oscillation Index [SOI] and Pacific Decadal Oscillation [PDO]), whereas recruitment was often associated with local weather. Projected future climate conditions have the potential to negatively affect annual survival, recruitment, and, consequently, population growth rates for spotted owls (Glenn et al. 2010). Climatic factors affecting vegetation and prey abundance likely have a greater effect on reproduction and population growth than direct effects of weather on nestlings or adult spotted owls (Glenn et al. 2011a, 2011b). Climate change models for the first half of the 21st century predict warmer, wetter winters

and hotter, drier summers for the Pacific Northwest (Mote et al. 2003) (chapter 2). These conditions are expected to decrease survival of spotted owls in some areas (Glenn et al. 2011a). Climate change can affect development of forest structure by altering temperature and precipitation regimes, and disturbance frequency and intensity (Dale et al. 2001). Altered understory vegetation can reduce prey availability and thus spotted owl fitness (Carey and Johnson 1995, Franklin et al. 2000). Carroll (2010) found that vegetation rather than climate variables best explained distributions of spotted owls. Potential climate-related forest cover losses resulting from large-scale, high-severity wildfires and increased mortality of old-growth trees (Van Mantgem et al. 2009) may be particularly important for future viability of spotted owl populations (chapter 2).

Franklin et al. (2000) found that forest cover patterns explained a high amount of spatial variation in fitness potential among territories occupied by spotted owls in northern California, but climate explained most of the temporal, year-to-year variation in fitness-related traits. Survival and reproduction, for example, were lower when the early nesting period (February–March) was cold and wet. Fecundity, recruitment, and survival decreased across the range of the spotted owl when winters or early springs were colder and wetter than average (Diller et al. 2012; Dugger et al. 2005, 2016; Forsman et al. 1984, 2011). Spotted owl populations in drier forests may be especially vulnerable to climate change because hot, dry summers can reduce prey abundance or availability, and subsequently reduce spotted owl survival (Glenn et al. 2011a). Regional climate patterns, including the SOI and PDO, have also been correlated with demographic rates of spotted owls (Dugger et al. 2016; Forsman et al. 2011; Glenn et al. 2010, 2011a, 2011b). Survival of spotted owls was greater when the PDO was in a warming phase and lower when the SOI was negative (i.e., El Niño events resulting in higher than average temperatures and below normal precipitation) (Dugger et al. 2016).

Extrapolation of the best combination of vegetation-climate models to predicted future climates suggests northward expansion of high-suitability forest cover for spotted owls (Carroll 2010). Increased winter temperature under future climates might be expected to increase winter survival and nesting success, and allow range expansion of prey species such as woodrats, which currently occur at high densities only in the southern portions of the range (Noon and Blakesley 2006). However, it is uncertain how barred owls will respond to changing prey populations, and model results suggest that an initial expansion in the suitable climatic niche may be followed by a contraction as climate change intensifies (Carroll 2010). An important qualifier is that these models did not account for losses of multilayered forests to wildfire and the potential for competition with barred owls to become even more prevalent as climatic change causes shifts in forest communities that in turn further constrain both owl species to a common set of increasingly limited resources.

Other Threats

Genetic diversity and hybridization—
Loss of genetic diversity within a population can contribute to inbreeding depression and decrease adaptive potential. Increased rates of hybridization with barred owls may further compromise the genetic integrity of the spotted owl population (Funk et al. 2010, Gutiérrez et al. 2007). Genetic studies have reinforced other studies that showed spotted owl population declines. Specifically, genetic evidence indicates a loss of genetic variation and increased potential for inbreeding depression in small populations. This suggests a vulnerability of spotted owls to extinction (Funk et al. 2010). Genetic data from spotted owls have indicated population bottlenecks for the Washington eastern Cascades, northern Oregon Coast Range, and Klamath Mountains (Funk et al. 2010), which corresponded temporally with population declines in most of those regions (Anthony et al. 2006, Dugger et al. 2016, Forsman et al. 2011). There was, however, no definitive evidence that suitable forest cover associated with dispersal was limited, or that gene flow was restricted in those regions (Barrowclough et al. 2005, Davis et al. 2011)

Hybridization with barred owls is another potential threat to spotted owl persistence, especially as the spotted owl becomes increasingly rare and the invading species becomes more abundant (Gutiérrez et al. 2007, Haig et al. 2004). Spotted owls occasionally mate with barred

owls (male spotted owl–female barred owl mating is most common) and produce fertile hybrids (Hamer et al. 1994, Kelly and Forsman 2004). In the southern portion of the spotted owl range, 3 percent of spotted owl genetic samples collected prior to 2004 (barred owls were still relatively rare on the landscape) contained barred owl mitochondrial DNA (Barrowclough et al. 2005). There are typical markings of hybrids that can be helpful in field identification (Hamer et al. 1994), but genotyping potential hybrids across generations has shown that field identifications were often wrong (Funk et al. 2007). Hybridization rates may also have changed substantially in recent years as barred owl populations have increased and spotted owls have decreased.

Hybridization with other spotted owl subspecies does not appear to be a concern for spotted owl conservation. The northern spotted owl and California spotted owl are two well-differentiated subspecies connected by a narrow hybrid zone in a region of low population density for both subspecies in north-central California (Barrowclough et al. 2005, 2011; Funk et al. 2008; Gutiérrez and Barrowclough 2005). Spotted owls in the contact zone are highly differentiated and may be a distinct population from other northern spotted owl and California spotted owl populations (Miller et al. 2017).

Diseases and pathogens—
Disease exposure could be a secondary consequence of climate change, blood parasites, and effects of barred owl interactions. Lewicki et al. (2015) found that spotted owls had a higher *Haemoproteus* spp. parasite diversity and probability of infection than sympatric barred owls. Further, avian malaria (*Plasmodium* spp.) is common in barred owls, and only recently was documented in spotted owls; therefore, barred owls likely have an additional competitive advantage because spotted owls are potentially immune-compromised owing to recent exposure to avian malaria (Ishak et al. 2008). Spotted owls are susceptible to West Nile virus and experience high rates of mortality when exposed (Courtney et al. 2004); however, it is unknown what, if any, population-level impacts the disease has caused. Wiens et al. (2014) reported that the leading cause of death in a sample of radio-marked barred owls was bacterial infection associated with endoparasitism.

Environmental contaminants—
Environmental contaminants, especially anticoagulant rodenticides, have recently emerged as a potential threat to spotted owls and their prey. In particular, anticoagulant rodenticides used in illegal marijuana cultivation and urban settings can have significant indirect impacts by the poisoning of nontarget forest predators, including owls (Albert et al. 2010, Gabriel et al. 2012, Riley et al. 2007, Stone et al. 1999). To our knowledge, no studies have addressed potential effects of anticoagulant rodenticides on spotted owls.

Research Needs, Uncertainties, Information Gaps, and Limitations

Research Needs

Effects of barred owls—
It has become increasingly clear that barred owls are a primary driver of spotted owl population declines, but many questions remain about the full impact of barred owls directly on spotted owls, and indirectly through alterations of forest communities. Research is needed to build on the work of Wiens et al. (2014) and others to identify potential processes by which spotted owls and barred owls use resources differently. More research is needed to establish the full suite of cause-and-effect relations of barred owl impacts on spotted owls, and how barred owls interact with other threats to spotted owls. Unfortunately, these types of studies are becoming increasingly difficult because spotted owl numbers are declining so rapidly on most study areas. In a pilot study, Diller et al. (2016) found that spotted owls responded positively to experimental removal of barred owls, but additional removal studies in other physiographic provinces, where owl populations and suitable forests are different, are needed. To determine the feasibility and effectiveness of barred owl removals as a tool for spotted owl recovery, the Fish and Wildlife Service and U.S. Geological Survey initiated a barred owl removal experiment on four study areas in Washington, Oregon, and northern California (USFWS 2013). Continued monitoring of spotted owl populations in those areas will be required to fully assess the short- and perhaps, in particular, long-term response of spotted owls to the removal of an important competitor. More genetic studies are needed to address the frequency

and impact of hybridization between spotted owls and barred owls, and how hybridization rates may have changed with changes in abundance of the two species.

It remains uncertain how climate change will affect interactions between spotted owls and barred owls, or even where barred owl populations are in terms of the invasion process. For example, little research has been conducted to investigate if populations of barred owls are continuing to increase or if carrying capacity has been met in some regions. Fundamental information on barred owl distribution and population trends is needed to address this important issue. Further, little is known about barred owl distribution and populations beyond forest cover types occupied by spotted owls. Ecologists are being challenged to predict how spotted owls will change in abundance and distribution under current climate, availability of suitable forest, and competitive interactions with barred owls. It is well documented that climate change influences species' abundances and distributions, and can have indirect effects on interspecific interactions (Angert et al. 2013). An important area of needed research related to barred owl-spotted owl interactions and climate change will be to better understand how the combined effects of barred owl competition and future changes in the amount and distribution of forests used by spotted owls might contribute to spotted owl population persistence and range shifts under a changing climate.

In addition to impacts on spotted owls, changes in the abundance and distribution of a generalist apex predator like the barred owl can have cascading effects on prey populations and food-web dynamics (Gutiérrez et al. 2007, Holm et al. 2016, Wiens et al. 2014). Barred owls have reached densities in the Pacific Northwest that are far greater than historical populations of northern spotted owls (Wiens et al. 2011, 2014). Moreover, as generalist predators, barred owls capture a greater proportion of diurnal, terrestrial, and aquatic prey than northern spotted owls (Forsman et al. 2004, Hamer et al. 2001, Wiens et al. 2014). These life-history traits indicate that barred owls are not direct functional replacements of northern spotted owls in forested ecosystems of the Pacific Northwest (Holm et al. 2016), and that a wide range of prey species may be affected if they replace northern spotted owls. Further research is needed to determine the potential effects of barred owls on other sensitive wildlife beyond spotted owls.

Finally, critical needs for managers are detailed assessments of those locations where spotted owls persist and a better understanding of the effects of forest management activities on interactions between spotted owls and barred owls, and the species individually. Many spotted owl sites with apparently suitable forest structure for nesting and roosting have been abandoned as a result of displacement by barred owls. Those sites that spotted owls have persisted in the face of barred owls may be a result of the behavioral characteristics of the territorial spotted owl, or perhaps those sites have unique forest characteristics that enhance coexistence between the two species. Thinning treatments could potentially affect competitive interactions either by displacing barred owls into areas occupied by spotted owls, or potentially increasing foraging opportunities for barred owls over spotted owls. These and many other responses are plausible, but it remains unknown how either species responds to many forest management techniques. Recent advances in lightweight geographic positioning system telemetry devices and high-resolution forest structure mapping technologies can provide new opportunities for advancing our understanding of these issues.

Prey populations and population performance— Previous studies have characterized the diet of spotted owls in different portions of the subspecies' range (Barrows 1980; Bevis et al. 1997; Cutler and Hays 1991; Forsman et al. 1984, 2001, 2004), investigated the relationship between forest cover selection, home-range size, and prey availability (Carey et al. 1992; Forsman et al. 1984, 2005; Irwin et al. 2000; Zabel et al. 1995), and evaluated diet overlap with barred owls (Hamer et al. 2001, Wiens et al. 2014). The importance of understanding relationships between spotted owl populations and their prey has repeatedly been acknowledged (Clark et al. 2011, Courtney et al. 2004, Forsman et al. 2004, Glenn et al. 2010, Olson et al. 2004, Rosenberg et al. 2003, Thomas et al. 1990, Wilson and Forsman 2013, Zabel et al. 1995). However, to our knowledge, no efforts have been undertaken to quantify the relationship between interannual fluctuations in prey abundance and

long-term demography of spotted owls. Research is needed to understand how spotted owl reproduction, stress levels, and survival are influenced by prey species composition and abundance, and how prey populations are influenced by disturbance or fluctuations in weather and climate. Population fluctuations in small mammals have been linked with variation in precipitation (Avery et al. 2005, Crespin et al. 2002). However, identifying the mechanisms by which climate influences population processes of spotted owls and their prey remains a challenge (Glenn et al. 2011a).

A better understanding of the effects of thinning treatments and the impacts that anticoagulant rodenticides have on spotted owl prey populations will be critical for managers. Research and an effect analysis is needed to address thinning impacts on spotted owl prey, both within treated stands and at broader landscape scales. This information would contribute to thinning prescription development throughout the range of the spotted owl. The use of anticoagulant rodenticides in natural systems is increasing, especially in areas where illegal marijuana cultivation is prevalent. Studies are also needed to better understand the individual- and population-level impact of rodenticides on spotted owls, and development of management options to reduce the ecological impacts.

Landscape restoration, silvicultural treatments, prescribed fire, and wildfire in moist and dry forests— Research is needed in both dry and moist forest landscapes to evaluate the short- and long-term effects of silvicultural treatments and wildfire on spotted owl occupancy, forest dynamics, and prey, but research questions differ between forest types. For example, the optimization of forest restoration and conservation of spotted owls will require more knowledge about the conditions under which restoration activities can benefit spotted owls in the long term without significant detrimental impact in the short term. Restoration activities and objectives are different between moist and dry forest landscapes. Current conditions in dry forests are generally not sustainable, and some measure of treatment is needed to increase fire resiliency of forest stands in at least some locations (USFWS 2012b). In these fire-prone landscapes, a common objective is to modify and reduce fuels to alter wildfire behavior and to manage for ecological integrity based on the natural range of variability (USDA 2012). Additional information is needed to evaluate the consequences of fuels reduction and restoration treatments relative to the long-term benefits of forest restoration, particularly as large, high-severity fires are expected to become more frequent because of climate change. This is especially true in the frequent low-severity fire regime of the eastern Cascades, where environmental conditions favor open pine-dominated forests. Studies are needed to identify resilient sites for spotted owls in the face of changing forests (e.g., species composition changes) caused by climate change, active forest management, and increased wildfire occurrence.

In moist forest landscapes, research is needed to determine how or if spotted owls use forest stands where thinning has been conducted to accelerate the development of late-successional forest characteristics. If spotted owls avoid these areas in the short term, work is needed to understand the time before they begin using the areas again. To fully understand restoration effects, long-term before/after control-impact studies are needed to elucidate spotted owl and prey responses to forest restoration treatment effects in different ecotypes.

Research to address restoration and silvicultural treatment on spotted owl space use and forest structure development will also need to account for the potential confounding impact that barred owls are likely to have on spotted owl response to restoration efforts. Beyond a better understanding of spotted owl response to silvicultural treatments, managers need information regarding how sympatric populations of barred owls respond to treatments. Additionally, research is needed to understand the effectiveness of ecosystem-scale conservation versus conservation that targets one particular stage of succession (e.g., late-successional forest characteristics for spotted owls). Finally, much more information is needed to evaluate the short- to long-term effects that wildfire has on spotted owls in all landscapes, with a focus on the relative susceptibility of old forest and young forest to high-severity wildfire under a range of weather conditions. Finally, it is important to note that these research topics become increasingly difficult to address as spotted owl populations decline and fewer individual owls are available to study in some landscapes.

Physiological consequences of stress—
An animal's ability to cope with stressors is an important determinant of its physiological conditions, and therefore, health and survival. Environmental perturbations and an individual's response can affect the body's production of hormones, such as glucocorticoids, with negative physiological consequences (Carrete et al. 2013, Strong et al. 2015). For many species, the level of stress hormone corticosterone can be an effective predictor of survival probabilities, reproduction, dispersal, and can have population-level impacts (Carrete et al. 2013, Romero and Wikelski 2001, Romero et al. 2000). Quantification of corticosterone in feathers, which is stable over time, represents an integrated measure of stress levels (Bortolotti et al. 2009, Sheriff et al. 2011). Stress hormones are accumulated in feathers during growth, so can provide a measure of stress levels during that time, and can be a strong predictor for future survival of individuals (Koren et al. 2012). Variation in feather corticosterone can also be quantified among individuals of a population, as well as through time to track stress over space and time to address questions about the health and ecology of a population (Bortolotti et al. 2009).

Hayward et al. (2011) found that spotted owls had a glucocorticoid response to acute noise disturbance and that spotted owls with nests near noisy roads fledged fewer young than those near quiet roads. Corticosterone analyses are needed to determine the physiological response to acute and prolonged exposure to environmental stressors (e.g., barred owls, prey abundance, weather, and human-caused disturbance) and response activity for both juvenile and adult spotted owls. Our understanding of spotted owl ecology will be improved with studies to evaluate the associations between stress levels and survival, reproduction, and dispersal of spotted owls. From a management perspective, it is important to understand the stress response of spotted owls related to management activities like prescribed fire, road construction, various logging systems, and the timing of these activities. Additional research will be important to understand key stressors for spotted owls and inform seasonal restrictions on human activities that can increase stress levels.

Dispersal and suitable forest connectivity—
Dispersal behavior for both juveniles and adults may increase survival and reproductive success, but also increase risks to establishing a home range in an unfamiliar landscape. Juvenile spotted owls disperse within their first year and the condition of matrix forest types between natal and breeding sites can facilitate or hamper survival and movement processes (Forsman et al. 2002). Available information for spotted owls suggests that stands used for roosting during natal dispersal movements have very similar structure as those stands used for nesting and roosting activities of adults (>70 percent canopy cover and large trees >50 cm d.b.h.), but this finding is based on only two studies with no data throughout most of the geographic range (Miller et al. 1997, Sovern et al. 2015). Further research is needed to understand the contemporary dynamics of juvenile dispersal because many assumptions are made about what constitutes forest cover suitable to facilitate dispersal by spotted owls. A better understanding of the forest structure and configuration characteristics of forest conditions that facilitate juvenile dispersal is needed to ensure demographic connectivity among isolated patches of remaining old forests. Further, it remains unknown how barred owls influence juvenile spotted owl survival or dispersal. It is possible that some of these questions could be addressed with a thorough analysis of existing dispersal data from demographic study areas.

Historically, adult spotted owls exhibited strong nesting-site and mate fidelity, with fewer than 8 percent of individuals dispersing to a different territory between years (Forsman et al. 1984, 2002). In recent years, however, field observations suggest that interterritory movements by resident spotted owls are increasing, and that such movements appear to coincide with the colonization of barred owls (Dugger et al. 2011, Olson et al. 2005). Research that addresses how forest alteration and the presence of barred owls interact with social conditions on territories to affect movement decisions and survival of individual spotted owls will improve our ability to implement forest management practices that benefit spotted owls. In addition to helping land managers identify the range of conditions within

individual owl territories that promote high site fidelity and survival, such data can also provide a powerful framework for testing broad ecological theories about the causes and consequences of breeding dispersal in a long-lived predatory bird with declining populations.

Testing alternative monitoring protocols— When the NWFP was developed, mark-recapture and random census (i.e., occupancy framework; the proportion of sites occupied by spotted owls) population monitoring methods were both considered. The decision was made to use the mark-recapture method, which was already in use. Precise estimates from mark-recapture studies require large samples of marked spotted owls; therefore, Lint et al. (1999) recommended the use of an independent estimate of population trend for comparison with the results from spotted owl demographic studies. Monitoring in an occupancy framework (i.e., MacKenzie et al. 2006) could provide an independent, empirical assessment of population trends to compare with estimates of the annual rate of population change. Because of uncertainty about the precision of the occupancy-based approach, Lint et al. (1999) recommended that statistical power and cost effectiveness of the method be explored.

The low number of spotted owls in some study areas suggests that passive acoustic monitoring may be an effective solution for future monitoring of spotted owl populations. Traditional call-back surveys at night (playing spotted owl calls and listening for a spotted owl response) are labor intensive, more risky compared to daytime work, and only generate reliable data for spotted owls. Further, detection probabilities for spotted owls—using call-back surveys—are negatively influenced by the presence of barred owls, and barred owls often do not respond to spotted owl calls (Bailey et al. 2009). Call-back surveys could also have unintended consequences by exposing spotted owls to predation or harassment by barred owls or great-horned owls. Primary advantages of passive acoustic monitoring are as follows: (1) surveys do not require an elicited response from target species; (2) surveys are able to detect and do not bias against many other species (e.g., barred owl, marbled murrelet, western screech-owl, northern pygmy-owl, northern saw-whet owl, and many others); (3) increased crew safety because all work would be conducted during daylight hours; (4) biological training and expertise needed for crew members will be much less than is needed for call-back surveys and demographic studies; and (5) sound recordings provide a permanent record of the detection. A limitation of this approach is the time required to process recordings and data storage. Automated call detection technology has been developed, but improvements are needed, especially for call recognizers for rare birds in areas with excessive background environmental noise (e.g., rain, streams). Research is needed to test alternative methods that take advantage of technological advancements in noninvasive detection equipment to monitor trends in rare populations. The transition to alternative methods to monitor spotted owl populations will be most effective if new methods have spatial and temporal overlap with traditional methods so that robust comparisons can be made between historical and contemporary data.

Population simulation modeling— The program HexSim (Schumaker 2015) provides a simulation framework for systematically investigating factors that influence population function, including forest conservation scenarios and emergent competitors. The implementation of HexSim by the USFWS (2011b) did not include spatially explicit representation of spotted owl interactions with barred owls. Modeling exercises that incorporate a more sophisticated representation of population interactions with barred owls are needed to simulate and predict responses of spotted owls to experimental removal of barred owls. Two-species models implemented in HexSim could also be used to simulate potential efficacy of long-term management programs for barred owls and spotted owls relative to critical habitat designations. Current modeling efforts are female-only models. A two-sex HexSim implementation for the spotted owl population is needed to get at small population processes (e.g., Alee effects and stochasticity in sex ratios) that can drive extinction.

Scientific Uncertainty

Survival estimates—

Adult survival is typically the most important factor influencing population performance in long-lived raptors, and survival estimates for spotted owls have been the focus of extensive research and monitoring. As in other meta-analyses of spotted owl demographic data (e.g., Burnham et al. 1996, Dugger et al. 2016, Forsman et al. 2011), Anthony et al. (2006) used capture-recapture methods to estimate apparent survival rates of spotted owls. Apparent survival is the product of probabilities that an animal survives and remains in the population. If a marked animal permanently emigrates, then it is, for purposes of the estimate, presumed dead, because emigration and mortality are confounded. Further, fates are not known for all individuals because recapture probabilities are less than one even when animals remain in the population. Therefore, models based on capture-recapture data account for imperfect encounter rates in estimates of survival (i.e., apparent survival). Apparent survival rates on individual study areas ranged from 0.75 (± 0.03) to 0.89 (± 0.01) for adults, 0.63 (± 0.07) to 0.89 (± 0.01) for 2-year-olds, and 0.42 (± 0.11) to 0.86 (± 0.02) for 1-year-olds. They found negative effects of reproduction and barred owls in survival rates on several study areas (Anthony et al. 2006).

Elsewhere, Loehle et al. (2005) used telemetry to study annual survival of spotted owls and obtained a known-fate estimate of 0.93 (± 0.07), which was considerably higher than the apparent survival estimates reported by Anthony et al. (2006). Known-fate models estimate survival rate when fates (i.e., alive or dead) of individuals can be determined with certainty. Loehle et al. (2005) used their results to cast doubt on apparent survival estimates from mark-recapture studies of spotted owls. They suggested that survival estimates from mark-recapture studies were too low because some marked individuals left the study areas and were assumed to be dead. Anthony et al. (2006) estimated a declining spotted owl population; Loehle et al. (2005) suggested that the true population change for spotted owls was likely stable and not declining. In response, Franklin et al. (2006) argued that Loehle et al. (2005) had inappropriately compared their study with the work of Anthony et al. (2006) in a number of ways, including (1) the manner in which missing radio-marked individuals were removed from analyses may have overestimated survival; (2) telemetry-based estimates of survival were not valid for estimating bias; and (3) results from the telemetry-based study should not be compared to the capture-recapture study because study areas differed dramatically in size and distribution. Both apparent survival estimates from mark-recapture data and known-fate estimates from telemetry studies are valid estimates of annual survival. However, in this circumstance it was inappropriate to compare telemetry-based survival estimates with results from capture-recapture studies, which was acknowledged by both sides of the disagreement (Franklin et al. 2006, Loehle and Irwin 2006).

Wildfire risk—

The 2008 recovery plan (now withdrawn) for spotted owls (USFWS 2008) suggested a change in the LSR network as the foundation of conservation strategies established in the NWFP. Because of concern about wildfire, the plan recommended a switch from a reserve to a no-reserve strategy in up to 52 percent of the spotted owl's range. For dry forests, the plan recommended thinning stands at regular intervals to reduce fuel loading, and thus wildfire risk. Hanson et al. (2009) suggested that the estimates of wildfire risk used by the USFWS (2008) were overestimated and that there was not a strong basis for major changes to the NWFP conservation strategy for the spotted owl. Spies et al. (2010) defended the estimates of wildfire risk and suggested that Hanson et al. (2009) had underestimated wildfire risk and were biased against active management. Hanson et al. (2010) then responded by calling for less focus on fuel treatments in the recovery plan for the spotted owl. Because of uncertainty about future wildfire occurrence, spatial extent, and severity, we cannot know with complete confidence whether wildfire risk has been over- or underestimated in these efforts. Both the 2008 critical habitat designation and the 2008 recovery plan were challenged in court, and the inspector general of the Department of the Interior issued a report concluding that the decisionmaking process for the

recovery plan was potentially jeopardized by improper political influence (Devaney 2008, USFWS 2011a). The court ordered the Fish and Wildlife Service to withdraw the 2008 recovery plan and issue a revised recovery plan and critical habitat designation.

Spies et al. (2017) projected that the extent of forest cover suitable for spotted owls in the eastern Oregon Cascades is expected to increase in coming decades under recent historical frequencies and severities of wildfire (and current levels of wildfire suppression). Treating the landscape to reduce potential loss of suitable forest cover for spotted owls with high-severity wildfire still resulted in increases in that forest cover type, but not as much as would occur without management. The results suggest that managing for resilience to fire and climate change could occur without necessarily reducing forest cover from its current levels (younger forest is growing into older closed-canopy forests to replace dense forests lost thinning or wildfire). However, these outcomes are likely to be different under climate change or if an alternative landscape-scale treatment design is used (Spies et al. 2017).

Despite the potential negative effects on spotted owl habitat, the overwhelming consensus in the scientific literature is that active management in dry forests is appropriate to reduce wildfire risk and improve ecosystem function. Therefore, the 2011 revised recovery plan (USFWS 2011b) and 2012 critical habitat designation (USFWS 2012a) for spotted owls contained proposals for active management in dry forests. In some regions, project planning has moved forward, and federal land managers are consulting with the Fish and Wildlife Service on a case-by-case basis. The debate about active management related to wildfire risk for forests used by spotted owls remains unresolved and reflects different goals (e.g., ecosystem versus single species) and assumptions about wildfire risk with a changing climate. These differences of opinion highlight legitimate concerns about where to place the burden of proof regarding ecosystem versus species management, but the fundamentals of this controversy lie in the diversity of philosophical views about ecological goals and the role that active management should play on public lands (see chapter 12).

Restoration framework—
Franklin and Johnson (2012) outlined a series of recommendations for an "ecological forestry" framework and a forest restoration strategy within the Plan area that reflect many of the elements of the revised spotted owl recovery plan (USFWS 2011b). They called for reserving older forest stands, thinning plantations to accelerate development of structural complexity, and implementing variable-retention harvests in younger forests to help provide diverse early-seral ecosystems on moist forest sites. On dry forest sites, their strategy called for silvicultural treatments that retain and release older trees, reduce stand densities, shift composition toward fire- and drought-tolerant tree species, and incorporate spatial heterogeneity at multiple spatial scales (Franklin and Johnson 2012). The framework included an extensive set of large patches of dense forests on approximately 30 percent of the forested landscape to retain some suitable forest for spotted owls while reducing the potential for landscape-level high-severity wildfires.

DellaSala et al. (2013) identified seven areas in which the ecological forestry framework may fall short of the stated goals of the NWFP, and offered 14 recommendations to improve the framework and its implementation. They also criticized decisions to incorporate some of the elements of ecological forestry in the revised recovery plan and revised critical habitat designation. Henson et al. (2013) agreed with many of the recommendations made by DellaSala et al. (2013), but differed on two key perspectives. Henson et al. (2013) regarded the potential impacts of wildfire to spotted owls as higher risk to species persistence, and suggested that in many circumstances, the adverse effects associated with active management may be preferable to adverse effects of passive management. As with wildfire risk, the fundamentals of this debate reside in philosophical disagreements about ecological goals and what role active management should play in managing public lands. Most research in dry or frequent-fire forest landscapes suggests that active management is needed to achieve or accelerate restoration objectives, but more study is needed to advance our understanding of disturbance effects on wildlife dependent on old forest, especially interactions between wildfire and a range of prefire and postfire active management actions.

Modeling to inform critical habitat designation— The Fish and Wildlife Service (USFWS 2012a) produced maps of distribution of potentially suitable habitat for spotted owls that did not include the effects of barred owls on spotted owl distribution, but the effort did incorporate the spatial arrangement of forest structure associated with nesting/roosting and foraging, and abiotic factors such as slope and topographic position, to determine the extent of critical habitat. In an alternate analysis, Loehle et al. (2015) conducted an accuracy assessment of vegetation data used as input to develop the USFWS (2012a) models, used independent locations to validate model prediction, correlated model output with spotted owl reproductive success in two study areas, and developed alternate models. Their independent locations and vegetation evaluations suggested a high rate of classification errors, and productivity did not correlate well with predictions in their study areas (Loehle et al. 2015). Dunk et al. (2015) defended the critical habitat model as scientifically rigorous and as meeting the goals established by the Fish and Wildlife Service. They suggested that Loehle et al. (2015) mischaracterized the literature and the Fish and Wildlife Service species distribution model, failed to demonstrate the locations used by the agency were biased, and failed to show significant flaws in analytical methods.

Bell et al. (2015) argued that Loehle et al. (2015) underestimated the predictive performance of critical habitat maps because the field plots they used potentially biased the accuracy assessment toward older forests, and that they examined accuracy at finer scales than the model was intended to predict. Loehle and Irwin (2015) responded to Bell et al. (2015) and Dunk et al. (2015) by arguing that, although the habitat models average out at large spatial scales, errors at smaller scales may limit their utility for conservation. This debate underscores the importance of acknowledging the appropriate scale at which predictive distribution models can be used for conservation purposes. The debate also serves as another example highlighting the need to recognize and carefully evaluate how habitat is defined. The definition of habitat for spotted owls must now consider that forests that were once suitable for spotted owls are less suitable habitat if occupied by barred owls.

Conclusions and Management Considerations

Spotted owls are a resilient subspecies but are faced with significant challenges. Research and monitoring efforts over the past several decades have documented the population declines and risks to spotted owls despite measures to address their long-term sustainability. The framework, standards, and guidelines of the NWFP have been both critical and necessary for spotted owl conservation, and underlie species recovery plans. However, because of barred owls and continued forest perturbations outside of federal lands, the NWFP alone is not sufficient for spotted owl recovery. Additional measures beyond the Plan will be needed for long-term persistence of spotted owls. Suitable habitat continues to decline because of current and lingering effects of extensive forest disturbance, and the recent invasion of a formidable congeneric competitor has reduced the space available for spotted owl recovery. The need to provide habitat for spotted owls has been a critical component of conservation plans and was a major catalyst for developing the NWFP. It is now clear that barred owl presence reduces habitat suitabiliy for spotted owls, so species recovery will require protections for old forest and management actions focused on reducing the threat from barred owls. After only two decades, it is too early to evaluate if the Plan has been effective at improving the conservation status of spotted owls; however, the framework, standards, and guidelines of the NWFP have aided spotted owl conservation; if logging had continued at pre-NWFP levels, spotted owl populations certainly would have declined more rapidly over the past 20 years. Further, the NWFP has put federal lands on a trajectory for providing enough suitable forest for recovery of spotted owl populations over the next several decades. The effectiveness of LSRs established under the NWFP is linked to the frequency, severity, spatial extent, and type of disturbance, as well as how those disturbances are offset by recruitment of suitable forest, primarily through succession. Disturbance events can reduce the suitability of forests used by spotted owls for several decades by creating open canopy conditions and reducing structural complexity. Although disturbance rates have exceeded suitable forest-cover

recruitment rates during the first 20 years of the NWFP, recruitment will likely outpace losses if current timber harvests and wildfire occurrence remain constant. However, climate models suggest that wildfire occurrence may increase, causing significant reductions in cover for spotted owls, and that suitable forest cover for spotted owls will move northward and occur at higher elevations. Therefore, other reserves designated before development of the NWFP, such as parks and wilderness areas, may become increasingly important for spotted owl conservation.

Several lines of compelling evidence indicate that interspecific competition between spotted owls and barred owls is causing accelerated population declines of spotted owls, despite widespread conservation of old forests under the NWFP. Competitive pressure from barred owls may negate the benefits of recruitment of suitable forest cover, because barred owls exclude spotted owls from sites that otherwise are suitable for spotted owls. It remains uncertain how, or if, spotted owls can coexist with barred owls. Although much research has been done on spotted owls, we identified many uncertainties in available information and have identified future research needs important for management of the subspecies. The long-term effects of barred owls and fine-scale partitioning of resources remain unknown, and studies are needed to identify resilient sites for spotted owls in the face of competitive interactions with barred owls, if they exist. Additionally, it remains unknown how, or if, spotted owls will respond to removals of barred owls from historical spotted owl territories.

Abundance and distribution of primary prey species can influence home range size and forest selection by spotted owls. But it remains unknown how spatially and temporally fluctuating prey populations influence the survival and reproduction of spotted owls. Studies are needed to quantify relationships between interannual fluctuations in prey abundance and long-term demography of spotted owls. The short- and long-term effects of silvicultural treatments and wildfire on spotted owl occupancy, forest dynamics, and prey remain unclear. The optimization of forest restoration and conservation of spotted owls will require more knowledge about the conditions under which restoration activities can benefit spotted owls in the long term without significant detrimental impact in the short term.

Management Considerations

Forest management and barred owls— Wiens et al. (2014) found that adult survival of spotted owls and barred owls was higher in home ranges with greater amounts of conifer forest dominated by trees age 120 years or older. Dietary studies also showed that barred owl diet is broader than spotted owls, but both owl species relied on similar prey associated with older forest types (e.g., northern flying squirrels and red tree voles). These findings have important implications for land managers because they suggest that (1) conservation of old forest under the NWFP not only promotes survival of spotted owls, but also survival of barred owls; and (2) availability of old forests (and associated food resources) is a key limiting factor in the competitive relationship between the two owl species (Wiens et al. 2014). As barred owls continue to increase in number, it has become clear that conservation of the spotted owl and its forest cover types need to be extended from ameliorating the effects of old-forest loss and fragmentation to accounting for the impacts of a widespread invasive competitor as well. Although spotted owls are known to use recently thinned stands (e.g., Irwin et al. 2015), it remains unclear how such silvicultural treatments can affect the fitness of spotted owls in the long term or how barred owls may respond to those management actions. Those silvicultural treatments with high disturbance likely increase long-term extinction rates of spotted owls by reducing forest complexity and thus suitability for spotted owls but not necessarily for barred owls (Dugger et al. 2016, Singleton 2015, Singleton et al. 2010, Sovern et al. 2014, Wiens et al. 2014).

Barred owl densities may now be high enough across the range of the spotted owl that, despite the continued management and conservation of suitable forest cover types under the NWFP, the spotted owl population will continue to decline without intervention to reduce barred owl populations (Dugger et al. 2016). Recommendations to conduct experimental removal of barred owls to benefit spotted owls have been criticized as being too difficult to accomplish owing to the effort and cost required to maintain sufficiently low numbers of invasive barred owls (Livezey 2010, Rosenberg et al. 2012). Nonetheless, experimental removal of barred owls on one study area in California suggests that

removal of barred owls may have positive, short-term effects on population trends of spotted owls (Diller et al. 2016, Dugger et al. 2016). In 2013, the Fish and Wildlife Service decided to expand removal experiments to additional sites in California, Oregon, and Washington to determine if similar results can be obtained in areas with different forest conditions and densities of barred owls (USDI 2013, USFWS 2013). Those experiments will yield information about how spotted owls respond, and will convey the economic and logistic feasibility of removal efforts as potential management actions. Such information will be useful in projecting possible long-term consequences and benefits of an active management program for barred owls in the future.

Current evidence suggests that a combination of habitat protection and active management of barred owls are the two highest priorities for stabilizing declining trends in populations of spotted owls. A recent analysis casts doubt on the likely effectiveness of barred owl removals for spotted owl conservation (Bodine and Capaldi 2017). Experimental culling of barred owls will provide information to validate those models and about how, or if, their populations can be controlled at scales sufficient to promote recovery of spotted owls. However, detailed studies of habitat associations and resource use by barred owls have been conducted in only a few limited areas within the range of the spotted owl. More detailed studies in other areas will better enable an understanding of how specific tree species, stand densities, or physiographic conditions are negatively associated with barred owls but not spotted owls.

Wildfire and active management—
Disturbance processes that increase forest or landscape heterogeneity (e.g., wildfire, management activities) can benefit spotted owls as long as the required forest structural conditions are available for foraging, nesting, and roosting activities. Processes that substantially simplify stand structure or landscapes often have negative impacts on the suitability of forest for spotted owls. Our basic understanding of forest structural conditions used by spotted owls has not substantially changed over the past 20 years, but there has been a growing recognition of the contribution of diverse forest conditions to broader ecosystem function and species diversity in conifer forests of the Pacific Northwest. This is especially true in historically moderate- and high-frequency fire regime landscapes where fire suppression and forest management have greatly reduced fire and altered forest structure and composition at stand and landscape scales (chapter 3). For example, nonconiferous vegetation, including shrubs and broad-leaved trees, makes an important contribution to the diversity of forest landscapes. Therefore, allowing shrubs and hardwood trees to develop and persist in early-seral stands, and curtailing vegetation control, will benefit many wildlife species associated with nonconiferous vegetation (Hagar 2007), including some spotted owl prey species (Diller et al. 2012). Additionally, diversity and configuration of different forest types are important for spotted owls at stand, home range, and landscape scales (Franklin et al. 2000). The function and diversity of an ecosystem is enhanced by the presence of high-quality early-seral patches (i.e., a mix of nonforest and forest) because they have high species and structural diversity (Swanson et al. 2011). These early-seral ecosystems can be created using low-intensity approaches for regeneration, combined with retention of biological legacies to promote the development of structurally diverse closed-canopy forest over time (Franklin and Johnson 2012). Indeed, under normal conditions, natural disturbances frequently result in patches of high-quality early-seral ecosystems, provided that intensive salvage and replanting does not occur after the disturbance (Swanson et al. 2011).

Disturbances have different impacts on spotted owls depending on the scale under consideration. A hypothesis that has emerged from recent research is that disturbance processes (e.g., low- and mixed-severity wildfire, light to moderate thinning) that increase stand or landscape heterogeneity can have long-term benefits for spotted owls, as long as enough suitable forest cover for nesting and roosting remain within the territory. Conversely, disturbances that substantially simplify stands or landscapes often have long-lasting negative impacts on spotted owls and their habitat. Finally, we emphasize the importance of conserving sites currently occupied by spotted owls as well as those that are known to have been historically occupied by the subspecies. Many sites, for example, have been abandoned as a result of disturbance to suitable forest cover or displacement by barred owls, but maintain structure suitable for nesting and roosting. Those remaining spotted owls and sites likely

represent unique behavioral or forest characteristics that may not yet be fully recognized, thus they are an important research need. Conserving the unique forest structural conditions of those few sites that remain, particularly in the northern portion of the geographic range, will likely have a positive benefit for the long-term persistence of spotted owls.

Prognosis for the future—

In the 2011 revised recovery plan for spotted owls, the Fish and Wildlife Service's modeling team used the HexSim modeling program (Schumaker 2008) to simulate population-level responses to various conservation strategies and other threats (USFWS 2011b). They developed models based on demographic data (Forsman et al. 2011), dispersal information (Forsman et al. 2002, Thomas et al. 1990), and home range size (Carey et al. 1990; Forsman et al. 1984, 2005; Glenn et al. 2004; Hamer et al. 2007). Objectives of the modeling effort were to (1) evaluate if future viable populations of spotted owls were likely given conditions at the time (demographic rates, LSR network, amount of suitable forest cover, barred owls); (2) estimate population viability under different conservation networks of suitable forest cover; and (3) quantify the effect of forest cover and barred owl management on recovery goals for spotted owls (USFWS 2011b). The modeling results suggested that availability of suitable forest cover was critical for territory acquisition and sustained occupancy by spotted owls. Population viability models suggest that barred owls reduce spotted owl survival and act to depress populations to about half of potential population size without barred owls (fig. 4-9). Simulations did not include the barred owl impact on spotted owl reproduction, forest selection, site fidelity, or detection probability, and were based upon early rates of population growth. More recent population change estimates (Dugger et al. 2016) indicate a further declining growth

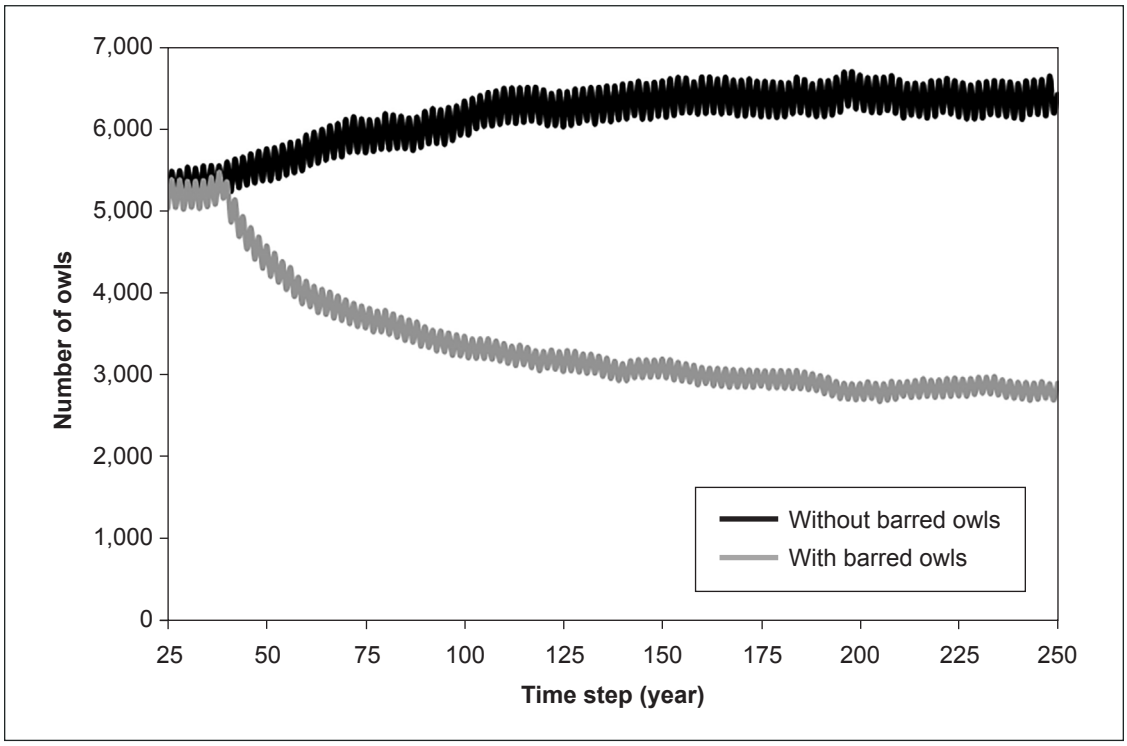


Figure 4-9—HexSim model runs with five replicates each for without barred owl impacts and with barred owl impacts for the spotted owl's geographic range in the United States. The apparent within-year variation that appears in the figure is a function of an "even-odd" year effect on reproduction (USFWS 2011b). The first 30 years of the simulation was a "burn-in" period, which provided for the simulated population to distribute according to available resources and develop an age structure determined by demographic processes. Barred owl effects were not included during the "burn-in" period and were introduced starting at year 30 (USFWS 2011b).

rate, suggesting that USFWS (2011b) projected estimates are more optimistic than what is likely to be observed in spotted owl populations. These studies provide further evidence that the framework, standards, and guidelines of the NWFP are critical components to spotted owl recovery plans, but the impacts of barred owls will likely need to be controlled if spotted owl species recovery is to be successful.

Schumaker et al. (2014) used the HexSim model originally developed by the Fish and Wildlife Service (USFWS 2011b) to simulate and quantify source-sink dynamics and landscape connectivity throughout the range of the spotted owl. Their results indicated that populations are likely to decline in most regions, but that southern Oregon and northern California may serve as source populations. Marcot et al. (2013) also used the HexSim model to evaluate how size and spacing of suitable forest cover types for spotted owls affected simulated population size and persistence. Their results indicated that long-term occupancy rates were significantly higher with suitable forest patches large enough to support 25 spotted owl pairs or more, with less than 9.3 mi (15 km) spacing between patches, and with overall landscapes of at least 35 to 40 percent suitable forest cover types for nesting and roosting. In a sensitivity analysis, Marcot et al. (2015) determined that spotted owl response variables in the HexSim model were most sensitive to the availability of highly suitable forest cover for nesting and roosting. All these studies used static habitat maps that did not incorporate climate change or wildfire impacts on spotted owls. Only the USFWS (2011b) model incorporated effects of barred owls.

Spotted owl populations have continued to decline under the NWFP, but because of slowed timber harvest on federal lands since the late 1980s, forests throughout most of the range of the spotted owl are on a trajectory—through succession—to develop suitable forest characteristics for spotted owls in coming decades. When the NWFP was adopted, spotted owl populations were expected to continue declining for up to 50 years because of lingering impacts of previous losses of suitable forest cover, yet the magnitude and characteristics of barred owl impacts were unknown and unexpected at that time. Per assumptions of the NWFP, we are unable, after only two decades, to use stable or increasing populations (i.e., improved conservation status) of spotted owls as the success criterion for the NWFP. However, if the success criterion is forests capable of supporting interconnected populations of spotted owls in the absence of barred owls, then the implementation of the framework, standards, and guidelines of the NWFP has put federal lands on a trajectory for success, despite recent losses of suitable forest cover to wildfire. In the Pacific Northwest, forest succession from early-seral to climax forest is a slow process, which is in part the reasoning for the NWFP to be a 100-year plan intended to span several human generations (USDA and USDI 1994). Further, conservation and management of spotted owls rests critically on continued implementation of the protections afforded by the NWFP and the Endangered Species Act (Noon and Blakesley 2006). It also rests on improving our understanding of how to minimize impacts of barred owls, and on fine-tuning our ability to retain needed forest structure while also increasing resiliency of forests through strategic management.

Acknowledgments

We are indebted to the many biologists and funding sources dedicated to studying northern spotted owl populations and factors affecting this threatened subspecies. Heather Roberts (Oregon State University, Department of Forest Ecosystems and Society) assisted with the plot analysis presented in the inset of this chapter. Author salaries were supported by the USDA Forest Service Pacific Northwest Research Station (D. Lesmeister and P. Singleton) and Pacific Northwest Region (R. Davis), and by the USDI Geological Survey, Forest and Rangeland Ecosystem Science Center (J.D. Wiens). We thank E. Forsman, E. Glenn, members of the public, and anonymous reviewers for providing comments and suggested edits that greatly improved this chapter.

General Technical Report PNW-GTR-975
May 2019

In accordance with Federal civil rights law and U.S. Department of Agriculture (USDA) civil rights regulations and policies, the USDA, its Agencies, offices, and employees, and institutions participating in or administering USDA programs are prohibited from discriminating based on race, color, national origin, religion, sex, gender identity (including gender expression), sexual orientation, disability, age, marital status, family/parental status, income derived from a public assistance program, political beliefs, or reprisal or retaliation for prior civil rights activity, in any program or activity conducted or funded by USDA (not all bases apply to all programs). Remedies and complaint filing deadlines vary by program or incident.

Persons with disabilities who require alternative means of communication for program information (e.g., Braille, large print, audiotape, American Sign Language, etc.) should contact the responsible Agency or USDA's TARGET Center at (202) 720-2600 (voice and TTY) or contact USDA through the Federal Relay Service at (800) 877-8339. Additionally, program information may be made available in languages other than English.

To file a program discrimination complaint, complete the USDA Program Discrimination Complaint Form, AD-3027, found online at http://www.ascr.usda.gov/complaint_filing_cust.html and at any USDA office or write a letter addressed to USDA and provide in the letter all of the information requested in the form. To request a copy of the complaint form, call (866) 632-9992. Submit your completed form or letter to USDA by: (1) mail: U.S. Department of Agriculture, Office of the Assistant Secretary for Civil Rights, 1400 Independence Avenue, SW, Washington, D.C. 20250-9410; (2) fax: (202) 690-7442; or (3) email: program.intake@usda.gov.

USDA is an equal opportunity provider, employer, and lender.

Pesticide Precautionary Statement

This publication reports research involving pesticides. It does not contain recommendations for their use, nor does it imply that the uses discussed here have been registered. All uses of pesticides must be registered by appropriate state or federal agencies, or both, before they can be recommended.

CAUTION: Pesticides can be injurious to humans, domestic animals, desirable plants, and fish or other wildlife—if they are not handled or applied properly. Use all pesticides selectively and carefully. Follow recommended practices for the disposal of surplus pesticides and pesticide containers.

Abstract

Nemens, Deborah G.; Varner, J. Morgan; Johnson, Morris C. 2019. Environmental effects of postfire logging: an updated literature review and annotated bibliography. Gen. Tech. Rep. PNW-GTR-975. Portland, OR: U.S. Department of Agriculture, Forest Service, Pacific Northwest Research Station. 35 p.

The practice of removing fire-killed trees from burned forests (or "postfire salvage logging") has sparked public controversy and scientific debate when conducted on public lands in the United States. This review synthesizes the current scientific literature on the subject, providing an update to a 2000 literature review (PNW GTR-486) and subsequent synthesis (PNW-GTR-776). Forty-three published studies are reviewed, summarizing ecological effects on wildlife, vegetation, fuels, soils, and other environmental variables. Several key themes emerge from the review and specific research topics for future study are suggested. An annotated bibliography is provided at the conclusion of the document.

Keywords: Ecological effects, fire, fuel dynamics, wildlife, salvage, soil erosion, wildfire.

Introduction

The harvesting of merchantable timber from forests and woodlands following stand-replacing wildfires (commonly referred to as "salvage logging") on federal lands has been the subject of considerable controversy, both in the public sphere and the scientific literature. The Society of American Foresters (Helms 1998) defines salvage logging as "the removal of dead trees or trees damaged or dying because of injurious agents other than competition, to recover economic value that would otherwise be lost." As such, this practice is often driven by economic concerns, as land managers are motivated to recover the value of fire-killed trees and to support local timber economies in rural areas (Gorton and Kays 1996, McIver and Starr 2000). Promoting future forest development and reducing future fire hazard are additional benefits cited from the harvest of fire-killed trees from burned forests. The use of these latter arguments by managers and policymakers has prompted debate in the scientific literature regarding the validity of these claims. In the past several decades, researchers attempting to assess the ecological effects of postfire logging have published dozens of studies evaluating effects of salvage logging on myriad aspects of forest ecosystems. These studies have been synthesized in several documents in an attempt to provide a cohesive source of information useful to managers and decisionmakers. Relevant research on this topic continues, such that it is occasionally necessary to include the most recent studies in new literature reviews. The purpose of this report is to provide an annotated bibliography of the relevant peer-reviewed literature published in the time since a previous review of the scientific literature on postfire logging (McIver and Starr 2000). As such, it is not intended to be a meta-analysis, or a synthetic review of the state of knowledge on the topic of salvage logging.

The review produced by McIver and Starr (2000) was written in response to a debate that was taking place both in the public arena and the scientific literature over the environmental costs and ecological justifications associated with postfire logging on public forest lands. This debate has a long history. Reacting to pressure from constituents in timber-dependent communities, U.S. Senator Slade Gorton (R-Wash.) attached a salvage rider to the Fiscal Year 1995 Rescissions Act.[1] The stated objective of the rider was to promote forest health and restore timber jobs in rural communities of the Pacific Northwest (Gorton and Kays 1996). The rider led to an open debate among scientists and managers in the region (Beschta et

[1] Oklahoma City Disaster Assistance and Rescissions Act: Emergency Supplemental Appropriations for Additional Disaster Assistance, for Anti-Terrorism Initiatives, for Assistance in the Recovery from the Tragedy that Occurred at Oklahoma City, and Rescissions Act, 1995. Pub. L. No. 104-19.

al. 1995, Everett 1995, McIver and Starr 2000). Beschta et al. (1995) posited that salvage logging had strong negative ecological consequences, arguing that the only value of such action is economic, and they offered a set of recommendations for management of postfire forests. Everett (1995) refuted the conclusions of Beschta et al., arguing for more active management of postfire landscapes, including timber harvest.

The 2000 literature review (McIver and Starr 2000) was an attempt to synthesize the current state of scientific understanding in the field, evaluate knowledge gaps, and provide managers with the basis from which to make informed decisions when applying postfire management practices. Using what they described as "scanty" information, they summarized the findings of 21 studies into several categories and predicted "likely" ecological effects based on the results of these studies. One of the better studied topics, the impacts of salvage logging on wildlife, was well documented, with variable effects on different clades depending on their habitat requirements. In particular, largely negative outcomes were documented for cavity-nesting birds. Additionally, the reviewers found that substantial changes in wildlife habitat, resulting from the removal of structural and functional elements in the form of large-diameter snags and their associated insect communities, were likely following harvest. A predicted result of postfire logging was that the removal of these attractants for forest insect pests may reduce the likelihood of infestation of nearby healthy stands. Although longer term studies were lacking at the time, there was evidence that impacts of logging-related disturbance to understory communities included declines in species richness and diversity, an increase in nonnative plant species cover, and a reduction in vegetative biomass. Negative effects on tree regeneration were predicted if salvage operations are not designed to reduce seedling mortality. The reviewers did not find studies that documented increased soil erosion following postfire logging, but posited that road-building and the use of skid trails might increase its incidence in already compromised burned watersheds. Conversely, one study included in the review found that logging slash remaining from salvage activities might reduce postfire erosion. Little research had been done on the impacts of salvage logging on postfire fuel dynamics, a deficit highlighted in the review. In their conclusions, the authors recommended further study of this and several other subjects. Many of these topics continue to be explored in current research, and more broadly applicable knowledge has been made available in the years since the 2000 review was completed.

In many ways, the 1995 debate continues in the present moment. Although more scientific study has been conducted on this topic (as detailed in this review),

both supporters and detractors of the practice can point to evidence in the literature to support their arguments. Since 2000, many of the scientific questions surrounding the practice of postfire logging have been explored at greater depth and in more detail, but these issues are by no means resolved.

Interpretations of the ecological effects of salvage logging are mutable, as observations depend on the scope, spatial and temporal scales, and class of metric studied. Some effects are initially quite dramatic, but dissipate over time. Other effects may vary based on the attributes of the studied ecosystem. Owing to the structural and functional impacts of severe wildfire on forested ecosystems (e.g., widespread tree mortality, depletion of soil organic matter, consumption of woody fuels), effects of postfire logging can be difficult to distinguish from the effects of the fire itself. All these concerns complicate attempts to synthesize the current state of knowledge in this field. This review seeks to present the last 18 years of published data on this topic in a way that is relevant to managers and scientists while acknowledging the limitations in interpreting the research.

In this report, we reviewed 43 scientific studies published since 2000, and confine our geographic scope to Western United States and Canada, in keeping with the focus of the 2000 review. As with the standards set by McIver and Starr (2000), we adhere to the same definitions to classify published scientific work. If treatments were not imposed by the researchers, the study is classified as **observational**, as opposed to a **replicated** study.

Only peer-reviewed studies reviewed for this paper are annotated in the bibliography; other citations mentioned are presented without additional text.

Ecological Effects of Postfire Logging

Wildlife

When the ecological effects of postfire timber harvest are examined, negative impacts to wildlife are frequently cited in arguments against this type of postfire management. Upon thorough review of the published literature on the subject, it is clear that negative consequences of postfire harvest exist for many species. However, it would not be accurate to apply these results universally to all wildlife species. The response of an individual species to the removal of fire-killed trees is often determined by its unique qualities and the habitat features on which it depends. Although many species experience a loss of habitat when dead trees are removed following a stand-replacing fire, others benefit from the resulting alteration of stand structure, reduction in stand density, increases in understory plant diversity, and changes to surface fuel loads.

Birds

The response of avian species to the removal of fire-killed trees is highly dependent on the habitat requirements of the studied species. In their review, McIver and Starr (2000) noted that birds that depend on snags for forage and nesting structures are the most affected by the removal of dead trees following stand-replacing wildfire, while those that favor open habitats appear to benefit from logging. Cavity-nesting birds, such as the black-backed woodpecker (*Picoides arcticus*), are the archetypal fire-dependent wildlife guild, and their response to postfire harvest has been the focus of much research since the 2000 review. Owing to their dependence on standing dead trees, cavity nesters are often strongly associated with severely burned forests. These species have been found to be more abundant following fire in unmanaged stands than in harvested stands (Cahall and Hayes 2009, Hutto and Gallo 2006, Kronland and Restani 2012, Morissette et al. 2002, Rost et al. 2013, Saab et al. 2007). One contradictory study (notably with low replication) found higher abundance and richness of cavity-nesting birds following salvage (Haggard and Gaines 2001). Other birds species, such as the federally threatened northern spotted owl (*Strix occidentalis caurina*), also appear to be negatively affected by salvage logging (Clark et al. 2013), but this effect is blurred by the impacts on owl site occupancy of high-severity fire. Another study of the related California spotted owl (*S. o. occidentalis*) did not find significant declines in owl populations resulting from either fire or postfire logging, but did emphasize the small yet potentially meaningful compounded effect of fire and logging, which marginally increased the probability of site extinction (Lee et al. 2013). Bird species that use more open habitats generally have positive or neutral responses to salvage logging (Cahall and Hayes 2009, Morissette et al. 2002, Rost et al. 2013, Saab at al. 2007). As studies of this topic have largely focused on the impact of postfire snag removal on birds species that are dependent on them, information is lacking on the influence of salvage logging on the avian community as a whole, as well as on the longer term effects of these postfire management activities.

Mammals

McIver and Starr (2000) observed that, as for bird species, mammal populations tend to shift toward those that prefer more open habitat in response to salvage logging. Few studies have examined the impacts of postfire logging on mammals since 2000, and findings have not been conclusive. In one study, populations of deer mice increased in density following salvage logging, likely owing to the temporary increase in downed woody debris that was the result of harvest (Kronland and Restani 2012). Another study that compared abundance of small terrestrial mammals

across three levels of harvest intensity (unlogged, moderate, and high) found no significant difference among treatments (Brown 2009). In this same study, bat densities were observed to be higher in harvested stands; however, this may have been a consequence of the availability of open habitat for feeding, and not an indication of increased population size resulting from logging. In a study of salvage logging's impacts on trophic relationships, Hebblewhite et al. (2009) found that elk avoided areas logged after fire, largely because of increased predation risk from wolves in these open sites. The authors pointed to the increased road construction associated with postfire harvest as major factors in this disruption of ecosystem dynamics, and recommended that it be minimized. Published studies on this topic are scarce, and as a consequence, little specific information is available on the effects of postfire tree harvest on mammal populations.

Invertebrates

Insects are often abundant following stand-replacing wildfires, and are a critical element of postfire landscapes, providing forage for insectivorous birds, advancing the decay of fire-killed trees, and influencing soil nutrient cycling. Postfire timber harvest has been found to be deleterious to populations of wood-boring beetles, negatively affecting both abundance and species richness (Cobb et al. 2010, Thorn et al. 2018). Cobb et al. (2010) noted that this decrease in populations of saproxylic insects can have cascading impacts on soil nutrients. In contrast, species richness, abundance, and biomass of benthic macroinvertebrates increased in salvage-logged watersheds, though only incrementally, above unharvested burned sites when compared with unburned controls (Silins et al. 2014). Studies of invertebrate response to salvage logging are few and narrow in focus; as such, this field would benefit from further investigation, particularly including a greater diversity of species and over greater time scales following harvests.

Vegetation

Tree Regeneration

Post-wildfire tree regeneration is of great concern to land managers, resulting in the common practice of postfire planting of timber species following stand-replacing fire. McIver and Starr (2000) noted that in the majority of the studies they reviewed, salvage logging operations occurred prior to the establishment of seedlings, avoiding the high mortality (75 percent in one study) that can be caused by logging equipment. In the intervening years, the effect of harvest of fire-killed trees on natural regeneration has been examined by several authors, but results are somewhat equivocal between studies. Two studies found that natural regeneration

of tree species was negatively affected by salvage logging operations (Donato et al. 2006, Keyser et al. 2009), which caused injury to establishing seedlings. Another study found no significant effect of postfire harvest (Peterson and Dodson 2016). Interestingly, these results do not appear to depend on the interval between wildfire and harvest, as at least one of each of the former and latter groups of studies was logged at a point where seedling establishment could be expected to have occurred (2 to 3 years postfire). It is important to note that the former group of studies were conducted within 5 years of wildfire occurrence, and the latter studies examined the longer term (15 and 10 years, respectively) impacts of salvage logging on regeneration. Additionally, although natural regeneration is a concern in many postfire environments, salvage logging prescriptions typically call for post-harvest tree planting. Although species selected for replanting may not accurately reflect local assemblages, the practice reduces the reliance on natural regeneration for forest restoration in salvage-logged stands, rendering any negative impacts to preexisting seedlings less consequential.

Understory

Postfire logging effects on understory vegetation are dependent on temporal scale and site-specific factors. Numerous studies have documented a convergence in understory development between logged and unlogged stands over time (Campbell et al. 2016, Keyser et al. 2009, McGinnis et al. 2010, Peterson and Dodson 2016). In one study, repeated measurements of species richness and community composition similarly demonstrated an initial effect of logging that dissipated over several decades and was overtaken by the influence of canopy structure in the long term (Kurulok and Macdonald 2007). This was not the conclusion of another long-term study, which documented significant changes to plant communities in salvaged sites, particularly along forest edges (Hanson and Stuart 2005). Several researchers have found that other factors, such as burn severity and postfire planting, had greater influence on understory vegetative development than salvage logging (Macdonald 2007, Morgan et al. 2015). Kurulok and Macdonald (2007) found greater short-term species richness and higher shrub abundance in salvaged stands, results that are in stark contrast to Knapp and Richie (2016), who found that shrub cover decreased with salvage intensity. These discrepancies are likely due to differences in the regenerative strategies of the prefire vegetation of the studied sites, as well as the timing of salvage operations, as described by Peterson et al. (2009). Most of these studies found no increase in nonnative plant species abundance resulting from salvage logging (Keyser et al. 2009, Knapp and Ritchie 2016, McGinnis et al. 2010, Peterson and Dodson 2016), though one did find a short-term increase that

dissipated over time (Kurulok and Macdonald 2007). Although most research on the topic has concluded that understory vegetation is resilient to postfire logging over intermediate time periods, this subject would benefit from longer term study, as well as the variable effects on plants with different fire-adaptive strategies (e.g., sprouting vs. reseeding species).

Fuels

Owing to the regular use of the "reburn hypothesis" (which posits that removing dead trees from a burned stand will reduce future wildfire risk and severity) as an ecological justification by managers for removing fire-killed timber, postfire fuel dynamics are an important element of study in the realm of salvage logging research. McIver and Starr (2000) emphasized the paucity of evidence for these claims, and since that time, substantial research has been conducted on this subject. Results of recent studies suggest divergent trajectories for coarse and fine fuels in logged and unmanaged postfire stands, as well as significant changes in fuel conditions through time. The dynamics of fine fuel (fuels < 7.6 cm in diameter; 1-, 10-, and 100-hr timelag fuels) loading are critical to understand in this context, as they are the primary driver of fire spread in wildland fires (Rothermel 1972). However, coarse fuels (fuels > 7.6 cm; 1,000-hr timelag fuels) can contribute to fire behavior as well, via increased local intensity, crown ignition potential to residual surviving trees, and as a source of long-range spotting (Brown et al. 2003). Coarse fuels can also substantially increase burn severity by means of long-term smoldering and local soil heating, which can exceed lethal temperatures for long periods, affecting nutrient cycling (Brown et al. 2003, McIver and Ottmar 2018, Reinhardt et al. 1997).

Many researchers have found that, in the short term, postfire logging increases fine fuel loading when compared with unmanaged stands (Donato et al. 2006, 2013; McGinnis et al. 2010; McIver and Ottmar 2007; Peterson et al. 2015). However, longer term measurements often reveal that this effect is short lived, leading to the convergence of logged and unlogged stands within a decade (Campbell et al. 2016, McGinnis et al. 2010, McIver and Ottmar 2018, Peterson et al. 2015). The temporal variation of fine fuel loads in severely burned sites is particularly compelling in studies that remeasured prior field sites, as in the latter three studies. Note that although some authors posit that increased fine fuel loading will increase fire risk, at least in the short term (Donato et al. 2006, 2013; Thompson et al. 2007), others contend that fire hazard is unaffected by these additional fuels, largely because of the characteristics of postfire fuelbeds (Newton et al. 2006, Ritchie et al. 2013). Empirical evidence that could substantiate either position is lacking on this subject, as opportunities to observe this phenomenon are limited.

Dynamics of coarse surface fuel loading, which are dependent on snag retention in postfire environments, often exhibit the opposite trend. As would be expected, logged stands contain fewer standing snags following harvest than untreated stands. The transition of these aerial fuels to surface fuels is highly dependent on the decomposition rates (which vary by species and local climate) and diameter of remaining dead trees (Campbell et al. 2016, Ritchie and Knapp 2014). A number of studies have found high accumulation of surface coarse woody fuels over time in unharvested stands when compared with logged sites (Dunn and Bailey 2015, Keyser et al. 2009, McIver and Ottmar 2018, Peterson et al. 2015, Ritchie and Knapp 2014, Ritchie et al. 2013) as snags begin to fall. Conversely, a single study (McGinnis et al. 2010) found that large woody debris increased following postfire logging in the Sierra Nevada, although the authors noted that this effect was not significant in older (19 to 21 years since harvest) study sites. Ritchie et al. (2013) observed that, regardless of treatment, the majority of standing dead material remaining following harvest was on the ground 10 years following fire and salvage logging in the Lassen National Forest in California, and suggested that the habitat provided for cavity-nesting wildlife was therefore transient.

Owing to the very small proportion of the forested landscape that has undergone postfire salvage harvesting in the Western United States and Canada, reburn of these areas is unlikely to occur within the timespan covered by this review or its predecessors. Thus, it has been difficult for researchers to design a study that tests the reburn hypothesis in the field. Instead, many studies of postfire salvage impacts on forest fuels use fire behavior and fuels consumption models to simulate a reburn event. Several of these studies, which often pair empirical fuel measurements with modeled fire behavior, have found that models do not project elevated fire behavior or increased fire effects in unlogged stands when compared to salvaged sites (McGinnis et al. 2010, McIver and Ottmar 2007). Researchers in this field note, however, that current fire behavior and consumption models do not accurately represent the influence of large logs and other heavy fuels, which could contribute to additional fire severity via longer residence times and subsequent soil heating (McIver and Ottmar 2018, Peterson et al. 2015). Others cite high postfire shrub cover as having a substantial effect on future fire behavior, potentially overwhelming any influence of post-burn tree harvest (Campbell et al. 2016, Donato et al. 2013, McGinnis et al. 2010). In a study of reburn severity that did not evaluate the impact of postfire salvage logging, Coppoletta et al. (2016) found that postfire shrub cover and snag basal area following an initial fire contributed significantly to fire severity in reburns, but the effect of these variables (particularly snag basal area) was dwarfed by weather conditions during reburn events.

The reburn hypothesis did not receive substantiation from the sole study we found that quantified the impact of postfire logging on reburn severity (Thompson et al. 2007). Although the authors were unable to separate the effects of postfire

planting from salvage logging, they found that fire severity increased in harvested areas when compared with unmanaged sites, potentially refuting the validity of the reburn hypothesis. However, it is important to note that determination of burn severity was based solely on remote sensing data (delta Normalized Burn Ratio, dNBR) and was not verified in the field. This method of measuring burn severity raises concerns about the accuracy of the data (Miller and Thode 2007) and adds an additional level of uncertainty to the study's results. Although it is difficult to arrange the necessary treatments in the field, the limitations of current models make it imperative for researchers to continue to pursue opportunities to examine the relationship of postfire logging and reburn severity when they occur on the landscape.

Soils

An important area of study has been the contribution of postfire logging to soils and watersheds, particularly its effect on erosion and sedimentation in streams. Noting the scarcity of published research on this topic, McIver and Starr (2000) posited that road building and subsequent use would have the greatest influence on post-salvage logging erosion. Since then, several studies have found that salvage logging operations can be a major contributor to soil disturbance and compaction (McIver and McNeil 2006; Slesak et al. 2015; Wagenbrenner et al. 2015, 2016), and the majority of these studies document increased erosion in burned watersheds that were subsequently logged (Slesak et al. 2015; Wagenbrenner et al. 2015, 2016). In contrast to these studies, McIver and McNeil (2006) noted that despite increased soil disturbance, erosion from harvested sites was not significantly greater than untreated stands, and that roads were the greatest contributor to movement of soil. Additionally, these researchers found that some of the impact to soils caused by machinery during postfire harvest can be mitigated by adjusting the employed techniques and the timing of operations (McIver and McNeil 2006). Note that the influence of postfire logging on erosion, when present, does appear to be short lived, as the observed effect can diminish over time (Slesak et al. 2015, Wagenbrenner et al. 2016).

Other effects on soils from postfire logging, such as effects on soil nutrients, soil microbial and fungal communities, and cation exchange capacity, can be difficult to distinguish from the often greater influence of the initial wildfire. However, some studies have noted lasting effects of salvage logging on certain soil parameters, most notably reduction in soil organic carbon (Jennings et al. 2012, Kishchuk et al. 2014). Another study documented changes in soil biogeochemistry, but only in certain horizons (Poirier et al. 2014). Bacterial and fungal communities in soils appeared to be resilient to the disturbance caused by postfire logging (Jennings et al. 2012). Similarly, the influence of postfire harvest on water quality and stream biota can be difficult to distinguish from the signal of wildfire; however, certain parameters show detectable differences (Emelko et al. 2011, Silins et al. 2014).

Abiotic Variables

Effects of postfire logging on abiotic variables are just beginning to receive attention. Recent studies have examined microclimatic changes following salvage logging, as well as the impact of the practice on carbon sequestration and storage. One study observed that surface air temperatures did not increase in logged stands, but noted other small microclimatic changes (such as earlier daytime heating and lower nighttime minimum temperatures) attributed to postfire harvest (Fontaine et al. 2010). Researchers documented a marked decrease in the amount of carbon stored in salvaged sites, particularly those that received intensive management (Powers et al. 2013). The authors of this study emphasized the competing interests of managers, who are likely to include carbon sequestration in an already complex analysis of how best to manage forests. Although more research has been conducted in the period since 2000, results are not conclusive, and much remains to be learned about salvage logging impacts on soils and the abiotic environment, both within salvaged sites and at the landscape level.

Conclusions

Limitations

In their 2000 review, McIver and Starr lamented the fact that little research had been conducted on the effects of postfire logging. Since that time, more than 40 additional studies have been conducted on this topic, but some important scientific questions remain unresolved. One topic of particular interest to researchers, managers, and decisionmakers is the scientific validation or rejection of the reburn hypothesis. Although most studies have documented greater long-term fuel loading in unmanaged stands when compared with logged ones, the majority of studies that attempt to evaluate the reburn hypothesis use simulation models to predict fire behavior and effects, as few opportunities for empirical study have presented themselves. The only empirical study of which we are aware (Thompson et al. 2007) refuted the premise: salvage-logged stands burned at higher severities than comparable unlogged stands, though the authors noted that the high live fuel loading resulting from postfire planting in logged stands was the most likely driver of fire severity, and were not able to separate this variable from the effect of logging alone. Research based on field experiments and modeled analyses using physics-based fire behavior models (such as the Wildland-Urban Fire Dynamics Simulator) presents a potential avenue for improved evaluation of the reburn hypothesis in the future.

Shortcomings with experimental study design mentioned by McIver and Starr (2000) have not been fully addressed in the research conducted since the publication of that review. Of particular concern to those authors was the lack of replicated experiments. In the study of postfire logging effects, researchers are rarely allowed

the opportunity to determine the locations of treatments or their distribution on the landscape, with the result that the majority of studies are observational in nature. This is largely a result of the logistics involved in planning these projects: managers tend to locate harvest units based on proximity to existing road networks, distance from sensitive areas, and operable slope location. As a result, replication is often limited, sites are not randomly distributed, and spatial autocorrelation and pseudo-replication are concerns in the analysis of results. Beyond these, the use of unsalvaged sites as proxies for prefire conditions brings up issues with space-for-time or chronosequence approaches that have been highlighted in other ecological research (Johnson and Miyanishi 2008). The implementation of long-term experiments employing repeated measures over time are necessary to avoid these pitfalls and produce widely applicable, meaningful conclusions.

We found that the geographic diversity of the region is not well represented in the literature: 37 percent of the studies reviewed here were conducted in one U.S. state (Oregon), and 23 percent of published studies focused on only two wildfires (Biscuit Fire and Summit Fire, both in Oregon) (fig. 1). This lack of replication to relevant ecosystems may lead to conclusions derived from the study of one area being broadly applied to other regions where ecosystems are quite distinct. Researchers

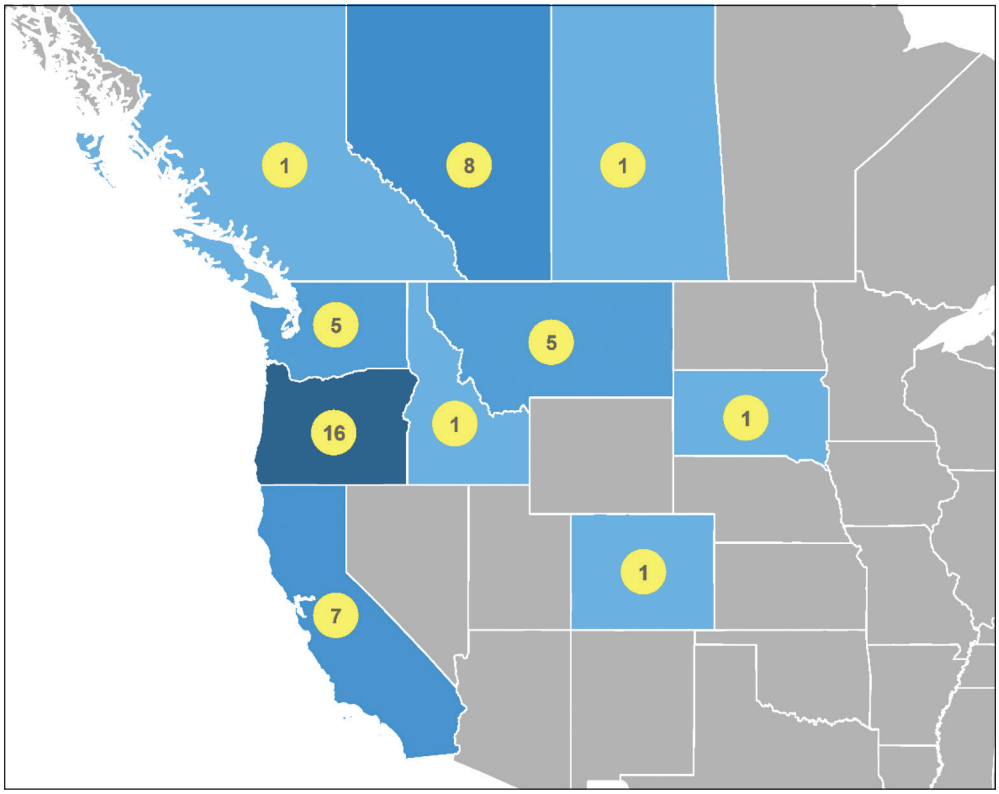

Figure 1—Salvage research locations by U.S. state and Canadian province in focus region. Most field sites featured in published studies between 2000 and 2018 were located in Oregon, particularly the Biscuit and Summit Fires.

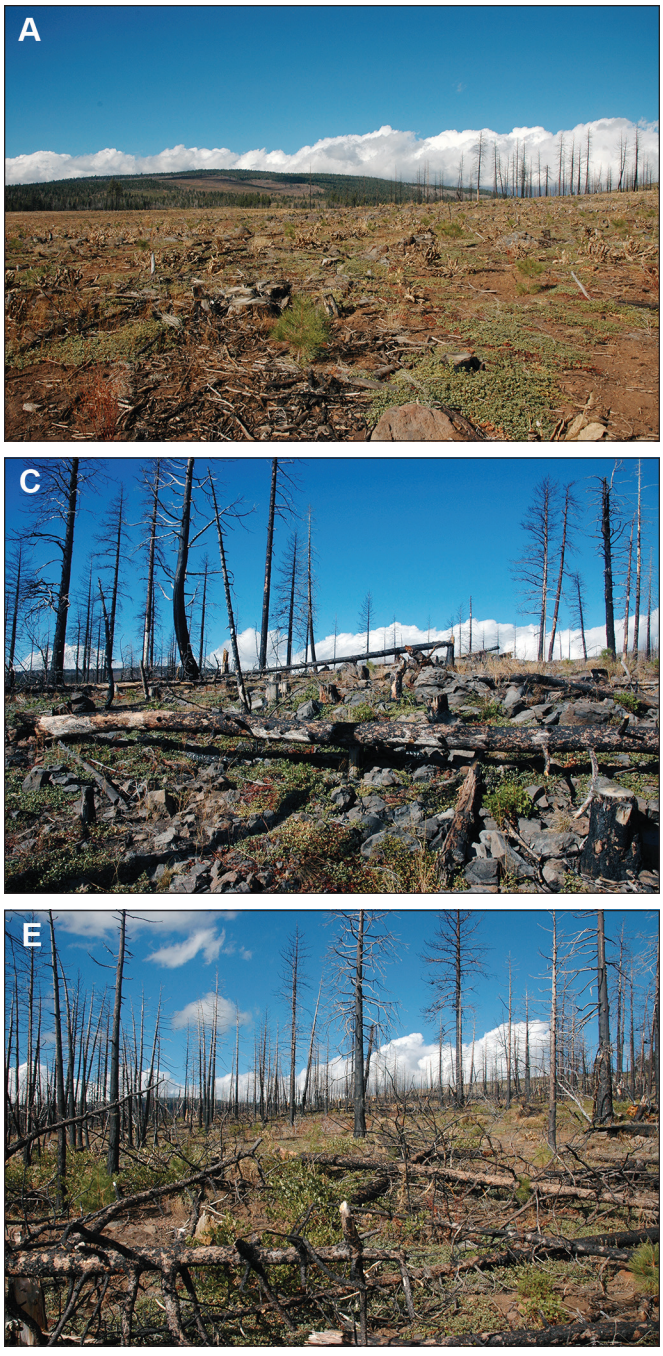

are limited by access to sites, communication with local managers, funding, and other logistical concerns when conducting field research, and these limitations are reflected in the number of fires that have received attention from scientists.

Another concern voiced by McIver and Starr (2000) is the frequent lack of unburned controls: this continues to be a common problem in salvage-logging research. Of the 43 studies reviewed here, only 14 (about a third) included unburned controls in their study design. This design shortcoming creates analytical problems for many studies. Many researchers were unable to tease out the confounding variables that affected their results. Often, the signal of a severe wildfire in the data overwhelmed the effect of postfire logging. In some cases, comparison with data from unburned controls may have aided in the clarification of these effects.

Typical of wildfire research, many of the studies reviewed here suffer from minimal knowledge of prefire conditions. Thus, confounding factors such as prefire vegetative characteristics are impossible to control in data analysis. Compounding these issues, many studies are short term in nature, which can lead to findings that are not representative of relevant ecological outcomes that occur over longer time scales. Researchers have begun to address these concerns by revisiting prior study sites, yielding valuable data on long-term trends. This practice should be continued and expanded to other previous research, as the information produced from long-term studies is critical to understanding the future trajectories of landscapes under differing management regimes and will be far more relevant to managers and policymakers.

Reducing Negative Effects of Postfire Logging

Although salvage logging is injurious to certain species guilds and habitat elements, steps can be taken to minimize these negative impacts in some situations (figs. 2 and 3). As suggested by McIver (2003), alterations to harvest methods (particularly type of equipment used and timing of operations) can substantially reduce soil disturbance and subsequent mortality of understory vegetation. Additionally, changing harvest prescriptions such that more of the large snags preferred by cavity-nesting birds remain on site may mitigate some of the effects of logging on these species, as well as provide for longevity of snag habitat (Hutto 2006, McIver and Ottmar 2007). These methods provide managers with avenues for reducing the negative effects of postfire logging, while maintaining a source of revenue for local timber economies affected by severe wildfire.

Figure 2—Photos of variable-retention salvage treatments from a multiyear study at the Blacks Mountain Experimental Forest, California, in fall 2006. Images were taken 4 years after the Cone Fire and 3 years after salvage operations: (A) 0 percent retention; (B) 25 percent; (C) 50 percent; (D) 75 percent; and (E) 100 percent.

D. Nemens, University of Washington

Figure 3—Fifteen years after the Storrie Fire, and 3 years after the Chips Fire, Lassen National Forest, California. The foreground shows an area where no action was taken, while postfire logging (on private timber holdings) is visible in the distance.

Directions for Future Research

Investigators in this field should consider the limitations of the current body of research and attempt to address these concerns in their work. Specifically, future research efforts should attempt to incorporate these elements:

1. Replicated study design using appropriate controls
2. Long-term experiments with repeated measurements
3. Expanded geographic diversity into understudied regions and ecosystems
4. Use of improved models, or seizing opportunities to directly measure fire behavior and severity
5. Integrated studies in which many variables are measured, in order to capture a more complete picture of impacts on the entire ecosystem.

Acknowledgments

Funding for this work was provided by the National Fire Plan. E. Knapp, D.W. Peterson, and J. Kane provided thoughtful comments and suggestions that improved the final version of this review.

Location: Davis Lake Fire, central Oregon.
Type of study: Observational.
Variables: Breeding bird population density, bat activity, and small mammal abundance.
Treatments: Burned/unlogged, burned/moderate salvage, burned/intensive salvage.
Results:

- Reducing the intensity of harvest did not reduce impacts to species that responded negatively to postfire logging.
- Small mammal populations did not demonstrate a response to harvest, or varied with harvest intensity.
- Negative effects of salvage logging on some bird species may be mitigated by maintaining islands of unlogged snags within larger harvest units.
- Bat activity was higher in open areas created by intensive salvage harvest.

Cahall, R.E.; Hayes, J.P. 2009. Influences of postfire salvage logging on forest birds in the eastern Cascades, Oregon, USA. Forest Ecology and Management. 257: 1119–1128.

Location: Davis Lake Fire, central Oregon.
Type of study: Observational.
Variables: Density and abundance of bird populations.
Treatments: Burned/unlogged, burned/moderate salvage, burned/intensive salvage.
Results:

- Reducing the intensity of harvest did not reduce impacts to species that responded negatively to postfire logging.
- Negative effects of salvage logging on some bird species may be mitigated by maintaining islands of unlogged snags within larger harvest units.

Keywords: Birds, fire, salvage logging, ponderosa pine–Douglas-fir forest.

Campbell, J.L.; Donato, D.C.; Fontaine, J.B. 2016. Effects of post-fire logging on fuel dynamics in a mixed-conifer forest, Oregon, USA: a 10-year assessment. International Journal of Wildland Fire. 25: 646–656.

Location: Biscuit Fire, southwest Oregon.
Type of study: Observational (remeasure).
Variables: Surface fuel mass, decay rates, shrub cover.
Treatments: Unburned control, burned/unlogged, burned/moderate logging, burned/heavy logging.
Results:

- Fine surface woody fuel loads were initially higher in salvaged stands, but loadings converged with unsalvaged stands within a decade.
- Snags decayed at a significant rate while standing, indicating that some surface fuels did not fall to the forest floor.
- Cover of resprouting shrubs was high 10 years following fire regardless of treatment, representing a high fire danger not mitigated by postfire harvest.

Keywords: Biomass, coarse woody debris, dead wood, decay, decomposition, fuel succession, Klamath-Siskiyou, salvage logging, snag, wildfire.

Clark, D.A.; Anthony, R.G.; Andrews, L.S. 2013. Relationship between wildfire, salvage logging, and occupancy of nesting territories by northern spotted owls. Journal of Wildlife Management. 77: 672–688.

Location: Timbered Rock, Biscuit, and Quartz Fires, southwest Oregon.
Type of study: Observational.
Variables: Site occupancy of northern spotted owls.
Treatments: Unburned, moderate burn/unlogged, high-severity burn/unlogged, high-severity burn/logged.
Results:

- Site occupancy of spotted owls showed short-term declines subsequent to wildfire, and postfire disturbance may have contributed to these declines.

Keywords: Colonization, extinction, northern spotted owl, occupancy, salvage logging, site occupancy, southwest Oregon, *Strix occidentalis caurina*, wildfire.

Cobb, T.P.; Hannam, K.D.; Kishchuk, B.E.; Langor, D.W.; Quideau, S.A.; Spence, J.R. 2010. Wood-feeding beetles and soil nutrient cycling in burned forests: implications of post-fire salvage logging. Agricultural and Forest Entomology. 12: 9–18.

Location: Chisholm Fire, Alberta, Canada.
Type of study: Observational.
Variables: Abundance of saproxylic beetles.
Treatments: Unburned, burned, unburned/logged, burned/logged.
Results:

- Beetles were not present in burned stands subjected to salvage logging.

Keywords: Beetle frass, boreal forest, coarse woody debris, IPDM, *Monochamus s. scutellatus* (Say), nitrogen cycling, saproxylic beetles, soil microbial activity, wildfire.

Donato, D.; Fontaine, J.B.; Campbell, J.; Robinson, W.; Kauffman, J.; Law, B.E. 2006. Post-wildfire logging hinders regeneration and increases fire risk. Science. 311(5759): 352.

Location: Biscuit Fire, southwest Oregon.
Type of study: Observational.
Variables: Surface fuel loads, tree regeneration density.
Treatments: Unburned, burned/unlogged, burned/logged.
Results:

- Salvage logging resulted in higher fine dead surface fuel loads than unlogged stands.
- Postfire tree regeneration was reduced by 71 percent in logged sites.
- Short-term fire risk was increased following salvage operations.

Donato, D.C.; Fontaine, J.B.; Kauffman, J.B.; Robinson, W.D.; Law, B.E. 2013. Fuel mass and forest structure following stand-replacement fire and post-fire logging in a mixed-evergreen forest. International Journal of Wildland Fire. 22: 652–666.

Location: Biscuit Fire, southwest Oregon.
Type of study: Observational.
Variables: Surface and aerial fuel mass, shrub cover.
Treatments: Burned/unlogged, burned/moderate, and burned/intensity harvest.
Results:

- Standing dead biomass was significantly reduced by salvage logging.
- Activity fuels remaining on site were greater following high-intensity (28 percent of felled material) than moderate intensity-harvest (14 percent of felled material).
- Cover of downed wood was three to five times greater in harvested stands.
- High-intensity salvage logging resulted in surface fuels that may require additional treatment to reduce fire risk.

Keywords: Biomass, Biscuit Fire, coarse woody debris, dead wood, fuel succession, Klamath–Siskiyou, legacy, logging intensity, postfire management, salvage logging, snag.

Dunn, C.J.; Bailey, J.D. 2015. Modeling the direct effects of salvage logging on long-term temporal fuel dynamics in dry-mixed conifer forests. Forest Ecology and Management. 341: 93–109.

Location: Multiple fires, central Oregon Cascade Range.
Type of study: Modelling.
Variables: Surface fuel loads, understory woody biomass.
Treatments: Burned/unlogged, burned/logged.
Results:

- In salvage harvest scenarios, fine woody fuel loads were greatest 17 to 18 years after high-severity fire.
- Postfire logging resulted in an increase in fine fuel loadings of 160 to 237 percent that persisted for 22 years after fire.
- 1,000-hr fuels loadings peaked 24 to 31 years following fire in untreated stands.
- 1,000-hr fuels were significantly reduced 7 years following postfire harvest.

Keywords: Fuel succession, reburn, salvage logging, hazardous fuels, snag dynamics, decomposition.

Emelko, M.B.; Silins, U.; Bladon, K.D.; Stone, M. 2011. Implications of land disturbance on drinking water treatability in a changing climate: demonstrating the need for "source water supply and protection" strategies. Water Research. 45: 461–472.

Location: Lost Creek Fire, Alberta, Canada.
Type of study: Observational.
Variables: Water quality.
Treatments: Unburned, burned, burned/logged.
Results:

- Wildfire and salvage logging contributed to increased turbidity and dissolved organic carbon in studied watersheds.
- Additional measures are needed to assure clean drinking water for downstream communities following large-scale wildfire.

Keywords: Source water supply and protection, treatability, adaptation, wildfire, climate change, integrated water management, drinking water treatment.

Location: Biscuit Fire, southwest Oregon.
Type of study: Observational.
Variables: Surface air temperature.
Treatments: Burned, burned/logged.
Results:

- Maximum daily surface air temperature was not affected by postfire logging.
- Salvage logging caused slight increase in nightly minimum temperatures and earlier daytime heating.

Gorton, S.; Kays, J. 1996. Legislative history of the timber and salvage amendments enacted in the 104th Congress: a small victory for timber communities in the Pacific Northwest. Environmental Law. 26: 641.

Haggard, M.; Gaines, W.L. 2001. Effects of stand-replacement fire and salvage logging on a cavity-nesting bird community in eastern Cascades, Washington. Northwest Science. 75: 387–396.

Location: Rat Creek Fire, Washington.
Type of study: Observational.
Variables: Abundance, species richness, and nesting populations of cavity-nesting birds.
Treatments: Burned/low, burned/medium, and burned/high-intensity salvage.
Results:

- Medium-intensity salvage sites had highest bird abundance, richness, and nesting population of the three treatments.
- Large-diameter snags (>48 cm) provided nesting habitat for greater number of bird species.

Hanson, J.J.; Stuart, J.D. 2005. Vegetation responses to natural and salvage logged fire edges in Douglas-fir/hardwood forests. Forest Ecology and Management. 214: 266–278.

Location: northwestern California.
Type of study: Observational.
Variables: Understory species composition and structure.
Treatments: Unburned, burned, burned/logged.
Results:

- Salvage logging resulted in significant changes to plant community along forest edges.
- Edge effects on intact forest patches were greater on salvaged sites than unsalvaged ones

Keywords: Edge effects, edge, fire, salvage logging, understory, old-growth, Douglas-fir.

Hebblewhite, M.; Munro, R.H.; Merrill, E.H. 2009. Trophic consequences of postfire logging in a wolf–ungulate system. Forest Ecology and Management. 257(3): 1053–1062.

Location: Alberta, Canada.
Type of study: Observational.
Variables: Forage (understory) biomass, spatial distribution of wolves and ungulate prey.
Treatments: Burned, burned/logged postfire, burned/logged prefire.
Results:

- Reductions in herbaceous biomass in logged units immediately post-harvest dissipated by the third year of the study.
- Elk avoided logged areas, despite increased forage abundance.
- Wolves selected open sites near roads and logged areas, increasing predation risk, and influencing elk movement and resource use.
- Postfire logging caused a top-down increase in predation risk for elk, affecting trophic interactions between elk and wolves.

Keywords: Edge effects, edge, fire, salvage logging, understory, old-growth, Douglas-fir.

Hutto, R.L. 2006. Toward meaningful snag-management guidelines for postfire salvage logging in North American conifer forests. Conservation Biology. 20: 984–993.

Hutto, R.L.; Gallo, S.M. 2006. The effects of postfire salvage logging on cavity-nesting birds. The Condor. 108: 817–831.

Location: Blackfoot-Clearwater Wildlife Management Area, Montana.
Type of study: Observational.
Variables: Nest abundance and density of cavity-nesting birds.
Treatments: Burned, burned/logged.
Results:

- Nest density was lower in sites subjected to postfire harvest.
- Sites which were unlogged had higher bird species richness.
- 50 percent of studied species were more abundant in unharvested areas.
- Six postfire specialist bird species were absent from logged sites.
- Nest abundance may be dependent on available foraging habitat.

Keywords: Black-backed woodpecker, cavity-nesting birds, fire, healthy forests, salvage logging.

Jennings, T.N.; Smith, J.E.; Cromack, K.; Sulzman, E.W.; McKay, D.; Caldwell, B.A.; Beldin, S.I. 2012. Impact of postfire logging on soil bacterial and fungal communities and soil biogeochemistry in a mixed-conifer forest in central Oregon. Plant and Soil. 350: 393–411.

Location: B&B Fire, central Oregon.
Type of study: Observational.
Variables: Soil nutrients, microbial and fungal species richness and community composition.
Treatments: Unburned, burned, burned/logged.
Results:

- Soil compaction resulting from postfire timber harvest decreased plant-available nitrogen.
- Subsoiling following harvest-related compaction decreased plant-available phosphorus.
- Bacterial and fungal richness did not vary between treatments.

Keywords: Soil microbial and fungal communities, nutrient cycling.

Johnson, E.A.; Miyanishi, K. 2008. Testing the assumptions of chronosequences in succession. Ecology Letters. 11: 419–431.

Keyser, T.L.; Smith, F.W.; Shepperd, W.D. 2009. Short-term impact of post-fire salvage logging on regeneration, hazardous fuel accumulation, and understory development in ponderosa pine forests of the Black Hills, SD, USA. International Journal of Wildland Fire. 18: 451–458.

Location: Jasper Fire, South Dakota.
Type of study: Observational.
Variables: Surface fuel loading, understory cover, tree regeneration density.
Treatments: Burned, burned/logged.
Results:

- Fine and coarse woody debris were greatly increased in unharvested sites.
- Tree regeneration was reduced by 75 percent in salvage-logged sites because of low seed-tree retention.
- Understory vegetation did not vary between treatments.

Keywords: Exotic species, fuel load, mixed-severity, *Pinus ponderosa*, wildfire.

Kishchuk, B.; Thiffault, E.; Lorente, M.; Quideau, S.; Keddy, T.; Sidders, D. 2014. Decadal soil and stand response to fire, harvest, and salvage-logging disturbances in the western boreal mixed-wood forest of Alberta, Canada. Canadian Journal of Forest Research. 45: 141–152.

Location: Chisholm Fire, Alberta, Canada.
Type of study: Observational.
Variables: Soil nutrients, forest floor properties, foliar nutrition, understory.
Treatments: Unburned, burned, unburned clearcut, burned/logged.
Results:

- Postfire logging caused changes in soil nutrition that remain evident 10 years after harvest.
- After 10 years, forest floor properties were comparable between harvested and control sites.
- Soil and foliar nutritional differences did not affect regeneration vigor.

Keywords: Compound disturbance, salvage logging, soil carbon, soil nutrients, boreal plains ecozone, boreal mixed-wood forest.

Knapp, E.E.; Ritchie, M.W. 2016. Response of understory vegetation to salvage logging following a high-severity wildfire. Ecosphere. 7(11): e01550. https://doi.org/10.1002/ecs2.1550.

Location: Cone Fire, California.
Type of study: Replicated experiment.
Variables: Understory species richness and cover.
Treatments: Burned/logged at five levels of intensity (control to 100 percent removal)
Results:

- Postfire logging at highest intensity significantly reduced shrub cover.
- Salvage intensity did not affect understory plant species richness.
- Factors unrelated to postfire logging may have a stronger influence on changes in postfire plant communities.

Keywords: High-severity wildfire, nonnative species, *Pinus ponderosa*, postfire management, salvage logging, species diversity, species richness, variable-retention salvage.

Kronland, W.J.; Restani, M. 2012. Effects of post-fire salvage logging on cavity-nesting birds and small mammals in southeastern Montana. Canadian Field-Naturalist. 125: 316–326.

Location: Kraft Springs, Montana.
Type of study: Observational.
Variables: Density of small mammals and cavity-nesting birds.
Treatments: Burned, burned/logged.
Results:

- Deer mouse density showed a positive relationship with postfire harvest.
- Postfire logging resulted in lower densities of cavity-nesting birds, particularly hairy woodpeckers.

Keywords: Cavity-nesting birds, downed woody debris, forest management, nest survival, salvage logging, wildfire, hairy woodpecker, *Picoides villosus*, deer mouse, *Peromyscus maniculatus*, Custer National Forest, Montana.

Kurulok, S.E.; Macdonald, S.E. 2007. Impacts of postfire salvage logging on understory plant communities of the boreal mixedwood forest 2 and 34 years after disturbance. Canadian Journal of Forest Research. 37: 2637–2651.

Location: Various fires, Alberta, Canada.
Type of study: Observational.
Variables: Understory species composition, shrub abundance.
Treatments: Burned, burned/logged.
Results:

- Salvage logging increased species richness, presence of weedy species, and shrub abundance, and reduced fire specialists in the short term.
- Older salvaged stands showed minimal effects of logging.

Lee, D.E.; Bond, M.L.; Borchert, M.I.; Tanner, R. 2013. Influence of fire and salvage logging on site occupancy of spotted owls in the San Bernardino and San Jacinto Mountains of southern California. Journal of Wildlife Management. 77: 1327–1341.

Location: Various fires, California.
Type of study: Observational.
Variables: Owl extinction and colonization probabilities.
Treatments: Unburned, burned, burned/logged.
Results:

- Effects of salvage logging on occupancy dynamics were not statistically significant, but may be biologically meaningful.
- A slight decrease in the probability of owl occupancy was observed in burned sites that were subsequently logged.

Keywords: California spotted owl, fire severity, forest structure, occupancy modeling, population dynamics, *Strix occidentalis*.

Macdonald, S.E. 2007. Effects of partial post-fire salvage harvesting on vegetation communities in the boreal mixedwood forest region of northeastern Alberta, Canada. Forest Ecology and Management. 239: 21–31.

Location: House River Fire, Alberta, Canada.
Type of study: Replicated experiment.
Variables: Understory species richness and composition; tree regeneration.
Treatments: Burned, burned/single-tree retention harvest, burned/patch retention harvest.
Results:

- Aspen regeneration was greater in harvested stands.
- Understory species richness and diversity were unaffected by salvage.

- Salvage logging affected plant community composition, but prefire composition and burn severity may have greater effects.
- Variation in harvest intensity had little effect on variables studied.

Keywords: Boreal forest, mixed wood forest, vascular plants, richness, composition, fire, salvage logging, salvage harvest.

McGinnis, T.W.; Keeley, J.E.; Stephens, S.L.; Roller, G.B. 2010. Fuel buildup and potential fire behavior after stand-replacing fires, logging fire-killed trees and herbicide shrub removal in Sierra Nevada forests. Forest Ecology and Management. 260: 22–35.

Location: McNally, Star, Cleveland and Stanislaus Fires, California.
Type of study: Observational.
Variables: Surface fuel loading, understory species richness and cover.
Treatments: Burned, burned/logged, burned/herbicide treatment.
Results:

- Short-term fuel loading was greater in logged stands.
- Modelling did not predict differences in fire behavior between logged and control stands.
- Postfire salvage did not affect understory cover or species richness.

Keywords: Salvage logging, conifer plantations, fuel, fire behavior, cheatgrass.

McIver, J.D. 2003. Sediment transport and soil disturbance after postfire logging. Hydrological Science and Technology. 19: 335–348.

McIver, J.D.; McNeil, R. 2006. Soil disturbance and hill-slope sediment transport after logging of a severely burned site in northeastern Oregon. Western Journal of Applied Forestry. 21: 123–133.

Location: Summit Fire, Oregon.
Type of study: Replicated experiment.
Variables: Soil disturbance, sediment transportation.
Treatments: Burned, burned/partial harvest, burned/full harvest.
Results:

- Soil compaction, displacement, and erosion were greater in harvested stands.
- Sediment transport out of salvaged units was minimal.
- Favorable site conditions and logging practices designed to reduce soil impacts likely limited effects of postfire harvest.

McIver, J.D.; Ottmar, R. 2007. Fuel mass and stand structure after post-fire logging of a severely burned ponderosa pine forest in northeastern Oregon. Forest Ecology and Management. 238: 268–279.

Location: Summit Fire, Oregon.
Type of study: Replicated experiment.
Variables: Surface fuel loading.
Treatments: Burned, burned/logged commercial, burned/fuel reduction.
Results:

- Ladder tree height and tree species composition were not affected by logging.
- Surface fuel mass was greatest in fuel reduction stands, particularly in slash component.
- Modelling of fuel bed predicted a 15-year duration of dissimilarity in slash fuels.
- Projections of 1,000-hr fuel dynamics predicted heavier accumulations in unlogged stands.
- Fire effects models did not predict a difference in tree mortality between treatments, partly because of reliance on flame length as cause of tree death.

Keywords: Salvage logging, reburn hypothesis, restoration.

McIver, J.D.; Ottmar, R. 2018. Fuel mass and stand structure 13 years after logging of a severely burned ponderosa pine forest in northeastern Oregon, U.S.A. Forest Ecology and Management. 424: 505–518.

Location: Summit Fire, Oregon.
Type of study: Replicated experiment.
Variables: Surface fuel loading, tree regeneration.
Treatments: Burned, burned/logged commercial, burned/fuel reduction.
Results:

- 13 years after harvest, discrepancies in slash fuel loading dissipated.
- Logged stands continued to lack snags and coarse woody debris after 13 years.
- Regeneration density was highly variable, but higher on average in unlogged stands.

Keywords: Salvage logging, postfire logging, reburn hypothesis, restoration logging, disturbance, wildfire.

McIver, J.D.; Starr, L. 2000. Environmental effects of postfire logging: literature review and annotated bibliography. Gen. Tech. Rep. PNW-GTR-486. Portland, OR: U.S. Department of Agriculture, Forest Service, Pacific Northwest Research Station. 72 p.

Morgan, P.; Moy, M.; Droske, C.A.; Lewis, S.A.; Lentile, L.B.; Robichaud, P.R.; Hudak, A.T.; Williams, C.J. 2015. Vegetation response to burn severity, native grass seeding, and salvage logging. Fire Ecology. 11(2): 32–58. doi: 10.4996/fireecology.1102031.

Location: School Fire, Washington.
Type of study: Observational.
Variables: Understory species richness and abundance.
Treatments: Unburned, burned/logged, burned/seeded, burned/seeded/logged; replicated with three burn-severity classes.
Results:

- Species richness and diversity were reduced by salvage logging.
- Burn severity and postfire seeding had a greater effect on vegetation response than logging.
- Differences between treatments were initially substantial, but declined after 6 years.

Keywords: Fire effects, mixed-conifer forests, plant succession, post-fire rehabilitation, salvage logging.

Morissette, J.; Cobb, T.; Brigham, R.; James, P. 2002. The response of boreal forest songbird communities to fire and post-fire harvesting. Canadian Journal of Forest Research. 32: 2169–2183.

Location: Hawk Fire, Saskatchewan, Canada.
Type of study: Observational.
Variables: Songbird abundance, species richness and diversity.
Treatments: Unburned, burned, burned/logged.
Results:

- Songbird community composition was distinct in all three treatments.
- Differences in bird species assemblage were greatest between burned

and salvaged sites.
- Generalists and species associated with open habitats were more abundant in logged areas.
- Cavity and canopy nesters, insectivores, and resident species abundance were negatively affected by salvage logging.
- Postfire salvage may be a greater disturbance to songbird communities than fire.

Newton, M.; Fitzgerald, S.; Rose, R.R.; Adams, P.W.; Tesch, S.D.; Sessions, J.; Atzet, T.; Powers, R.F.; Skinner, C. 2006. Comment on "Post-wildfire logging hinders regeneration and increases fire risk." Science. 313: 615–615.

Peterson, D.L.; Agee, J.K.; Aplet, G.H.; Dykstra, D.P.; Graham, R.T.; Lehmkuhl, J.F.; Pilliod, D.S.; Potts, D.F.; Powers, R.F.; Stuart, J.D. 2009. Peterson, D.W.; Dodson, E.K. 2016. Post-fire logging produces minimal persistent impacts on understory vegetation in northeastern Oregon, USA. Forest Ecology and Management. 370: 56–64.

Location: Summit Fire, Oregon.
Type of study: Replicated experiment.
Variables: Understory plant cover, species richness, diversity, community composition.
Treatments: Burned, burned/logged commercial, burned/logged fuel reduction.
Results:
- No significant effect of postfire logging was observed 15 years following treatments.
- Understory species appear resilient to disturbance.
- Low-impact harvest methods may have minimized negative effects on understory.

Keywords: Postfire logging, salvage logging, understory vegetation, species richness, biodiversity, postfire forest management.

Peterson, D.W.; Dodson, E.K.; Harrod, R.J. 2015. Post-fire logging reduces surface woody fuels up to four decades following wildfire. Forest Ecology and Management. 338: 84–91.

Location: Various fires, Oregon and Washington.
Type of study: Observational.
Variables: Surface fuel loading.
Treatments: Burned, burned/logged.
Results:

- Postfire logging created a temporary pulse of increased fine and medium fuels that lasted 5 to 7 years following harvest.
- In the long term, all woody fuel loadings were lower in salvage-logged stands.
- Coarse woody fuels were reduced by logging for nearly 40 years.

Keywords: Ponderosa pine, Douglas-fir, post-fire logging, salvage logging, fuel succession, forest restoration.

Poirier, V.; Paré, D.; Boiffin, J.; Munson, A.D. 2014. Combined influence of fire and salvage logging on carbon and nitrogen storage in boreal forest soil profiles. Forest Ecology and Management. 326: 133–141.

Location: Various fires, Quebec, Canada.
Type of study: Observational.
Variables: Soil organic carbon (SOC), total soil nitrogen (N), soil structure.
Treatments: Unburned, burned, burned/logged.
Results:

- SOC was lower in organic layer in logged stands compared with burned only.
- Logging increased SOC and N in mineral horizons.
- Whole-soil SOC and N stocks of burned soils were unchanged by salvage logging.

Keywords: Soil organic carbon, total soil nitrogen, soil horizons, wildfire, salvage logging, black spruce forest.

Powers, E.M.; Marshall, J.D.; Zhang, J.; Wei, L. 2013. Post-fire management regimes affect carbon sequestration and storage in a Sierra Nevada mixed conifer forest. Forest Ecology and Management. 291: 268–277.

Location: Storrie Fire, California.
Type of study: Observational.
Variables: Carbon storage and sequestration.
Treatments: Low-severity burn, burned, burned/logged/planted, burned/logged/planted/intensive management.

Results:

- Postfire salvage logging reduced total ecosystem carbon storage.
- Belowground carbon storage in mineral soil was lowest in intensively managed treatment.
- Total carbon sequestration did not vary significantly among treatments.

Keywords: Carbon flux, carbon storage, forest management, fire, climate change.

Ritchie, M.W.; Knapp. E.E. 2014. Establishment of a long-term fire salvage study in an interior ponderosa pine forest. Journal of Forestry. 112: 395–400.

Location: Cone Fire, California.
Type of study: Replicated experiment.
Variables: Snag dynamics, surface fuel loading, tree regeneration.
Treatments: Burned/logged at five levels of intensity, including unlogged control.
Results:

- Transition of snags to surface fuels was rapid.
- Stands with higher snag retention levels (basal area > 60 ft²/acre) exceeded historical surface fuel loads after 10 years.
- White fir and incense-cedar snags had greater longevity than pine snags.
- Regeneration was minimal, and seedling density appeared unrelated to treatment.

Keywords: Snag dynamics, biomass, regeneration.

Ritchie, M.W.; Knapp, E.E.; Skinner, C.N. 2013. Snag longevity and surface fuel accumulation following post-fire logging in a ponderosa pine dominated forest. Forest Ecology and Management. 287: 113–122.

Location: Cone Fire, California.
Type of study: Replicated experiment.
Variables: Snag dynamics, surface fuel loading.
Treatments: burned/logged at five levels of intensity, including unlogged control.
Results:

- Fuel loading of coarse materials increased with snag retention level.
- Greatest loading of 1,000-hr fuels occurred in control units.
- More than 80 percent retained snag biomass had transitioned to surface fuel by year 8.
- Pine snags were more susceptible to breakage and decay than white fir or incense-cedar.

Keywords: Coarse woody debris, snag dynamics, salvage logging.

Rost, J.; Hutto, R.L.; Brotons, L.; Pons, P. 2013. Comparing the effect of salvage logging on birds in the Mediterranean Basin and the Rocky Mountains: common patterns, different conservation implications. Biological Conservation. 158: 7–13.

Location: Various fires, Montana and Catalonia, Spain.
Type of study: Observational.
Variables: Species richness and abundance of birds.
Treatments: Burned, burned/logged.
Results:

- Species that are dependent on snags were negatively affected by salvage logging.
- Logging had positive effect on open-habitat species in Mediterranean sites.

Keywords: Catalonia, conifer forests, fire specialists, forest management, Montana, wood harvesting.

Rothermel, R. 1972. A mathematical model for predicting fire spread in wildland fuels. Res. Pap. INT-115. Ogden, UT: U.S. Department of Agriculture, Forest Service, Intermountain Forest and Range Experiment Station. 40 p.

Saab, V.A.; Russell, R.E.; Dudley, J.G. 2007. Nest densities of cavity-nesting birds in relation to postfire salvage logging and time since wildfire. The Condor. 109: 97–108.

Location: Foothills Fire and Star Gulch Fire, Idaho.
Type of study: Observational.
Variables: Nest density and success of open space and cavity-nesting (bark-foraging) birds.
Treatments: Burned, burned/partially logged.
Results:

- Nest densities of cavity nesting (bark foraging) were higher in unlogged than logged burn.
- Logged burn had higher nest density of two open-space-foraging species vs. unlogged burn.
- Mountain bluebird nest density was higher in unlogged than logged burn, while western bluebirds did not show an effect of treatment.
- Hairy woodpecker nest survival was reduced in logged burn vs. unlogged during early postfire period.

Keywords: Cavity-nesting birds, nest densities, nest survival, ponderosa pine forests, postfire salvage logging, wildfire.

Silins, U.; Bladon, K.D.; Kelly, E.N.; Esch, E.; Spence, J.R.; Stone, M.; Emelko, M.B.; Boon, S.; Wagner, M.J.; Williams, C.H. 2014. Five-year legacy of wildfire and salvage logging impacts on nutrient runoff and aquatic plant, invertebrate, and fish productivity. Ecohydrology. 7: 1508–1523.

Location: Lost Creek Fire, Alberta, Canada.
Type of study: Observational.
Variables: Water chemistry, algal production.
Treatments: Unburned, burned, burned/logged.
Results:

- Phosphorous concentrations were highest in logged watersheds.
- Although wildfire had a greater effect on measured variables, salvage logging added incremental impacts.
- Wildfire and salvage logging caused a cascading series of effects on the ecohydrology of studied watersheds.

Keywords: Forest fire, natural disturbance, hydrologic recovery, stream ecology, phosphorus, sediment, algae macroinvertebrates.

Slesak, R.A.; Schoenholtz, S.H.; Evans, D. 2015. Hillslope erosion two and three years after wildfire, skyline salvage logging, and site preparation in southern Oregon, USA. Forest Ecology and Management. 342: 1–7.

Location: Timbered Rock Fire, Oregon.
Type of study: Observational.
Variables: Sediment transport, vegetative cover.
Treatments: Burned, burned/logged.
Results:

- Erosion was more pronounced in salvage-logged sites in year following harvest.
- In second year, no differences in erosion were detected.
- As little soil disturbance was observed, increased erosion in harvested sites was most likely due to vegetation control prior to replanting salvaged areas.

Keywords: Vegetation control, plot scale measurements, postfire erosion, Pacific Northwest.

Thompson, J.R.; Spies, T.A.; Ganio, L.M. 2007. Reburn severity in managed and unmanaged vegetation in a large wildfire. Proceedings of the National Academy of Sciences of the United States of America. 104: 10743–10748.

Location: Biscuit Fire and Silver Fire, Oregon.
Type of study: Observational.
Variables: Burn severity (differenced normalized burn ratio (dNBR) from remote sensing data).
Treatments: Burned, burned/logged/planted, replicated across continuous dNBR indices of burn severity of both fires.
Results:

- Sites that burned at high severity in Silver Fire tended to burn again at high severity in Biscuit Fire.
- Harvest of fire-killed trees reduced large fuels but did not decrease reburn severity.
- Replanting of conifers in harvested areas may have increased burn severity in salvaged-logged stands.

Keywords: Public land management, salvage logging, Biscuit Fire, landsat, landscape ecology.

Thorn, S.; Bässler, C.; Brandl, R.; Burton, P.J.; Cahall, R.; Campbell, J.L.; Castro, J.; Choi, C.-Y.; Cobb, T.; Donato, D.C.; Durska, E.; Fontaine, J.B.; Gauthier, S.; Hebert, C.; Hothorn, T.; Hutto, R.L.; Lee, E.-J.; Leverkus, A.B.; Lindenmayer, D.B.; Obrist, M.K.; Rost, J.; Seibold, S.; Seidl, R.; Thom, D.; Waldron, K.; Wermelinger, B.; Winter, M.-B.; Zmihorski, M.; Müller, J. 2018. Impacts of salvage logging on biodiversity: a meta-analysis. Journal of Applied Ecology. 55: 279–289.

Location: Various fires, worldwide.
Type of study: Meta-analysis.
Variables: Species richness and community composition of 24 taxonomic groups.
Treatments: Disturbed, disturbed/logged (including fire).
Results:

- Salvage logging negatively affected richness in eight taxonomic groups.
- Post-disturbance harvest had disproportionally negative impacts on saproxylic organisms.
- Species that use open habitats had generally positive responses to logging.

Keywords: Bark beetle, climate change, dead wood, disturbed forest, fire, natural disturbance, post-disturbance logging, salvage logging, saproxylic taxa, windstorm.

Wagenbrenner, J.W.; MacDonald, L.H.; Coats, R.N.; Robichaud, P.R.; Brown R.E. 2015. Effects of post-fire salvage logging and a skid trail treatment on ground cover, soils, and sediment production in the interior western United States. Forest Ecology and Management. 335: 176–193.

Location: Tripod, Kraft Springs, Red Eagle, and Hayman Fires, Washington, Montana, and Colorado.
Type of study: Observational.
Variables: Ground cover, soil disturbance, runoff, sediment production.
Treatments: Burned, burned/logged replicated across various harvest methods.
Results:

- Soil compaction increased in salvage-logged sites.
- Harvested stands in areas with greater disturbance produced more sediment.
- Vegetative cover was negatively associated with salvage, and vegetation recovery was delayed in these sites.
- Sediment production did not increase with logging in larger swales.
- Treatment of skid trails with logging slash resulted in decreased sediment yields but did not affect soil properties.

Keywords: Erosion, wildfire, water repellency, soil compaction, salvage logging, mitigation.

Wagenbrenner, J.W.; Robichaud, P.R.; Brown, R.E. 2016. Rill erosion in burned and salvage logged western montane forests: effects of logging equipment type, traffic level, and slash treatment. Journal of Hydrology. 541: 889–901.

Location: Red Eagle, School, and Terrace Mountain Fires, Montana, Washington, and British Columbia, Canada.
Type of study: Observational.
Variables: Vegetative cover, runoff, sediment production, soil disturbance.
Treatments: Burned, burned/logged, replicated across various harvest methods.
Results:

- Erosion was more pronounced in logged stands, but effects diminished over time.
- Runoff rates were higher in logged sites.
- Equipment used for harvest did not have measureable effects.
- Using logging slash to cover skid trails did not affect runoff or sedimentation.

Keywords: Salvage logging, wildfire, runoff, soil compaction, soil water repellency, sediment.

The Ecology and Management of Moist Mixed-Conifer Forests in Eastern Oregon and Washington: a Synthesis of the Relevant Biophysical Science and Implications for Future Land Management

Peter Stine, Paul Hessburg, Thomas Spies, Marc Kramer, Christopher J. Fettig, Andrew Hansen, John Lehmkuhl, Kevin O'Hara, Karl Polivka, Peter Singleton, Susan Charnley, Andrew Merschel, and Rachel White

Forest Service
Pacific Northwest Research Station
General Technical Report PNW-GTR-897
September 2014

The **Forest Service** of the U.S. Department of Agriculture is dedicated to the principle of multiple use management of the Nation's forest resources for sustained yields of wood, water, forage, wildlife, and recreation. Through forestry research, cooperation with the States and private forest owners, and management of the National Forests and National Grasslands, it strives—as directed by Congress—to provide increasingly greater service to a growing Nation.

The U.S. Department of Agriculture (USDA) prohibits discrimination in all its programs and activities on the basis of race, color, national origin, sex, religion, age, disability, sexual orientation, marital status, family status, status as a parent (in education and training programs and activities), because all or part of an individual's income is derived from any public assistance program, or retaliation. (Not all prohibited bases apply to all programs or activities.)

If you require this information in alternative format (Braille, large print, audiotape, etc.), contact the USDA's TARGET Center at (202) 720-2600 (Voice or TDD).

If you require information about this program, activity, or facility in a language other than English, contact the agency office responsible for the program or activity, or any USDA office.

To file a complaint alleging discrimination, write USDA, Director, Office of Civil Rights, 1400 Independence Avenue, S.W., Washington, D.C. 20250-9410, or call toll free, (866) 632-9992 (Voice). TDD users can contact USDA through local relay or the Federal relay at (800) 877-8339 (TDD) or (866) 377-8642 (relay voice users). You may use USDA Program Discrimination Complaint Forms AD-3027 or AD-3027s (Spanish) which can be found at: http://www.ascr.usda.gov/complaint_filing_cust.html or upon request from a local Forest Service office. USDA is an equal opportunity provider and employer.

Abstract

Stine, Peter; Hessburg, Paul; Spies, Thomas; Kramer, Marc; Fettig, Christopher J.; Hansen, Andrew; Lehmkuhl, John; O'Hara, Kevin; Polivka, Karl; Singleton, Peter; Charnley, Susan; Merschel, Andrew; White, Rachel. 2014. The ecology and management of moist mixed-conifer forests in eastern Oregon and Washington: a synthesis of the relevant biophysical science and implications for future land management. Gen. Tech. Rep. PNW-GTR-897. Portland, OR: U.S. Department of Agriculture, Forest Service, Pacific Northwest Research Station. 254 p.

Land managers in the Pacific Northwest have reported a need for updated scientific information on the ecology and management of mixed-conifer forests east of the Cascade Range in Oregon and Washington. Of particular concern are the moist mixed-conifer forests, which have become drought-stressed and vulnerable to high-severity fire after decades of human disturbances and climate warming. This synthesis responds to this need. We present a compilation of existing research across multiple natural resource issues, including disturbance regimes, the legacy effects of past management actions, wildlife habitat, watershed health, restoration concepts from a landscape perspective, and social and policy concerns. We provide considerations for management, while also emphasizing the importance of local knowledge when applying this information at the local and regional level.

Keywords: Disturbance ecology, landscape restoration, land management, resilience, stewardship.

Executive Summary

One priority of the USDA Forest Service is to restore resiliency to forest and range ecosystems, enabling them to cope with an uncertain future.

Millions of hectares of Western forests have been negatively affected by drought and by insect and disease outbreaks, and are overloaded with fuel, priming them for unusually severe and extensive wildfires. In light of these trends, public support for forest restoration has grown. One priority of the USDA Forest Service is to restore resiliency to forest and range ecosystems, enabling them to cope with an uncertain future. Natural resource managers and policymakers are awash in information from a growing body of science, with little time to sort through it, let alone assimilate the many different sources and interpretations of the best available science.

Regional research and management executives requested a review of the large body of scientific information on eastside moist mixed-conifer (MMC) forests within the context of the broader forest landscape in eastern Oregon and Washington. This focus was motivated by a lack of up-to-date management guidelines, scientific synthesis, and consensus among stakeholders about management direction in the diverse MMC type.

Understanding complex ecological and social processes and functions across landscapes requires an integrated assessment that combines multiple scientific disciplines across spatial and temporal scales. Accordingly, this synthesis compiles existing research, makes connections across disparate sources, and addresses multilayered natural resource issues. It has been prepared to assist land managers in updating existing management plans and on-the-ground projects that are intended to promote resilience in MMC forests and riparian areas. We consider management flexibility at the local scale critically important for contending with specific legacy effects of management and the substantial ecological variation in MMC forest conditions, as well as for adapting management to local social and policy concerns.

Our hope is that this synthesis will serve as a reference that provides a condensed and integrated understanding of the current state of knowledge regarding MMC forests, as well as an extensive list of published sources where readers can find further information. We also hope to enhance cross-disciplinary communication and enrich dialogue among Forest Service researchers, managers, and external stakeholders as we address common restoration concerns and management challenges for MMC forests in eastern Oregon and Washington.

Key sections of this synthesis include:

- A description of MMC forests and their context in the broader landscape of eastern Oregon and Washington.
- Key concepts of restoration and the landscape perspective.
- A comprehensive summary of pre-Euro-American settlement conditions in MMC forests.

- A description of the socioeconomic context in the region.
- A summary of human impacts on MMC forests.
- Broad management implications of research findings.
- A practical list of management considerations for diagnosing restoration needs and designing landscape approaches.

Moist Mixed-Conifer Forests

Mixed-conifer forests are a major component of the dry-to-wet conifer forest complex that is widely distributed across eastern Oregon and Washington. Among other factors, these forests are important for carbon sequestration, watershed protection, terrestrial and aquatic wildlife habitat, and outdoor recreation, and they provide economic opportunities through provisioning of a wide variety of forest products. MMC forests cover a large area east of the crest of the Cascade Range in Oregon and Washington, where grand fir, white fir, and Douglas-fir are the dominant late-successional tree species. MMC forests can be considered intermediate between drier conifer forests where pine was historically dominant and fire was typically frequent and low in severity, and wetter or cooler mixed-conifer forests where fire was less frequent and burned at higher severities. The MMC forest type is in a central position along a complex moisture, composition, and disturbance gradient of conifer forests in this region. This forest type is diverse and difficult to define, but potential vegetation types and current conditions can be used to help identify places where stands and landscapes need restoration. Historically, the forest landscape (from dry to wet) was a mosaic driven by variation in climate, soils, topography, and low- to mixed- and occasional high-severity fire.

Decades of wildfire suppression and exclusion, domestic livestock grazing, and selective and clearcut timber harvesting have interacted to alter the structure, composition, and disturbance regimes of these forests. MMC forests have become denser, have lost large individuals of fire-resistant tree species, and, on many sites, have become dominated by dense patches of shade-tolerant tree species that are less resistant to fire and less resilient to drought. These vegetation changes and management activities have shifted fire regimes toward less frequent, but larger and more severe fires, which tend to simplify the landscape into fewer, larger, and less diverse patches resulting in more homogenous conditions. Currently, many mixed-conifer forests are denser and more uniform in structure, and contain more live and dead fuel than they did historically. But the relative effects of human-caused changes, like fire suppression and timber harvesting, on these forests differ widely across the region. Thus, it is important to develop local, first-hand knowledge of the historical and contemporary disturbance regimes of these forests.

Key Management Considerations

As we reviewed the scientific literature, our primary objective was to synthesize the large body of information into succinct findings that are supported by credible research and relevant to practitioners and others interested in management of MMC forests. Some of our findings are that:

- **Historical range of variation (HRV) is useful as a guide but not as a target.** Returning to it is no longer feasible or practical in some places because of changing climate, land use, and altered forest structure and composition. The contemporary concept of restoration goes beyond the oft-stated goal of reestablishing ranges of resource conditions that existed at some time in the past (e.g., prior to Euro-American settlement). Our ecological process-oriented approach supports restoration of conditions that may have occurred in the past under certain circumstances. However, the objective of ecological restoration is to create a resilient and sustainable forest under current and future conditions. It must be forward looking. Managers have some capacity to influence the future range of variability (FRV) to achieve desired future ecosystem conditions for a landscape.
- **Disturbance regimes have been significantly altered after 150 years of Euro-American land use.** Wildfires (along with insects, pathogens, and weather) were the dominant disturbance process shaping historical forest structure and composition. Low-, mixed-, and high-severity fires occurred in MMC forests, varying in size and occurrence across ecoregions. Small and medium fires were the most numerous, but large fires accounted for the majority of the area burned. Forests today neither resemble nor function as they did 150 years ago.
- **Moist mixed-conifer forests are more vulnerable to large, high-severity fire and insect outbreaks.** Widespread anthropogenic changes have created more homogenized conditions in this forest type, generally in the form of large, dense, and multilayered patches of fire-intolerant tree species. These changes have substantially altered the resilience mechanisms associated with MMC forests.
- **Patterns of vegetation structure and composition in an eastside forest landscape shaped by intact disturbance regimes are diverse and differ over space and time.** Resilience in these forests depends on this ecological heterogeneity. Euro-American settlement and early management practices put these landscapes on new and rapidly accelerating trajectories of change

in vegetation composition and structure. Despite the change and variability, topography, soils, and elevation constrain these vegetation patterns and provide a template for understanding and managing landscape patterns. For example, south-facing aspects and ridges tended to burn more often and less severely than north-facing aspects and valleys. Landscape restoration strategies can capitalize on these tendencies.

- Several wildlife species of conservation concern require structural complexity typical of mature and old forests, which are currently limited or at risk. With no action, maintaining adequate area and spatial patterns of old-forest habitats will be a challenge with the anticipated increases in severe fire and insect infestations expected in response to changed forest conditions and climate change. Restoration at a landscape scale will encounter challenges in retaining existing old-forest patches while transitioning to a more heterogeneous and resilient forest condition.
- Community-based collaborative groups can facilitate restoration in east-side national forests. One of the major constraints to increasing the pace and scale of restoration treatments on lands administered by the National Forest System (NFS) in eastern Oregon has been the lack of social agreement about how to achieve it. The Forest Service promotes collaboration as a means for helping diverse stakeholder groups come together and find an agreeable path forward. The creation of local groups and the Forest Service's Collaborative Forest Landscape Restoration Program both offer innovations and demonstrate opportunities to improve capacity for restoration through collaborative processes.

Potential Applications

In the midst of complicated social and political forces, forest managers make decisions that require the application of complex scientific concepts to project-specific conditions. Decisions often must balance risks (e.g., elimination of fuels hazards vs. preservation of old-forest conditions) while acknowledging and allowing for uncertainties. Decisionmakers also must weigh tradeoffs associated with alternative courses of action to obtain multiple-use policy and land management objectives. We acknowledge this difficult task and the concurrent need to have access to and thoughtfully apply the best available scientific information.

It is not the role of the research community to direct management decisions. However, synthesis of research, identification of core scientific findings, and discernment of management implications in specific contexts are appropriate roles.

Research also has a role of working alongside managers to learn from successes and failures. We provide considerations for management and emphasize that their application to local and regional landscapes requires the skill and knowledge of practitioners to determine how best to apply them to a local situation with its particular management history. Legacy effects do matter, and one size does not fit all.

In chapter 5, we synthesize principle findings gleaned from the body of scientific literature (summarized in chapter 4) as they pertain to management of MMC forests. These constitute the "take-home" messages that are intended to assist land managers in the execution of their work.

The social agreement and institutional capacity for restoring MMC forests is every bit as important as the scientific foundation for doing so. The ability to institute the kinds of changes managers will consider is directly a function of the capacity of the larger community to form working partnerships and a common vision.

Some of the potential changes in forest management evoked within this document represent a departure from "business as usual." Land managers will decide how to proceed, and this will depend in large part on budget, policy, local circumstances, and ultimately the judgment of line officers. However, there are some ideas and observations from past work, both research and management, that suggest the need for some prudent adjustments in management approach.

Chapter 1—Introduction

> There is and always will be uncertainty and unpredictability in managed ecosystems, both as humans experience new situations and as these systems change because of management.
>
> Surprises are inevitable. Active learning is the way in which this uncertainty is winnowed. Adaptive management acknowledges that policies must satisfy social objectives but also must be continually modified and be flexible for adaptation to these surprises. Adaptive management therefore views policies as hypotheses—that is; most policies are really questions masquerading as answers. Since policies are questions, then management actions become treatments in the experimental sense. The process of adaptive management includes highlighting uncertainties, developing and evaluating hypotheses around a set of desired system outcomes, and structuring actions to evaluate or "test" these ideas.
>
> —Lance Gunderson (2000), *Annual Review of Ecology and Systematics*

Purpose and Scope of This Synthesis

Fire-prone mixed-conifer forests east of the crest of the Cascade Range in Oregon and Washington (hereafter, "the east side") provide clean water, recreation, wildlife habitat, and many other important ecosystem goods and services (fig. 1). However, over the last century, many of these forests have become denser and less resilient to disturbance as a result of human activity, altered disturbance regimes, and climate warming. In the last few decades, many of these forests have also become further drought stressed and increasingly vulnerable to high-severity fire (Westerling et al. 2006) and insect outbreaks as a result of climate change (Preisler et al. 2012).

In the Pacific Northwest, research and management executives from the USDA Forest Service recently highlighted the need to update management guidance, scientific synthesis, and consensus among stakeholders regarding these challenges. This synthesis responds to this need. In particular, executives asked us to focus on eastside moist mixed-conifer (MMC) forests (see definition in chapter 2), within the context of the broader forest landscape on the east side. We have written this synthesis for a diverse audience of forest planners, managers, and engaged citizens.

For this effort, we convened a team of government and university scientists to review the literature, synthesize knowledge and management options, and compile a bibliography. Team members were selected based on their experience and expertise, spanning a range of disciplines including aquatic ecology and fish biology, climate change, disturbance ecology, fire and forest ecology, landscape ecology, silviculture, social science, and wildlife biology.

John Marshall

Figure 1—A moist mixed-conifer forest, Glass Creek Watershed, Okanogan-Wenatchee National Forest, eastern Washington.

We focused the synthesis on the ecology of MMC forests but acknowledge that decisionmakers must address major issues surrounding the needs and values of human communities, so these decision processes are addressed as well. The forests of the east side represent complex patchworks of temperature, moisture, productivity, climate, and disturbance regimes, and their associated forest types (fig. 2), so we occasionally discuss forest types that adjoin the MMC type to improve overall context. The synthesis specifically addresses:

- Vegetation, landscape, and disturbance ecology.
- Wildlife habitats and populations; and aquatic ecosystems and associated species.
- Landscape approaches and perspectives.
- Silvicultural approaches.
- Climate change influences and climate futures.

Research findings summarized here can make a valuable contribution to restorative management, but it will be up to managers and program leaders to consider the unique ecological conditions of each landscape and to determine how this information guides specific land management decisions. To that end, findings here are intended to conceptually frame—not prescribe—land management. Such guidance is available in the new Forest Service Planning Rule (36 CFR Part 219), an important new administrative rule that applies current science to planning and

We consider management flexibility at the local site level critically important for contending with specific legacy effects of management and the substantial ecological variation in moist mixed-conifer forest conditions, as well as for adapting management to local policy concerns.

management. We consider management flexibility at the local site level critically important for contending with specific legacy effects of management and the substantial ecological variation in MMC forest conditions, as well as for adapting management to local policy concerns.

In related dry mixed-conifer and ponderosa pine (*Pinus ponderosa* Lawson & C. Lawson) forest types, research and social license to begin restoration is relatively more advanced (e.g., see Franklin et al. 2013, Jain et al. 2012), and managers are proceeding with restoration treatments (e.g., see Hessburg et al. 2013, OWNF 2012). However, we include the pine and dry mixed-conifer types in our discussions because these dry and MMC types are entwined spatially and ecologically in eastern Oregon and Washington.

Current Management Context and Restoration Mandate

Federal and state forest managers are charged with maintaining and restoring diverse, resilient (see "Glossary"), and productive forests in these fire-prone landscapes. Restoration can increase the resilience of eastside MMC forests, and reduce the ecological costs of high-severity wildfire and economic costs of fire suppression activities and postfire rehabilitation, along with the ecological and socioeconomic threats to adjoining state, private, and tribal lands. But achieving these goals is challenging without sufficient investment. Twentieth-century harvesting of large trees has reduced commercial operability in many eastside forests (e.g., see Rainville et al. 2008), and the value of remaining commercial products is often insufficient to cover the costs of restoration.

Developing and implementing sound management strategies requires up-to-date knowledge of biological and physical processes that regulate forest ecosystem structure and function. We also require information on how humans have modified these processes, especially disturbance processes, which are a key to sculpting habitat and structural patterns (e.g., see Spies 1998). In this context, a number of factors are particularly relevant to eastside MMC forests:

- The processes and patterns of eastside forests have been altered over the past 100 to 150 years (depending upon location) by the combined cumulative effects of mining, livestock grazing, road and railroad construction, conversion of grasslands and shrublands to agriculture, timber harvesting, fire suppression and exclusion, urban and rural development, invasions of alien plant and animal species (including pathogens, insects, and aquatic organisms), expanding infestations of native diseases and insects, and anthropogenically induced climate change.

- In many areas (e.g., those not burned in recent decades), today's dry and MMC forests are denser, have more small trees and fewer large fire-tolerant trees, and are dominated by shade-tolerant and fire-intolerant tree species. These conditions have reduced the fire and drought tolerance of these forests. Large increases in surface and canopy fuel loads are widespread, resulting in greater risk of large and often severe wildfires, especially during extreme fire weather conditions. Furthermore, high stand densities increase competition for growing space among trees, thereby reducing the amount of water and nutrients available to individual trees and increasing their susceptibility to some insect and disease disturbances. These changes threaten the long-term sustainability of dry and MMC forests in general, and in particular the long-term survival of remaining large and very large trees that persist in overcrowded conditions.
- Climate change is already transforming forests in eastern Oregon and Washington because it is linked to ongoing drought as well as elevated levels of tree mortality attributed to insects, diseases, and wildfire. This transformation is occurring at a brisk pace, and the window of opportunity for effecting change in this trajectory is relatively short (likely a few decades).

Mandated conservation of threatened or endangered species, some of which have been threatened by landscape alterations (first bullet above), has added ecological and regulatory complexity to forest management. For example, in the eastern Cascades, restoration of dry and MMC forests, fire regimes, and fuel patterns is often constrained by the need to minimize disturbance in areas around active nest locations of the northern spotted owl (NSO) (*Strix occidentalis caurina*), to conserve its dense, late-successional and old-forest nesting, roosting, and foraging habitats.

Currently, many landscapes of the east side have late-successional forest patterns that are out of sync with past and current fire regimes and are ecologically unsuited to providing large contiguous areas of late-successional habitat over time. In addition, much of the structural diversity in those stands is relatively short-lived because of the dominance of shade-tolerant tree species. Conservation of habitat for old forest species including NSO, northern goshawk (*Accipiter gentilis*), and pileated woodpecker (*Dryocopus pileatus*) needs to address the sustainability and continuous recruitment of that habitat. The revised recovery plan for the NSO (USFWS 2011) has called for an active management approach for sustaining and recruiting old forest habitats in fire-prone forests of eastern Washington and Oregon. Similar considerations are also an issue for species outside of the range of the NSO, particularly northern goshawks and pileated woodpeckers.

Forest environments throughout the east side are ecologically and physiographically variable: rates of change in forest conditions and effects of historical influences vary with forest type, cultural geography, and physiographic region. Although broad-scale direction can have value at times, one-size-fits-all solutions generally will not work. Instead, considerations of local conditions, land use histories, and biophysical and landuse classifications can help address this variability.

Managers report that maps of forest types across the east side are inconsistent in their classifications of vegetation associations. This creates a significant challenge for managing that vegetation for myriad uses and habitats. Managers also lack adequately detailed characterizations of how each forest type has been affected by natural, human, and climatic influences.

The relative merits of active versus passive management of forests to achieve ecological and socioeconomic goals are subject to fierce debate, which is driven by wide-ranging and often competing or conflicting societal values and is not likely to subside. Many citizens have expectations for sustainable delivery of ecosystem services from forests on public lands. Delivery is confounded by uncertainties regarding the long- versus short-term effects of various management practices on goods, services, and values.

In the Western United States, Forest Service priorities focus on restoring ecosystems, managing wildland fires, and strengthening communities while providing jobs (Chief of the Forest Service address to the Pinchot Institute, 2013). Restoration on public lands[1] implies reenabling forests and grasslands and their associated species to adequately cope with increased climate-related stresses, and enhancing their recovery from climate-related disturbances, while continuing delivery of forest-derived values, goods, and services to citizens. **A central purpose of restoration then is to reestablish the adaptive and resilient capacities of landscapes and ecosystems in each unique physiographic region. A second, related purpose is to restore the adaptive capacity and social resilience of associated human communities, while restoring ecological systems.** The first purpose is served by restoring ecological patterns and processes that are in synchrony with the biota, geology, and climate. The second is served by enabling human communities to derive benefit from forest goods and services while conducting restoration and maintenance activities.

A central purpose of restoration is to reestablish the adaptive and resilient capacities of landscapes and ecosystems in each unique physiographic region.

[1] The USDA Forest Service has defined restoration as "the process of assisting the recovery of an ecosystem that has been degraded, damaged, or destroyed. Ecological restoration focuses on reestablishing the composition, structure, pattern, and ecological processes necessary to facilitate terrestrial and aquatic ecosystem sustainability, resilience, and health under current and future conditions" (USDA FS 2013).

The concept of restoration includes, but is larger than, the goal of reestablishing the historical range of variability (HRV). A process-oriented approach supports restoring ranges of conditions that have occurred in the past (e.g., eradicating invasive species and reconnecting fragmented habitats of threatened or endangered species), in environments where the future climate will strongly resemble the recent climate, and where the results are socially understood and acceptable. Where the future climate is not expected to resemble the recent climate, the objective of ecological restoration would be to create resilient forests and rangelands that are adapted to the future climate. This idea is captured in the related notion of future range of variability, or FRV, as coined by several authors (Binkley and Duncan 2010, Hessburg et al. 2013, Keane et al. 2009, Moritz et al. 2011, Weins et al. 2012). In addition to being forward-looking, contemporary concepts of ecological restoration may emphasize social context and the connectivity and interactions among people, societies, and the biophysical elements of ecosystems. For some landscapes, it will simply be impossible and inadvisable to return them to prior conditions (Harris et al. 2006), while for others it may be well advised.

To effectively implement restoration goals across eastside mixed-conifer forests, managers can consider applying already completed assessments of conditions across the eastside landscape (e.g., the Interior Columbia Basin Ecosystem Management Project and Eastside Forest Ecosystem Health assessments), perhaps expanding on them, and then prioritizing the location and nature of treatments that would be most beneficial to ecosystems and to people. This will involve both regional and local landscape assessment.

In some places, there may be a need to increase the pace and scale of restoration to address a variety of immediate threats—including fire, climate change, bark beetle infestations, and others—for the health of public forest ecosystems, watersheds, and natural-resource-dependent communities. However, for these efforts to be sustainable, both ecological and socioeconomic vantage points would be best considered in the context of regional and local landscape patterns and processes, because in the long run the natural system must support the social system.

Structure of This Report—Where to Find Sections of Interest

Overview of contents—This report progresses from a review of the relevant science to a presentation of management considerations.

Chapter 2 discusses how MMC types fit within a regional coniferous mosaic. In this chapter, the reader will understand our definition of MMC forests, what forest types are typically included within this classification, and generally where they are located.

Chapter 3 presents ecological concepts that are foundational to landscape restoration.

Chapter 4 explains and summarizes the detailed scientific information that constitutes our synthesis. We provide a large number of citations to guide the reader through the scientific literature. Major findings are also summarized in chapter 4. Appendix 3 is provided to complement chapters 4 and 5.

Chapter 5 is the core of this report, in which the reader will find relevant management concepts gleaned from the scientific literature. We also provide a list of considerations that can help guide a landscape evaluation process. This list arises from recent experiences of eastside land managers who have adopted a landscape perspective and are conducting landscape evaluations. Silvicultural options and innovations are discussed as they relate to landscape prescriptions and their component stand-level prescriptions. We also present ideas about adjustments that may help increase institutional capacity to implement the ideas contained in this report. We close this section with an overview of the socioeconomic conditions that underlie most land management decisions.

Chapter 6 provides a brief discussion of the important institutional considerations that influence how these concepts might be implemented. This chapter also presents a summary discussion on the socioeconomic issues that are clearly in the foreground of any management strategy that seeks to restore lands and resources.

Chapter 7 provides brief conclusions and summary thoughts about how our findings may be incorporated into land management and project-level plans.

Chapter 2—Definition of Moist Mixed-Conifer Forests and the Regional Context

Moist mixed-conifer (MMC) forests are diverse and cover a large area east of the crest of the Cascade Range in Oregon and Washington, where grand fir (*Abies grandis* (Douglas ex D. Don) Lindl.), white fir (*Abies concolor* (Gord. & Glend.) Lindl. ex Hildebr.), and Douglas-fir (*Pseudotsuga menziesii* (Mirb.) Franco) are the potential late-successional (climax) tree species (fig. 3). These forests grow in environments that are subsets of the white fir–grand fir and Douglas-fir "series," broad potential vegetation types used by Forest Service managers (Powell et al. 2007, Simpson 2007) to characterize the land's general ecological and vegetative capability.

Depending upon the environment and local site climate, patches of MMC forest typically occur where the current vegetation (not necessarily the same as potential natural vegetation or the vegetation that would develop under historical fire regimes) is a mixture of shade-intolerant ponderosa pine (*Pinus ponderosa*

Tom Spies

Figure 3—A mixed-conifer forest with overstory of ponderosa pine and patchy understory of post-1900 grand fir on the Sisters Ranger District, Deschutes National Forest, central Oregon.

Lawson & C. Lawson) or western larch (*Larix occidentalis* Nutt.), and shade-tolerant Douglas-fir, white or grand fir, and occasionally Engelmann spruce (*Picea engelmannii* Parry ex Engelm.), as in the moist grand fir zone of the Blue Mountains (Powell 2007). In areas of complex, dissected topography, the MMC forest intermingles with ponderosa pine and dry mixed-conifer types and wetter or cooler conifer types (fig. 4) (Powell et al. 2007, Simpson 2007). Other conifers occasionally associated with MMC forest include lodgepole pine (*Pinus contorta* Douglas ex Loudon), western white pine (*Pinus* monticola Douglas ex D. Don), sugar pine (*Pinus lambertiana* Douglas), Shasta red fir (*Abies magnifica* A. Murray bis), Pacific silver fir (*Abies* amabilis (Douglas ex Loudon) Douglas ex Forbes), and western hemlock (*Tsuga heterophylla* (Raf.) Sarg.). Dry ponderosa pine and dry mixed-conifer conditions tend to occupy lower montane settings, ridgetops, and southern exposures, whereas MMC conditions typically occur in mid to upper montane settings; on northerly and sometimes southerly aspects, especially in the upper elevations; in valley bottoms; and in lower headwall positions.

The focus of this report is not so much about forests of a particular moisture class, but mixed-conifer forests where fire exclusion has altered forest composition, structure, and function from their historical range of variability. Wetter mixed-conifer forests with longer fire return intervals may also have restoration needs, but these typically are not associated with changed fire regimes and thus are not examined in this report. The historical vegetation of MMC forest was controlled by frequent to moderately frequent fires (<20 to 50 years) that burned with mixed severity, containing both low- and high-severity patches. In most parts of the MMC forest, this fire frequency has been suspended, and disturbance regimes have been altered through a combination of historical drivers including grazing, loss of Native American fire ignitions, and active fire suppression. Consequently, the current MMC forest vegetation contains a significantly greater component of shade-tolerant tree species (e.g., white or grand fir or understory Douglas-fir) than occurred in the historical vegetation. Under historical or more fire- and drought-resilient states, these shade-tolerant species would have been less common in the understory in many areas, and large fire-resilient ponderosa pine, Douglas-fir, and western larch would have dominated the canopy layer. See appendix 3 for additional information about the variety of historical forest conditions that occurred in the Blue Mountains forest province early in the 20th century. Data are adapted from the Interior Columbia Basin Assessment (Hessburg et al. 1999a, 2000a).

Dry mixed-conifer and ponderosa pine sites (ponderosa pine series, or drier grand-fir/white or Douglas-fir subseries) typically experienced frequent fire return intervals (10 to 25 years), and exhibited a relatively open forest structure. Wetter

Miles Hemstrom

Figure 4—Dry mixed-conifer and pine-oak, grading into moist mixed-conifer in a drainage, Columbia River Gorge, near Rowena, Oregon.

and cooler mixed-conifer sites experienced longer fire return intervals (>50 years), and greater frequency of higher severity fire, and would have had a component of older shade-tolerant trees in the overstory, with dense areas of multistoried forest. Because few detailed fire history studies exist for the mixed-conifer forest in general, we use potential vegetation types (PVTs, see discussion below) as a surrogate for the fire regime and the degree to which mixed-conifer forests have departed in terms of composition and structure. These potential natural vegetation types, which include both series and approximations of subseries (e.g., dry, dry-moist, moist, and moist to wet variants of grand, white, and Douglas-fir series) can be a starting place for identifying the environments and locations of MMC forest (table 1). The PVTs used by managers (e.g., series, subseries, and plant associations) are often the best available source of local information, but are only an approximate surrogate for the fire regime of a site or local landscape. Figure 5 illustrates the continuum of forest types found along an elevational gradient on the east side of the Cascade Range and the relationship of forest type to general fire regimes.

Table 1—Area of major forest potential vegetation types in eastern Oregon and Washington

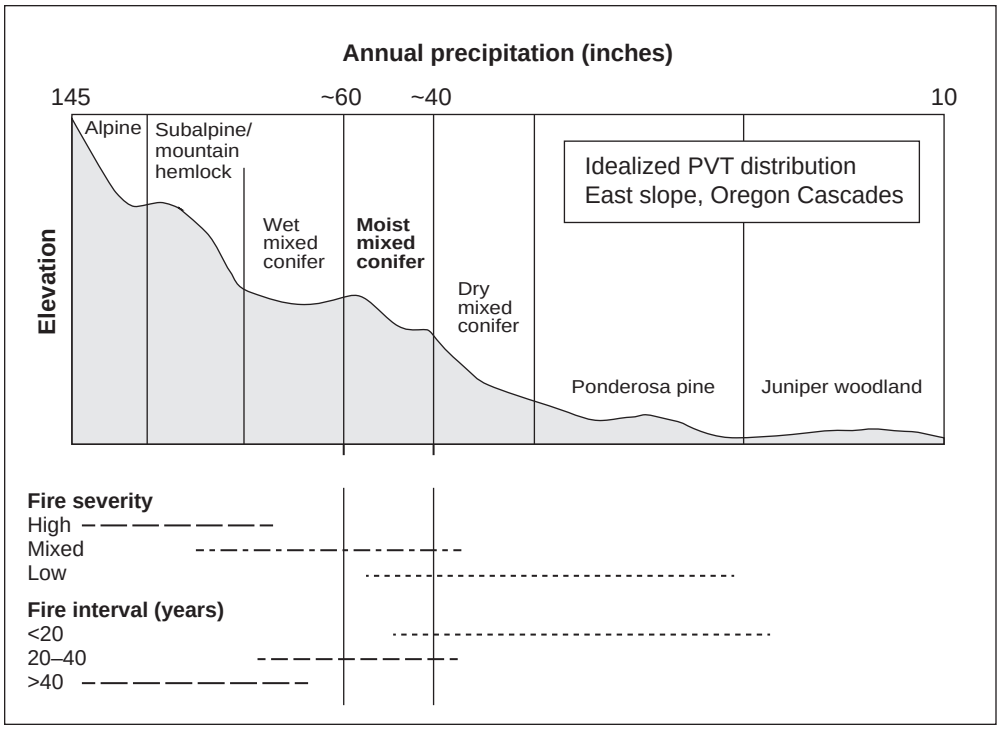

Figure 5—Continuum of forest types found along an elevational gradient on the east side of the Cascade Range and the relationship of forest type to general fire regimes. PVT = potential vegetation type.

Variation in slope, topographic position, and landscape context can create a high degree of variation in fire regimes within the same PVT. For example, for a given PVT, areas with steep or concave slopes often experience more high-severity fire than gentler and more convex slopes. Likewise, MMC PVT patches embedded within large dry forest patches or adjacent to grass or shrub patches may experience a higher fire frequency than they would if they were embedded in MMC forest. Context matters, and is critical to interpreting the native fire regime. Final determination of MMC forest for restoration purposes should be based on landscape context, local environment, and disturbance history. Figure 6 provides a conceptual model of the complex ecological setting in which we find MMC forests. There are many biological and physical conditions that will influence what kind of vegetation is found at a site.

Variation in slope, topographic position, and landscape context can create a high degree of variation in fire regimes within the same potential vegetation type.

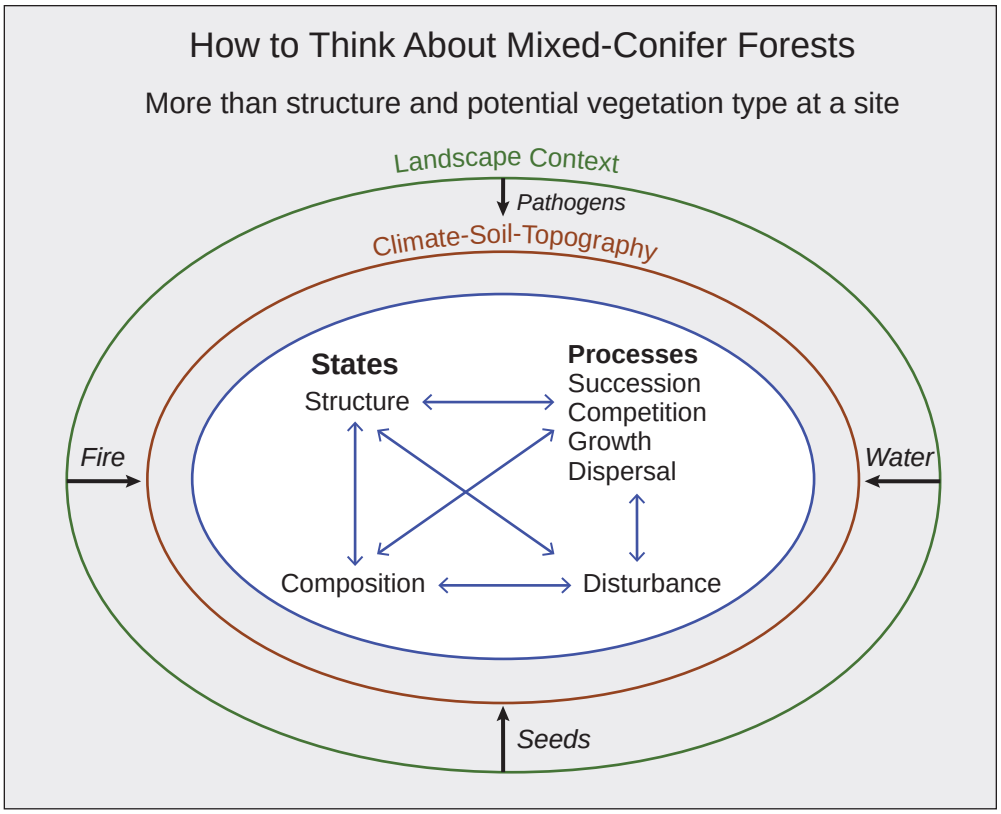

Figure 6—Conceptual model of the complex ecological setting of moist mixed-conifer forests.

The MMC type is widely distributed across the east side (fig. 7) occupying particular environments and elevations along the east slope of the Cascade Range and large patches within the northern and central portions of the Blue Mountains. It often is sandwiched between the drier mixed-conifer and pine types and cooler and wetter mixed-conifer types. Figure 7 is intended to give a general depiction of the distribution of MMC forest. No standard, peer-reviewed maps of dry, moist, or wet PVTs exist for the entire region. See "Ecological Composition, Patterns, and Processes Prior to Euro-American Settlement (Before About 1850)" in chapter 4 for more details on sources of regional information and details on vegetation in general.

Chapter 3—Ecological Principles of Restoration and Landscapes

Restoration of ecological processes and patterns requires a multi-scale spatial and temporal perspective. Historically, the forests in eastern Oregon and Washington were diverse and complex in their species composition and structure (e.g., tree sizes, ages, density, layering, clumpiness). These patterns influenced the frequency, severity, and spatial extent of native insect, disease, wildfire, and abiotic disturbance processes such that signature "disturbance regimes" were apparent. However, a century or more of management has significantly altered patterns of structure and composition, and as a direct consequence, the associated disturbance regimes are highly altered as well. Figure 8 illustrates the large disparity in historical vs. current species composition and structure of forests in eastern Oregon and Washington.

Moist mixed-conifer (MMC) forests were and continue to be hierarchically structured systems with complex interactions between spatial scales. Part of what concerns us today is uncertainty driven by these cross-scale disturbance interactions. For example, very large wildfires, insect outbreaks, and changes in winter

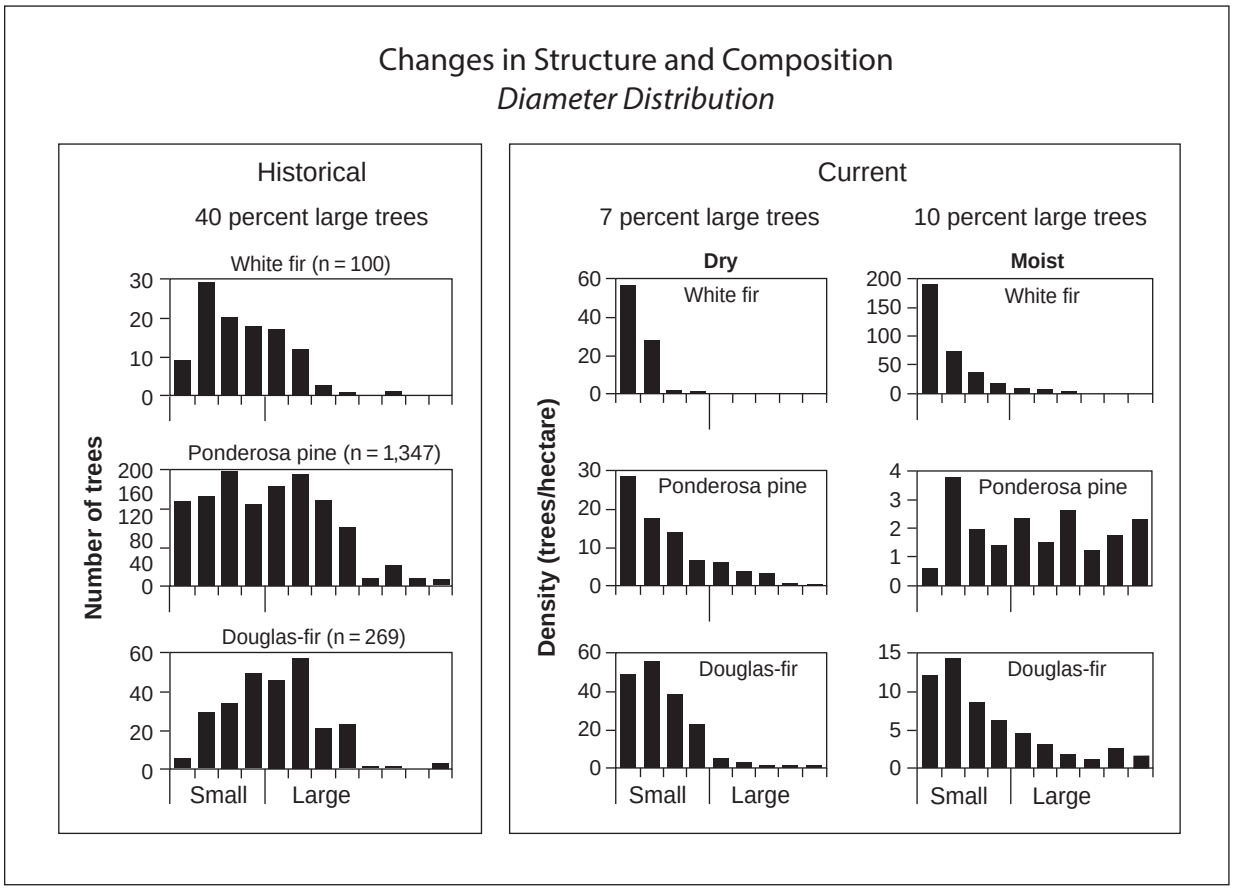

Figure 8—Disparity in historical vs. current species composition and structure of forests in eastern Oregon and Washington.

snowpack and hydrology occurring at a regional scale threaten to alter meso-scale patterns and disturbance processes of local landscapes. Simply working at meso-scale (local landscapes, e.g., watersheds and subwatersheds) does not address these concerns. The answer lies in regional- or ecoregional-scale solutions.

At a meso-scale, patterns of forest structure and composition emerge, which are primarily maintained by interactions among environments, topography, weather, soils, geomorphology, and disturbances. But other broader and finer scale patterns also exist, and these are also influential to maintaining and changing meso-scale vegetation patterns over space and through time.

Forest ecosystem responses to disturbances or weather changes are often nonlinear, or involve complex feedback loops or time lags, particularly when we allow for longer observation periods.

Forest ecosystem responses to disturbances or weather changes are often nonlinear, or involve complex feedback loops or time lags, particularly when we allow for longer observation periods. Thus, some interactions are relatively more unpredictable and may not manifest in any sort of change in the short term, until some kind of threshold is reached (Malamud et al 1998, Moritz et al. 2013, Peterson 2002). The challenge for scientists and managers seeking to restore landscape resilience is to develop a better understanding of ecological complexity that can more readily be translated into practical strategies for restoration.

Our review of recent theory, observation, and understanding in the field of landscape ecology shows it is critical to consider long-term spatial and temporal phenomena prior to drawing conclusions or developing simplified decision rules based solely on temporally short or narrow geographic observation windows.

The Concept of Resilience

The concept of resilience promises a robust alternative to management goals based on static conditions or simple applications of the historical range of variability.

The resilience of current and future forest ecosystems is a major concern of land managers today. The concept of resilience promises a robust alternative to management goals based on static conditions or simple applications of the historical range of variability (HRV). However, resilience is not an easily defined concept in a practical sense (Gunderson 2000). Furthermore, operational metrics of resilience have received little attention to date (Carpenter et al. 2001). To become more operational, resilience must be defined in terms of specific system attributes and in relation to specific disturbances or perturbations. It is important to understand that resilience is a relative term and is constrained by space and especially time. Eventually change will be significant enough that a previously resilient system will reset itself into a new state. Thus, some bounding of space and time is necessary to define resilient states.

Folke (2006) and Gunderson (2000) have identified three conceptual domains of resilience: (1) engineering resilience, which focuses on recovery or return time to a stable equilibrium (e.g., return to a particular forest structure or composition); (2) ecological resilience, which focuses on maintaining function and persistence with multiple equilibria (e.g., HRV); and (3) socioecological resilience, which focuses on reorganization, adaptive capacity, and multiscale interactions among the many community members, stakeholders, and responsible government organizations that have an interest in the outcome of land management. Although we focus mainly on ecological resilience in this report, we acknowledge that the ecological system is imbedded in a socioeconomic system that interacts with ecological systems.

The degree of alteration of an ecosystem and its dynamics (patterns of change over time and space) must be understood before we can consider if and how the system can be restored (fig. 9).

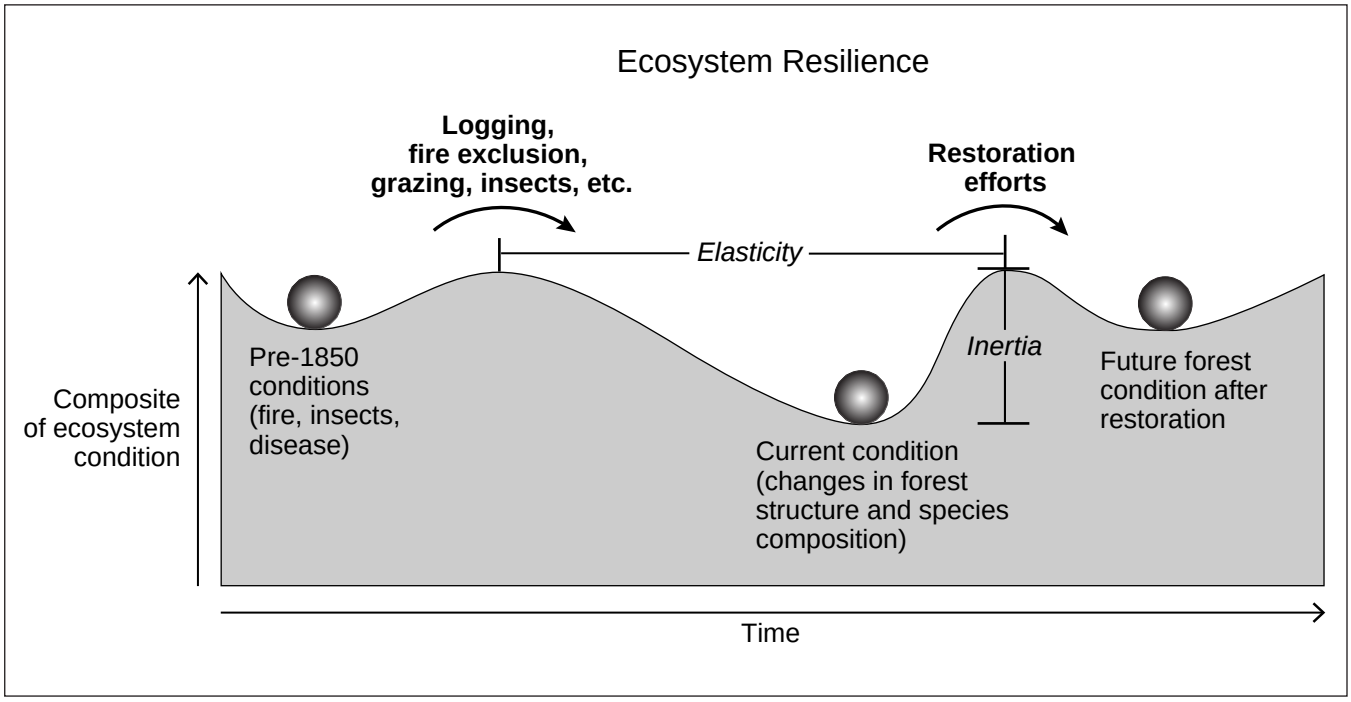

Figure 9—Ball and cup heuristic of ecosystem stability (adapted from Gunderson 2000). Valleys represent the boundaries in which ecosystems are coping with disturbances, balls represent the ecosystem, and arrows represent disturbances. Some disturbances push the system out of a past "stable" state into a different ecosystem condition. The influences of inertia and elasticity are indicated in the diagram.

Westman (1978) suggested five characteristics that depict the potential resilience of a system:

Inertia: The resistance of a system to disturbance.

Elasticity: The speed with which a system returns after disturbance.

Amplitude: A measure of how far a system can be moved from a previous state and still return.

Hysteresis: The lagging of an effect behind its cause, such as delayed response of the system to a disturbance.

Malleability: The difference between the pre- and postdisturbance conditions. The greater or lesser the malleability, the lesser or greater will be the system's resilience.

These technical terms from systems analysis illustrate the complexity of system responses to change and the challenge of restoring dynamic systems. The characteristics of resilience described here are not all measured with equal ease; some may simply be immeasurable in a short period because of a lack of historical data or reliable ecosystem models (Westman 1978). Given these limitations on data availability and the overall understanding of ecosystem interactions, we are reminded of a compelling need to employ an adaptive management approach in both research and monitoring, where we can track the results of management efforts and follow disturbances and recovery efforts over a long term. This would give managers the ability to inform subsequent management decisions with what was learned from previous management decisions and thus make appropriate adjustments. It also suggests the value and need for ecosystem models and tools that can include consideration and measurement of both inertia and resilience. Early versions of these tools have given us a better understanding of the complex dynamics of forest ecosystems and, in turn, how we can craft management strategies to achieve desired outcomes. In short, management for ecosystem resilience necessitates iterative steps to allow for adjustments at each juncture of trial and learning.

Resilience does not always result in desirable conditions on the land (Folke 2006). Degraded and nonnative vegetation can also be resilient in its own way; e.g., landscapes dominated by cheatgrass (*Bromus tectorum* L.), which is generally considered undesirable, can be resilient in the face of restoration efforts by land managers. In this example, managers have experienced significant difficulties attempting to restore sagebrush steppe ecosystems invaded by cheatgrass (Chambers et al. 2009, D'Antonio et al. 2009).

Landscapes often have considerable inertia because of alterations of pattern and process after more than a century of human activity. For example, Wallin et al. (1994) found that landscape patterns generated by past forest management or disturbance can take decades or centuries to restore (see also Heinselman 1973). Hysteresis (in a large dose) can operate in altered landscapes to create undesirable resilience or a delay in desired response to management. For example, the widespread accumulation of Douglas-fir (*Pseudotsuga menziesii* (Mirb.) Franco) and, to a lesser degree, grand fir (*Abies grandis* (Douglas ex D. Don) Lindl.) across many eastside landscapes now means that disturbance patches created by management or wildfire are more likely to regenerate to Douglas-fir and grand fir than they would have in the recent past. These relations can create significant challenges in executing successful restoration because of the large scale of the effect.

Ecological Principles for Landscape Planning and Management

Our perspective on the scientific principles underlying restoration of landscape resilience in eastside landscapes is based on three central ideas: (1) the biophysical environment (i.e., vegetation, climate, geology, and topography) and disturbances interact to control system behavior at several key spatial and temporal scales; (2) Euro-American activities have altered these ecological interactions and reduced landscape resilience; and (3) increasing resilience of desired conditions requires management actions that restore processes and patterns at these key scales. Without a broad geographic and ecosystem perspective that includes the past, present, and future role of humans and the climate, it will be impossible to restore resilient forests across a wide range of ecoregions and landscapes. Such a systems view should enable more effective application of treatments to meet restoration or resilience goals.

We use the terms **local** and **regional** to describe landscapes. We define local landscapes as variably sized areas, typically ranging in size from one to several subwatersheds (hydrologic unit code [HUC] 6 or 12-digit watersheds) (Sieber et al. 1987) (see also the National Hydrography Dataset at http://nhd.usgs.gov/), or a watershed (HUC 5 or 10-digit watershed). These subwatersheds collectively reside in a single ecological subregion (sensu Hessburg et al. 2000a), and exhibit characteristic patchworks of successional stages and topography consistent with the climate, biota, physical processes, and disturbance regimes of that subregion. Subwatersheds (i.e., HUC level 6) typically range in size from about 10,000 to 40,000 ac (4050 to 16 200 ha), but larger and smaller subwatersheds also occur. We define a regional landscape as the complete collection of all local landscapes that comprise an ecological subregion.

We define (local or regional) landscape resilience as the capacity of the ecosystems to absorb disturbance and climate change while reorganizing and changing but essentially retaining the same function, structure, identity, and feedbacks (adapted from Walker et al. 2004). Resilient landscapes maintain a dynamic range of species, vegetation patterns, and patch size distributions (broad- or meso-scale) that emerge under the constraints of the climate, geology, disturbance regimes, and biota of the area.

We are motivated by eight core ecological principles that are foundational to restoring eastside forests, including moist mixed-conifer forests.

In this chapter, we outline eight core ecological principles that are foundational to restoring eastside forests, including MMC forests. We expand on these in later chapters; however, our aim here is to highlight key ideas that motivate our thinking.

Physical and biological elements of an ecosystem interweave, creating distinctive patterns on a landscape. Climate, interacting with vegetation, disturbance, topography, soils, and geomorphology created domains of ecosystem behavior at local and regional landscape scales. During every historical climate period, a range of patterns and patch sizes of forest successional stages likely emerged. This emergent natural phenomenon is referred to as the natural range of variation (NRV), also referred to as the HRV. As the climate shifted, so did the NRV. The notion of a static NRV is a common misperception and provides a misleading objective for land managers. It does not exist. Prolonged periods of warming or cooling, wetting or drying, or combinations of these have occurred repeatedly over time. Whenever these changes have happened, they have pushed the NRV in new directions. But sudden and extensive shifts in the NRV were typically constrained, except under the most extreme climatic circumstances, by the lagged landscape memory encoded in existing patterns of living and dead vegetation. This is the quality of a natural system that we represent as landscape resilience.

Vegetation dynamics and fire regimes of MMC forests were and are among the most variable. In the historical forest, this forest type exhibited low-, mixed-, and high-severity fires; the amount of each severity type varied with the climate regime, and by physiographic region. Patterns of vegetation structure and composition and fire frequency and severity changed gradually across landscapes with variation in climate and the impacts of settlement and early management. But before management, fire regimes of MMC forests were variable, depending on topography and ecoregion. In some locations, fires occurred relatively frequently (every 10 to 30 years), in others, fire frequency was more variable (25 to 75 years). In the former, fire severity would have been primarily low- and mixed-severity, with surface fire effects dominating. In the latter case, fire severity would be primarily mixed- and high-severity, with active and passive crown fire effects dominating. In some ecoregions, the fire regimes and tree composition of the dry ponderosa pine, dry

mixed conifer, and MMC types were quite similar and there were no clear lines of demarcation. In others, the differences in these types in terms of aspect orientation, tree density, layering, and species mixes were pronounced. With the advent of fire suppression, understories of the ponderosa pine (*Pinus ponderosa* Lawson & C. Lawson) and dry mixed-conifer forests were in-filled largely by ponderosa pine and shade intolerant Douglas-fir, respectively, but the MMC forests were in-filled by grand or white fir (*Abies concolor* (Gord. & Glend.) Lindl. ex Hildebr.) and Douglas-fir. Grand fir and Douglas-fir understories may have been transient in some historical MMC forests: if they got established during a period without fires, they may or may not have been eliminated by subsequent frequent low-severity fires. During longer intervals between fires, significant fuel ladders may have developed and mixed-severity fire effects would have been typical. On wet mixed-conifer forest sites, shade-tolerant tree species were persistent and fire intervals were long enough to allow development of old shade-tolerant trees and larger patches of dense multilayered forests within stands and landscapes.

Eastside forest patterns and influential processes are constantly shifting over space and time. However, topography, soils, and elevation constrain these patterns and provide a relatively simple template for understanding and managing landscapes for them. As a first approximation, the topographic and edaphic patterns of landscapes provide a natural template for pattern modification and restoration. For example, spatial patterns of ridges and valleys, and north- and south-facing aspects, strongly represent characteristic patterns and size distributions of historical vegetation patches. North-facing aspects and valley bottoms historically supported the densest and most complex forest structures, and when fires occurred, these sites experienced more severe fire behavior than south-facing aspects and ridges, owing to site climate and growing season factors. The same is true today. In contrast, south-facing aspects and ridges tended to burn more often and less severely than north-facing aspects and valleys. Wildfire conditions in summer were typically drier and fine fuels were conditioned for burning, even during average summer burn conditions.

Ecosystems and their component parts are organized in an interactive, hierarchical arrangement. Processes associated with the regional landscape exert a measure of control over patch dynamics of local landscapes, and ultimately, some fine-scale patterns and processes within patches. For this reason, no forest type, its disturbance regime, or its variation may be thought of in isolation. Some landscapes are dominated by one topographic aspect (e.g., north- or south-facing); consequently, vegetation on minor aspects may be different than would otherwise be expected from knowledge of their site conditions alone. In landscapes with more

southerly aspects and ridges, corresponding northerly aspects typically also see more frequent fires and lower than typical severity. Knowledge of specific context and scale can help guide patch-level decisions.

Postsettlement human activities have resulted in increasingly homogenized forests and, in turn, significant changes in the scope and effects of natural disturbances. Widespread human-caused changes to vegetation structure, composition, and fuelbeds have created more homogenized conditions in the MMC forest, generally in the form of large, dense, and multilayered patches of intermediate-aged fire-intolerant tree species. These changes have increased the area and frequency of large, high-severity fire patches, and the extent and frequency of other biotic disturbances (e.g., bark beetle and budworm outbreaks). The changes have also substantially altered the resilience mechanisms associated with the native forests. Climate and the characteristic disturbance regimes and landscape patterns regulated the composition, frequency, and size of the largest patches. Prior to Euro-American settlement, local and regional landscapes had developed over a period long enough for coarse and fine-scale patterns and species composition to be in some degree of synchrony with their physical environments and the climate system. Much of this synchrony has been lost through the cumulative effects of relatively recent human activities on the landscape. Current and future fire regimes and landscape patterns are on new trajectories trending away from a previously established resilience. To restore this coupling between patterns and processes (wildfire, insects, pathogens, and weather), forest structure, composition, and landscape patterns must be modified at a scale that is consistent with the scale of the current vulnerabilities. Pattern modifications should be consistent with the inherent disturbance regimes of large landscapes and forest types, and with the climate regime.

Rare ecological events can have a disproportionately large effect on ecosystems. Rare, large-scale events (disturbance, climatic, biotic, geologic) can significantly affect future landscape dynamics, especially if their frequency, size, or severity are unprecedented for the climatic, biotic, and environmental conditions. Large wildfires, dramatic climatic extremes, rapid changes in plant and animal species distributions, and large insect outbreaks are examples of natural and human-caused events that are rare but can have a strong and lasting effect on future landscape patterns and processes. Typically, these events are hard to predict and some are outside the control of managers. Nevertheless, they shape current landscapes and can be anticipated when developing and gaging the extent and timing of risk mitigation strategies. To a modest degree, managers can, through cumulative smaller actions, prepare landscapes in a manner that reduces the likelihood or impact of these large and rare events. However, to be effective, the timing and extent of the actions must match the level of inertia that supports the large-scale

events. For example, large areas of eastern Oregon and Washington are susceptible to chronic western spruce budworm (*Choristoneura occidentalis*) infestation owing to the wide prevalence of Douglas-fir, grand fir, and white fir in large, dense, multilayered patches. Changing this situation would require the reduction in the prevalence, complex layering, and density of these host tree species over a very large area to match the scale of the vulnerability to this disturbance.

Resilience depends on ecological heterogeneity and varies with spatial and temporal scale. At no time were all patches of a landscape resistant to fires or other disturbances. At any given time, some patches within a landscape were always susceptible to insect attack, stand-replacing fires, pathogen infections, or a combination of these. In some ecoregions, as much as 25 to 35 percent of the forest had been recently burned by high-severity fire, and a significant area was in an early-seral condition (grass, shrub, or seedling/sapling) or was recently burned and recovering (e.g., see the tables in app. 3). This is how forest habitats with complex structure and age classes continuously emerged on the landscape and were retained despite ongoing disturbances. In other ecoregions, where surface fire effects stemming from low- and mixed-severity fires were clearly dominant, fine-scale patterns in forest composition, structure, and tree age created a fine-scale mosaic of susceptibility to disturbance. This is how forest habitats with fine-scale structure and age classes continuously emerged on this landscape. The interplay of fine- and coarse-scale drivers (e.g., disturbance, topography, soils, and microclimate) across the regional landscape created fine-, meso-, and coarse-scale forest habitats with complex structure and age classes. In this way, local and regional landscapes, but not all stands or patches, were resilient.

Completely natural or historical landscape patterns cannot be the goal for current and future climate and landscape conditions. However, the past (e.g., HRV) can be an important guide to creating resilient forests. Knowledge of how forests and landscapes changed in response to disturbances and climate variation in the past is valuable for providing future forests and landscapes that have desired ecological patterns and processes. Where human-driven changes (e.g., fire suppression, grazing, past logging) have significantly altered forests relative to HRV, it will take significant inputs of human energy (i.e., ecologically motivated management) to create desired landscape conditions.

The size, diversity, and complexity of eastside mixed-conifer landscapes necessitate a prioritized approach to management. Though generalized, this concept, as well as those listed above, are critical to restoring resilience in these forests. These concepts have a strong ecological foundation, focus on restoring a more natural coupling of pattern and process, and can help managers create conditions that

conserve options, are adaptable, and can be implemented with available skills and abilities common on the staff of a forest or district (or equivalent). Developing this characterization of a forest, although new to contemporary forest management, is not overly difficult and will enable a much more effective treatment strategy at the stand level where managers typically do their on-the-ground work.

Topography as a Template for Landscape Heterogeneity

Previous research efforts have highlighted the predictive importance of topography (and more broadly, geomorphology) in landscape management (e.g., see Underwood et al. 2010). Studies and assessments from mixed-conifer forests (e.g., Hessburg et al. 2005, 2007; North et al. 2009; Taylor and Skinner 2003) have established that patterns of forest condition and fire behavior are strongly affected by topographic and physiographic features. Variability in soils also contributes to landscape heterogeneity, usually at a finer spatial scale. There are simple rules-of-thumb that can be gleaned from this work and applied to landscape management.

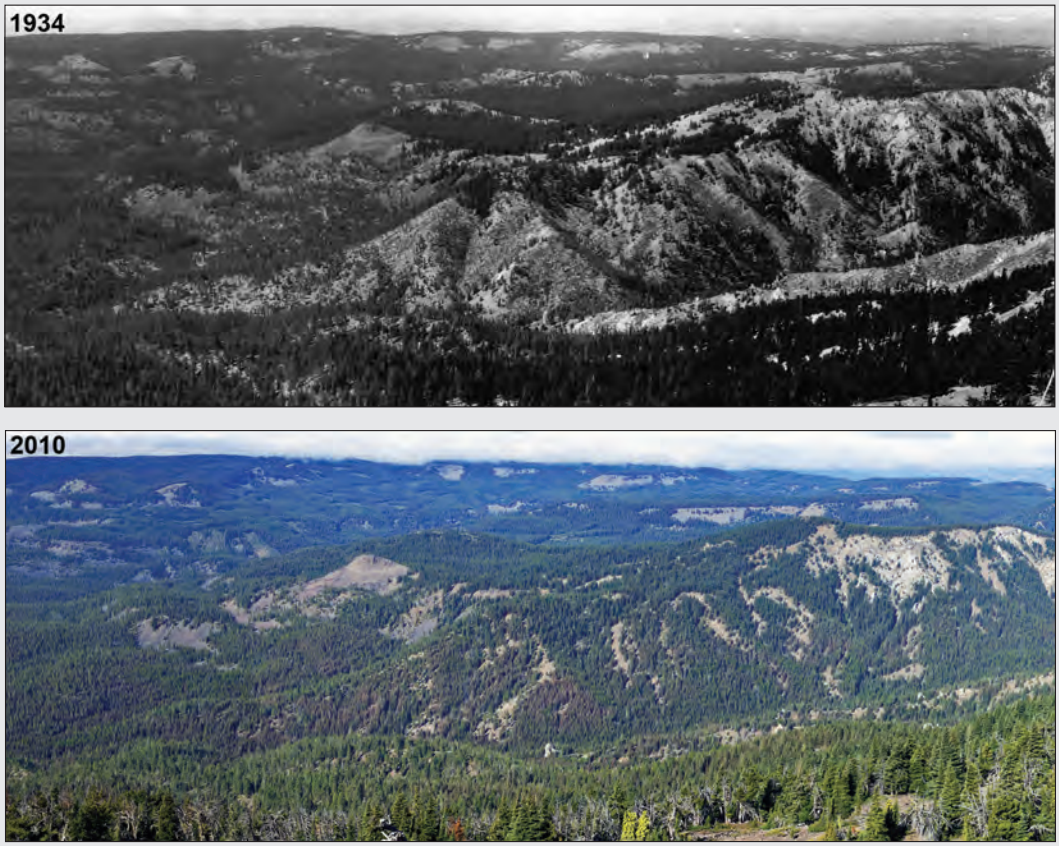
Simple partitioning of the landscape into basic topographic positions is a straightforward method for parsing the forest into subunits with different inherent growth potential and disturbance regimes.

Simple partitioning of the landscape into basic topographic positions, such as drainage bottoms, ridgetops, or south- and north-facing slopes, is a straightforward method for parsing the forest into subunits with different inherent growth potential and disturbance regimes. Aspect patches of all sizes can be used to tailor treatments to the landscape; these can be readily generated in a geographical information system (GIS). There are now a number of easy-to-use GIS tools for doing this on any landscape using standard digital elevation model (DEM) data. The following provides a brief overview of some of the insights that topography provides.

South-facing aspects and ridges tended to burn more often and less severely than north-ridges, and fine fuels were typically conditioned for burning, even during average summer burn conditions. One can imagine that ridges, with their more exposed conditions and open grown forests, provided a rather elaborate network of natural fuel breaks owing to high lightning ignition frequency and limited fuel accumulations. This was typically not the case on north-facing aspects and in valleys, hence their reduced fire frequency. Although exceptions to these generalizations abound, landscape restoration can capitalize on these general tendencies without using a one-size-fits all approach. Instead, landscape restoration can apply a rule-of-thumb approach, as follows.

Managing south-facing aspects and ridgelines. In application, southerly aspects and ridges could be managed to support fire-tolerant species in clumped and gapped distributions by: (1) favoring very large-, large-, and medium-sized trees so that they occupied, e.g., 40 to 50 percent of the tree cover in the majority of these patches, and represented, e.g., 50 to 60 percent of their total area; (2) stocking to support a dominance of surface fire behavior stemming from low- and mixed-severity fires, and tree densities that support endemic but not epidemic bark beetle populations (i.e., resulting in the mortality of only a few trees over time); (3) maintaining tree species composition that strongly discourages the spread and intensification of root diseases, while allowing their presence; and (4) maintaining stocking on south slopes and ridges by low and free thinning and similar methods, especially by prescribed burning at regular intervals. Size class and canopy cover dominance would certainly vary from place to place, but ranges of conditions could be calibrated from historical reconstructions and modified as needed by incorporating expected climate changes. Prescribed burning and thinning activities could discriminate against the most severe dwarf mistletoe infestations. This would adequately mimic historical fire influence, but allow some of the most ecologically beneficial aspects of dwarf mistletoe infestation. Where fire- and drought-tolerant species are not dominant on south slopes and ridges, managers can regenerate them using methods that are best adapted to local site conditions.

Managing north aspects and valley bottoms. In application, north aspects and valley bottoms tend to support a mix of fire-tolerant and fire-intolerant tree species in relatively dense, often multilayered arrangements. Stocking can support surface and crown fire behavior stemming from mixed- and high- with occasional low-severity fires. Landscape patchiness of denser north aspect and valley bottom forest conditions can help constrain the frequency, severity, and duration of defoliator and bark beetle outbreaks. Ideal stocking on north slopes and valleys would reflect species compositions that encourage or allow the spread of root disease as a natural process; mixed fire-tolerant and fire-intolerant species compositions should adequately restrain the spread of root diseases while allowing ecologically beneficial fine-scale habitat and forage conditions stemming from root disease centers. Stocking on north slopes and valleys may be maintained by free selection thinning or similar methods, especially where density is quite high and layering is simple. Where fire-tolerant species are not present in north-facing slopes and valley bottom settings, they may be regenerated using methods that are adapted to local site conditions, depending on other local habitat constraints. Some patches may be dominated by drought- and fire-intolerant species without harm to the larger landscape.



Forest types and their fire regimes are interconnected. Disturbance regimes and their variations in each forest type offered a regulating influence in adjacent but differing forest types. For this reason, no forest type and its disturbance regime and variation may be thought of in isolation. Some landscapes have significantly more north- or south-facing aspects than others;

(continued on next page)

(from page 27)

consequently, variations emerge that increase landscape complexity and these should be noted. In landscapes with more southerly aspects and ridges,north-facing aspects typically see more frequent fires and lower than typical severity. The converse is also true. These ideas can help shift the focus away from an overly simplistic topographically driven landscape template.

Figure 10 illustrates this intrinsic landscape pattern driven by topographic position with two photographs of Mission Peak on the Wenatchee National Forest. The photo from 1934 shows very little tree growth on the south-facing slopes and ridgetops with dense forest on the north-facing slopes and drainage bottoms. Because of fire exclusion, the forests have filled in as shown by the 2010 photo.

John Marshall

Chapter 4—Scientific Foundations

Ecological Composition, Patterns, and Processes Prior to Euro-American Settlement (Before About 1850)

The mountains of Oregon and Washington exert strong orographic control on climate, vegetation, disturbance, and land use across the region. Steep precipitation and temperature gradients have a significant influence on the vegetation east of the Cascade Divide (Franklin and Dyrness 1988) (fig. 11). Moist mixed-conifer (MMC) forest patches frequently occur within a broader continuum of mixed-conifer forest types (fig. 12) and within topographic locations juxtaposed with mixed conifer or ponderosa pine vegetation types, or grassland and shrubland patches (fig. 13) (Hessburg et al. 1999a, 2000b; Spies et al. 2006). This mosaic of landscape composition and physiognomic conditions can alter the disturbance regime as well as the functioning of these patches across broader spatial scales. For example, the frequent fire regimes of grassland and shrubland influence adjacent forests by increasing their fire frequency. This occurs because grass and shrub patches often function as "conveyor belts," readily spreading wildfire to adjacent patches. Likewise, dry mixed-conifer patches that experience frequent surface fires can also influence adjacent MMC patches. However, when MMC forest is surrounded by cold or wet forest types, the fire regime may be influenced by this context; and fires may tend to be less frequent and more severe.

Where Is the MMC Forest Located?

No standardized, peer-reviewed maps of the potential vegetation subseries covering the MMC forest are published for the entire region. The Region 6 Area Ecology Program has developed plant association classifications and maps for individual subregion ecology areas, but the names and environmental conditions of the plant associations differ. Currently the region is using the vegetation classification represented in the Integrated Landscape Assessment Program (a partnership jointly managed by the Forest Service Pacific Northwest Research Station and Oregon State University's Institute of Natural Resources) for defining MMC forest distribution and abundance (fig. 7, table 2). The map we presented is intended solely for the purpose of initial regional-scale planning and analysis and has limited spatial accuracy for project planning. Local classifications and maps that are spatially accurate at a patch scale are more appropriate for defining the distribution of the MMC forest for project level planning and management.

Local classifications and maps that are spatially accurate at a patch scale are more appropriate for defining the distribution of the moist mixed-conifer forest for project level planning and management.

Other classification strategies also exist (e.g., Henderson et al. 2011, Simpson 2007) for vegetation zones that have resulted in different depictions of this forest type across the region. Confounding this issue, national forests often have their own local maps of potential vegetation types (PVTs) that they use for management, and the scale of these maps varies from forest to forest. These maps do not correspond to the regional maps shown here. We suggest that any future regionwide strategy for MMC forest be underpinned with a single map that uses a regionally coherent classification standard and mapping protocol. The map would accurately identify the major areas that support the MMC type, and its relation to other types. This regional map would enable cross-forest data sharing and landscape assessment and management coordination. Local forest-level maps would then be needed to estimate departure from historical dynamic and threats to forest resilience.

Mixed-Conifer Plant Association Classification

The plant associations of series associated with mixed-conifer forest can be placed into different moisture/fire regime groups using published and unpublished information (table 2). We present these as a first approximation for defining the occurrence of different mixed-conifer-disturbance regime types and aid to communication. As stated elsewhere, potential vegetation types (e.g., series, subseries, and associations) are only approximate indicators of fire regime, a concept which is best applied at landscapes scales (larger areas that are mosaics of local climate, topography, soils and vegetation).

(continued on next page)

(from page 31)

We grouped plant associations of the grand fir, Douglas-fir, and Shasta red fir (*Abies magnifica* A. Murray bis) series into subgroups based on moisture and historical fire regime: dry-low severity, moist-dry-low- to mixed-severity, moist-mixed severity, and moist to wet-high-severity (table 2). Associations in the subalpine fir and Shasta red fir series were included if ponderosa pine is an overstory component in the series or if plant association guides mentioned that low-severity fires were part of the historical fire regime. We assigned plant associations to a mixed-conifer moisture-fire regime group based on published information and expert opinion about the historical disturbance regime, environmental setting, and species composition. Plant associations in dry environments where historical fire regimes were predominately low severity and ponderosa pine was common in both the overstory and understory were classified as dry mixed-conifer.

Plant associations were classified as MMC forest if the following conditions were met: (1) mixed-severity fire regime; (2) intermediate environmental setting; and (3) Douglas-fir or grand fir are the most common understory tree species and are co-dominant in the overstory with ponderosa pine or other early-seral dominant, or those tree species are predicted to be dominant in the overstory and understory community based on the primary indicator plant species. Plant associations that could not be classified as dry or moist because of broad variability in historical disturbance regimes and species composition were classified as moist-dry. We expect the variability in the moist-dry group represents associations where dry and MMC forest intermingle on the landscape. The moist to wet classification was given to all plant associations with an infrequent, high-severity fire regime and species composition that were inconsistent with our definition of eastside mixed-conifer forest. Some of these associations would be classified as "moist" in some subregions but their historical fire regimes are still dominated by high-severity fire at relatively longer intervals. In these latter associations, ponderosa pine was usually absent in all strata; early-seral species including lodgepole pine, Douglas-fir and western larch were often even-aged; and shade-tolerant fire-intolerant species were common in the overstory. Plant associations in these moist to wet environments may still merit restoration due to past timber management activities, but fire does not play the same role as it does in dry and MMC forests, and it is unlikely that fire exclusion has modified structure, composition in these wetter types.

Table 2—Mixed-conifer plant associations grouped by moisture and approximate fire regime (app. 2)

National forest (NF)/region[a]	Vegetation series/ plant association	Extent[b]	Species composition[c]	Source[d]
Dry with low-severity fire—*characterized by low-severity fires and relatively short return intervals of less than 35 years. Natural fire regimes in order of prevalence are I, III A, III B, and IV A.*				
Blue and Ochoco Mountains	Douglas-fir/elk sedge	Widespread	PSME, PIPO, ABGR	Johnson and Clausnitzer 1992

Note: This table is intended as an interim classification subject to further revision as new information becomes available. Note that terms used to describe climatic environment are relative terms and have different definitions among regions. Therefore, this regional classification may differ from local classifications.

[a] National forest/region = subregion of the plant association.

[b] Extent = geographic distribution and approximate area of a plant association relative to other associations within the region.

[c] Species composition = all tree species recorded in each association, ordered by prominence within each association.
ABGR = *Abies grandis* (grand fir); ABLA = *Abies lasiocarpa* (subalpine fir); ABPR = *Abies procera* (noble fir); ACGL = *Acer glabrum* (Rocky Mountain maple); CADE = *Calocedrus decurrens* (incense cedar); CONU = *Cornus nutallii* (Pacific dogwood); JUOC = *Juniperus occidentalis* (western juniper); LAOC = *Larix occidentalis* (western larch); PICO = *Pinus contorta* (lodgepole pine); PIEN = *Picea engelmannii* (Engelmann spruce; PILA = *Pinus lambertiana* (sugar pine); PIMO = *Pinus monticola* (western white pine); PIPO = *Pinus ponderosa* (ponderosa pine); PSME = *Pseudotsuga menziesii* (Douglas-fir); QUGA = *Quercus garryana* (Oregon white oak); TABR = *Taxus brevifolia* (Pacific yew); TSHE = *Tsuga heterophylla* (western hemlock); TSME = *Tsuga mertensiana* (mountain hemlock).

Vegetation Classification and Disturbance Regimes

Effective restoration depends on having an accurate classification of vegetation and its disturbance regime. There are various schemas for classifying vegetation for purposes of ecological stratification, including current vegetation, historical vegetation, and potential natural vegetation (PNV). PNV in application is organized into a taxonomic hierarchy consisting of series, subseries, and plant associations, which are named for dominant overstory and undergrowth plants (Powell 2007). The standard system of vegetation classification and mapping used by the Forest Service and other federal agencies is based on this taxonomic hierarchy. Mixed conifer is composed of grand fir, white fir and Douglas-fir series, but the distinction of dry, moist and wet mixed-conifer types (i.e., disturbance regimes) requires the use of lower levels in the hierarchy, including subseries and groups of plant associations. We provide a first approximation for how associations could be grouped into four moisture/disturbance regime classes, (equivalent to subseries; table 2), but caution that this classification is interim and subject to revision as more knowledge becomes available. In this synthesis we use the term PVT in a general way to refer to any potential natural vegetation class regardless of level in the hierarchy (series, subseries, and plant associations).

A PVT is the native, late-successional (or "climax") plant community that reflects the regional climate and the dominant plant species of an area that would occur on a site in the absence of disturbance (Pfister and Arno 1980). This approach assumes that disturbances still occur, but that the composition of the late-successional community occurring when disturbance is absent is a reasonable indicator of the biophysical environment. Hence, PVTs may be considered as approximate surrogates for the environmental conditions of a site (in terms of moisture, solar, nutrient, and temperate regimes) that exert some control on productivity, habitat potential, regeneration rates, and the frequency and severity of disturbance regimes.

Concepts of orderly succession and climax vegetation are questionable in mixed-conifer and other fire-prone eastside environments (O'Hara et al. 1996). These forests actually exhibit non-equilibrium dynamics, where the potential climax conditions were typically never realized due to myriad interacting and multi-scale disturbance processes, especially fire, that both advanced and retarded succession. Potential natural vegetation classifications can also take into account the reality that vegetation structure and composition is altered and controlled by periodic wildfire (Winthers et al. 2005). Much of the dry and MMC forests in Oregon and Washington would belong to these "fire climax" potential natural vegetation types. Despite these complexities of nature and the limits of our conceptual models,

PVTs can be a useful starting place for identifying the ecological potential, fire regime, and restoration needs for an area.

At finer scales (below subseries) the plant association is a unit defined on the basis of a characteristic range of species composition, diagnostic species occurrence, habitat conditions, and physiognomy (USDA FS 2005). A number of plant associations are included in the MMC type and some grade into the drier or wetter mixed-conifer types. See the list in table 2 for an interim assignment of plant associations to our mixed-conifer moisture/disturbance regime types.

Tree species of the MMC forest are characterized as either early-, mid-, or late-successional (late-seral), and as either shade-intolerant or tolerant, respectively. The most common early-seral forest tree species are western larch (*Larix occidentalis* Nutt.), ponderosa pine (*Pinus ponderosa* Lawson & C. Lawson), lodgepole pine (*Pinus contorta* Douglas ex Loudon), western white pine (*Pinus monticola* Douglas ex D. Don), trembling (quaking) aspen (*Populus tremuloides* Michx.; especially where a seasonally high water table exists), Douglas-fir (*Pseudotsuga menziesii* (Mirb.) Franco), and mixed conditions of these types. With the exception of Douglas-fir, each of these species is shade-intolerant, all readily regenerate after fire, and western larch, ponderosa pine, and Douglas-fir can become exceptionally fire-tolerant as they advance in age, owing to an ever thickening bark (Agee 1993). Dominant late-seral tree species are grand fir (*Abies grandis* (Douglas ex D. Don) Lindl.), white fir (*Abies concolor* (Gord. & Glend.) Lindl. ex Hildebr.; in central and southern Oregon), and subalpine fir (*Abies lasiocarpa* (Hook.) Nutt.) and Engelmann spruce (*Picea engelmannii* Parry ex Engelm.), where local environmental conditions (e.g., cold-air drainage or pockets) occur that will promote dominance of these species. All are shade-tolerant and fire-intolerant. Exceptions can occasionally be found in mature grand fir and white fir, which may also possess a thick bark and occasionally occur in park-like stands (Hessburg et al. 1999a, 2000a).

Under native fire regimes, the moist mixed-conifer forest would have displayed highly variable structure and composition regionally, making it among the most diverse and complex of all forest types.

Under native fire regimes, the MMC forest would have displayed highly variable structure and composition regionally, making it among the most diverse and complex of all forest types (e.g., see the tables in app. 3 for the Blue Mountains province). The MMC forest landscape included a wide range of cover type and structural class combinations that would derive from a mixture of low- to mixed-severity fires with lesser amounts of high-severity fire in the mix (e.g., see app. 3, Hessburg et al. 2007, Perry et al. 2011). Recent studies in MMC forest in central Oregon suggest that the amount of low- and mixed-severity fire and forest structure (e.g., density) and tree layer composition in pre-Euro-American times may not have differed much from nearby dry mixed-conifer PVT (Hagmann et al. 2013, Merschel 2012).

The PVT is not the same as the current or actual vegetation, which may exist in an early-, mid-, or late-successional state or in a nonnative and human-altered state (e.g., agricultural patch, urban or rural development area, pasture, or road right-of-way). The difference between the current and potential vegetation types can be important to restoration and should be known before undertaking restoration activities. The current vegetation type needs to be considered to determine which restoration trajectories are most probable, given local site conditions, landscape context, disturbance history, and potential climate change effects.

Finally, with changing climate, PVT classifications based on the relationship of potential late-successional communities to their environment will be related to current and recent past climate conditions, but not to the future climate. Consequently, managers are best served by using a variety of sources of information about a site, including potential climate change effects, when making management decisions. Individual trees or populations exposed to climate conditions outside their climate niches may be maladapted, resulting in compromised productivity and increased vulnerability to disturbance. In some locations the future will not resemble the past with respect to potential vegetation, and assemblages of tree species that we currently recognize may be quite different in the future. This will be especially true where there is a rapid change in environment and vegetation (e.g., current ecotone edges). We suggest that a current PVT map be developed to the full extent of subwatersheds of each national forest, using regionally standardized protocols for PVT definitions and mapping.

Although it is generally accepted that the PVTs differ in their disturbance regimes, only a handful of dendroecological and landscape reconstruction studies have characterized variability in wildfire regimes in eastern Washington and Oregon (Agee 1994; Hessburg et al. 2007; Heyerdahl et al. 2001, 2013; Perry et al. 2011; Wright and Agee 2004), and have been conducted in the eastern Washington Cascades and Blue Mountains. More work is needed to better understand fire regime variability and relations with physiography. Studies of dry and MMC forests, which were characterized by highly variable low-, mixed-, and high-severity fire regimes, have been conducted in three eastern Washington ecoregions (Hessburg et al. 2007), and data are available to complete similar studies in the Blue Mountains and eastern Cascades of Oregon.

Similarly, syntheses of existing studies indicate relatively high variation in fire frequency within major plant series, especially at longer return intervals. For example, fire return intervals in the grand fir series range from 17 to 100 years (Agee 1994). Agee (1994, p. 17) stated that "the [warmer and drier] mixed-conifer forests of the Douglas-fir, white fir, and grand fir series show the most frequent

fire activity of all eastside forests, although cooler, wetter sites of the grand fir series have longer fire return intervals. Frequent fires in drier plant associations of these series are likely due to higher productivity of fine dead fuels needed to carry another fire compared to the ponderosa pine series." Hessburg et al. (2007) corroborated this finding. In dry mixed conifers, they found that low- and mixed-severity fires dominated by surface fire effects affected most of the area of this type. In the MMC type, they found that mixed-severity fires were also dominant, but crown fire effects stemming from mixed-and high-severity fires were more obvious.

High variability in fire regimes as a function of environmental and vegetation context means that the correspondence of a MMC PVT with a particular narrow range of frequency and severity of fire and other disturbances should be viewed with caution. Variation in effects of fire suppression and logging on forest structure and composition is relatively large within the MMC type, especially as it is expressed in different geographic areas of the region. Thus, it is important to develop first-hand knowledge of the historical and contemporary disturbance regimes of local landscapes, and of their expression by PVT. Other factors to be considered when assessing the local disturbance regime include topography, soil physical and chemical characteristics, overall geomorphology, disturbance and management history, and climatic variability. Figures 14 and 15 illustrate the inherent heterogeneity that typically exists on these complex landscapes. Figure 14 shows the complex spatial configuration that results simply from basic topographic position at the southern end of the Wallowa-Whitman National Forest. Figure 15 illustrates the more complex patchwork of landscape units that result from a combination of topography, simplified categories of precipitation, and soils in the Wenaha River watershed on the Umatilla National Forest. This is a simple example of the concept of using a Land Type Association (LTA) that incorporates a number of landscape features into an ecological classification system based on the associations of biotic and environmental factors, which include climate, physiography, water, soils, hydrology, and potential natural communities.

General patterns of landforms, climate, and vegetation—
The ecological dynamics of the region are set within a geological and geomorphic template that controls climate, vegetation, and disturbance. Plate tectonics and volcanism, along with glacial and fluvial processes over geologic time, have produced distinct land surface forms, environments, and biotic assemblages across Oregon and Washington. These bio-geo-climatic contexts provide the basis to classify province-scale ecoregions (fig. 16) (Bailey 1995, Omernik 1987), and ecological subregions (Hessburg et al. 2000b) that reside within them. The location of the region on the windward Pacific Coast results in a predominantly marine-type

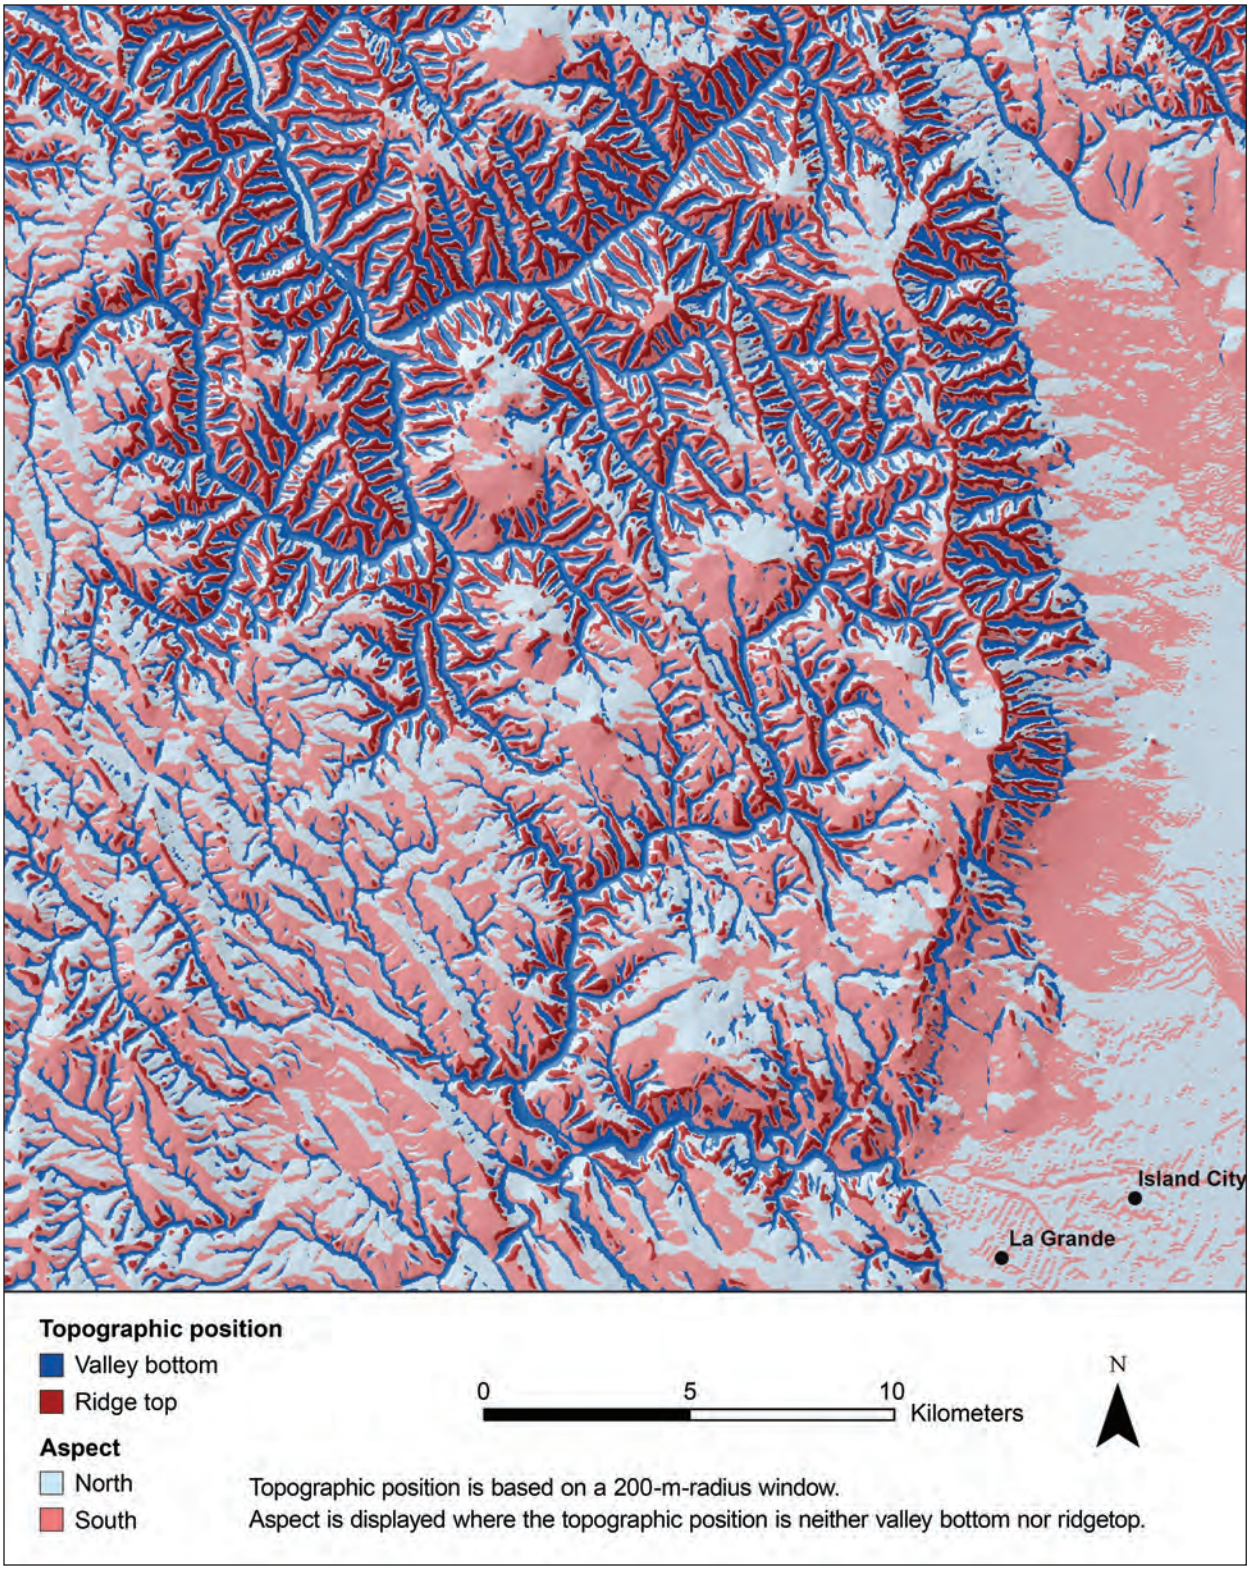

Figure 14—A map of the lower Grande Ronde Watershed on the Wallowa-Whitman National Forest in northeast Oregon, illustrating the spatial heterogeneity of the watershed simply as a function of basic topography.

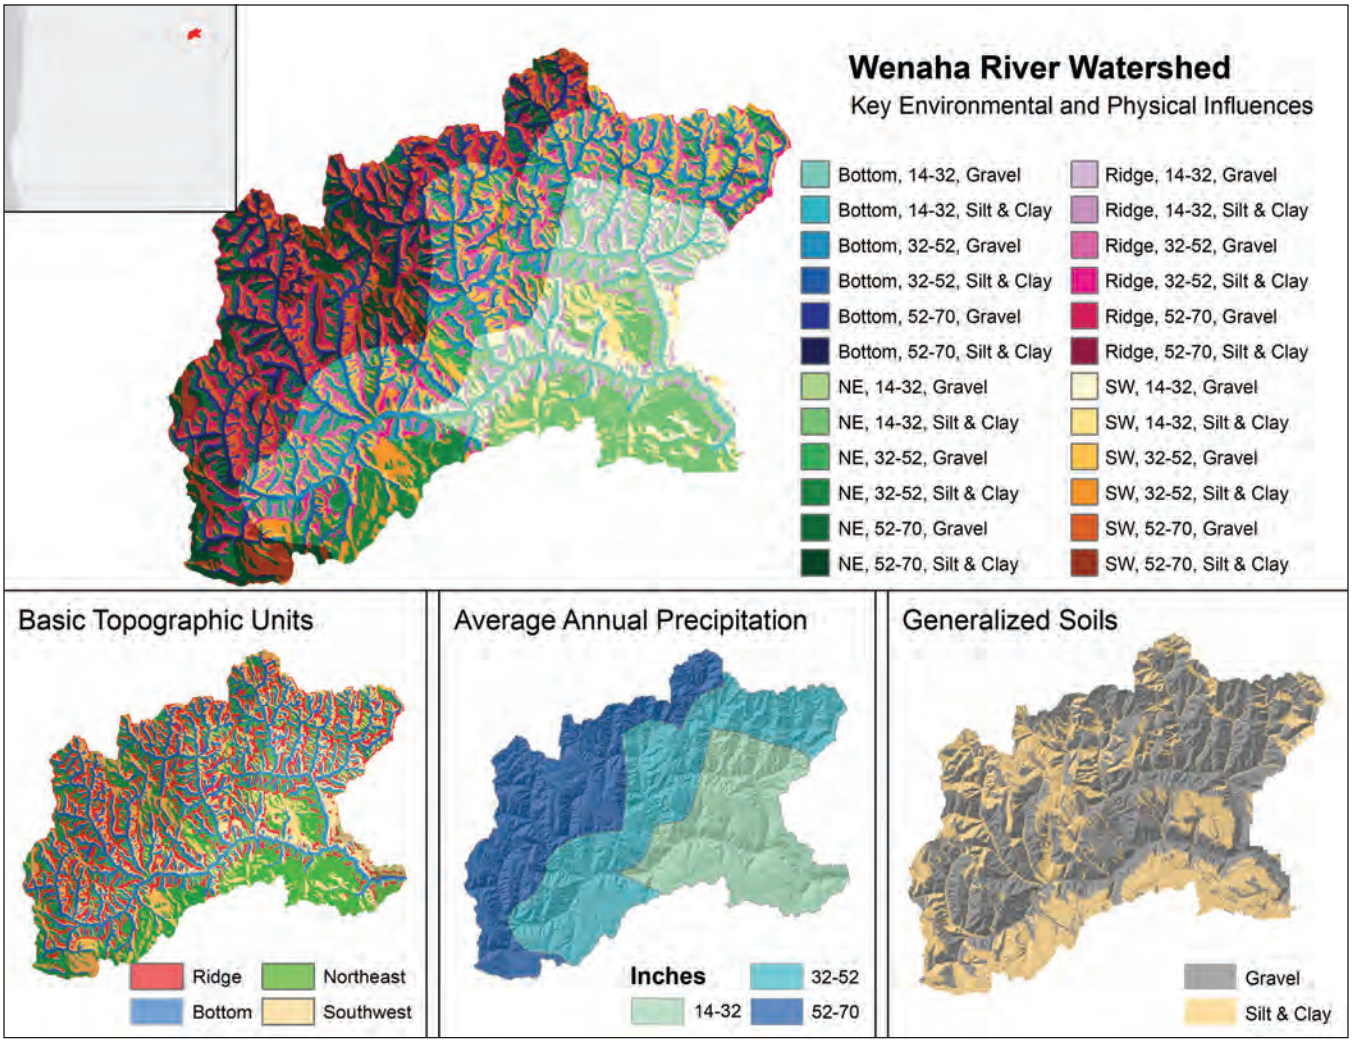

Figure 15—A map of the Wenaha River watershed on the Umatilla National Forest in northeast Oregon, illustrating the landscape complexity derived from an integration of simplified topography, soils, and climate spatial data.

climate west of the Cascade Mountains, while east of the Cascades, the climate possesses both continental and marine characteristics (Western Regional Climate Center, http://www.wrcc.dri.edu). In fall and winter, a low-pressure system in the North Pacific Ocean brings moist and mild (i.e., pacific) westerly airflow across the region, resulting in a wet season that begins in mid to late October, reaches a peak in winter (January to March), then gradually decreases later in spring. Blocking pressure in the North Pacific in summer brings a prevailing westerly and northwesterly flow of comparatively dry, cool, and stable air into the Pacific Northwest.

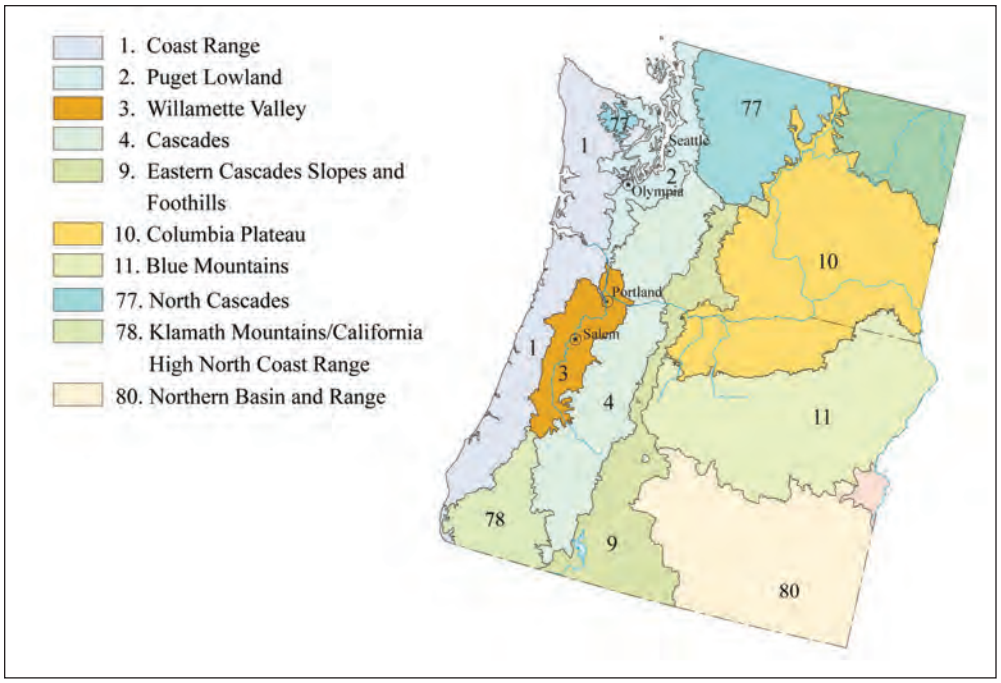

Figure 16—Ecological regions of Oregon and Washington based on the LEVEL III Ecoregions of the Continental United States, Environmental Protection Agency (revised in April 2013).

The orographic effects of the deeply dissected mountain ranges in the region result in occasionally heavy precipitation on the west slope of the Cascades and at higher elevations and relatively dry conditions on the east slope and at lower elevations (fig. 17). Temperatures vary from mild maritime conditions west of the Cascades crest to continental and temperate or Mediterranean conditions east of the Cascades.

Plant life forms and community types vary predictably across these landforms and climatic gradients. The Douglas-fir/western hemlock (*Tsuga heterophylla* (Raf.) Sarg.) habitat type dominates west of the Cascade crest, except in the Willamette River, Umpqua River, and Rogue River valleys in the rain shadow of the Coast Mountains and portions of the Puget Trough (in the rain shadow of the Olympic Mountains), where oak savannas and dry coniferous forests occur (Franklin and Dyrness 1973). From the Cascades crest east to the west slope of the Rocky Mountains, there is a strong climate-induced stratification of vegetation types from valley bottoms to mountain tops. Sagebrush and grassland habitats dominate the Columbia Basin, the Great Basin, and the Snake River Plain. Ponderosa pine and juniper (*Juniperus* L.) habitats make up the lower forest and woodland ecotone. Douglas-fir occupies intermediate elevations, western larch and grand fir occupy still higher elevations, and Engelmann spruce and subalpine fir are found near upper tree line. Lodgepole pine inhabits subalpine environments and other low and mid-montane

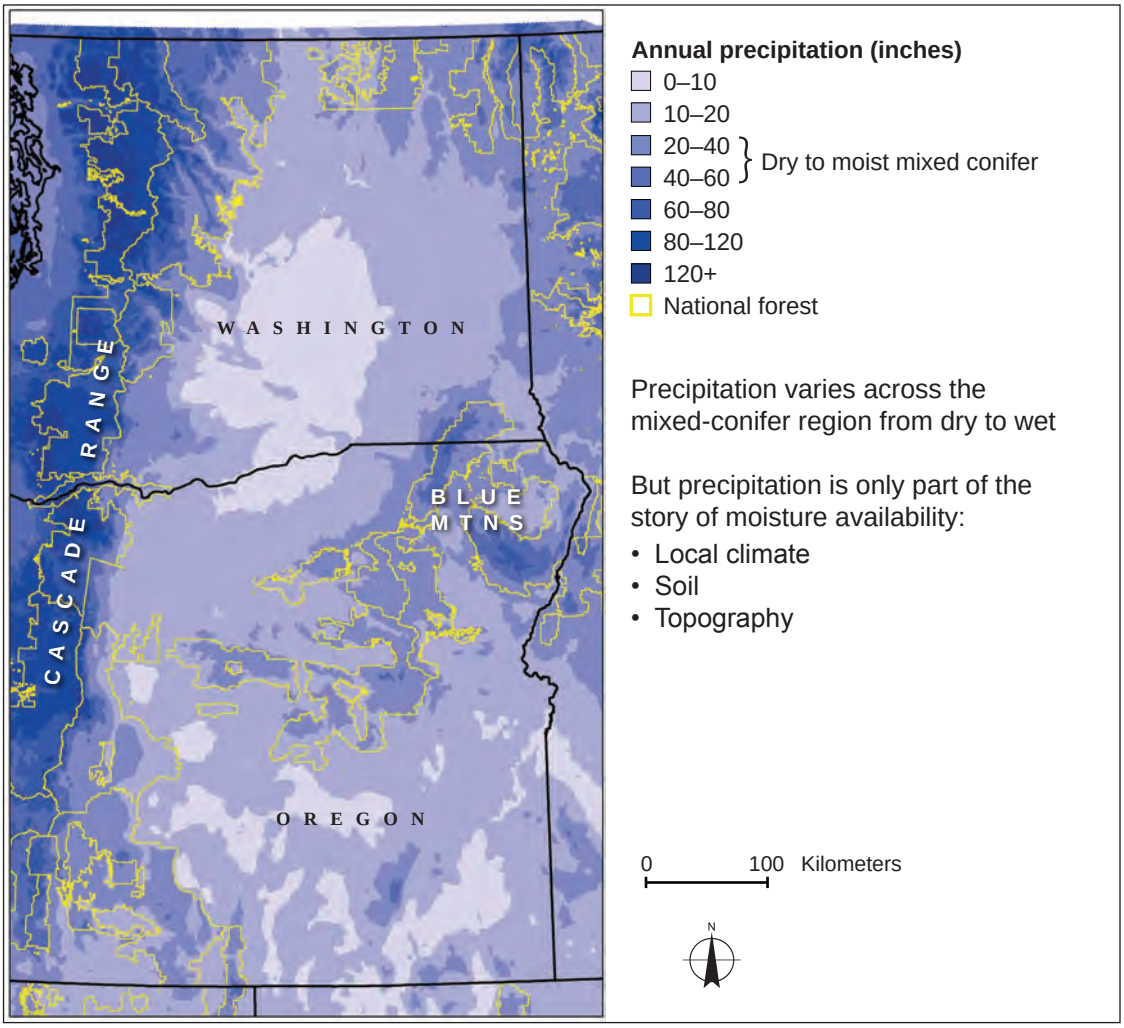

Figure 17—Generalized annual precipitation map of eastside Oregon and Washington. Note the significant rain shadow created by the Cascade Range and relatively high precipitation in some areas of the Blue Mountains.

environments that are prone to cold air pooling. Gradients extending from dry, low-elevation rangeland vegetation to moist conifer forests are especially sharp in the East Cascades, Okanogan Highlands, and Blue Mountains. In these locations, topographic controls (e.g., aspect, slope position) on vegetation composition, density, and productivity are also especially pronounced.

At the coarsest level, net primary productivity (NPP) is limited by temperature at the highest elevations, by moisture in the driest locations east of the Cascades crest, and by insolation (direct sunlight) west of the Cascades crest (Running et al. 2004). As a consequence, NPP is highest in the Coast and Cascade Ranges, intermediate in the East Cascades, Okanogan Highlands, and Blue Mountains, and lowest in the Columbia River basin and the Great Basin (Verschuyl et al. 2008).

Vegetation dynamics—
Vegetation dynamics result from the interplay between succession and disturbance processes. In the simplest case, vegetation development at a patch scale may be characterized by change in composition and structure following stand-replacement disturbance (e.g., from fire, insects, or disease). In such cases, succession can initially be relatively rapid (years to decades) and obvious, but successional change is occurring all the time, even centuries after major disturbances. The rate and nature of succession is advanced or retarded by a myriad of major and minor disturbances (O'Hara et al. 1996, Oliver and Larson 1996). In this sense, at each occurrence, disturbances may reset the vegetation condition of any patch on new trajectories that play out over space and time (Peterson 2002, Peterson et al. 1998). Patch boundaries are non-stationary as well. Patches are blended or bisected by disturbances of various kinds and combinations.

Large or severe disturbances may imprint the landscape for centuries before attenuating.

Large or severe disturbances may imprint the landscape for centuries before attenuating. The effects of small and low-intensity disturbances can be shorter in duration but still shape succession by altering site and microsite conditions that affect plant life histories by their influence on seed-fall, seed dispersal, post-dispersal seed losses, germination and recruitment, growth and mortality of juvenile and adult plants, reproduction, and a range of other factors.

Given the environmental complexity, diversity of species and processes, and variation in frequency and severity of disturbances that affect MMC forest, the number of successional pathways and development stages is quite large (fig. 18). Consequently, the structure and composition of the MMC forest across eastern Oregon and Washington was highly diverse under pre-Euro-American disturbance regimes. It was a mosaic driven by low- to mixed- and occasional high-severity fire, and the patchwork of size and age class structure and species composition differed considerably. With wildfire exclusion, domestic livestock grazing, and timber harvesting, the fire regime has shifted toward increasingly larger and more severe fires, which tend to simplify the landscape into fewer, larger, and less-diverse patches and ultimately more homogenous landscapes.

Ecological researchers are just beginning to understand ecoregional variation in the dynamics, structure, and composition of MMC forests. Given the generally sparse network of dendroecological and landscape reconstruction studies (especially in Oregon) our understanding of ecoregional and PVT-scale variation is provisional. In the eastern Cascades of Washington where high-severity fire was a component of the disturbance mix, the vegetation in MMC was a mosaic of small to very large patches comprised of early-, mid-, and late-successional forest conditions, and a broad variety of pure and mixed-cover types. In the eastern Cascades

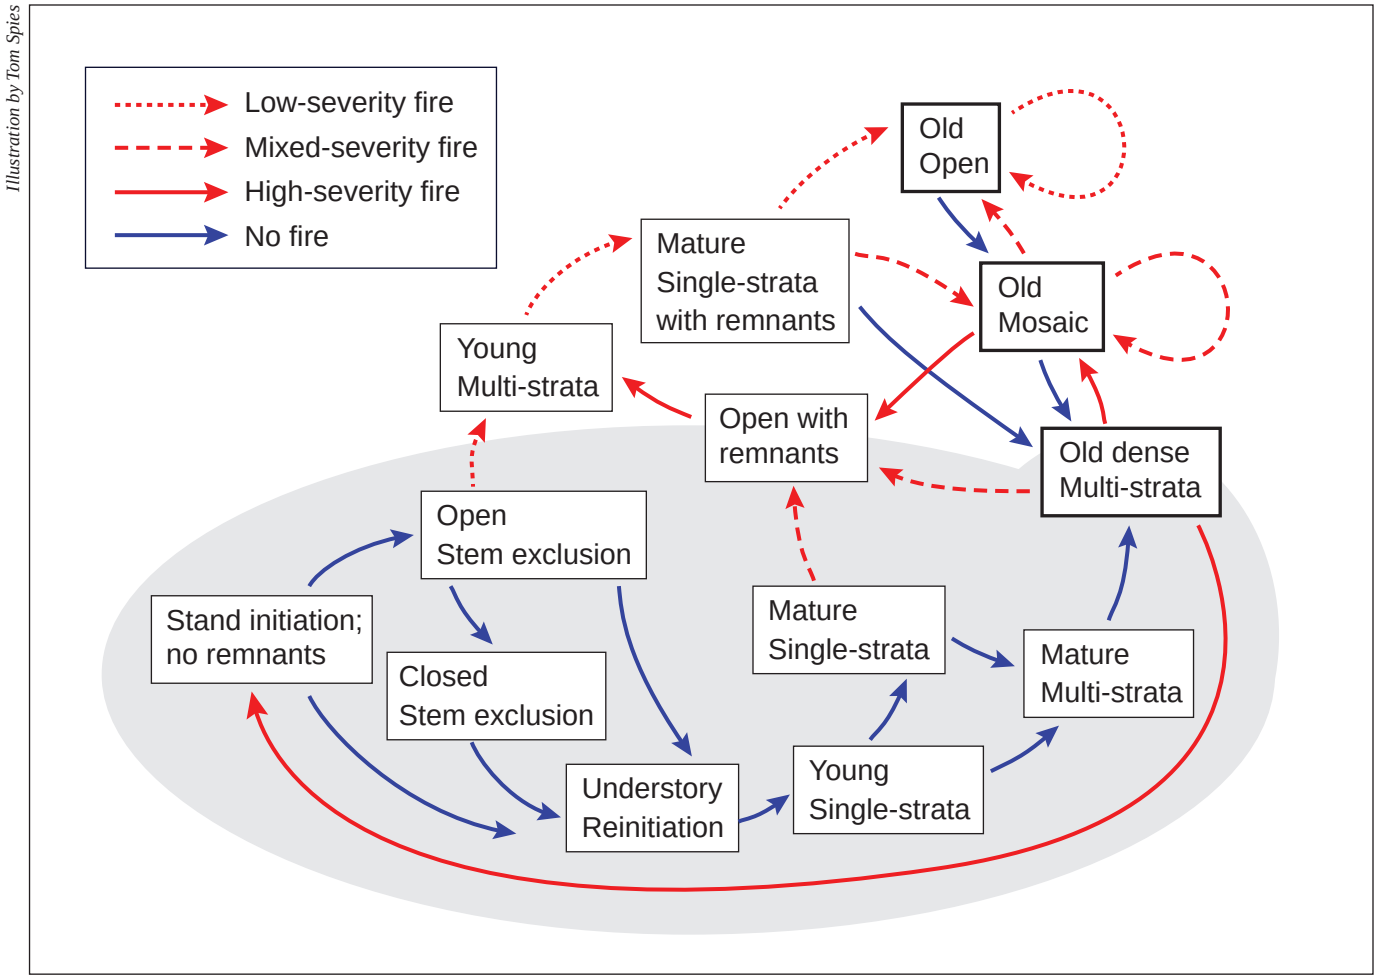

Illustration by Tom Spies

Figure 18—Conceptual model of vegetation states and transitions associated with fire severity. Under low- to mixed-severity fire regimes, moist mixed-conifer forest landscapes were dominated by patches characterized by old trees and relatively open understories or old trees in a mosaic of open and dense understory patches (bold boxes in upper right). Forest structure and composition shifted among various structurally diverse stages (boxes in upper non-gray area) depending on ecoregion, fine-scale environmental variation, and amount of high-severity fire. Under fire exclusion and even-age management, forest structure and disturbance regimes have shifted potential forest stages and pathways into the lower region of the diagram (gray area) where the amount of dense old forest, high-severity fire, and uniform young forest is much greater than it would have been under the pre-Euro-American fire regime. Some old, dense multi-strata forest would have existed under the pre-Euro-American period but it probably was a small portion of the moist mixed-conifer type across the region.

of Oregon, where the disturbance mix may have had less high-severity fire, MMC forests might have been a mosaic of large shade-intolerant forest species that can resist fire, and sparse or patchy understories of species that regenerated in areas that were disturbed by surface fires, insects, or disease, or in patches where disturbance had not occurred for several decades (Merschel 2012). On drier sites where fires were less severe and more common (<25 years), the environment may have favored growth and establishment of ponderosa pine or Douglas-fir, and understories would have been relatively open or patchy as surface fires from low- and mixed-severity fires periodically cleared them out. More work is underway and in time our understanding of this complex issue will be more complete.

Some sites within the mosaic of MMC forest would have had long intervals (>75 to 100+ years) between fires. It is on these sites that dense, multilayered forest conditions would have developed. In areas of high topographic complexity (e.g., eastern Washington Cascades and Blue Mountains) such sites are found on north-facing slopes at mid to upper elevations or at lower elevations near streams where moisture conditions would have made fuels too wet to burn except under infrequent hot dry weather conditions (Camp 1999, Camp et al. 1997). In areas of simpler topography defined by broad elevation gradients and isolated cinder cones (e.g., eastern Oregon Cascades), elevation and climate may explain the distribution of shade-tolerant species and fire regimes (Merschel 2012). Thus, many successional pathways occur in these landscapes but only a few of them would have reached old forest conditions where forests are relatively dense and dominated by shade-tolerant species, which are maladapted to fire-prone environments and droughty climate.

Despite the variation in disturbance regimes and environments, historical stand densities of large fire-tolerant trees in both dry and MMC were typically low and fell within a relatively narrow range (table 3). Of 15 estimates of historical small, medium, and large tree stand densities from different dry and MMC types and environments (based on seven total studies), 12 estimates fell within the range of 40 to 170 trees per hectare (16 to 70 trees per acre) and most of these estimates probably represent the minimum because most trees from cohorts that were regenerated in the 18th and 19th centuries were removed by disturbances. Regardless of their size, those that remain are simply the subset of survivors. Historical densities of large trees, most of them ponderosa pines and Douglas-firs, appear to fall within a relatively narrow range of low values from around 20 to 40 trees per hectare (8 to 16 trees per acre) (table 3). Figure 19 illustrates the strong contrast in historical versus current tree density in five locations in eastern Oregon and Washington.

Table 3 —Historical and current density (trees per hectare) of large diameter (typically >50 cm) trees in dry and moist mixed-conifer forest

Region	Forest description	Historical density	Current density	Source	Notes
		Mean ± standard deviation (range) and time period			
Eastern slope of the Cascade Range, southern Oregon	Mixed-dry	35 ± 15 (3–105) 1914–1922	21 ± 12 (0–45) 1997–2006	Hagmann et al. 2013	Historical density is reported for trees >53 cm diameter at breast height (dbh) based on timber inventory transects that covered 10 to 20 percent (6646 ha) of a 38 641-ha study area of ponderosa pine and dry and moist mixed-conifer forest. Current density is based on 24 current vegetation survey (CVS) plots within the study area, and density is reported for all trees >53 cm dbh. Inventory plots were assigned to habitat types (dry or moist) using mapped potential vegetation types (ILAP).
	Mixed-moist 1914–1922	35 ± 17 (3–147) 1997–2006	16 ± 15 (0–114)		
Warm Springs Indian Reservation, eastern slope of the Cascade Range, Oregon	Mixed-dry	24 ± 10 (1–62) 1922–1925	NA	Hagmann, unpublished data, 2013[a]	Historical density is reported for trees >53 cm dbh based on timber inventory transects. Plot size varied by species. Transects covered >20 percent (6952–11 327 ha) of a 32 293–ha study area of dry and MMC forest. Inventory plots were assigned to habitat types using mapped potential vegetation types (ILAP).
	Mixed-moist	26 ± 12 (0–102) 1922–1925	NA		
Eastern slope of the Cascade Range, Wenatchee National Forest, Washington	Mixed-dry/moist (estimates for several Douglas-fir potential vegetation types)	HDSG[b]—32 WDSH—2 WDTS—41 WMSH—27 1899	HDSG—77 WDSH—82 WDTS—99 WMSH—94 CDG—28 1999	Ohlson and Schellhaas 1999[c] CDG—71	For trees >40 cm (16 in) dbh. See table 5 for more information.
Blue Mountains, central Oregon	Mixed-conifer	27–32 1916–1932	NA	Forest Service inventories	Historical density reported for trees > 50 cm.
Eastern slope of the Cascade Range, central Oregon	Mixed-dry (Douglas-fir)	28 ± 19 (0–71) Early 20th century	17± 17 (0–50) 14 sample sites 2009–2010	Merschel et al. [N.d.]	Sample sites (~ 1.0 ha) were widely and randomly distributed in mature forest mapped in any of the mixed-conifer dry or mixed-conifer dry plant association groups. The number of sample sites used in each estimate is noted following the reported density. Density is reported only for shade-intolerant trees >50 cm. Historical density is based on diameter reconstruction of cut stumps, and current density is based on live trees only. Estimates refer to areas that were selectively logged, but 66 of 177 sites sampled had no evidence of logging. Period of historical density is estimated to be early to mid-20th century.
	Mixed-dry (grand fir)	30 ± 19 (17–85) Early 20th century	20 ± 15 (0–45) 16 sample sites 2009–2010		
	Mixed-moist	21 ± 17 (0–67.5) Early 20th century	12.9 ± 11 (0–45) 24 sample sites 2009–2010		
Ochoco Mountains, central Oregon	Mixed-dry (Douglas-fir)	32 ± 13.8 (5–64) Early 20th century	25.1 ± 15 (0-64) 26 sample sites 2009–2010		
	Mixed-dry (grand fir)	38 ± 19 (7.1–67) Early 20th century	19 ± 20 (0-65) 14 sample sites 2009–2010		
	Mixed-moist	18 ± 16 (0–48) Early 20th century	13 ± 13 (0-40) 14 sample sites 2009–2010		

Table 3 —Historical and current density (trees per hectare) of large diameter (typically >50 cm) trees in dry and moist mixed-conifer forest (continued)

Region	Forest description	Historical density	Current density	Source	Notes
		Mean ± standard deviation (range) and time period			
Eastern slope of the Blue Mountains, eastern Oregon	Mixed-conifer	NA	38 TPH 2012	Johnston 2013, unpublished data[d]	Density is reported for trees >50 cm in unlogged areas and provides an estimate of historical large tree density in logged areas in dry and MMC forests.
Eastern slope of the Cascade Range and foothills, Oregon and Washington	Mixed-dry	NA	21 ± 23 (n = 512) 1994–2004	Reilly 2012, unpublished data[e]	Density based on forest CVS plots distributed on a 2.5 by 2.5 km grid (5 km in wilderness areas) throughout national forests of Oregon and Washington. Sample sites include developmental stages ranging from early seral in recently disturbed areas (logging, wildfire, etc.) to mature old-growth forest. Density estimates are reported for trees >50 cm dbh. The number of CVS plots used to calculate density is reported in parentheses. CVS plots were assigned to PVTs based on ILAP.
	Mixed-moist	NA	27 ± 27 (n = 280) 1994–2004		
	Mixed-dry	NA	19 ± 16 (n = 471) 1994–2004		
Blue Mountains ecoregion, Oregon and Washington	Mixed-moist	NA	23 ± 21 (n = 1041) 1994–2004

Note: see table 5 for more information. Diameter thresholds, methods of estimation, and spatial coverage used to develop estimates differs among authors.

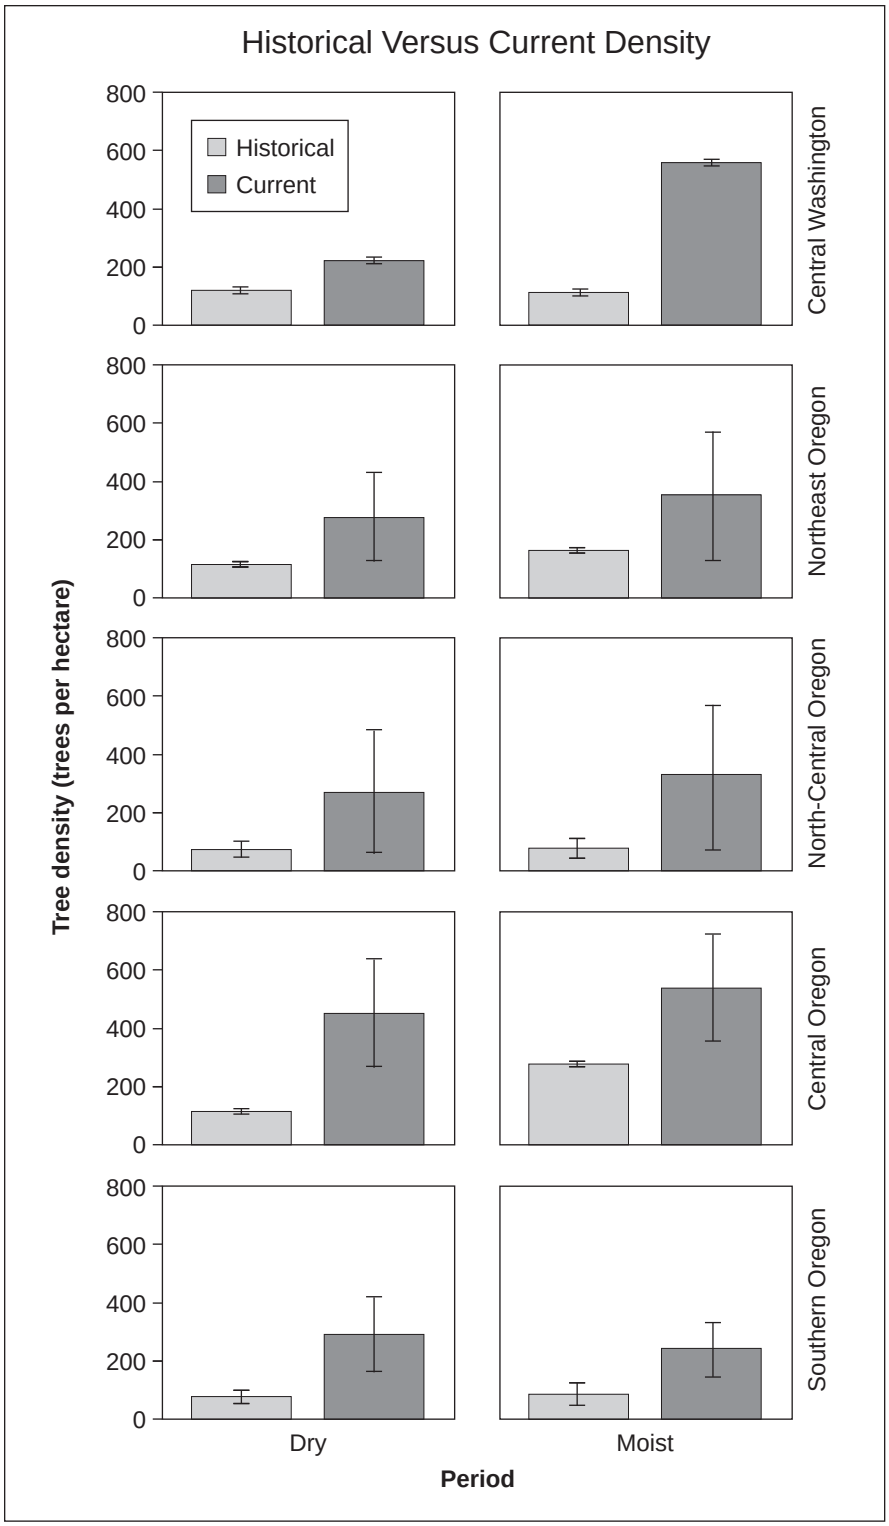

Figure 19—Historical versus current tree density in dry and moist mixed-conifer forest summarized from five study areas. Methods used to calculate density vary by reference period and study region, and diameter thresholds for tree density vary slightly among regions (10 to 15 cm). See the notes section in table 5 for citations and detailed information on how density was estimated in each region and time period.

Landscape Concepts

Provincial or regional landscapes consist of nested local landscapes, which are themselves comprised of yet smaller land units often referred to as stands or patches (Wu and David 2002, Wu and Loucks 1995). At each nested scale, species and ecosystems are controlled by spatial and temporal heterogeneity of patterns and processes. What occurs within a patch is affected by its surroundings and vice-versa. Figure 20 shows four east-west transects across montane regions of eastern Oregon and Washington and illustrates the continuous gradients of forest types that are found on these landscapes. MMC and other mixed-conifer types are thus part of a complex and intermingled landscape mosaic. The outcome of silviculture at the stand or patch level is thus inextricably linked to the interacting parts of the local and regional landscapes.

What occurs within a patch is affected by its surroundings and vice-versa.

Regional or broad-scale patterns of biota (e.g., life form zones and broad land cover types), geologic substrates (surface lithologies), geomorphic processes (land surface forms), and climatic patterns (e.g., spatial patterns of seasonal temperature, precipitation, solar radiation, and wind) constrain ecological patterns and processes occurring at a meso-scale. We call these constraints top-down spatial and temporal controls. For example, Bunnell (1995) found that the species composition of vertebrates in forest types is controlled by the disturbance regimes and mix of forest development stages found in biogeoclimatic zones in British Columbia, Canada. Changes to regional climate over relatively long time frames (100 to 1,000 years) affects relatively large spatial domains (1 million to 10 million ha). In other words, multi-century to millennial-scale changes in climate and geology can have a significant influence on species ranges. New plant and animal communities are potentially organized, new landform features emerge, and new patterns of environments and dominant disturbance regimes arise. A well-known example of landform effects in eastern Oregon is the eruption of Mount Mazama (current Crater Lake) about 7,700 years ago, which created a landscape of deep pumice deposits that control the composition and productivity of forest vegetation across central Oregon (Franklin and Dyrness 1988).

Likewise, fine-scale patterns of endemic disturbances (e.g., native insects and pathogens), topography, environments, vegetation, and other ecological processes provide critical context for patterns and processes over narrower scales or extent. These are termed bottom-up spatial and temporal controls. Bottom-up controls occur over relatively small spatial domains (1 to 100 ha), and drive processes that can vary temporally from hourly to annual time scales. For example, cool, moist, north-facing slopes can create fire "refugia" in which disturbance regimes and environment favor the development of forest containing old, fire-intolerant tree

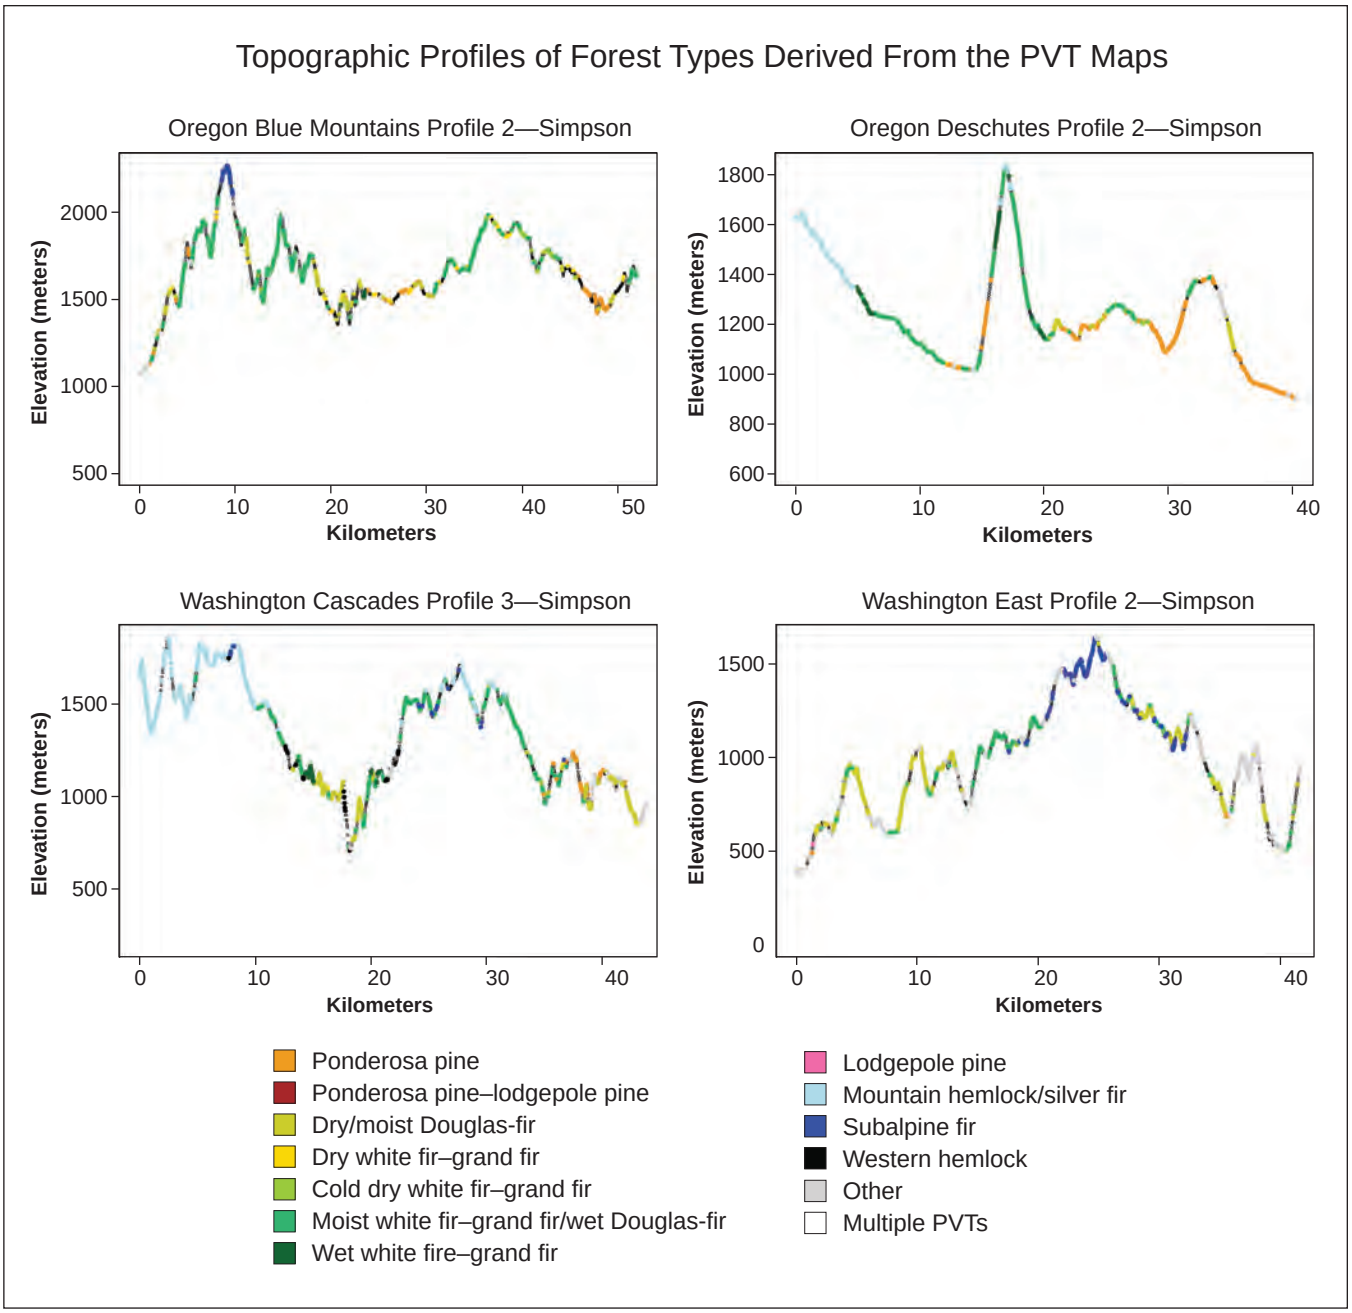

Figure 20—Profiles of predominant forest types, derived from potential vegetation types (PVTs) of Simpson (2007), across an east-west transect for four locations in eastern Oregon and Washington. Topography is exaggerated to show topographic effects.

species (Camp et al. 1997) (fig. 21). These small patches of old forest tree species can serve as seed sources that can affect rates and patterns of succession across the larger landscape (Wimberly and Spies 2001).

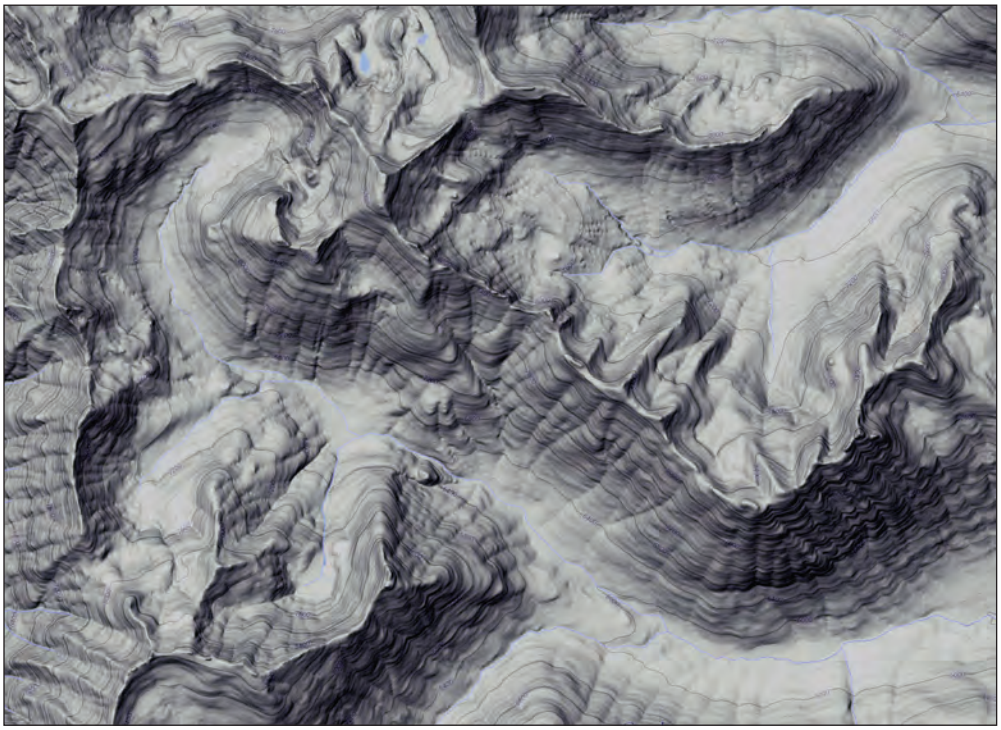

Figure 21—At the localized scale, mountainous terrain creates localized gradients in soil moisture, driven principally by differences in exposure to sunlight and wind (e.g., dry windy south-facing aspects versus cool moist north-facing hillslopes).

At all spatial and temporal scales of the hierarchy, landscapes exhibit transient patch dynamics and nonequilibrium behavior, resulting in ecosystem patterns and processes that may or may not change in linear or predictable ways. This is due to both random and deterministic properties of the supporting land and climate systems, and of ecosystem processes occurring at each level. Lower-level processes are incorporated into the next higher level of structures and processes, and this happens at all levels (figs. 11 and 21) (Wu and Loucks 1995).

Landscape patterns drive processes at local and regional landscape scales; at either scale, no two landscapes exhibit the same patterns across space or time. However, landscape patterns historically exhibited predictable spatial pattern characteristics. For example, a large sample of local landscapes (e.g., subwatersheds) comprised of dry and MMC forest in the lower and mid-montane settings, with subalpine forests in upper montane environments, reflected a predictable frequency-size distribution of cover type and structural class patch sizes (figs. 22 and 23).

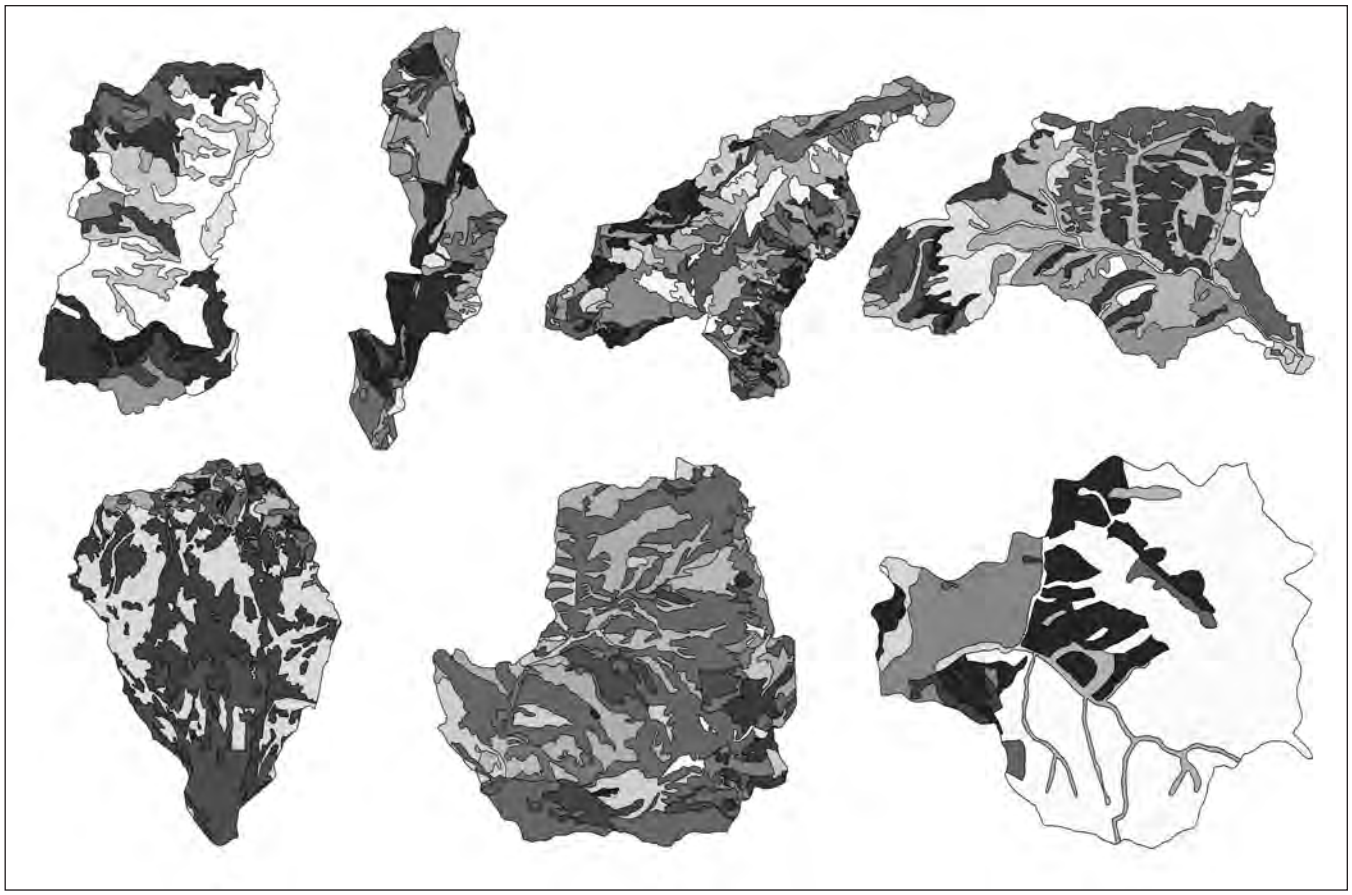

Figure 22—A sample of seven historical (ca. 1900) maps of combined cover type and structural class conditions from subwatersheds of the eastern Washington Cascades. Gray tones indicate unique cover type-structural class combinations. Note the highly variable patch sizes, with many small and fewer large patches. Despite their fewer numbers, the large patches actually make up the majority area of each subwatershed (adapted from Perry et al. 2011).

Here, think of histograms showing patch sizes in an inverse-J shaped distribution, with many small to medium-sized patches, and fewer large patches (fig. 23). Patterns and spatial arrangements of combined cover type and structural stage patch sizes (synonymous with O'Hara et al. [1996] structural classes) and their associated fuel beds provided constraint to the patch size and severity of disturbances. These patterns worked in concert with patterns of topography and weather influences to limit disturbance (Malamud et al. 1998, 2005; Moritz et al. 2010; Perry et al. 2011). This constraint probably appeared to be relatively stationary over multidecadal timeframes, but varied over multicentury periods.

As top-down controls such as regional climate or land surface forms significantly changed over large spaces and long time frames, these ranges were constantly being nudged and redefined. Moreover, because context and constraint

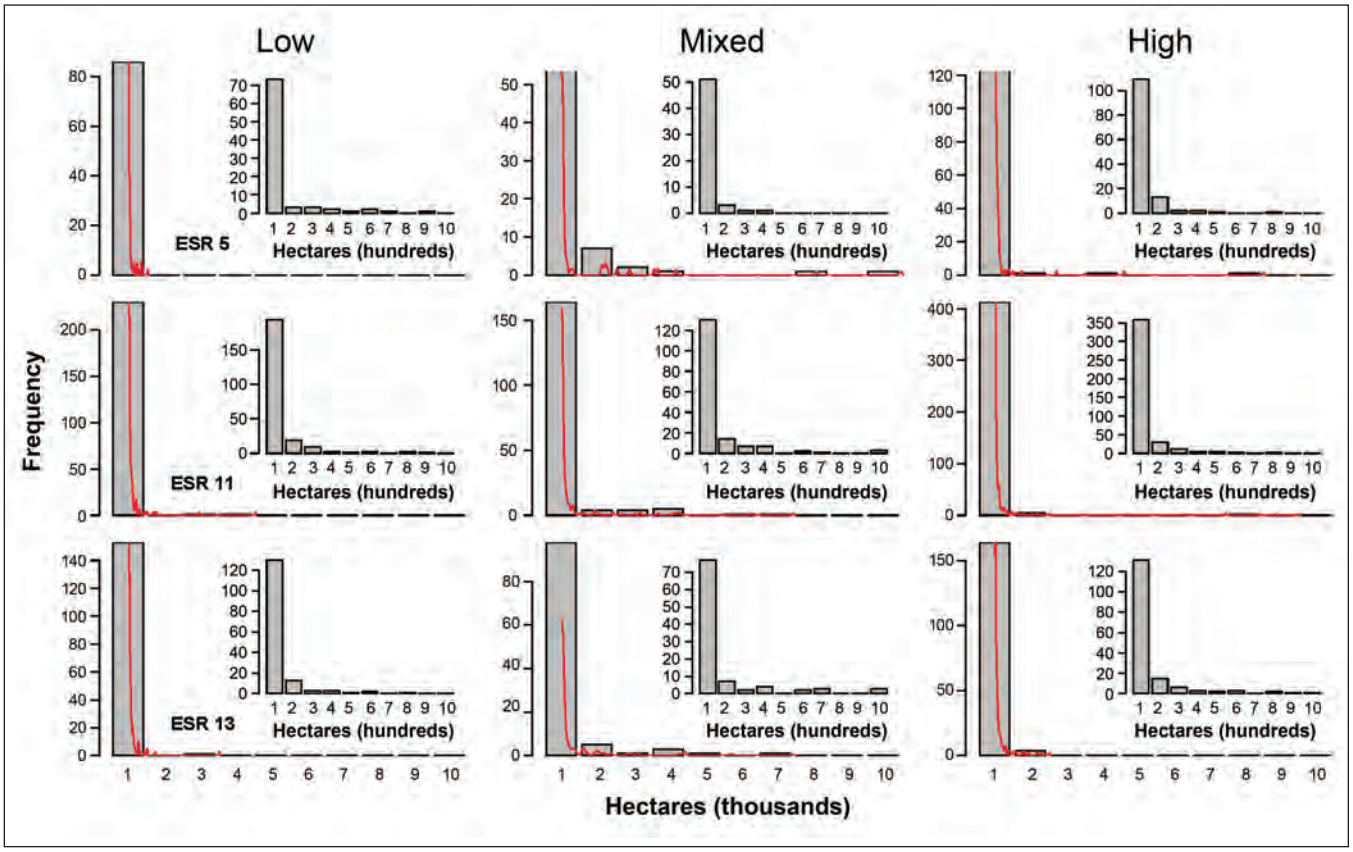

Figure 23—Frequency-size distributions of reconstructed historical (ca. 1900) fire severity patches in three ecoregions of the eastern Washington Cascades. Low, mixed, and high denote severity corresponding with <20 percent, 20 to 70 percent, and >70 percent of the overstory crown cover or basal area killed by fires, respectively. Data are from Hessburg et al. (2007). See Hessburg et al. 2000a for ecoregion details.

varied in the long term, the processes and patterns they reflected also varied over time. In a warming climate, e.g., the envelope of ecological patterns and processes at each level in the spatial hierarchy (literally the range of variation, RV) is reshaped by the strength and duration of warming (fig. 24). Reshaping of landscape patterns within a level can be figuratively represented as an envelope of conditions that drifts directionally in time (e.g., Nonaka and Spies 2005). Hessburg et al. (2000b) developed quantitative ecoregions for the interior Columbia River basin. They showed that there are strongly overlapping spatial patterns of regional climate, geology, and geomorphic processes (fig. 25). Later, they showed that these ecoregions explained some of the variance between various physiographic settings in the amount of low-, mixed-, and high-severity fires (Hessburg et al. 2004). This was first-order evidence of broad-scale spatial controls on meso-scale fire regimes.

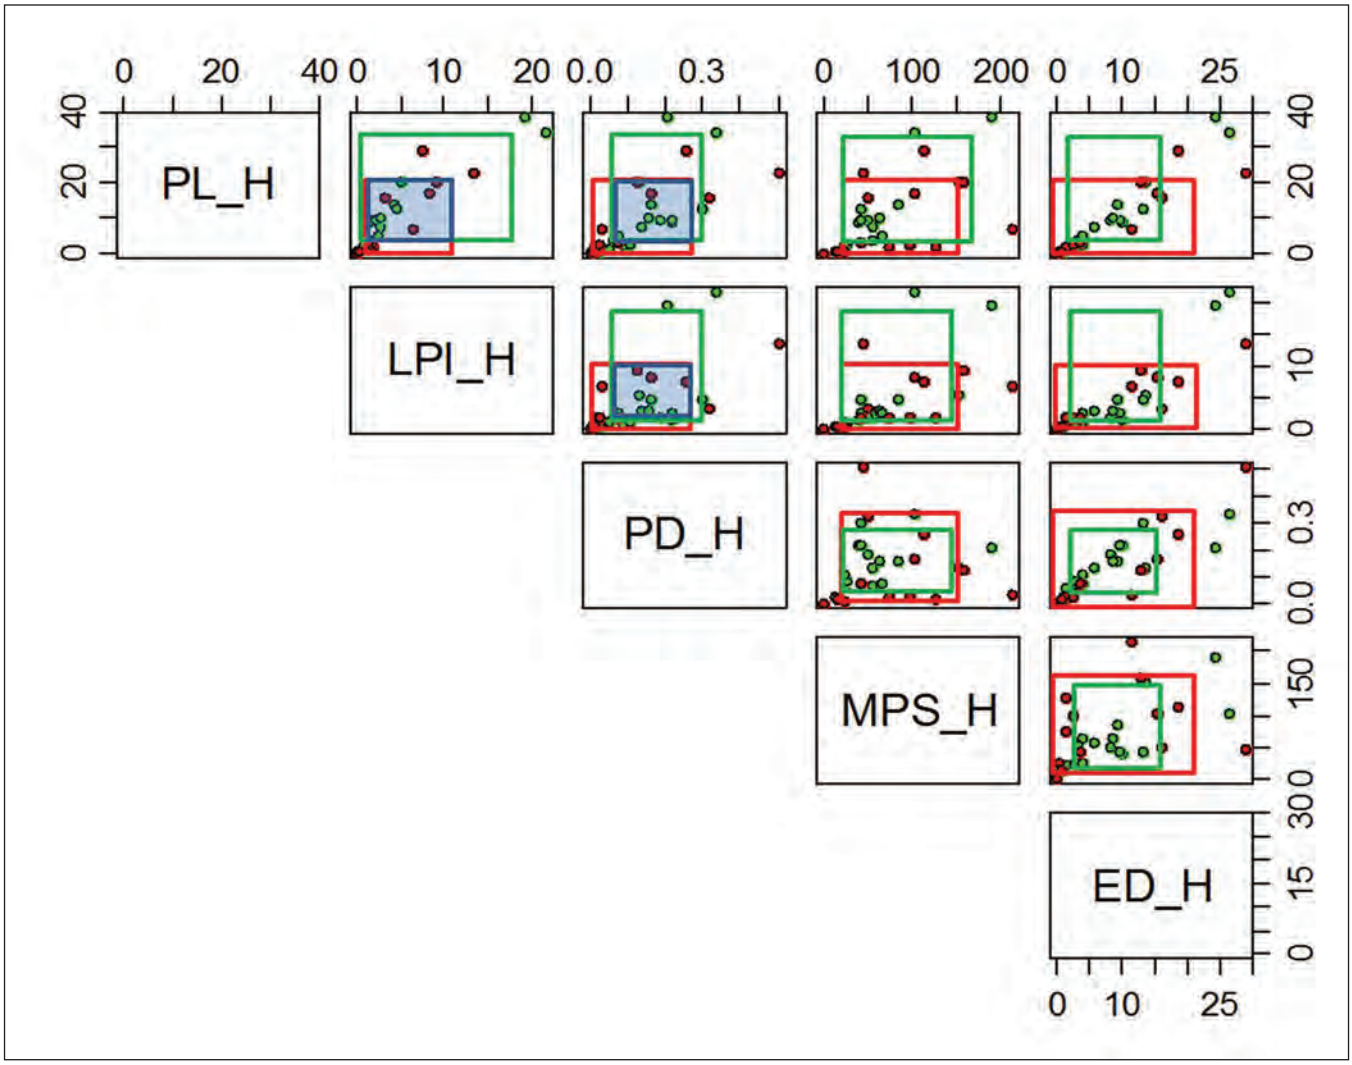

Figure 24—Comparing the historical range and variation (HRV, green dots and squares) and future range and variation (FRV, red dots and squares) with climate warming of five class metrics (paired in all possible combinations) of combined cover type–structural class patch types from a 10-percent random sample of subwatersheds of an eastern Washington Cascades ecoregion. The class metrics are the percentage of landscape area (PL_H, percent), the largest patch index (LPI_H, percent of the landscape), the patch density (PD_H, #/10,000 ha), the mean patch size (MPS_H, ha), and the edge density (ED_H, m/ha). The green square outlines the median 80 percent range of the subwatershed HRV sample. The red square outlines the median 80 percent range of the subwatershed FRV sample. Note the strong overlap between the HRV and FRV ranges in the pairwise combinations. In this example, we show paired combinations in a 2-space representation. Although impossible to graph here, one can imagine these metrics combined in a 5-space representation. In landscape analysis, any number of measures may be combined in an n-space representation to portray the HRV, the FRV, or both. In this way, departures or significant changes in spatial patterns of any contemporary landscape can be compared with the HRV and FRV to decipher the main characteristics of the changes.

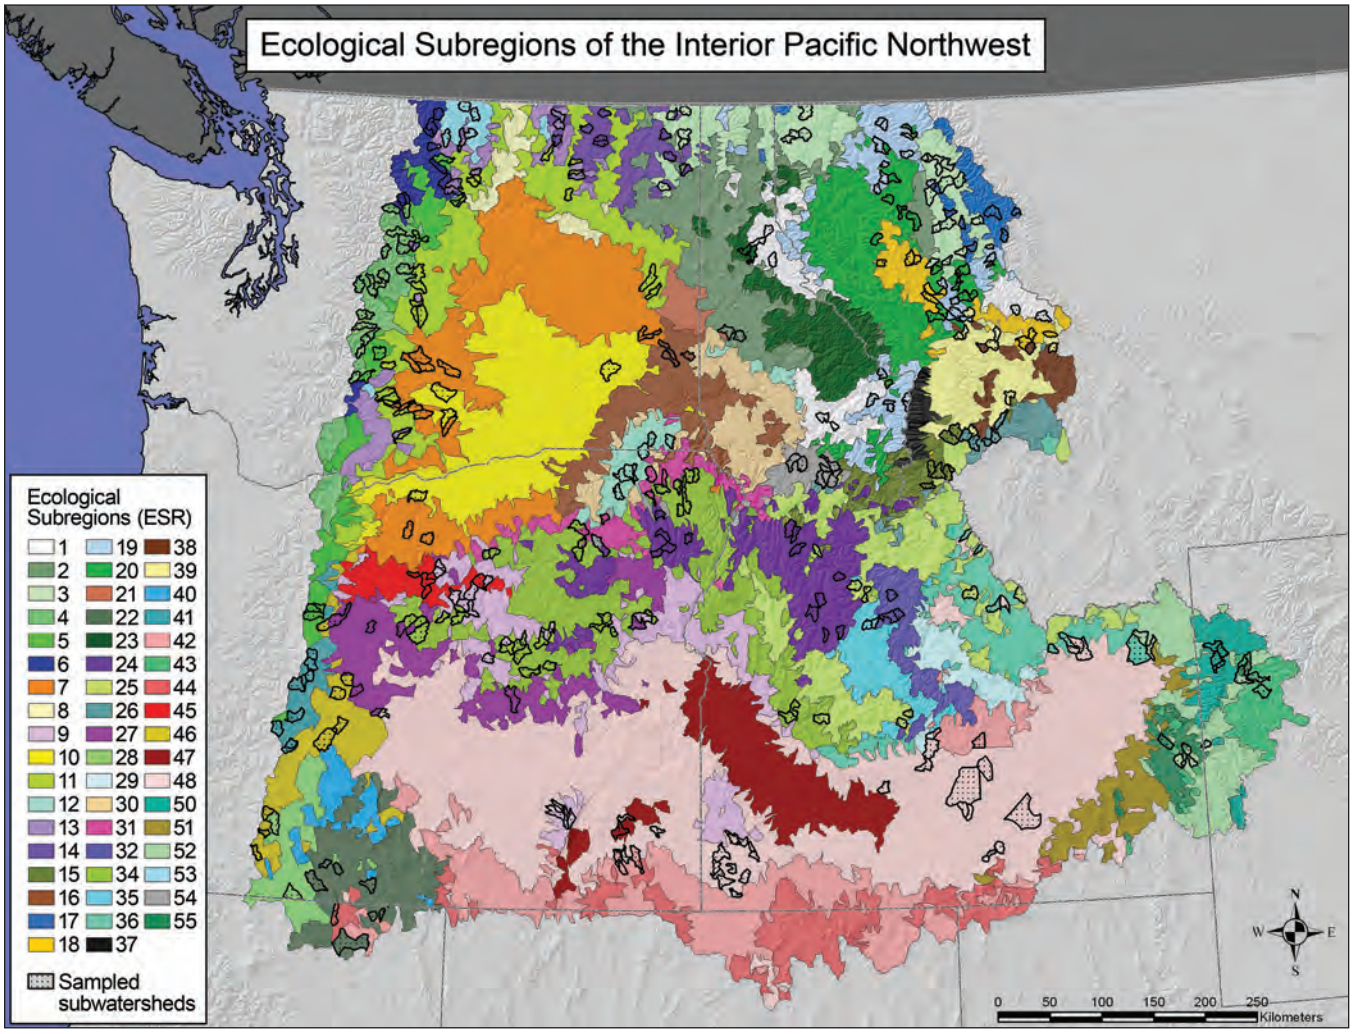

Figure 25—Ecological subregions of the interior Columbia River basin (Hessburg et al. 2000a). Names corresponding with ESR numbers are of the form: [ESR number = Bailey's (Bailey et al. 1994) ecoregion—Dominant Precipitation class(es)—Dominant Temperature class(es)—Dominant Potential Vegetation Group(s)—Dominant Solar Radiation class(es)]: 1 = M330–Wet–Warm–MF–Mod solar; 2 = M333–Moist–Warm–MF/DF–Low solar; 3 = M333–Moist–Cold–MF–Low solar; 4 = M242C–Wet–Warm–MFCF–Low solar; 5 = M242C–Moist–Warm–MF/CF–Mod solar; 6 = M242C–Wet–Cold–CF–Mod/Low solar; 7 = 342I–Dry–Warm–DS–Mod solar; 8 = M333A–Dry–Warm/Hot–DG–Mod solar; 9 = 300–Moist/Dry–Warm–DS/CS–High solar; 10 = 342I–Dry–Hot–DS/DG–Mod solar; 11 = 200/300–Dry/Moist–Warm–MF/DF–Mod solar; 12 = M330–Moist–Warm–DF–Mod solar; 13 = 200/300–Moist–Warm/Cold–MF–Mod solar; 14 = M333A–Moist–Warm/Cold–MF–Mod solar; 15 = M332–Moist/Wet–Cold–CF/DF–Mod/High solar; 16 = 330–Moist–Hot–DG–Mod solar; 17 = M333C–Wet–Cold–MF/CF–Low solar; 18 = M330–Moist–Warm–DF/DG–Mod solar; 19 = M330–Wet–Cold–MF/CF–Mod solar; 20 = M330–Moist–Cold/Warm – MF–Mod solar; 21 = 331A–Moist–Warm–DG–Low solar; 22 = 200–Moist/Dry–Warm–DF–Very high/High solar; 23 = M333D–Wet–Warm/Cold–MF–Low solar; 24 = M332–Moist/Wet–Cold–CF/DF/MF–High solar; 25 = M332–Moist–Cold–DF/CF–High solar; 26 = M332–Moist/Dry–Cold–CF–High/Mod solar; 27 = 300–Dry–Warm–CS/DF–High solar; 28 = 200 – Moist–Warm–DF/DG–High solar; 29 = M332–Dry–Cold–DS/CS–High solar; 30 = 300–Moist–Warm–DG/DF–Mod solar; 31 = 300–Moist–Warm–DF/DG–Mod solar; 32 = M332F–Moist–Cold/Frigid–CF–High/Very high solar; 34 = M332–Moist–Warm/Cold–DF/CS–High solar; 35 = M332–Moist–Cold–CF/DG–High/Very high solar; 36 = M332–Dry–Cold/Warm–DS/CS – High solar; 37 = M332B–Wet–Cold–RK/CF–Mod solar; 38 = M332–Moist–Cold–CF/DF/DG–Mod solar; 39 = M332B–Moist–Warm/Cold–DF/CF/DG–Mod solar; 40 = 200–Moist–Warm/Cold–DF–High/Very high solar; 41 = M242C–Moist–Warm–MF/DF/CF–High solar; 42 = 300–Dry–Warm–DS/CS–Very high solar; 43 = M331D–Moist–Cold–CF/DF/WD–Very high solar; 44 = 342–Dry/Moist–Warm–DS/CS–Very high solar; 45 = 342H–Dry–Warm/Hot–DS/CS–High solar; 46 = M242C – Moist–Warm–DF–High solar; 47 = 342C–Dry–Hot–DS/RS–High solar; 48 = 342–Dry–Warm–DS–High solar; 50 = M331–Moist/Wet–Cold/Frigid–CF–High solar; 51 = 300–Moist/Dry–Warm–DS/WD–High solar; 52 = M331–Moist–Cold–CF/WD – High solar; 53 = M242C–Moist–Cold–CF–Mod solar; 54 = M332–Moist–Warm–MF/DF–Mod solar; 55 = M331D–Moist – Cold–WD–High solar. Potential Vegetation Groups are: AL = Alpine; CF = Cold Forest; CS = Cool Shrub; DF = Dry Forest; DG = Dry Grass; DS = Dry Shrub; MF = Moist Forest; RS = Riparian Shrub; RW = Riparian Woodland; RK = Rock; WA = Water; WD = Woodland. Precipitation classes are: Very Dry = 0–150 mm/yr; Dry = 150–400 mm/yr; Moist = 400–1100 mm/yr; Wet = 1100–3000 mm/yr and Very Wet = 3000–8100 mm/yr. Temperature classes are: Frigid = –10––1 °C; Cold = 0–4 °C; Warm = 5–9 °C; Hot = 10–14 °C. Solar radiation classes are: very low = 150–200 W/m^2; low = 200–250 W/m^2; moderate = 250–300 W/m^2; high = 300–350 W/m^2; very high = 350–400 W/m^2. Mixed composition of attributes is indicated with a " / " and mixed attributes are listed in order of decreasing abundance. Sampled subwatersheds shown are those sampled by Hessburg et al. 2000a.

Large-amplitude and long-term changes relative to organism tolerance (often over several decades to centuries) reshape pattern envelopes by imprinting those landscapes with new disturbance and recovery patterns over large areas.

Changes that are small in amplitude and short term relative to the tolerances of dominant organisms (often multiannual to multidecadal) will do little to reshape the envelope because of the strength of system memory (inertia and elasticity; existing patterns of disturbance and recovery), expressed in successional stages and composition of vegetation. But large-amplitude and long-term changes relative to organism tolerance (often over several decades to centuries) reshape pattern envelopes by imprinting those landscapes with new disturbance and recovery patterns over large areas. For example, changes to the climate of the Southwestern United States desert biome since the last glacial maximum have been so substantial that plant and animal species ranges have fundamentally shifted and reorganized, along with their disturbance regimes (Betancourt et al. 1990).

It is informative for managers to understand the ranges of structural and compositional conditions that occur within landscapes of a region or subregion. Forest ecosystem response will be consistent with the current biophysical conditions and their disturbance regimes, including current climate forcing. For example, it is not clear how much the existing distribution of MMC forest will change with projected future climates and altered disturbance regimes. Fine-scale and gradual processes of mortality, dispersal, and range expansion are probably operating now to "adjust" patterns of species and ecosystems to the prevailing climate and disturbance trends of recent decades. Knowledge of factors controlling movement of species across landscapes provides insights to managers about how current landscape conditions will likely change, and thus how MMC forests may be able to persist under a changing climate. Multiscale research and monitoring are needed to elucidate these trends. Such information would enable a clearer vision to anticipate trends and develop tools for maintaining management options.

Natural Disturbance Factors

In this section, we highlight key disturbance factors in the MMC forest. Disturbance regimes vary across climate and environmental gradients in a relatively predictable fashion. These disturbances strongly influence vegetation composition, structure and habitat conditions, which themselves influence the variability of disturbances. These are brief synopses of complex topics, and we encourage the reader to delve deeper into the literature cited for more detail.

Wildfire—

Fire histories are not adequately documented in many moist forests in eastern Oregon and Washington. Our knowledge of past fire regimes and forest structure comes from proxy records, all of which are rich sources of data, but none of which is complete. Tree rings are one source of empirical data that can lead to

multicentury reconstructions of fire and forest history, but only over small areas. Fire and forest vegetation histories reconstructed from aerial photos from the 1930s and 1940s are another source of empirical data, and although many such reconstructions predate most logging, most represent conditions that occurred 30 to 60 years after fires were already excluded. Thus our inferences are constrained by data limitations, especially when we need to apply them to particular potential vegetation types or ecoregions.

Historical fire regimes across the region—In this region, several spatially extensive studies have reconstructed multicentury histories of low-severity fire regimes from fire scars in dry and MMC forests and inferred their climate, topographic, and land-use drivers at landscape and regional scales (Everett et al. 2000, Hessl et al. 2004, Heyerdahl et al. 2001, Kellogg et al. 2008, Wright and Agee 2004). However, few studies have focused specifically on MMC forests as we define them (Hessburg et al. 1999a, 1999c, 1999d, 2007; Heyerdahl et al. 2001; Perry et al. 2011; Tiedemann and Woodard 2002; Woodard 1977; Wright and Agee 2004). These studies suggest that mixed-severity fire was likely a dominant influence with smaller amounts of low- and high-severity fire. Current forest structure and life history strategies of trees typically found in mesic forests support our assumptions that historical fires were less frequent than in dry ponderosa pine and mixed-conifer forests and were of mixed severity (Agee 1993).

Although we have little quantitative information on the size (but see Perry et al. 2011) and frequency of past fires in MMC forests, mean fire return intervals may have much less importance than the range of fire intervals in this forest type (Halofsky et al. 2011). From only a few reconstructed fires (e.g., eight fires in Heyerdahl et al. 2001), there was a broad range of return intervals (several decades to more than 100 years, often within a single stand), but information on historical fire size was unobtainable with these methods. No studies have been designed to identify fine-scale variation in fire severity (i.e., patch size) within individual fires and only one within PVTs (see Hessburg et al. 2007). Landscape-scale reconstructions of forest structure from early to mid-20th century aerial photographs across the region also indicate that fires were of mixed severity (Hessburg et al. 2007). Perry et al. (2011) provided fire severity patch size distributions relating to dry and MMC forests in eastern Washington using the Hessburg et al. (2007) data set.

Historical fire regimes in MMC forests of this region likely varied across a broad range of spatial and temporal scales in response to regional variation in climate and physical geology, and local variation in topography and environments (Gedalof et al. 2005, Heyerdahl et al. 2001, Littell et al. 2009). These factors also control vegetation distribution, but PVT as mentioned above is only one predictor

of historical fire frequency or severity (Hessburg et al. 2007, Heyerdahl et al. 2001). Historical fire regimes have been reconstructed in MMC forests elsewhere in the Interior West, but presently we do not have enough information about spatial and temporal variation in the drivers of fire in these forests to know how well these reconstructions capture historical fire regimes throughout eastern Oregon and Washington. Low-severity fires were strongly synchronized in dry forests across the region by climate in the past (Heyerdahl et al. 2008) and the same may be true for moist forests, but the case has not been clearly made. Historical fire severity patterns have been reconstructed using dendroecological methods from about 10 percent of the total area of dry and MMC forests of the eastern Cascades in Washington. Extensive data sets are available from the Hessburg et al. (1999a, 1999b, 1999c, 1999d) Interior Columbia River Basin data archive to continue this work in the Blue Mountains and eastern Oregon Cascades.

Fire dynamics: resulting spatial patterns and tree mortality rates—Fire is a significant driver of mixed-conifer forest and aquatic ecosystems. The periodic influences of fire largely control the rates and patterns of succession and determine forest structure and composition, and aquatic and riparian condition. Despite recent contributions to the literature, there is still much scientific uncertainty and lack of consensus on the characteristics of fire regimes of mixed-conifer forests (amounts of low, mixed, and high severity), and how these varied by ecoregion. This lack of understanding (and investment in understanding) of the fire ecology of MMC forests limits the ability of managers to effectively identify appropriate steps toward ecosystem restoration. We do know that natural fire regimes in MMC forests varied somewhat predictably within areas that shared a similar climate and vegetation type, as well as topographic, edaphic (soil related), and environmental settings (Perry et al. 2011) (app. 3).

Low- to mixed-severity fires produced a highly variable mosaic of living and dead trees at multiple spatial scales, resulting in patchy regeneration in stands and landscapes, and perpetuating the low- and mixed-severity fire cycle. Low-severity fires (killing less than 25 percent of the overstory) typically occurred where fires were most frequent (e.g., every 10 to 30 years). MMC patches that experienced low-severity fire occurred in areas and slope positions that were adjacent to dry mixed-conifer and ponderosa pine woodlands. Low- and mixed-severity fire appear to be dominant in the eastern Cascades and parts of the Blue Mountains based on recent and ongoing work (Merschel 2012). Elevation and aspect influences on plant available soil moisture played important roles. Figure 26 illustrates a forest subject to a typical low-severity fire regime.

Tom Iraci

Figure 26—An example of a low-severity prescribed fire. These fires are characterized by minimal short-term ecosystem effects. The result of a low-severity fire is fuel reduction and topkill of understory vegetation.

Mixed-severity fires (killing 25 to 75 percent of the overstory) were common in the MMC forest because much of the area in these productive systems was visited by wildfires on a relatively infrequent basis (i.e., about every 25 to 75 years). This allowed for the development of a patchy vegetation mosaic, with patchy patterns of surface and ladder fuels, and both open and closed canopy conditions (app. 3). One may contrast fire severity in this way: low-, mixed-, and high-severity fires produced fine-, meso-, and broad-scale patchiness of tree structure and species composition within local and regional landscapes. Figure 27 illustrates a forest subject to a typical mixed-severity fire regime.

High-severity fires (resulting in over 75 percent overstory mortality) occurred occasionally (Agee 1990, 1993, 1994, 1998; Baker 2012; Hessburg, et al. 2007; Heyerdahl et al. 2001, 2008; Williams and Baker 2012), especially where fire return intervals exceeded 100 to 150 years. These conditions tended to occur in slope and aspect conditions adjacent to wet and cool to cold forests (e.g., western hemlock, mountain hemlock [*Tsuga mertensiana* (Bong.) Carrière], Shasta red fir, and Pacific silver fir [*Abies amabilis* (Douglas ex Loudon) Douglas ex Forbes)]) and did not appear to dominate the fire regime of MMC forests. Figure 28 illustrates a forest subject to a high-severity fire regime.

John Marshall

Figure 27—An example of the impacts of a mixed-severity fire, exhibiting a wide range of effects on the dominant vegetation. Some areas exhibit low fire severity, with little damage to overstory trees, while others exhibit moderate fire severity. Some areas exhibit high severity as indicated by complete mortality of the overstory.

John Marshall

Figure 28—An example of a high-severity fire, characterized by high levels of tree mortality, significant fuel consumption, and often extensive soil heating.

Landscape patterns: patch size and shape resulting from fire—There is still much to learn, but we know from fire history reconstructions using fire scars that small (1 to 50 ha [~2 to 123 ac]) to medium-sized (100 to 5,000 ha [~247 to 12,355 ac]) fires were most numerous, and pock-marked the landscape. They represented 85 to 95 percent of fire events, but only accounted for 5 to 15 percent of all of the landscape area burned by historical wildfires (Malamud et al. 1998, 2005) (fig. 29). The primary role of these smaller fires was to spatially isolate patterns of combustible surface and canopy fuels across the landscape (Moritz et al. 2010). In fact, the common small fires (that are currently suppressed) played a key role in shaping the larger landscape. Burned and newly recovering patches to some extent spatially interrupted the flow of larger fires, often limiting their spread. This was the primary mechanism maintaining the frequency-size distributions of wildfires. Large fires (>5000 ha [12,355 ac]) were much rarer, but they typically burned most of the landscape area that was subject to fire (75 to 95 percent).

We know from fire history reconstructions using fire scars that small to medium-sized fires were most numerous, and pock-marked the landscape.

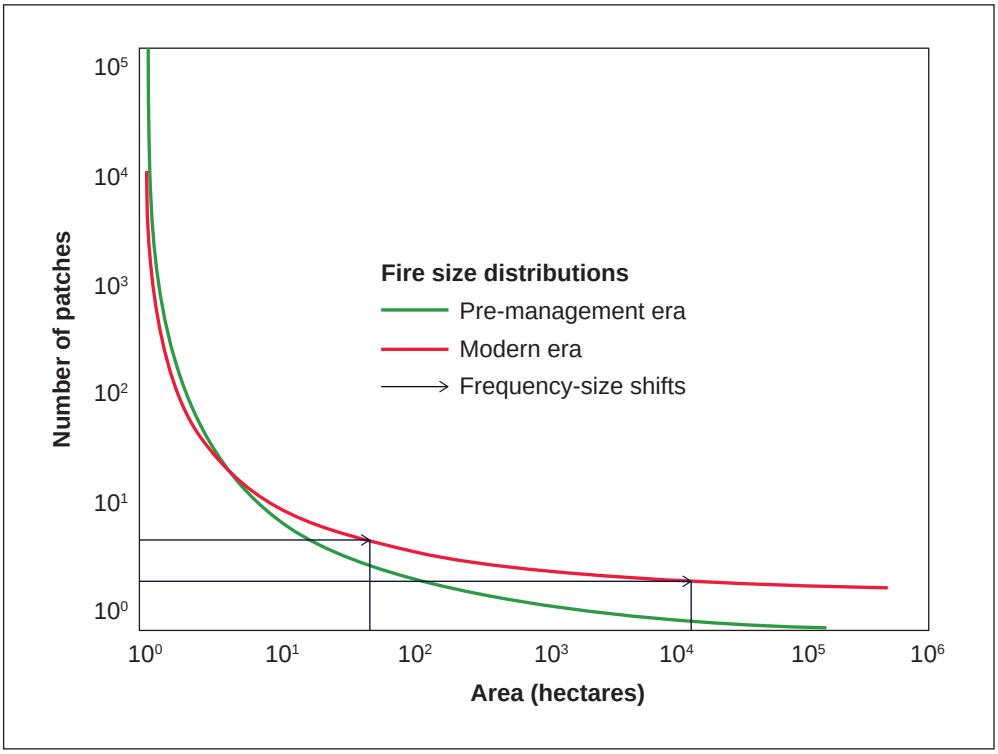

Figure 29—A comparison of fire size distributions in the pre-management and modern era. This illustrates the frequency-size shift toward larger burn patches in the modern era.

The distribution of fire event sizes approximated the negative exponential (an inverse-J distribution in the native form), and this appeared to be true regardless of fire severity (Perry et al. 2011). Overall fire frequency controlled the size of the largest fires. Numerous small- and medium-sized fires created patches of burned areas, in some stage of recovery, which reduced the likelihood of future fire spread. This mechanism likely provided a self-reinforcing type of resilience to the regional landscape. With relatively high fire frequency (as in surface fire dominated fire regimes), the largest fires were generally smaller than with relatively low fire frequency (characteristic of high-severity fire regimes).

Both landscapes and patches provided important feedbacks to wildfire frequency, severity, and size. At a landscape scale, low-, mixed-, and high-severity fires likely maintained patchworks of burned and recovering vegetation. Patches varied by size, age, density, layering, species composition, and surface fuelbed, and these landscape patterns spatially interrupted conditions that supported large disturbances, except under extreme conditions. Low- and mixed-severity fires also provided important patch level feedbacks, which encouraged subsequent low- or mixed-severity fires (Agee 2003, Agee and Skinner 2005, Hessburg and Agee 2003). Such fires frequently reduced surface fuels, which favored shorter flame lengths, and reduced fireline intensities (rate of heat release per unit length of fire front). They also increased the height to live crowns, which favored less torching, and reduced the likelihood of crown fire initiation. They decreased crown density, which reduced crown fire initiation and spread potential, favored young forest tree species, which increased tree survival during wildfires and droughts, and favored medium- and large-sized trees, which increased tree survival during wildfires. Finally, low- and mixed-severity fires produced patchy tree and surface fuel cover, which favored fire-tolerant species, and repeated low- and mixed-severity fires.

During periods of extreme weather or during rare climate events, wildfires could become very large, and fire behavior was often unrelated to the initial forest conditions, but was instead correlated with the conditioning climate or weather influences. Fire size distributions and the vegetation patchwork that supported them have been altered by a host of management and settlement influences, which we have summarized.

Insects—

In eastern Oregon and Washington, several insect species are significant disturbance factors in MMC forests, including four native bark beetle species and two native defoliating species (Hayes and Daterman 2001, Hayes and Ragenovich 2001, Torgersen 2001). In addition to these, there is one nonnative defoliating species and

one nonnative sap-sucking species of importance (table 4). The impact of these insects is influenced by other disturbances (e.g., root disease, extreme weather events, wind storms, or wildfire) while outbreaks influence the frequency, severity and extent of other disturbances.

Unlike defoliating insects, bark beetles feed on the phloem tissue beneath the bark, often directly killing the host quickly via girdling. Beetles that initiate host selection are often killed by drowning or immobilization in resin, so successful colonization requires a minimum number of beetles to "mass attack" the tree and overcome its defenses (Franceschi et al. 2005). This number varies, as more vigorous hosts require higher densities of beetles (Fettig et al. 2007). Therefore, the legacy of past disturbances influences the susceptibility of forests to future bark beetle outbreaks by affecting their structure and composition. Many bark beetle species exhibit a preference for larger diameter trees growing in high-density stands with a high percentage of host type (Fettig et al. 2007). Larger diameter trees generally provide for a higher reproductive potential and probability of survival (e.g., Graf et al. 2012, Reid and Purcell 2011) because of the greater quantity of food (phloem) available on which larvae feed. The effects of density are mediated through factors that affect host finding and colonization success, primarily microclimate, tree spacing, and changes in host vigor as mediated through the influence of growing space. Over the last decade, the majority of insect-caused tree mortality detected during aerial surveys in the region has been attributed to outbreaks of the mountain pine beetle (*Dendroctonus ponderosae*). The impact of this insect seems to be increasing in eastern Oregon and Washington, likely owing to changes in tree density and the abundance of preferred hosts (table 4), and is expected to intensify in the future (see "Climate Change" on page 102 and "Changes in Disturbance Factors: Insects and Disease" on page 115).

Defoliators consume, mine, or skeletonize the foliage of trees and may cause tree mortality depending on the species and host, and the timing, frequency and severity of feeding. Without question, the two most important defoliators in MMC forests of eastern Oregon and Washington are the Douglas-fir tussock moth (*Orgyia pseudotsugata*) and western spruce budworm (*Choristoneura occidentalis*) (table 4, figs. 30 and 31), which are notable for their infrequent, but occasional large-scale outbreaks (Torgersen 2001). Natural enemy populations (parasites, predators, and parasitoids) have a strong regulatory effect on their populations resulting in long time lags between outbreaks. In particular, western spruce budworm populations are well-coordinated with climate (Kemp et al. 1985, Volney and Fleming 2007). From the 1950s to 1980s, large-scale efforts were implemented to control Douglas-fir tussock moth and western spruce budworm outbreaks using aerially applied

Table 4—Insects considered major disturbances in moist mixed-conifer forests of eastern Oregon and Washington

Common name	Scientific name	Primary host(s) in region	Scale of outbreaks	Impacts
Bark beetles:				
Douglas-fir beetle	*Dendroctonus pseudotsugae*	Douglas-fir	Local to landscape	Mortality of individual trees or small groups of trees is typically associated with defoliation, drought, windthrow, wildfire, or root disease. Once established, outbreaks may cause large amounts of tree mortality over extensive areas.
Fir engraver	*Scolytus ventralis*	Grand fir, white fir	Local to landscape	Mortality of individual trees or small groups of trees is typically associated with drought and defoliation. Once established, outbreaks may cause large amounts of tree mortality.
Mountain pine beetle	*Dendroctonus ponderosae*	Lodgepole pine, ponderosa pine, western white pine	Local to regional	Episodic outbreaks are a common occurrence, but the magnitude and extent of recent outbreaks have exceeded the range of historic variability in much of the Western United States.
Western balsam bark beetle	*Dryocoetes confusus*	Grand fir, subalpine fir	Local to landscape	Mortality of individual trees or small groups of trees is common and associated with windthrow.
Defoliators and other:				
Balsam woolly adelgid	*Adelges piceae*	Grand fir, silver fir, subalpine fir	Local	Accidentally introduced into the United States from Europe and first detected in the Pacific Northwest in 1929. Adelgids are sap-sucking insects. Feeding causes abnormal growth responses in affected trees termed "rotholtz." Severe infestations cause growth loss, top-kill, and tree mortality.
Douglas-fir tussock moth	*Orgyia pseudotsugata*	Douglas-fir, grand fir, white fir, subalpine fir	Local to regional	Larval feeding causes growth loss, top-kill, and tree mortality. Outbreaks are often short-lived.
Larch casebearer	*Coleophora laricella*	Western larch	Local	Accidentally introduced into the United States from Europe and first detected in the Pacific Northwest in the 1950s. Larvae mine needles. Severe defoliation occurs, but larch (a deciduous conifer) withstands repeated defoliation. Growth loss is common, but tree mortality is rare.
Western spruce budworm	*Choristoneura occidentalis*	Douglas-fir, grand fir, white fir, subalpine fir, western larch	Local to regional	Early instar larvae mine needles and buds. Late instar larval feeding causes growth loss, top-kill, and tree mortality. Feeding on staminate flowers and conelets affects regeneration.

Figure 31—Spruce budworm larvae.

Although insect infestations affect timber and fiber production, and indirectly affect a range of ecosystem goods and services, numerous organisms depend on insect-related disturbances for their existence.

chemical and biological (bacteria- and virus-based) insecticides, but were thought to have little effect on population dynamics or levels of tree mortality (Torgersen 2011, Torgersen et al. 2005). A successful example of classical biological control has significantly limited the impact of larch casebearer (*Coleophora laricella*) in the region (Ryan 1997).

Although insect infestations affect timber and fiber production, and indirectly affect a range of ecosystem goods and services, numerous organisms depend on insect-related disturbances for their existence. Trees weakened or killed by insects and other disturbances (e.g., pathogens) can result in the transience of old forest structural conditions, and also create structure and food sources that have significant value to wildlife communities. The section "Animals of the Moist Mixed-Conifer Ecosystem" on page 75 provides some detail on the role of snags and downed logs to wildlife. Furthermore, mortality of individual or small groups of overstory trees has a significant influence on the fine-scale spatial heterogeneity of mixed-conifer forests (Fettig 2012). For example, some insects, specifically bark beetles, inflict density-dependent tree mortality (Fettig et al. 2007), and consequently maintain a mix of tree species, ages, sizes and spatial heterogeneity that influence other disturbances (e.g., wildfire).

There is some evidence that large-scale tree mortality events associated with insect outbreaks may increase fire risk and severity in affected forests. In recent years, these relationships have been studied most extensively in lodgepole pine forests affected by mountain pine beetle (fig. 32). Although there is some disagreement over predicted changes in fire behavior during and after mountain pine beetle outbreaks (reviewed most recently by Jenkins et al. 2014), most studies predict increases in surface fire rates of spread and fireline intensities resulting from increases in fine fuel loadings and reductions in sheltering (e.g., Hicke et al. 2012, Klutsch et al. 2011, Page and Jenkins 2007). During outbreaks, changes in foliar chemistry and moisture content may also increase probabilities of torching and crowning, and the likelihood of spotting (Jolly et al. 2012, Page et al. 2012). Similarly, feeding by defoliators reduces crown cover, increasing the amount of light reaching the forest floor and influencing understory and mid-story vegetative dynamics. For example, western spruce budworm outbreaks have been shown to increase surface fuel loads, yet changes in fire behavior were not significant (Hummel and Agee 2003).

The current structure and composition of dry and MMC forests is thought to be more susceptible to large-scale defoliation by Douglas-fir tussock moth and western spruce budworm in areas where fire suppression and selective harvesting of ponderosa pine and larch have favored Douglas-fir, grand fir, and white fir.

Figure 32—Mortality of lodgepole pine attributed to mountain pine beetle (*Dendroctonus ponderosae*) in northern Utah. In recent years, the effects of mountain pine beetle on fuels and fire behavior have been studied most extensively in the lodgepole pine forests of the Rocky Mountains. This species, however, now represents a significant threat to the mixed-conifer forests of eastern Oregon and Washington.

Defoliation, largely the result of infestation of these two insects, often predisposes trees to subsequent mass attack by other insects, specifically bark beetles such as the Douglas-fir beetle (*Dendroctonus pseudotsugata*).

Diseases—

In eastern Oregon and Washington, several notable forest pathogens produce significant disturbance in MMC forests, including five host-specialized dwarf mistletoes and four native root pathogens. Disturbance comes in the form of tree mortality and reduced tree growth, both of which are influential to forest succession and stand dynamics processes. Numerous stem decay organisms are also common in large and older trees of most species. These are excluded for brevity here, but we urge interested readers to delve into this literature. For a concise survey of the most common diseases and insects affecting inland Pacific Northwest forests, we refer the reader to Goheen and Willhite (2006), and recommended references therein.

Four tree-killing root diseases naturally occur in MMC forests: laminated root rot, caused by *Phellinus weirii*; Armillaria root disease, caused by *Armillaria ostoyae*; and both the P- and S-type annosum root diseases (formerly *Heterobasidion annosum*, now *H. irregular* and *H. occidentale*, respectively) (Filip 1990; Filip and Goheen 1982, 1984; Goheen and Filip 1980; Hadfield et al. 1986). Root diseases were common (<5 to 10 percent of patches affected) but not dominant in most presettlement-era MMC forests, where they provided structural diversity within patches and enhanced heterogeneity in size of openings, amount and shape of edge, and size of patches. They were likely most visible in areas with relatively infrequent fire, and less visible in areas influenced by frequent low- and mixed-severity fires (e.g., south-facing slopes and ridges), and where the dominant tree cover was ponderosa pine or western larch.

Laminated root rot infects and kills susceptible Douglas-fir, grand fir, and white fir that grow in patches missed by fire. Transmission of the fungus that causes this disease occurs via mycelial growth, when roots of susceptible host trees come in contact with those of infected trees. Because the root systems of host trees are often well rotted after they are infected, these trees usually fall over in a jackstraw arrangement (Hadfield et al. 1986). Owing to the dominance of historical wildfires and the relative rarity of root rot centers (in comparison with current conditions), historical root disease centers likely provided small to large gaps that contained root disease resistant hardwood shrubs and trees and other resistant conifer species, which enhanced plant species richness, and provided mast and a variety of habitats suitable for small mammals (Maser et al. 1979; Thomas et al. 1979a, 1979b).

Armillaria root disease also infects and kills susceptible grand and white fir, and occasionally Douglas-fir that grow in patches missed by fire. Transmission of the fungus that causes this disease occurs when roots of susceptible host trees come in contact with those of infected trees. Inter-tree transmission is facilitated by fungal mycelia and by specialized root-like fungal structures called rhizomorphs. Armillaria root disease ecology at the end of the 19th century was probably very similar to that of laminated root rot. Armillaria root disease probably played a role in forest succession and stand dynamics of many refugia dominated by grand or white fir. Refugia were found in shaded draws, on cool north slopes, in riparian areas and stream confluence zones (Camp et al. 1997), and adjacent to rock outcroppings and talus slopes, where fires burned with difficulty. This pathogen also overwhelmed low-vigor, mature, weakened, and injured trees, and those stressed by drought or lightning strike, scorched by fire, or attacked by other root pathogens (Filip and Goheen 1982, Goheen and Filip 1980). Thus, it is fairly common to find more than a single root pathogen colonizing trees.

P- and S-type annosum root disease centers were relatively uncommon in presettlement-era forests. These diseases require freshly cut stumps or wounds for windborne spores to infect and initiate new root-disease centers. Before tree harvesting, annosum root disease existed as a butt rot of trees with root collar and stem wounds. In central, southern, and northeastern Oregon, stands that have had multiple entries to harvest trees have been shown to have the highest annosum root disease and associated bark beetle-caused tree mortality (Filip et al. 1992; Schmitt et al. 1984, 1991). Most surprising in the MMC forest is the rate of increase in S-type annosum root disease (*H. occidentale*) in grand and white fir. These forests contain large increases in S-type annosum because stumps were infected by spores when stands were logged (Filip et al. 1992, Hadfield et al. 1986, Otrosina and Cobb 1989). Because S-type isolates are primarily pathogenic on true firs and spruces, the roles these stumps will play in the future incidence of disease is uncertain. Infection centers will continue to expand until fire or silvicultural activities create conditions for the reintroduction of young forest species.

Pine stump infection by P-type annosum (*H. irregular*) is often high in Douglas-fir and grand fir forests, but mortality in ponderosa pine is uncommon. With prolonged warming, however, P-type annosum may become more serious on what are now mesic white and grand fir sites.

In the current condition, all major tree-killing root diseases except P-type annosum are widespread, following landscape colonization by grand fir, white fir, and Douglas-fir (Hessburg et al. 1994). Collectively, the effects of root diseases on tree growth and mortality, and their contributions to flammable fuels are ecologically significant. At a watershed or subwatershed scale, as much as 7 to 10 percent of the area can be influenced at any one time by active infection centers.

Dwarf mistletoes have occurred for many millennia in Douglas-fir, ponderosa pine, western larch, lodgepole pine, and true firs but none was particularly threatening to the long survival of its host species (Alexander and Hawksworth 1975, Parmeter 1978, Tinnin 1981). Douglas-fir dwarf mistletoe (*Arceuthobium douglasii*) and western larch dwarf mistletoe (*A. laricis*) were probably common in mid-seral and old forests before the 20th century. Areas infested with these mistletoes tended to be the more mesic plant associations, in which fires appeared with moderate frequency. Mistletoes were probably most common on south-facing slopes, where fires were low- or mixed-severity, maintaining multiple cohorts, sizes, ages and layers of host trees. High-intensity fires would typically eliminate most (but not all) mistletoe-infested trees over large areas, and mistletoes would slowly re-invade from the perimeter at the rate of 3 to 4.5 m (10 to 15 ft) a decade (Hawksworth 1958, 1960; Parmeter 1978; Wagener 1965), or from islands of infested trees that

escaped burning. Especially in ponderosa pine and Douglas-fir, severe mistletoe infections provide an abundance of mistletoe brooms, fine fuels, resinous stems, branches, and cankers. Even low- and moderate-intensity fires would often torch these trees, destroying severely infected trees and infection centers (Koonce and Roth 1980, Parmeter 1978, Weaver 1974). No doubt active and passive crown fires were initiated in areas of severe mistletoe infestation.

Dwarf mistletoe in Douglas-fir was probably more common on northerly aspects and in riparian areas, where the interval between fires was longer. Under historical fire regimes, Douglas-fir dwarf mistletoe was probably widely distributed but at low to moderate severity (Arno 1988, Fischer and Bradley 1987, Harrington 1991). Mature Douglas-fir, with thick outer bark and crown bases elevated well above the forest floor, were quite resistant to surface fires. Douglas-fir dwarf mistletoe was well distributed in scattered, thick-barked overstory trees that had developed on young forest dominated landscapes under the influence of low-intensity fire, but further influence was minimal because understory Douglas-fir stocking was minimal.

Conversely, young Douglas-fir had thin, resinous outer bark and crowns close to the forest floor, two characteristics that increased vulnerability to surface fires. When mistletoe brooms occurred on young trees, the likelihood of tree torching was increased (Harrington 1991, Tinnin 1984, Tinnin and Knutson 1980). Under the right wind and weather conditions, fires crowned from mistletoe-infected understories. In addition, mistletoe brooms in Douglas-fir nullified benefits of inter-tree competition and natural branch pruning by maintaining a flammable link with the forest floor. In patches where Douglas-fir was abundant in the understory, e.g., in northerly aspects, Douglas-fir dwarf mistletoe was probably quite abundant.

Given the range of fire frequency and severity in historical MMC forests, the western larch mistletoe was likely the most prevalent and influential in terms of tree growth and mortality. Western larch dwarf mistletoe was perhaps the most widespread of mistletoes in old forest stands. Of all the dwarf mistletoes, larch mistletoe survived fire in overstory western larch with the greatest constancy (Bolsinger 1978), perhaps because of larch's exceptional resistance to damage by fire (Lotan et al. 1981), its resistance or tolerance to both tree-killing and opportunistic root pathogens (Filip and Schmitt 1979, Hadfield et al. 1986), and the lack of primary bark beetle associates. Larch mistletoe brooms are weak and brittle and frequently break off when still relatively small. Under historical fire regimes, branch litter accumulating under infected hosts caused lethal fire scorching of some infected trees (Alexander and Hawksworth 1975). According to Tinnin et al. (1982), the increased burn potential accentuated the advantage of fire-adapted species such as western larch.

Dwarf mistletoes create brooms in trees, sometime quite large, and this produces critically important habitat structure for many species of wildlife. Brooms are used for nesting, roosting, and hiding cover (e.g., see Bull and Henjum 1990, Bull et al. 1989, Forsman 1983, Sovern et al. 2011). Birds and squirrels also contributed to reintroduction of mistletoes to large host patches (Hawksworth et al. 1987). Mistletoes would persist in residual ponderosa pine and western larch overstory trees by virtue of their resistance to fire, or from irregularities in fuel continuity or arrangement, or fire behavior, and the spread of these mistletoes to newly regenerating patches would be much quicker (Parmeter 1978). The presence of mistletoe brooms is a prime example of a long-standing struggle between objectives to manage for wood production (i.e., foresters would be inclined to remove diseased trees) and objectives to maintain or enhance wildlife habitat (wildlife specialists would advocate keeping these trees).

At least 40 percent of all of the Douglas-fir, western larch, ponderosa pine, and lodgepole pine forests east of the Cascade crest are infected with dwarf mistletoe (Bolsinger 1978). Infections are more widely distributed and have had a greater impact on tree health than ever before, except where large wildfires have recently occurred. Because of fire exclusion and selective timber harvesting, many remaining forests are densely stocked and multilayered, conditions that are conducive to spread of mistletoes. Conifers such as Douglas-fir or ponderosa pine with severe mistletoe infections exhibit declining crown vigor and reduced resistance, and are eventually attacked and killed by bark beetles and opportunistic root pathogens like Armillaria root disease (Hadfield et al. 1986, Morrison et al. 1991).

Animals of the Moist Mixed-Conifer Ecosystem

The landscape ecology concepts of resilience and natural range of variation described in the previous sections of this report provide important tools for understanding animal habitat and population function within MMC forests of the Pacific Northwest. Native animals evolved in the context of historical disturbance regimes and resultant landscape patterns. Managing for the natural range of variability (NRV) provides a conceptual starting point for capturing the habitat needs of native wildlife. Landscape resilience is also important to animal populations because it represents the tendency of a landscape to return to conditions that the native animal community is adapted to. Landscapes that are not resilient may shift into novel environmental conditions that can contribute to substantial changes in the animal community and loss of biodiversity. However, it is important to note that simply managing for resilient landscape conditions that are within the NRV may not be sufficient for the conservation of all animals (Wiens et al. 2008).

Native animals evolved in the context of historical disturbance regimes and resultant landscape patterns.

Some native species have been affected by threats not related to habitat amount and distribution, including interactions with invasive species (e.g., northern spotted owls [NSO] [*Strix occidentalis caurina*] and barred owls [*Strix varia*] [Gutierrez et al. 2007]), exposure to exotic diseases (e.g., bighorn sheep [*Ovis canadensis*] [Schommer and Woolever 2008]), or sensitivity to effects of specific human activities (e.g., disturbance associated with roads or recreation [Gaines et al. 2003]). Conservation of these species often requires more specific strategies that address habitat in combination with the specific risks to which they are sensitive. Several recent assessments have used this conceptual approach to compare the current landscape to estimates of habitat patterns under historical disturbance regimes to provide a "coarse filter" for evaluating the amount and distribution of habitat conditions, in conjunction with "fine filter" assessments of conditions for selected individual species that are sensitive to specific risks (Gaines et al., in press; Suring et al. 2011; Wales, et al. 2011, Wisdom et al. 2000). Results of these assessments are summarized in "Effects of Altered Disturbance Regimes, Land Use, and Climate Change on Animal Populations and Habitats" on page 115. Our focus in this section is to provide an overview of important considerations for managing fish and wildlife habitat and animal populations in MMC forests.

As highlighted in previous sections, the MMC forest type is characterized by environmental conditions that are intermediate between warm/dry and cold/wet forest types that are often adjacent to or intermixed with the MMC. This pattern results in an animal community that is composed of an overlapping mix of species that are also found in the adjacent forest types. The composition of the animal community and abundance of individual species within MMC forests depends on many factors including landscape patterns, forest structure, and how wet or dry conditions are within an individual stand and the surrounding landscape.

Using the wildlife habitat relationships database of Johnson and O'Neal (2001), Lehmkuhl (2005) concluded that bird and mammal communities in eastside interior MMC forests were a mix of species typical of low-severity low-elevation ponderosa pine forest (84 percent species similarity) and high-elevation high-severity mixed-conifer forest (71 percent species similarity). About 40 percent of all species were shared in common among the three types. Mixed-conifer forest was more similar to ponderosa pine forest in supporting relatively more generalist or young forest species than higher elevation forests. Within eastside habitat types and disturbance regimes, the fire-prone ponderosa pine cover type supports the most species of amphibians, reptiles, and birds; whereas mammals are most species-rich in mixed-conifer types (Bunnell 1995; Kotliar et al. 2002; Sallabanks et al. 2001, 2002).

A key concept for understanding animal distribution and abundance in MMC forests is that animals need to acquire a variety of resources to meet their life-history needs and most animals use a variety of different habitats and structural features to acquire those resources. Morrison et al. (1998: 10) described wildlife habitat as "an area with a combination of resources (like food, cover, water) and environmental conditions (temperature, precipitation, presence or absence of predators and competitors) that promotes occupancy by individuals of a given species (or population) and allows those individuals to survive and reproduce." In MMC forests, these wildlife habitat components are emergent properties of the forest communities and their growth, disturbance, and stand dynamics (sensu Oliver and Larsen 1996) processes. How these processes work at a variety of scales is important in determining where habitat components occur and whether they are arranged in a manner that allows animals to survive and reproduce. Like landscapes, areas used by animals can be thought of as "habitats within habitats" (fig. 33).

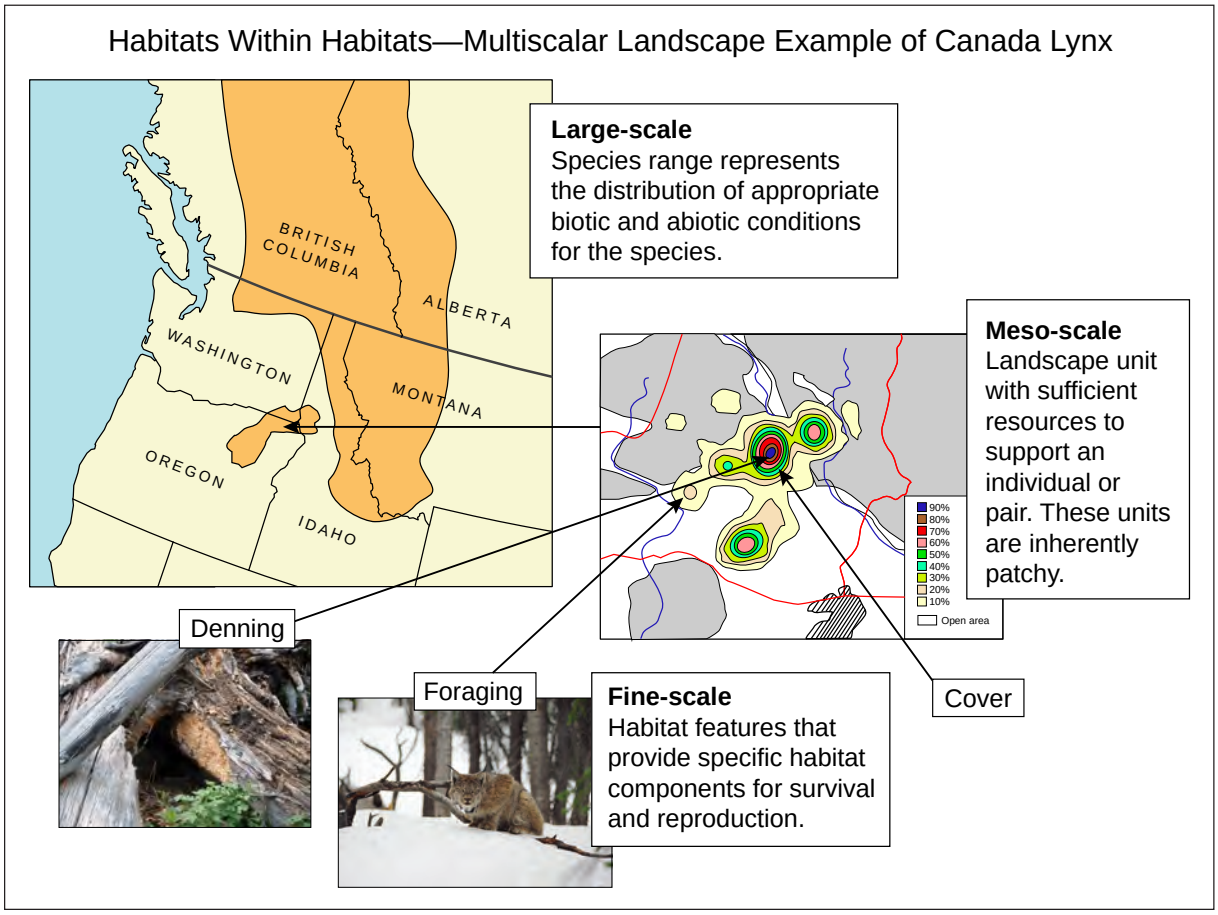

Figure 33—Wildlife habitat is represented at different scales. Individual animals are connected to key features of their environment over a confined spatial domain, small groups of a species interact regularly over a larger area, and populations of a species are distributed across large geographic areas. This multiscalar view illustrates the importance of considering habitat requirements of a species at different spatial scales.

At the finest scale, animals use habitat features associated with specific forest structure attributes (e.g., snags for foraging and nesting); at the meso-scale (sub-basin or watershed scale), they must find the appropriate configuration of those resources to meet their life-history requirements (e.g., the right combination of food availability and security from predators); and at the broadest scale, animals need to be able to move to find mates, disperse to new areas, prevent genetic isolation, and maintain broad-scale population function (meta-population dynamics). Selection of a finer-scale habitat feature is therefore constrained by habitat selection decisions made at broader scales (e.g., the forest stand an animal chooses to use is constrained by the variety of stands within the watershed where the animal is located [Johnson 1980]).

Landscape heterogeneity at a variety of scales plays an important role in determining the assortment of habitat conditions and resources available to the animal community in that landscape.

Landscape heterogeneity at a variety of scales plays an important role in determining the assortment of habitat conditions and resources available to the animal community in that landscape. At the broadest scale, the distribution of wildlife and fish species is determined by regional to subcontinental gradients in climate, topography, soils, and vegetation (Hansen et al. 2011). The tolerances of species to these biophysical gradients result in predictable patterns of community diversity. Across Oregon and Washington, species richness of birds, trees, and shrubs is highest in the Okanogan Highland and Siskiyou ecoregions (Hansen et al. 2006, Swenson and Waring 2006). The lower forest ecotones across the East Cascades, Okanogan Highlands, and Blue Mountains are also high in species diversity (Olson et al. 2001). These locations have intermediate precipitation, warm growing season temperatures, and intermediate primary productivity. These conditions provide diverse food resources, variable vegetation structure, and high levels of habitat diversity, with grassland/shrubland, dry forest, and moist forest habitats all in proximity. Amphibian diversity is low in the eastern Cascades compared to western Oregon and Washington, primarily because the dry climate in the eastern Cascades is less conducive to occupancy by amphibians (Olson et al. 2001).

The spatial patterning of habitats across Oregon and Washington is also important in influencing connectivity for wildlife and fish populations. Genetic diversity, metapopulation dynamics, and population viability for many species is dependent upon the ability of individuals to move across landscapes (Bennett 2003, Crooks and Sanjayan 2006, Hilty et al. 2006). Regional-scale landscape permeability patterns for forested landscapes in eastern Washington and Oregon (fig. 34) are important because these forests serve as important potential source areas for a variety of species in their own right, and they provide critical linkages between ecosystems in the Rocky Mountains, the Cascade Range, and into Canada (Singleton et al. 2002, Theobald et al. 2012, WHCWG 2010).

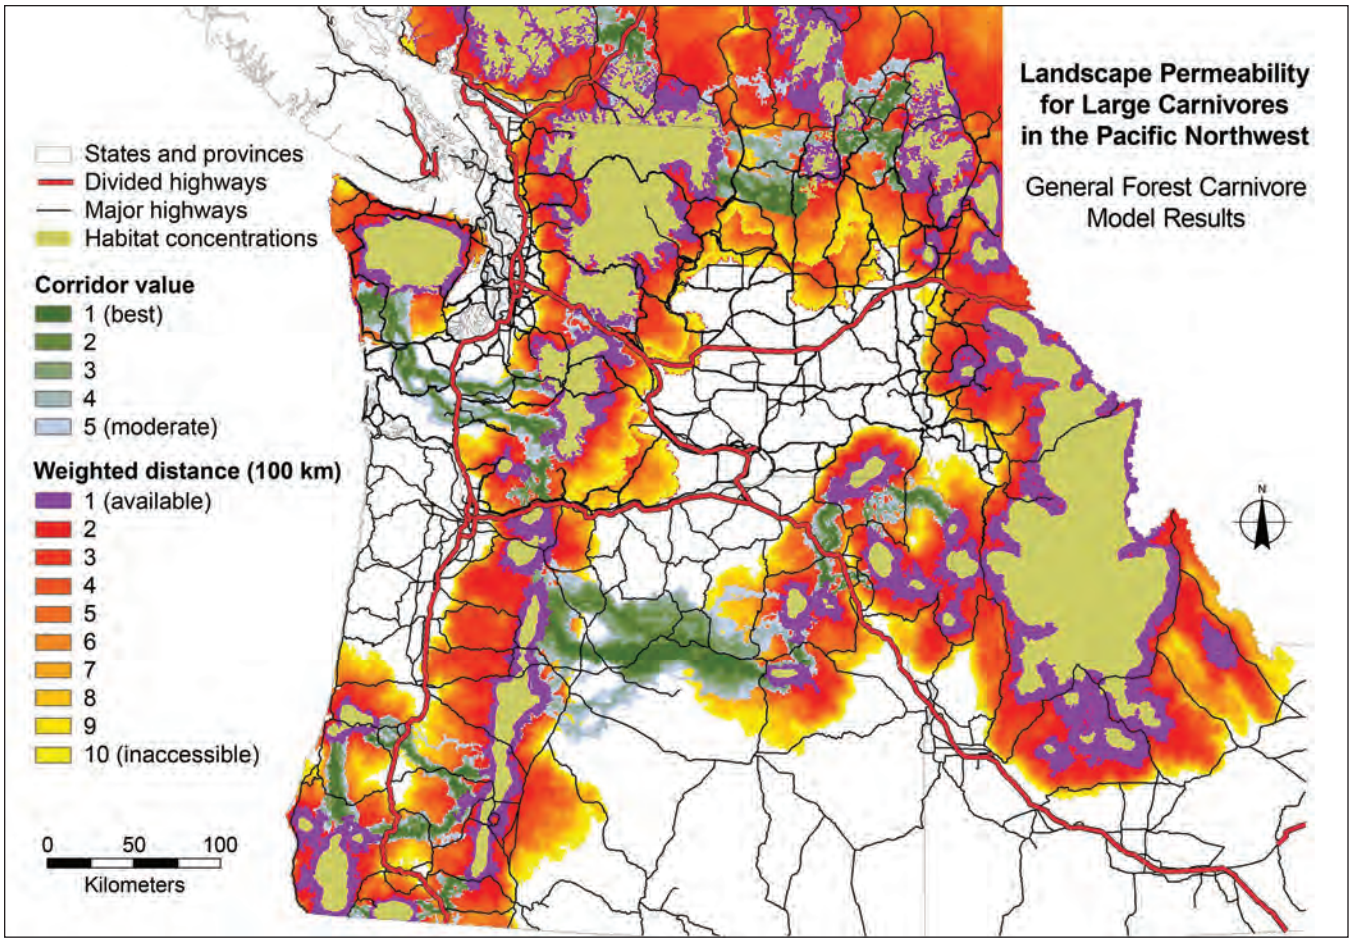

Figure 34—At a regional scale, habitat for large carnivores is more or less permeable to movement, depending on various vegetation and topographic conditions. This information is an important consideration when planning treatments for forests at a landscape scale.

Meso-scale landscape patchiness determines the arrangement of habitat resources for animals. A critical feature of wildlife habitat in mixed-conifer landscapes in eastern Washington and Oregon is the multiscale (landscape and stand) diversity and juxtaposition of patch types of differing composition and structure (Perry et al. 2011). Habitat heterogeneity on presettlement landscapes was largely a result of mixed-severity fire. As reviewed in previous sections of this report, the combination of extensive topographic variability, other intrinsic factors of the landscape (e.g., soils, accumulation of fuels, etc.), and the vagaries of weather interacted in each fire event to create complex mosaics of habitat with soft boundaries that distinguish the effects of varying fire severity. Forest patches in different stages of development typically have different habitat characteristics and provide different sorts of habitat features (Johnson and O'Neal 2001, Thomas 1979). These processes result in a variety of forest structure and composition patterns that can support different terrestrial wildlife communities (Smith 2000). Again, NRV provides a

conceptual guide for providing the mosaic of habitat conditions that native species evolved with, but species with specific habitat needs or sensitive to specific risks often require special consideration (e.g., Suring et al. 2011).

Fine-scale within-stand diversity of vegetation composition and structure provides specific wildlife habitat features required for denning, nesting, foraging, and security for individuals of many wildlife species. Different stand development stages provide different habitat structures and resources.

Recently disturbed patches tend to support high plant productivity, and often exhibit a particularly high diversity of plant and animal species, including many specialist species (Hagar 2007, Swanson et al. 2011) (fig. 35). Focal species for assessing early-seral and postfire habitats in interior MMC communities in the Pacific Northwest include fox sparrow (*Passerella iliaca*), white-headed woodpecker (*Picoides albolarvatus*), western bluebird (*Sialia mexicana*), and Lewis's woodpecker (*Melanerpes lewis*) (Gaines et al., in press; Wales et al. 2011).

Peter Singleton

Figure 35—Postfire and other recently disturbed forest sites provide productive habitat for many wildlife species. This recently burned area on the Okanogan-Wenatchee National Forest has shrub and herbaceous vegetation that provides habitat features generally not found in more mature forests.

Early successional habitats are also important for ungulate summer forage. Recent research has highlighted the importance of high-quality late-summer forage for elk survivorship and reproduction (Cook et al 2013). Early-seral openings within MMC forests can play a particularly important role by providing late-summer forage resources for ungulates (Lehmkuhl et al. 2013). Several species of migratory songbirds are also associated with deciduous shrub communities found in early-seral forest patches (Betts et al. 2010). Structural legacies (including live trees, snags, and logs) from predisturbance stands contribute important habitat components in recently disturbed areas by providing cavities, perches, escape cover, and protected microclimates (Bull et al. 1997, Franklin et al. 2000, Van Pelt 2008). The abundance of large snags and logs is a particularly important characteristic of post-fire habitats (Smith 2000).

Vertebrate communities within even-age young forest patches are generally less diverse and abundant than those found in other stand development stages, particularly for sites dominated by dense, closed-canopy conditions with little structural or understory diversity. Nevertheless, mid-seral stands can provide important ecological functions, depending on specific habitat conditions and landscape context. Dense even-age stands can provide security cover for prey species where conditions support the prey but prevent effective access for foraging predators. For example, avian predators like NSO and northern goshawks (*Accipiter gentilis*) select areas with structurally diverse forest canopies to facilitate foraging, even while their prey can often be relatively abundant in nearby dense stands (e.g., Greenwald et al. 2005). The presence of biological legacies (big old trees, snags, and logs) from predisturbance stands can provide important structural diversity in mid-seral stands by breaking up an otherwise continuous canopy, providing cavities for nesting and denning, and adding structure to the forest floor (Bull et al. 1997, Franklin et al. 2000). Mid-seral stands also serve an important role as "old growth in waiting." Late-successional forest conditions can be relatively transient in interior mixed-conifer forests compared to forests west of the Cascade Mountains owing to the variety of disturbance processes associated with this forest type (reviewed in this section and in "Natural Disturbance Factors" and "Aquatic Habitats"). Mid-seral forest stands can provide an important "conveyor belt" of forest stands that are developing structural characteristics of older forests that can serve as replacements when other older stands are affected by disturbance. Active management to facilitate the development of old forest characteristics including canopy structural diversity and small openings has become an important principle for management of mid-seral stands and is particularly important for the recruitment of old forest habitat conditions for wildlife (Franklin and Johnson 2012).

Older forests with a diversity of tree ages and sizes (including larger, older trees) provide many unique ecological functions. Across the variety of forest structural conditions found in MMC forests, animal abundance and species diversity are favored by structural complexity in the form of varied tree sizes, abundant snags, and coarse woody debris (McComb 2001). Big old trees, living and dead, standing and down, provide unique and important habitat structures within old forest stands (reviewed by Bull et al. 1997, Thomas et al. 1979, and Van Pelt 2008). For example, snags and down logs provide denning and resting sites for American marten (*Martes americana*) (Bull et al. 2005). Long-legged myotis bats (*Myotis volans*) roost in snags and bark crevices of large old trees (Ormsbee and McComb 1998). Stout lateral epicormic branches can provide nest sites for northern goshawks and other species (Daw and DeStefano 2001). Cavities (in snags or living trees) are particularly important keystone structures for wildlife communities. Such cavities are created by the interactions of pathogens, fire, strong winds, and primary cavity excavators, and are subsequently used by a variety of species (Bednarz et al. 2004, Parks et al. 1999).

The security, thermal, and moisture characteristics found beneath and within large down logs can be especially important for small mammals, amphibians, reptiles, and invertebrates.

The security, thermal, and moisture characteristics found beneath and within large down logs can be especially important for small mammals, amphibians, reptiles, and invertebrates (Bull et al. 1997). Large old trees, especially in dense mixed-conifer patches, have higher loads of epiphytic forage lichens, which are critical winter food for some species (Lehmkuhl 2005).

The multilayer canopies found in older stands contribute to unique thermal characteristics within stands and provide structural complexity important for arboreal mammals and their avian predators. Goshawks and NSO use multilayered canopies (often found in MMC forests subject to periodic fire) because such layering provides room to fly within forest stands. Canopy gaps allow for understory tree establishment and allow for sunlight to penetrate the canopy to the forest floor, contributing to understory productivity and diversity. Understory productivity is the foundation of food availability for many species. For example, northern flying squirrels (*Glacomys sabrinus*) are more abundant in stands with diverse understories with plants that provide critical fruit and mast foods (Lehmkuhl et al. 2006b); diverse understory vegetation can provide important forage resources for ungulates (Lehmkuhl et al. 2013); and fruit-bearing shrubs provide important food resources for black bears (*Ursus americanus*) and other species (Lyons et al. 2003).

Typical focal species for assessment of MMC old forest habitat conditions in Washington and Oregon are northern goshawk and pileated woodpecker (*Dryocopus pileatus*) (Gaines et al., in press; Wales et al. 2011; Wisdom et al. 2000). Northern goshawks are broadly distributed throughout the Interior West, and are

Impacts of Wildlife Herbivory

Herbivory (i.e., grazing and browsing) by wild ungulates, primarily elk, can significantly affect forested and grassland ecosystems and is worthy of consideration in any management plan (see Lehmkuhl et al. 2013 for a recent review). Elk and deer can account for a significant portion of the animal unit months (AUMs) on a range: e.g., elk and deer made up about 90 percent of the estimated 78,000 AUMs on the Yakima elk herd range in the eastern Washington Cascades. Utilization rates in grassland and forest are typically 40 to 60 percent of annual production, with herbivory concentrated in productive riparian areas and meadows but occurring in all forest types. Herbivory effects may intensify in some areas with a spring and summer forage base that has declined since the early 1900s with meadow contraction, development of dense forests due to fire suppression, regrowth of old burns and pre-1990 clearcuts, and infrequent forest clearcut harvesting as a result of regulatory changes during the last 20 years. Sustaining livestock and elk on a diminishing habitat base may have degraded habitat and enhanced establishment of exotic species in sensitive meadow and riparian areas.

The impact of wild ungulate herbivory has been well documented in the Blue Mountains from long-term exclosures and other research. In Douglas-fir and grand fir forests, Riggs et al. (2000) found that ungulate herbivory seriously depressed biomass of shrub genera *Acer, Linnaea, Amelanchier, Salix, Sorbus, Ceanothus, Physocarpus,* and *Rubus* outside of 25-year-old exclosures, within which understory biomass was two times greater than that outside exclosures. Johnson (2007) found that the shrubs *Rosa, Symphoricarpos,* and *Purshia* increased dramatically in the absence of long-term browsing in shrubland communities in the Blue Mountains. Tiedemann and Berndt (1972) reported five times more shrub cover, primarily snowbrush ceanothus (*Ceanothus velutinus*) with Saskatoon serviceberry (*Amelanchier alnifolia*), chokecherry (*Prunus virginiana*), and common snowberry (*Symphoricarpos albus*), inside versus outside a 30-year-old exclosure in a Douglas-fir/pinegrass (*Calamagrostis rubescens*) habitat type dominated by ponderosa pine with Douglas-fir. Likewise in the eastern Washington Cascades, Lehmkuhl et al. (2013) documented high long-term grazing impacts on some species of typical and atypical forage shrubs, such as common snowberry, oceanspray (*Holodiscus discolor*), and pinemat manzanita (*Arctostaphylos nevadensis*) in mid-elevation Douglas-fir and grand fir cover types, sticky currant (*Ribes viscosissimum*) in high-elevation subalpine fir cover types, and little sagebrush (*Artemisia arbuscula*), scabland sagebrush (*A. rigida*), and desert bitterbrush (*Purshia tridentate*) in low-elevation nonforest cover types. Impacts on ungulate herbivory on shrubs are likely underestimated because historically high levels of herbivory by both wild ungulates and livestock in the study area already may have suppressed or eliminated highly palatable shrubs.

Proposed forest restoration management in the Blue Mountains (mainly the Douglas-fir and dry grand fir types) to reduce uncharacteristic fuel loads and restore resilient stand structures and processes likely will increase the forage base for ungulates by reducing canopy cover to <40 percent and stimulating understory development (Hedrick et al. 1968, Long et al. 2008, Lyon and Christensen 2002, Skovlin et al. 1989, Vavra et al. 2005; but see Sutherland and Nelson 2010). Opening the canopy of long-closed stands with diminished seed banks of herbaceous species might increase invasive species cover (McGlone et al. 2009, Sabo et al. 2009; but see Wienk et al. 2004); however, responses of invasive species can vary considerably because of site conditions (Sutherland and Nelson 2010) and can be mitigated by management (e.g., weed control along roads). See Lehmkuhl et al. (2013) for a complete discussion of restoration impacts on ungulate habitat.

associated with structurally diverse old forest conditions that provide nest sites and foraging opportunities (reviewed by Greenwald et al. 2005, and Squires and Kennedy 2006). Pileated woodpeckers are also broadly distributed in wet to dry mixed-conifer forests throughout the Interior West. They are strongly associated with large snags and down logs for nesting and foraging (Bull and Holthausen 1993, Bull et al 1992). American marten are also included as a focal species for assessment of old forest conditions, but are more closely associated with forest types that are colder and wetter than the moist mixed-conifer forest (Gaines et al., in press; Munzing and Gaines 2005).

Conservation concerns about the NSO, a federally listed threatened species, have had a substantial impact on management of MMC forests in the eastern Cascade Range (USFWS 2011). We do not have the space for an exhaustive review of the substantial literature on NSO in the eastern Cascade Range, however we will highlight a few key aspects of spotted owl biology directly related to MMC forests. These highlights are important for understanding spotted owl management in MMC forests, but they also provide some useful insights for conservation of other old forest species associated with MMC forest outside of the range of the NSO (management considerations for old forest species are discussed in "Effects of Altered Disturbance Regimes, Land Use, and Climate Change on Animal Populations and Habitats" on page 115).

Spotted owls in the eastern Cascade Range have similar requirements for spatial and structural heterogeneity as in other parts of their range (reviewed by Courtney et al. 2004), but differences in disturbance processes (i.e., mixed-severity fire regimes, past selection harvest practices, and presence of mistletoe clumps) contribute to some differences in apparent habitat associations. The classic description of NSO nesting, roosting, and foraging habitat is "a multilayered, multispecies canopy dominated by large (>76.2 cm [30 in] diameter at breast height [d.b.h.]) conifer overstory trees, and an understory of shade-tolerant conifers or hardwoods; a moderate to high (60 to 80 percent) canopy closure; substantial decadence in the form of large, live coniferous trees with deformities—such as cavities, broken tops, and dwarf mistletoe infections; numerous large snags; ground-cover characterized by large accumulations of logs and other woody debris; and a canopy that is open enough to allow owls to fly within and beneath it" (Thomas et al. 1990: 164). Although NSOs in the eastern Cascade Range inhabit patches that meet this description (particularly in moist sites), they also use patches with smaller trees, where structural heterogeneity is enhanced by the presence of mistletoe brooms and biological legacies from previous, more open stand conditions (Buchanan et al. 1995, Everett et al. 1997, Sovern et al. 2011). These stand structure conditions are

often highly divergent from historical conditions (Everett et al. 1997, Hessburg et al. 2005, Lehmkuhl et al. 1994), and provide fuel characteristics and spatial patterns that are conducive to uncharacteristically high-intensity, widespread wildfire events (Agee 2003).

Spatial and structural heterogeneity is also important for spotted owl prey. Bushy-tailed woodrats (*Neotoma cinerea*) and northern flying squirrels compose more than 50 percent of NSO prey biomass in these areas (Forsman et al. 2001, 2004). Lehmkuhl et al. (2006a, 2006b) found that bushy-tailed woodrats and northern flying squirrels were associated with the presence of large snags, mistletoe brooms, and downed logs, with woodrats being found in both mixed-conifer and ponderosa pine types. Presence of diverse understory vegetation that provided a variety of food items was also important for flying squirrels (Lehmkuhl et al. 2006b).

Competitive interactions with barred owls are an important factor contributing to recent NSO population declines (Forsman et al. 2011). Spotted owl populations in Washington and northern Oregon declined by approximately 40 to 60 percent from 1989 to 2008 (Forsman et al. 2011). Many experts expect that NSO populations will continue to decline through much of their range as barred owl numbers increase (USFWS 2011). Barred owls in the eastern Cascade Range are most abundant in flatter valley bottom moist forest settings (Singleton et al. 2010). Interactions with barred owls may have contributed to the displacement of NSO pairs into drier midslope settings as early as the 1990s when most NSO activity centers were documented, resulting in relatively few historical NSO sites being documented in valley-bottom MMC settings that otherwise appear to be suitable NSO habitat (Singleton 2013). Persistence of the NSO population in mixed-conifer forest landscapes may depend on the ability of the local NSO population to adapt to the presence of barred owls (Gutteriez et al. 2007). Substantial habitat loss from natural or human-caused disturbances (e.g., fire or forest management activities) has the potential to exacerbate the negative impacts of interactions with barred owls by increasing competition for limited habitat resources (Dugger et al. 2011, Forsman et al. 2011).

Several other unique habitats also occur in landscapes that support MMC forests, including deciduous forest patches, meadows, riparian areas, rock piles, cliffs, and caves (reviewed in Johnson and O'Neil 2001 and Thomas et al. 1979). Deciduous tree patches provide important habitat characteristics for a variety of species (Hagar 2007), particularly migratory birds (Betts et al. 2010), and can provide abundant cavities for woodpeckers and other species (Martin et al. 2004). Aspen stands were an important component of the historical landscape in areas that support MMC forest, but the availability of aspen habitats has been reduced

substantially by altered disturbance regimes and herbivory impacts from both native and domestic animals (Shirley and Erickson 2001, Strong et al. 2010). Natural moist meadows are another particularly productive community within landscapes that support MMC forest. Meadows provide important ungulate forage resources (Lehmkuhl et al. 2013) and contribute to unique edge conditions that are important for a variety of wildlife including great grey owls (*Strix nebulosa*) (Bull and Henjum 1990) and long-eared owls (*Asio otus*) (Bull et al. 1989).

Area of meadows has been reduced by tree encroachment as a consequence of altered disturbance regimes (Haugo and Halpern 2007). Meadow communities have also been altered by domestic livestock grazing and intense use by native ungulates (Beebe et al. 2002). Large carnivores (particularly wolves) historically played an important role in limiting concentrations of native ungulates in these highly productive areas (Beschta and Ripple 2009). Ecological functions of streams and associated riparian areas are reviewed below, but it is worth emphasizing that in the context of animal habitat in disturbance-prone landscapes, riparian areas can provide unique linear landscape features that contribute to important ecological flows through the landscape, including animal movement. Rocks, cliffs, and caves also provide unique landscape elements that can be important for many species (Thomas 1979). Rocky talus and scree slopes can provide unique habitat features for amphibians including larch mountain salamander (*Plethodon larselli*) (Crisifulli 2005) and secure areas for rodents including bushy-tailed woodrats and pika (Simpson 2009). Cliffs provide nesting opportunities for raptors (including peregrine falcon [*Falco peregrinus*]), and caves can provide hibernacula for bats.

The literature on wildlife habitat associations within MMC forests in western North America is vast and beyond the scope of this document. However, two main themes emerge from our review of the information: (1) natural disturbance processes play a key role in the development of stand structure conditions and landscape patterns that determine habitat values for animals, and (2) biological legacies (big old trees, snags and logs) provide important habitat structures across all stages of stand development. Within-stand structure is influenced by disturbance processes that function at a variety of scales. Endemic levels of disturbance can contribute to stand and landscape heterogeneity, while large-scale, high-intensity disturbances can reduce stand and landscape heterogeneity. Within-stand structural diversity is generally much greater in stands with a variety of tree age and size classes, even if those stands are recently disturbed or dominated by younger trees. Big trees and logs are often a legacy of previous stand conditions that have been retained after some disturbance event, like fire or harvest (Franklin et al. 2000). The variety of extremely valuable habitat structures provided by these large old

trees include cavities, large branches, broken tops, brooms, and platforms (Bull et al. 1997). The presence of large old trees within a stand can make a big difference for wildlife habitat values in both old and young forests.

Aquatic Habitats

From the literature, two concepts emerge as foundational for managing linked terrestrial and aquatic ecosystems: (a) watersheds and their aquatic habitats and species are dynamic and adapted to insect, disease, weather, and wildfire disturbances, and (b) the climate will continue to have a profound influence on terrestrial and aquatic ecosystems, disturbance processes, and their interactions (Bisson et al. 2003; Luce et al. 2013, 2014; Tague and Grant 2009).

Disturbances play a vital role in structuring aquatic ecosystems.

Disturbances play a vital role in structuring aquatic ecosystems. Wildfires influence hydrological and physical processes, such as surface erosion, sedimentation, solar radiation, wood recruitment, and nutrient exchange in streams (Benda et al. 2003, Luce et al. 2009, Miller et al. 2003, Wondzell and King 2003). The timing and severity of erosion and sedimentation differ by the physical geography, geology, and geomorphic processes; precipitation; and fire regime. Erosion contributes to sedimentation and can depend on riparian vegetation density and the speed of vegetation recovery after disturbance. Chronic erosion delivers fine sediment for a fairly long time, usually in the absence of revegetation after disturbance, or it comes from road rights-of-way, trails, and bulldozer lines. Postfire riparian erosion results in larger pulsed sediment and wood delivery to streams, and in some circumstances, channels can be reorganized, affecting aquatic habitats (Benda et al. 2003, Miller et al. 2003, Minshall 2003, Reeves et al. 1995). Water retention properties of the soils and reduced evapotranspiration from vegetation loss in the surrounding landscape affect runoff dynamics. Over time, coarse wood and sediment are depleted. Fluvial action and rot tend to break down stream wood, which can then be transported downstream along with sediment and rock. These processes continue until the system is replenished by subsequent postfire erosional events (Benda et al. 2003, Miller et al. 2003).

In general, episodic large-scale disturbances (e.g., fire) to aquatic ecosystems are inevitable and often beneficial when spaced out over long periods, and this knowledge can form an important ecological foundation for fire and forest management. Anadromous and resident species in such landscapes evolved with these disturbances and the attendant shifts in habitat quantity and quality. These species are affected by habitat reorganization associated with wildfires, including addition of wood material and sediment deposition; thus, they are considered to be fire-adapted. The natural frequency, severity, and extent of historical fires governed the

pulse of erosional events that carried wood, rocks, and soil to streams and created variation in the level of stream shading and aquatic habitat available to fish provided by riparian vegetation. Fish populations have been shown to recover rapidly to the natural fire regime in burned reaches, depending on connectivity of stream networks (Burton 2005). Thus, restoration of conditions that promote a natural fire regime will benefit fish populations overall. Where fish populations are robust, recolonization of stream segments disturbed by fire is tenable (Burton 2005).

This dynamic view diverges from traditional frameworks that suggest that aquatic ecosystems should be managed as stable systems perpetually maintained for select species. Stable equilibrium and balance of nature views are equally intractable in terrestrial and aquatic ecosystems. The dynamic view of aquatic systems accepts patterns of disturbance and recovery across landscapes as necessary processes to interconnect mosaics of diverse and changing habitats and communities.

Streams draining burned areas of the Entiat Experimental Forest (EEF) on the east side of the Cascades crest in Washington had peak flows 120 percent higher than prefire conditions (Siebert et al. 2010). Additionally, there were deeper snowpacks and more rapid snowmelt as a result of the disturbance. However, only the upper elevations of the EEF consist of mixed-conifer forest with slightly higher moisture (mean annual precipitation at mid-elevation = 580 mm) (Seibert et al. 2010). Similar hydrologic issues could likely prevail following fire disturbance in moist forests. The primary lesson from Siebert et al. (2010) is that prefire hydrologic data are essential to quantifying the postfire response.

Climate change affects forest landscapes, wildfire regimes, aquatic habitats, management options, and their interactions. Climate variability can have important effects on stream hydrology (Jain and Lall 2001, Poff et al. 2002, Tague and Grant 2009) and related physical processes (Bull 1991, Meyer et al. 1992, Pederson et al. 2001, Schumm and Hadley 1957). Changes in hydrology can happen rather abruptly (i.e., 10 to 100 years), and decadal- to multidecadal-scale climate regime shifts can influence stream flows more than the management practices on which we focus most attention (Jain and Lall 2001). April 1 snowpack has declined in mountainous regions across the Western United States (Mote 2003, Mote et al. 2005). Changes are largely attributed to elevated winter and spring temperatures (Hamlet et al. 2007, Stewart et al. 2005). Snowpack decline is expected to continue as temperatures rise throughout the region. Changes in the timing and magnitude of precipitation are expected because of interactions between rising air temperatures, snowfall, and rainfall across complex local terrain. Warming will result in more precipitation falling as rain than snow, and earlier snowmelt timing (e.g., Hamlet et al. 2005).

Climate change profoundly affects processes that create and maintain aquatic habitats. Some effects are direct, particularly those involving stream temperature, water yield, peak flows, and timing of runoff (Luce et al. 2014). Other effects occur indirectly as climate change forces alteration of the structure and distribution of forest communities and the characteristics of wildfire. These processes will indirectly affect fish in relevant watersheds. Altered snowmelt run-off regimes in the mixed-conifer forests will affect downstream fish-bearing reaches. Discharge patterns affect water depth; thus, earlier low flows downstream may reduce habitat availability for fish dependent on deeper, slower flowing habitats. Changing precipitation and fire regimes are expected to compound the effects of warming trends by shifting hydrologic patterns and those of sediment transport and solar radiation (Dunham et al. 2007, Isaak et al. 2010). The structure and composition of riparian vegetation imparts important influences on temperature and soil moisture gradients immediately adjacent to streams (Anderson et al. 2007).

Fish and other aquatic biota are likely to be affected by wildfire and climate change in MMC forests. Aquatic ecosystems consist of interacting species at all trophic levels. Productivity in each level can depend on inputs and transfers across the terrestrial-aquatic ecotone. Movement of terrestrially derived production into streams can affect primary production with implications further up the food web, including aquatic insects and fish (e.g., Baxter et al. 2004, Nakano et al. 1999). Resources transported downstream and organic matter of terrestrial origin can alter downstream fish-bearing habitats according to spatial variation in the headwaters (Baxter et al. 2004, Binckley et al. 2010, Wipfli et al. 2007). Convergence of low-order streams that drain large landscapes at downstream habitats potentially results in productivity "hot-spots" (e.g., Kiffney et al. 2006). Efforts to establish transport distances and specific responses in fish have been limited in mixed-conifer areas (but see Polivka et al. [N.d.][1]). Nevertheless, some successional stages can have measurable influence on the standing crop of aquatic macroinvertebrates (Medhurst et al. 2010).

Streams in dry and MMC forests are not especially diverse in terms of fish species, but they do consist of species that are sensitive to temperature increases in spawning and rearing streams and that respond to disturbances such as wildfire. Less is known about how fire will affect macroinvertebrate communities that serve

[1] Polivka, K.M.; Dwyer, G.; Mehmel, C.J.; Sirianni, K.M.; Novak, J.L. [N.d]. Effects of temperature and virus persistence time on wild and pesticide strains of the nucleopolyhedrovirus (NPV) pathogen of larval Douglas-fir tussock moth (*Orgyia pseudotsugata*). Manuscript in preparation. On file with: Karl Polivka, Pacific Northwest Research Station, Forestry Sciences Laboratory, 1133 N. Western Ave., Wenatchee, WA 98801.

as food resources for fish. Successional patterns following disturbance can affect macroinvertebrate communities, but it is unclear whether changes at one trophic level will be detectable at levels above (i.e., fish) (Medhurst et al. 2010).

In fish-bearing streams of Idaho, the intensity of fire determined the density and age structure of rainbow trout (*Oncorhynchus mykiss*) (Dunham et al. 2007). Relative to controls, streams adjacent to habitats that burned showed relatively more rapid growth of age 1+ rainbow trout, an effect that was augmented in streams that were physically re-organized by erosion and sedimentation following the fire (Rosenberger et al. [N.d.]). This study ranged from lower elevation dry forest to elevations containing MMC and subalpine forest in the Boise River basin. Fish recovery following riparian fire can be fairly rapid in streams where there is a robust local population to recolonize disturbed habitat, and management of fire severity might be most important in areas where local populations are weak and isolated (Burton 2005). Management of roads might also be necessary, given that fragmentation of stream habitat might not only affect the ability of a fish population to recolonize stream segments affected by fire, but might also affect patterns of genetic diversity in resident trout species (Neville et al. 2009).

Cutthroat trout (*Onchorhynchus clarki*) and bull trout (*Salvelinus confluentus*) are the most temperature-sensitive species likely to be present in mixed-conifer zones. Bull trout occupy the coldest freshwater habitats of all salmon and trout species and these habitats are predicted to be severely affected by climate change in coming decades (Isaak et al. 2010, Rieman et al. 2007, Wenger et al. 2011). Bull trout life histories include migratory forms that spawn and rear in cold streams close to headwaters, then migrate downstream to larger rivers where they live as adults prior to spawning ("migratory") or migrate to lakes following rearing ("adfluvial"). Fragmentation of cold water habitats by stream warming can increase physiological stress to bull trout and decrease interconnectivity of adequate spawning and rearing aggregations. In the "resident" life history form, bull trout remain in cold headwater streams for spawning and rearing, and as adults. Thus, they are subject to these physiological stressors at all life stages. Cutthroat trout are also common to upland streams in mixed-conifer forests of the eastern Cascades. Management for the persistence of these and other coldwater fish species in the face of climate change should again focus on maintaining strong, genetically diverse populations in well-connected stream networks. This may mean road management as a means of addressing climate change, by increasing passage and opening stream networks. In small streams within mixed-conifer watersheds of the Wenatchee River sub-basin, cutthroat trout density and total biomass are limited

by higher flows (fig. 36).[2] Thus, changing flow regimes as a result of precipitation and snowmelt-timing shifts can potentially have consequences for the persistence of populations of this species.

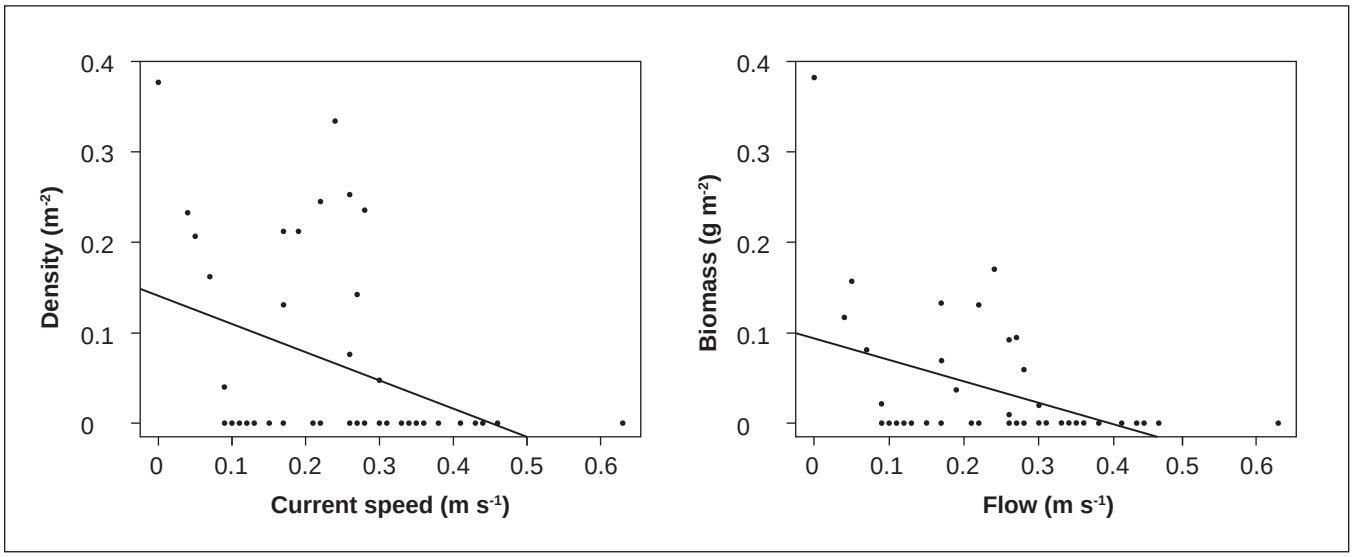

Figure 36—(Left) Cutthroat trout (*Oncorhynchus clarki*) density as a function of current velocity in habitat units (usually pools) distributed among six first-order streams in moist mixed-conifer forests in the Wenatchee River Basin (Washington, USA). Decreasing linear relationship was significant with much unexplained variation ($F_{1,43} = 7.75$, $p = 0.008$, $r^2 = 0.133$). (Right) Cutthroat trout biomass as a function of current velocity in habitat units (usually pools) distributed among six first-order streams in moist mixed-conifer forests in the Wenatchee River Basin (Washington, USA). Decreasing linear relationship was significant with much unexplained variation ($F_{1,43} = 8.34$, $p = 0.006$, $r^2 = 0.143$) (see footnote 2).

Active management can restore a full spectrum of ecological patterns and processes. Long-term restoration and maintenance of the physical, biotic, and ecological processes that are important to maintaining diverse terrestrial and aquatic systems requires strategies that go beyond simply treating fuel accumulations, attempting to prevent high-severity fires, or attempting to maintain existing fish strongholds. The most effective means to minimize negative consequences of expected climate change, and related effects on aquatic systems, is to protect the evolutionary capacity of these systems to respond to disturbance. In this light, management would focus on protecting relatively undisturbed aquatic habitat, and, where necessary, restoring habitat structure, the processes that support it, and the life history complexity of native species, to the best practical extent (Gresswell 1999). Restoring degraded aquatic ecosystems requires a similar perspective. To conserve or promote resiliency in aquatic (as in terrestrial) systems,

[2] Bennett, R.L.; Polivka, K.M. [N.d]. Factors important to monitoring of headwater fish populations and possible effects of landscape features. Manuscript in preparation. On file with: Karl Polivka, Pacific Northwest Research Station, Forestry Sciences Laboratory, 1133 N. Western Ave., Wenatchee, WA 98801.

land managers can turn their focus to conserving and restoring the physical and biological processes and patterns that create and maintain diverse networks of habitats and populations, rather than engineering the condition of the habitats themselves (Benda et al. 2003, Ebersole et al. 1997, Frissell et al. 1997, Gresswell 1999, Minshall 2003, Naiman et al. 2000, Rieman et al. 2003). This means that management is capable of restoring (1) natural patterns in the timing and amount of stream flows (Poff et al. 1997); (2) natural production and delivery of coarse sediment and large wood to streams (Beechie and Bolton 1999, Meyer and Pierce 2003, Reeves et al. 1995); (3) riparian communities that function as sources of organic material, shade, and stream buffering (Gregory et al. 1991); (4) streams, flood plains, and hyporheic zones that are reconnected (Naiman et al. 2000); and (5) habitats that are required for the full expression of native life history strategies, gene flow and variability, and demographic support among populations (Dunham et al. 2003, Gresswell et al. 1994, Healey and Prince 1995, Poole et al. 2001, Rieman and Dunham 2000; Rieman et al. 2003, Roghair et al. 2002). Management maintains forests and streams that can respond to and benefit from disturbances across a broad range of event sizes and intensities, rather than minimizing the threat of the disturbance.

Logical priorities for restoration activities emerge from an evaluation of the changes and constraints imposed by these changes (e.g., Beechie and Bolton 1999, Luce et al. 2001, Pess et al. 2002). Habitat loss and fragmentation, channelization, chronic sediment inputs, accelerated erosion, and changes in hydrologic regime (Lee et al. 1997, NRC 1996) are all problems that merit attention. However, restoring physical connections among aquatic habitats may be one of the most effective first steps to restoring productivity and resilience of many native fish populations (Rieman and Dunham 2000, Roni et al. 2002), given that network connectivity is a key component of the adaptive response by fish to disturbances (Burton 2005). Eliminating the threat of large and severe disturbance may be insufficient to prevent local fish population extinctions in many streams (Dunham et al. 2003, Rieman et al. 2003).

The geographic location and sensitivity of watersheds can be used to guide priority setting for management actions (Rieman et al. 2000, 2010). From an aquatic conservation and restoration perspective, priorities for active vegetation and fuels management occur as follows:

Priority 1. Watersheds in which the threat of extensive, high-severity fire is high and local populations of sensitive aquatic species are at risk because they are isolated, small or vulnerable to invasion of exotic fish species (Dunham et al. 2003, Kruse et al. 2001). In these instances, the first priority for management is to restore connectivity among patches of favorable fish habitat (Dunham et al. 2003,

Rieman et al. 2003). Where this is impractical, active forest management to reduce the severity and impact of potential fires could be an important short-term strategy (Brown et al. 2001, Rieman et al. 2003).

Priority 2. Watersheds in which there is little to lose, but much to gain. In some watersheds, habitat degradation is extensive and remaining native fish populations are depressed or locally extinct. Watersheds that are heavily roaded and influenced by past intensive management often contain forests vulnerable to severe fires (Hessburg and Agee 2003, Rieman et al. 2000). Existing road systems can initially facilitate understory vegetation treatments and fuel reduction, and can subsequently be removed, moved, or improved to reestablish hydrologic and biological connectivity (e.g., Roni et al. 2002). Here, short-term risk of ground-disturbing activities may be offset by the potential long-term benefit of reconnecting and expanding habitats and populations. In many of these locations, ongoing treatment with fire will likely be needed.

Priority 3. Watersheds in which sensitive aquatic species are of limited significance. Given that the vulnerability of dry and MMC forests to high-severity fire is associated with lands that have been intensively managed (and absent any subsequent composition or stocking management following treatment), the need for active fire and fuels management now may be greatest in areas where aquatic ecosystems and related physical processes have been most significantly altered (Rieman et al. 2000). In some locations, complete restoration of all native plants and animals may be impractical. These are logical places to experiment with active management, where learning can proceed without taking unacceptable risks (Ludwig et al. 1993; see Rieman et al. 2010 for an example).

Management for climate change requires consideration of dynamic hydrologic simulations that are used to represent climate change scenarios (e.g., see Hamlet et al. 2005, Miller et al. 2003). These must relate sensitivity of models and inferences to the main assumptions about climate change, and the low-frequency climate variability that is assumed (e.g., decadal and longer scale fluctuations). Additionally, dialogue between landscape ecologists and hydrologists will be necessary to integrate the effects of climate change on watersheds in MMC forests and how these will be transmitted across the terrestrial-aquatic ecotone to stream habitats. In other words, climate will affect fire frequency and intensity, and management options for aquatic habitats will require consideration of processes discussed above and how the ecological outcome is related to them (Bisson et al. 2003). Landscape heterogeneity will contribute to the issues faced on the ground by managers in MMC ecosystems throughout the interior northwest (Rieman et al. 2003).

There will be key uncertainties to consider in the management of aquatic habitat in MMC landscapes as well. Variable incidences of fire, variable need for fuels treatment, variable current quality of aquatic habitat, and management tradeoffs between human well-being (property, resources) and conservation all increase the complexity of management decisions (Bisson et al. 2003). Establishment of an effective adaptive management program will incorporate all of these considerations, as well as the spatial and temporal scale. Specific areas might require a more explicit management approach, whereas across the entire MMC forest ecosystem, a more generalized approach based on existing research might be effective (Bisson et al. 2003). Success will depend on continued dialogue between landscape ecologists, aquatic ecologists, and forest managers. Also stakeholders in the public should be asked to consider the scientific recommendations and to participate in further development of management and research objectives.

Riparian habitats—
There are relatively few studies that focus specifically on the historical disturbance regimes and structure and composition of riparian zones of mixed-conifer forests. The little that we do know comes from what can be gleaned from the studies of Agee (1988, 1994), Camp (1999), Camp et al. (1997), Everett et al. (2003), Fetherston et al. (1995), Garza (1995), Gregory et al. (1991), Gresswell (1999), Naiman and Decamps (1997), Naiman et al. (1993, 1998), Olson (2000), Olson and Agee (2005), Skinner (1997), Taylor and Skinner (1998, 2003), and Wright and Agee (2008). With the exception of low-gradient stream reaches (e.g., ≤5 degrees of in-stream slope angle), the fire regimes of riparian zones track fairly well with those of the adjacent upslopes. In contrast, the disturbance regime of low-gradient and often fish-bearing reaches tracks with the hydrologic regime. Low-gradient reaches were often depositional zones during flood events, with intact flood plains, and often supported hardwood tree and shrub vegetation cover. Disturbance in these environments was typically driven by flooding and ice flows, and their spatial and temporal variability, rather than wildfires, although wildfires do burn through these areas.

Riparian areas are key wildlife habitats in interior dry forests because of the presence of free water, cool moist microclimates, and soil moisture that supports diverse vegetation.

Gaining a better understanding of the historical disturbance regimes and vegetation patterns of riparian zones is a fertile area of research. The existing datasets of the Interior Columbia River Basin mid-scale assessment (Hessburg et al. 1999a, 2000a) provide extensive reconstructions of now nearly 400 subwatersheds whose riparian zones could be reevaluated to provide further insights on successional patterns and historical fire severity.

We also know that riparian areas are key wildlife habitats in interior dry forests because of the presence of free water, cool moist microclimates, and soil moisture

that supports diverse vegetation (Lehmkuhl et al. 2007b, 2008). Small mammals are more diverse in dry forest riparian areas compared to adjacent uplands. Several species, such as the water shrew (*Sorex palustris*), are associated with free water, whereas species typical of wet or mesic forests become obligate riparian species as the surrounding upland vegetation becomes dryer (Lehmkuhl et al. 2008). Forest birds are no more diverse in riparian areas than in adjacent uplands, but the composition of birds differs with the addition of many riparian obligate species associated with deciduous trees, dense shrubs, and herbaceous vegetation (Lehmkuhl et al. 2007b).

Postfire riparian conditions can have long-term effects on aquatic biota owing to changes in temperature and sedimentation according to local geomorphology and burn severity. In fish-bearing streams of Idaho, the intensity of fire determined the density and age structure of rainbow trout (Dunham et al. 2007). Relative to controls, streams adjacent to habitats that burned showed relatively more rapid growth of age 1+ rainbow trout, an effect that was augmented in streams that were physically reorganized by erosion and sedimentation following the fire (Rosenberger et al. [N.d.]). This study ranged from lower-elevation dry forest, to elevations containing MMC and subalpine forest in the Boise River basin. These observations are thus relevant to management strategies in mixed-conifer forests at higher elevations.

Human Impacts to Moist Mixed-Conifer Systems: Influences of the Last 100 to 150 Years

Humans have inhabited parts of eastern Oregon and Washington for more than 10,000 years. Native American communities developed many land management practices to serve their needs for sustenance and used fire extensively in woodland environments east of the Cascades (Agee 1993; Langston 1995; Robbins 1997, 1999; Robbins and Wolf 1994; White 1983, 1991, 1992, 1999). However, there is limited knowledge of the impacts of their management on MMC forests (Whitlock and Knox 2002).

With the arrival and settlement of Euro-Americans in the early 1800s came another wave of human impacts. Key change agents included initial widespread timber harvests, highly effective fire prevention and suppression (largely since the 1930s), extensive sheep and cattle grazing and livestock fencing, development of extensive road and railroad networks, subdivision of regional landscapes by ownership, widespread and repeated timber harvest entry via selection cutting and clearcut logging, conversion of native grasslands and shrublands to agricultural uses, and urban development. As a result, today these forests neither resemble nor function as they once did 100 or 200 years ago.

Changes to the landscape that naturally flowed from these impacts include:

- A highly fragmented range of forest patch sizes, stemming from 4, 8, and 16 ha (10, 20, and 40 acre) treatment areas and from other land uses near urban areas. The resulting patchiness differed greatly from the original spatial pattern of the landscape. In some places, patches created by repeated harvesting entries created homogenous forest with a skewed species composition and more uniform age and size classes. The original mosaic, more of a gradient of seral stages created by the complex patterns of fire and other tree mortality factors, included an array of different sized patches and a full complement of seral or successional stages.
- After regeneration harvests, a more homogenized forest structure emerged, in which treatments drove stand structure and composition toward a single cohort and commercially desired species. After selection cutting, stand structure moved toward multiple cohorts because of continuous regeneration and release (some stands were entered several times), and species composition moved toward domination by shade-tolerant species in dense multilayered arrangements.
- A simplified vegetation mosaic was created by removal of large, fire-tolerant trees over repeated harvest entries, which typically left many smaller and fewer large trees. The result was ever increasing density and a surplus (in comparison with the native disturbance regimes) of young and mid-aged forests.
- A shift from fire-tolerant to intolerant tree species composition (timber harvest removed large ponderosa pine, Douglas-fir, western larch, western white and sugar pine [*Pinus lambertiana* Dougl.], and regenerated grand fir, white fir, Douglas-fir, and subalpine fir dominated stands).
- An increased vulnerability to large and severe fires, insect outbreaks, and disease pandemics.
- Fewer grasslands and shrublands.

Management activities have also had a profound effect on the spread of nonnative species, especially in the dry rangeland and forest ecosystems. As the climate continues to change, conditions for spread of some nonnative invasive (e.g., cheatgrass [*Bromus tectorum*]) and native invasive (e.g., barred owl) species will improve. Despite substantial efforts to control invasive species in the United States, the threat will remain high in coming years unless significant steps are taken to slow the advance of invasive plants and animals.

Timber Harvest and Associated Activities

Timber harvest and road development over the last 100 years have had a significant impact on the landscape patterns of MMC forests in eastern Oregon and Washington (fig. 37). Harvest activity was quite intense for nearly five decades beginning at the start of World War II. Clearcutting, selective harvesting, and subsequent planting for reforestation created substantial areas of structurally simple early- to mid-aged stands. Present-day stand structure of these previously harvested areas is

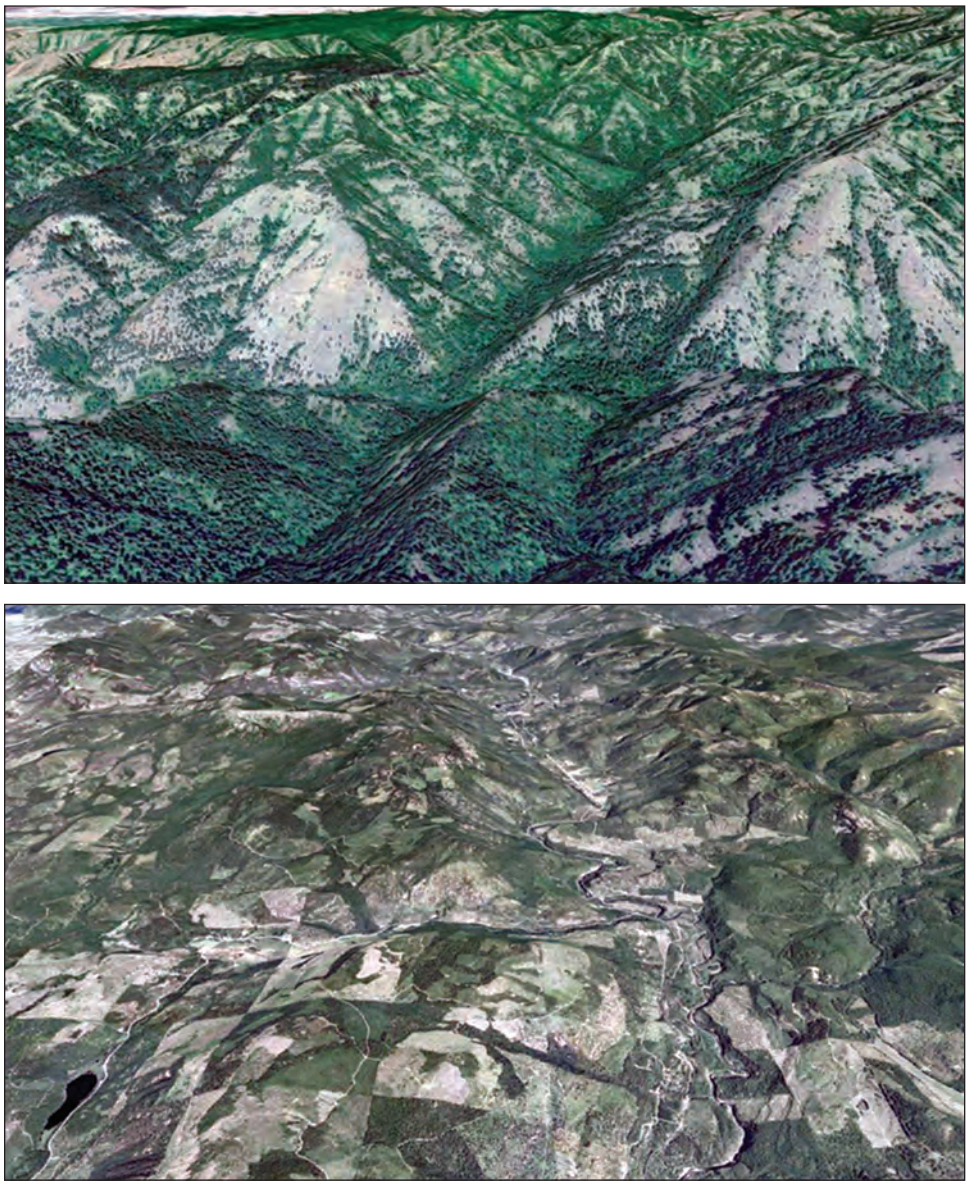

Figure 37—Timber harvest and road development over the last 100 years have had an impact on the spatial configuration of mixed-conifer forests in eastern Oregon and Washington. The upper image shows a portion of the Umatilla National Forest without stand management, fragmentation with land ownership, and roads. The lower image shows the effects of land ownership, roads, and harvest units on forest pattern. Images are from Google Earth™.

predominantly even-aged where regeneration harvesting was practiced and uneven-aged where selection cutting was more common, with tree species and genetic compositions that are often not particularly well-adapted to the environment. Large and old live and dead trees (snags) are conspicuously absent from many forests (Churchill et al. 2013; Franklin and Johnson 2012; Hessburg et al. 2003, 2005; Larsen and Churchill 2008, 2012; Merschel 2012).

Historical replanting at many sites used maladapted seedling stock from distant seed sources, and frequently with species compositions that were not ecologically appropriate for the site conditions (e.g., overly high proportions of economically important ponderosa pine and Douglas-fir). Seed collection zones were not yet established and there was only rudimentary understanding of the relationships linking seed provenance adaptation to particular site conditions. Prior to replanting, broadcast burning treatments were often employed. If omitted, significant surface fuel accumulations were often left behind (Agee 1998, Hann et al. 1997, Hessburg et al. 1999a, Huff et al. 1995). These and others factors have limited the function of some present-day MMC forests and the ecosystem services that can be obtained from them. Some of the post-harvest stands across this region contain large (more than about 53 cm [21 in] d.b.h.) young trees with species compositions and stand structures that may succumb to bark beetles or fire, and may benefit directly from manipulation of tree species composition and density.

Since the early 1990s, when certain management constraints (e.g., the "eastside screens") were adopted, timber harvest has been scaled back by about 90 percent. Currently, the scale and scope of active management focuses on a limited number of cautiously selected locations, primarily for the purposes of restoring ecological processes and reducing fuel loads.

Fire Exclusion and Natural Fire Dynamics

In the absence of fire, forest density increased, the role of shade-tolerant tree species expanded, and fuel loads have increased.

Fire frequency in the region declined because of land-use changes in limited areas as early as 1880 or 1890. By 1900, fire frequency in dry forest types was in sharp decline (Everett et al. 2000; Haugo et al. 2010; Hessburg et al. 1999a, 1999c, 2000a, 2005, 2007; Hessl et al. 2004; Heyerdahl et al. 2001, 2008; Wright and Agee 2004), resulting in further changes to forest structure and composition. In the absence of fire, forest density increased, the role of shade-tolerant tree species expanded, and fuel loads have increased (Baker 2012; Everett et al. 1994; Hessburg et al. 2000b, 2003, 2005; Huff et al. 1995; Lehmkuhl et al. 1994; Merschel 2012; Perry et al. 2011). Not coincidentally, human population densities have increased rapidly as many people prefer to live at the lower forest ecotone. The amount of area classified as wildland-urban interface (WUI) has increased dramatically in recent decades (Gude et al. 2008, Radeloff et al. 2005).

Departure from historical fire regimes—
Land use activities and fire-suppression efforts from the early 20th to early 21st centuries have been effective at controlling small fires, eliminating the landscape patchiness that was historically important for interrupting fire flow at large spatial scales (Moritz et al. 2011, Perry et al. 2011). Large wildfires today typically result from rare or extreme weather or climatic events (Littell et al. 2009, Moritz et al. 2011). That was also the case historically. The significant difference associated with 20th century vegetation and climate change is the increase in frequency of very large (>10,000 ha) wildfires in many ecoregions of the West as a result of both more flammable landscapes and changing weather conditions. Owing to their increasing frequency and size, some large wildfires may synchronize large areas of the mixed-conifer landscape, setting the stage for more large and severe fires in the future. This happens because large fires, especially those dominated by crown-fire effects, can simplify and homogenize landscape patterns of species composition, tree size, age, density, and layering.

However, this is not always the case. A recent study in California found that some wildfires can achieve ecological and management goals by reducing landscape-scale fire hazard and increasing forest heterogeneity (Miller et al. 2012). This is likely to be true when the pattern and dispersion of fire severity and fire event patches are more or less consistent with the native fire and climatic regimes. We note here that despite referenced changes in fire regimes, many contemporary fires are still substantially dominated by mixed-severity fire, and the building blocks for landscape restoration are readily apparent. One can still observe the interactions of bottom-up, local (e.g., stand and landscape structure, topography), and top-down spatial controls on fire extent and fire severity (Perry et al. 2011).

Grazing

Sheep and cattle entered the region with the first settlers, but the earliest of them focused on agriculture, and their herds were typically small, including just enough livestock to work and support their family farms. Cattlemen initially believed that their stock could survive the harsh winters, and by 1860 there were at least 200,000 head of cattle in the region. A severe winter in 1861–1862 killed many cattle (Galbraith and Anderson 1991). Severe winters occurred again in 1880–1881 and in 1889–1890, after which most cattlemen recognized that shelter and feed were required for a sustainable operation.

By the late 1880s, severe grazing by cattle left the rangelands stressed (overgrazed). Large cattle herds also grazed adjacent dry forests and nearby grassy riparian zones. Because cattle require a lot of water, they preferred to graze the riparian zones, creek bottoms, and wet meadows that supported lush grasses through the dry

summers, and provided a ready supply of water. Riparian zones constitute 1 to 4 percent of the land area of eastern Oregon and Washington national forests (Kauffman 1988), yet supply more than 80 percent of the grasses and herbs consumed by livestock (Roath and Krueger 1982).

Introductions of sheep, which require less water and are capable of using varying rangeland conditions, boomed in the mid- to late 1880s coincident with the decline in cattle. Eventually sheep numbers outstripped cattle, and violent conflicts often arose between Basque and Mormon sheepherders and resident cattlemen. The battles were the fiercest in Crook, Lake, Wheeler, and Deschutes Counties in south-central Oregon, where 8,000 to 10,000 sheep were killed per year for several years (Galbraith and Anderson 1991). Extensive grazing by sheep left native bunchgrasses and forbs in worse condition than was caused by cattle grazing. By the late 19th century, numerous exotic plants such as the bull and Canada thistles (*Cirsium vulgare* and *C. arvense*), cheatgrass, Dalmation and yellow toadflax (*Linaria dalmatica* and *L. vulgaris*), diffuse and spotted knapweeds (*Centaurea diffusa* and *C. maculosa*), and leafy spurge (*Euphorbia esula*) had become established in the region (Hann et al. 1997; Langston 1995; Wissmar et al. 1994a, 1994b).

Grazing permits and fees were required on national forest lands beginning in 1906, although grazing intensity increased until the 1920s (Wilkinson 1992). Congress approved the Taylor Grazing Act of 1934, which regulated grazing on the public domain (later, Bureau of Land Management lands) through the use of permits; subsequently, cattle and sheep numbers declined. Recent assessments of grassland condition suggest that grasslands are slowly recovering from some of the impacts of historical grazing, and current conditions are perhaps the best they have been in 100 years (e.g., see Harvey et al. 1994, Johnson et al. 1994, Skovlin and Thomas 1995). However, because of countless nonnative plant species introductions, some changes in native plant community structure and productivity are likely permanent (Lehmkuhl et al. 2013). There is ongoing public debate over whether livestock grazing on public lands should be continued under the Taylor Grazing Act (e.g., see Belsky et al. 1999, Beschta et al. 2012). Although public land managers have made steady progress in reducing cattle impacts to riparian vegetation and sediment load in small streams and creek bottoms, this is likely an area for continued improvement.

Land Development

The national forests of eastern Oregon and Washington are largely surrounded by private lands. Throughout most of the 1900s, these lands were used for natural resource extraction or agriculture. In recent decades, rural home development has

expanded. The rapid increase of these exurban homes adjacent to wildlands poses a major threat to ecological functioning, fire management, and native biodiversity. Exurban development can fragment habitats, create barriers to animal movement and other ecological processes, alter natural disturbance, extirpate top predators, increase weeds, increase mesocarnivores (medium-sized predators) and diseases, and ultimately, cause local extirpation of some native species (Hansen et al. 2005, McKinney 2002, Pickett et al. 2001). The presence of homes in the WUI also strongly affects fire management options in adjacent national forests, increasing the need to suppress fire to protect property and lives, requiring identification and mitigation of hazard trees, and increasing firefighting costs.

Theobald et al. (2011) evaluated changes in abundance and connectivity of "high-quality" forest patches resulting from land use changes in the Western United States. They estimated that land uses associated with residential development, roads, and highways have caused roughly a 4.5-percent loss in area (20 000 km^2 [7,722 mi^2]) of large, unmanaged forested patches, and continued expansion of residential land will likely reduce forested area by another 1.2 percent by 2030. Projected losses for 2000–2030 were particularly high in Oregon and Washington (fig. 38). When considering both patch size and overall landscape connectivity for forests across the West in 2000, the most important forested areas were found in the Cascades Ecoregion and the Canadian/Middle Rockies Ecoregion, which includes the Okanogan Highlands and the Blue Mountains (Theobald et al. 2011). This

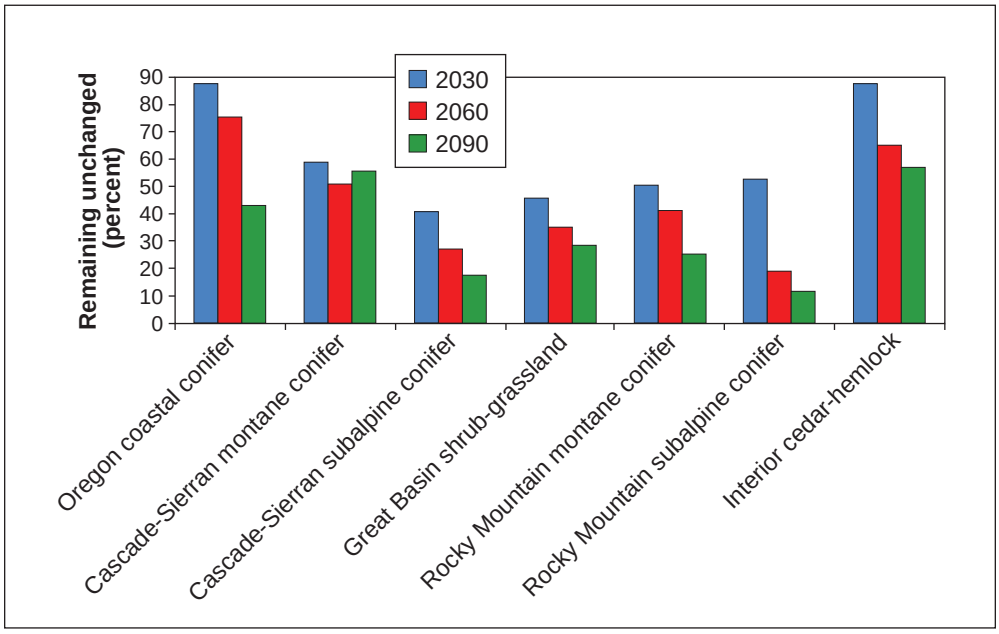

Figure 38—For biomes in Oregon and Washington, the model results among scenarios indicate that Rocky Mountain subalpine conifer in the Blue Mountains and Cascade Range will undergo the greatest loss in area. Data from Rehfeldt et al. (2012).

analysis illustrates the high contribution to subcontinental forest connectivity made by forests in Oregon and Washington, and the vulnerability of this connectivity to future land use changes.

Climate Change

Climate change is affecting MMC forests in eastern Oregon and Washington through changes that include warmer temperatures (Mote and Salathé 2010) and snowpack declines (fig. 39; Mote 2003, Mote et al. 2005). Over the next 100 years, because CO_2 concentrations are projected to rise, these impacts will likely increase in magnitude and extent over the region (Littell et al. 2010). Impacts to terrestrial ecosystems include increased fire frequency and severity, increased susceptibility to some insects and diseases (Fettig et al. 2013, Preisler et al. 2012), and increases in the presence of some invasive species (CIG 2009). Regionally, increased summer temperature and decreased summer precipitation and snowpack (Cayan et al. 2001) are projected to result in a doubling of the area burned by fire by the 2040s and a tripling by the 2080s (CIG 2009). Changes in the length and timing of seasons, especially the growing season, the timing of bud break (phenology), and the seasonal availability of soil moisture are expected to produce large positive and negative shifts in forest growth, with a net effect of increased forest mortality in the eastern Cascades (Choat et al. 2012, Grant et al. 2013, Williams et al. 2012).

In addition to general regional changes in temperature and precipitation predicted by models is the likelihood that change at the local scale could be quite variable owing to high variability in physiographic environments where moist mixed-conifer forests are found.

In addition to the general regional changes in temperature and precipitation predicted by various regional models there is the likelihood that change at the local scale could be quite variable owing to high variability in physiographic environments where MMC forests are found (Daly et al. 2007). While most areas may become warmer, some may become moister and others drier, particularly during certain seasons of the year. Canyon bottoms may remain cool due to accentuated cold air drainage.

For wildlife, changes in climate and vegetation will impact habitat characteristics, reproductive success, and food and water availability. These changes will alter species assemblages and distributions, migration routes, interactions with competitors and predators, and may impact population viability for many species (Staudinger et al. 2013). Impacts may be particularly severe for currently rare or endemic species with restricted distributions (Parmesan 2006). Anticipated changes to wildlife include (1) the susceptibility of high-elevation habitats and species dependent on snowpack (e.g., wolverine [*Gulo gulo*] for the Blue Mountains), (2) impacts on wetlands and associated species, especially those sensitive to water temperature (e.g., tailed frog [*Ascaphus montanus*]), and (3) phenological mismatches for migratory birds and other species (Parmesan 2006). Changes are expected to happen more quickly than species' potential to adapt (Staudinger et al. 2013).

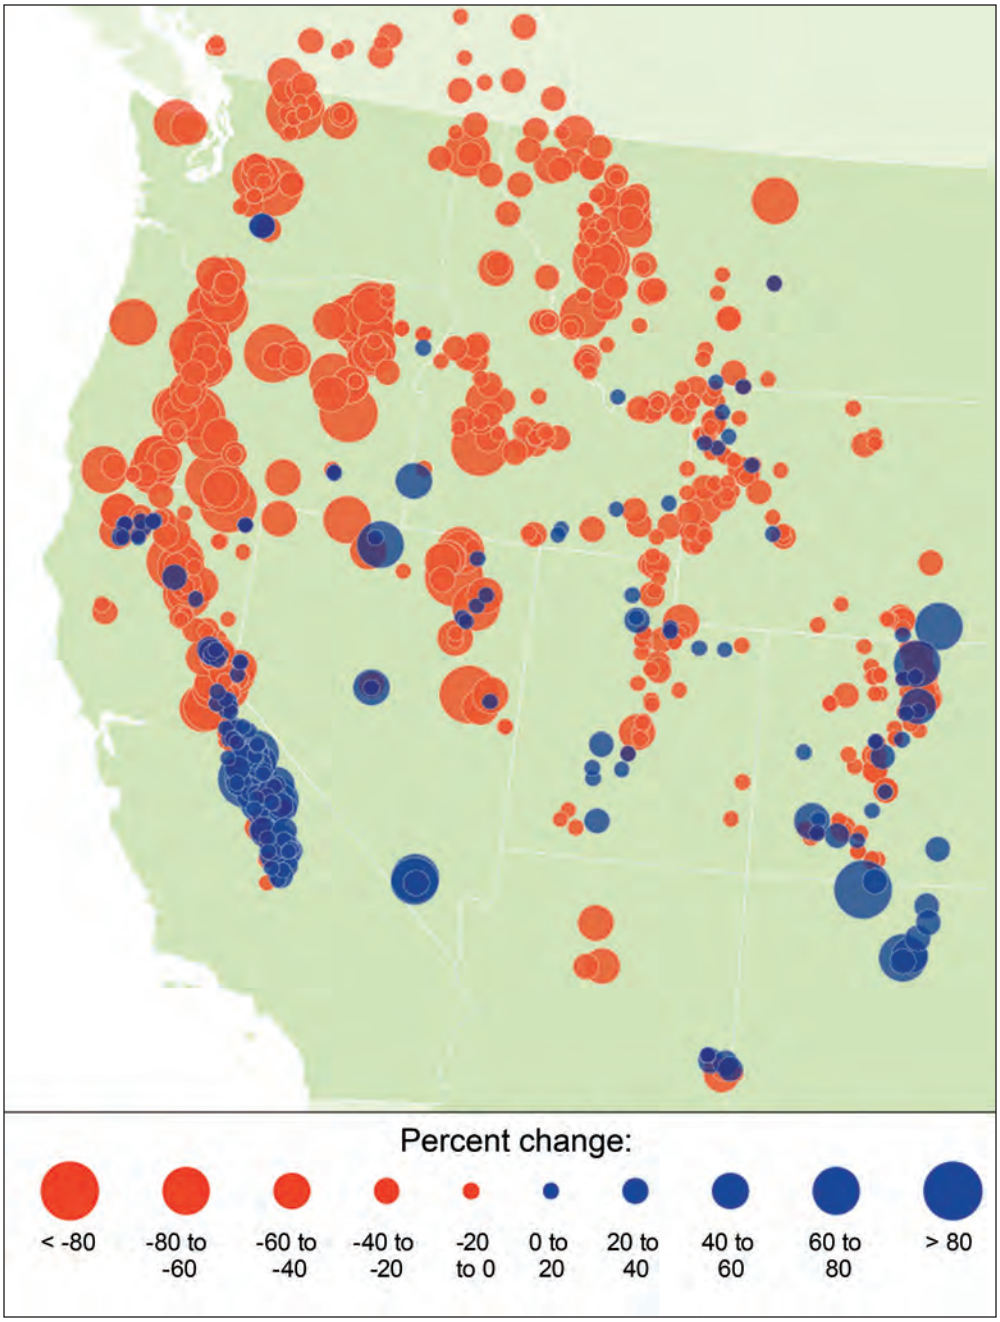

Figure 39—Historical snowpack decline in the Pacific Northwest region 1950–2000 (Mote 2009).

Maintaining landscape patterns that allow species to move in response to changes in climatic and habitat conditions may be particularly important for conservation of sensitive species (Heller and Zavaleta 2009, Nuñez et al. 2013).

Change in climate and disturbance: 1950 to present—
El Niño/Southern Oscillation (ENSO) remains the most important coupled ocean-atmosphere phenomenon to cause climate variability on seasonal to interannual

time scales in the Pacific Northwest. Across decadal timescales, longer-term oscillations such as the Pacific Decadal Oscillation (PDO) come into play. The PDO was in an extended cool phase from about 1945 to 1976 and in a warm phase from 1977 to 1998 (Mantua and Hare 2002, Mantua et al. 1997, Mote et al. 2003, Waring et al. 2011). Minimum temperatures have increased most rapidly in the semi-arid Columbia River basin and the Great Basin, and in semi-arid portions of the Okanogan Highlands, but have changed relatively little west of the Cascade Crest and in the Blue Mountains (fig. 40). Mean average temperature has been observed to have increased by 0.8 °C (1.50 °F) since 1900 (Mote and Salathé 2010). Climate

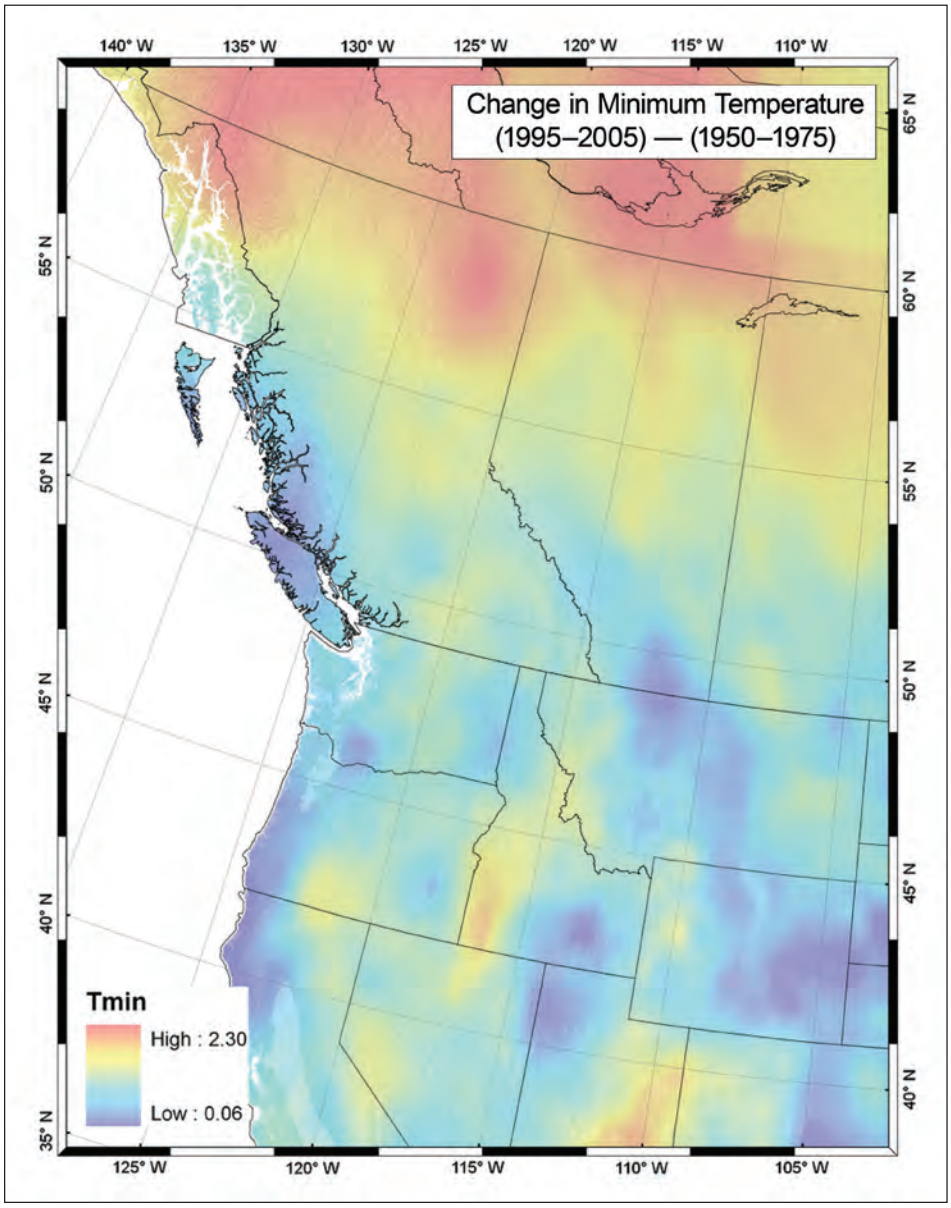

Figure 40—Changes in minimum temperature throughout the Pacific Northwest. Source: Waring et al. 2011.

forecasting models, when averaged, project increases in annual temperature of 1.1 °C (2.0 °F) by the 2020s, 1.8 °C (3.2 °F) by the 2040s, and 3.0 °C (5.3 °F) by the 2080s, compared with the average temperature from 1970 to 1999.

Trends in historical and projected future changes in precipitation in the Pacific Northwest are less clear than for temperature (Stephens et al. 2010). For example, precipitation in the Pacific Northwest has increased by 13 to 38 percent since 1900, but has shown substantial interannual and interdecadal variability during the 20th century (Mote et al. 2003), which current climate models are unable to simulate under future warming scenarios (Ault et al. 2012). Some, but not all models predict slight future increases in annual precipitation (1 to 2 percent in 2030 to 2059, and 2 to 4 percent in 2070 to 2099; Littell et al. 2009).

The ecoregions of eastern Oregon and Washington (notably the eastern Cascades and the Blue Mountains) have a Mediterranean type of climate characterized by warm dry summers and cool moist winters. The lack of summer precipitation coupled with earlier springs and later winters suggest increased vulnerability of forests and forest associates to climate change. Anticipated changes in fire regimes in the Northwest United States is a direct result of these changes in climate (Westerling et al. 2006). The following summarizes the key climate change projections and impacts to moist mixed conifer forests in the Pacific Northwest region (CIG 2009, IPCC 2013, Mote et al. 2005).

Projected outcomes:

- Reduced snowpack amounts (up to 50 percent projected decline)
- Increased rain on snow
- Warmer air temperatures (up to 3 °C by 2080)
- Change in the timing of snowmelt (earlier)
- More climate extremes

Projected impacts to moist mixed-conifer forests:

- Reduced soil moisture
- Increased drought stress
    - Increased fire intensity, severity, and frequency
    - Increased susceptibility to insect attack
- Phenologic shifts (earlier onset of budbreak, longer growing season)

Climate change impacts on forest ecosystems—
Climate change influences on forest tree species are a function of the ecophysiological tolerances unique to each species. Waring et al. (2011) used a process-based forest model to estimate changes in tree species competitiveness (influenced by a variety of ecological factors) between 1950–1975 and 1995–2005 based on climate

effects on simulated leaf area index (LAI). Although LAI may not be the prime indicator of a conifer tree's capacity to respond to changing climates, it provides an index of potential response. Across their western North America study area, they found a significant decrease in the competitiveness of over 50 percent of the evergreen species in ecoregions in the northern and southern portions of the study area. Within Oregon and Washington, competitiveness changed little in the West Cascades and was moderately reduced in the East Cascades, the Okanogan Highlands, and the Blue Mountains (fig. 41). Furthermore, regions exhibiting reduced competitiveness under climate change scenarios were predicted to experience higher rates of disturbance by insects, fire, and other factors (Waring et al. 2011).

These changes in climate are also projected to influence the area of suitable climate for vegetation types differently and shift vegetation assemblages over the landscape. Rehfeldt et al. (2012) developed climate envelope models for biomes of North America and projected change in area and distribution under six climate change scenarios. However, there is still debate about whether this approach realistically captures physiological tolerances of forest species (Loehle 2011).

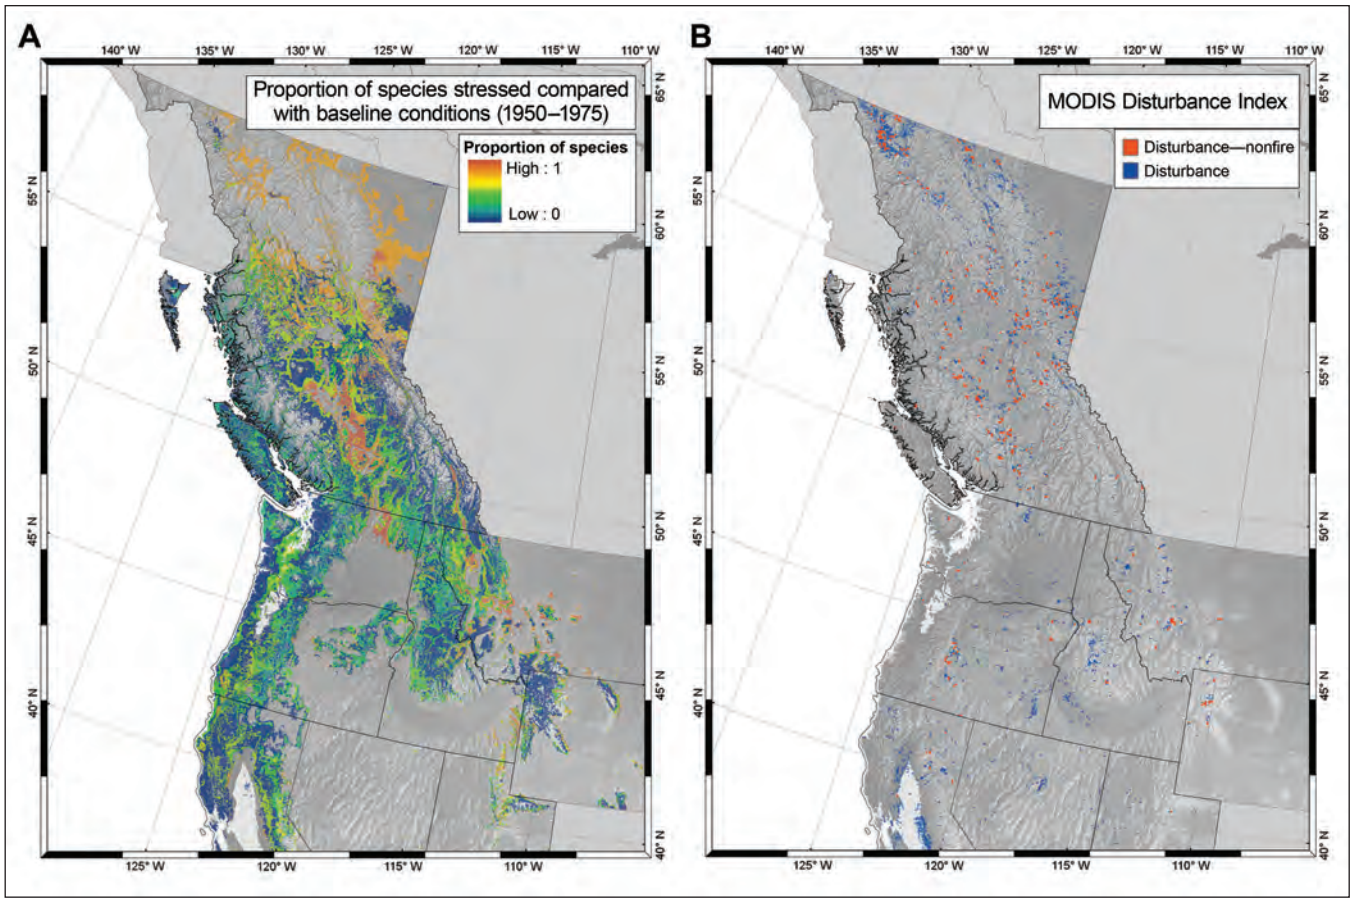

Figure 41—Map presenting the proportion of 15 coniferous species predicted as no longer well-adapted in the years 1995–2005 compared with baseline conditions (1950–1975). From Waring et al. (2011).

We acknowledge that limitations to the use of climate envelope approaches for modeling potential species distribution changes are well known (Fettig et al. 2013). Nonetheless, modeling approaches provide some insight into the possible magnitude and geography of projected changes in species distribution in the coming decades.

For biomes in Oregon and Washington, model results among scenarios estimate that all Oregon Coastal Conifer and Interior Cedar-Hemlock types will undergo the least reduction in the areas they currently occupy. Subalpine biomes in the Cascades and the Rockies are projected to eventually undergo substantial reduction in currently occupied areas, with only 27 percent and 19 percent of these biome types remaining. Drier conifer forest area is also forecasted to decline substantially: 41 percent of Rocky Mountain Montane Conifer, which currently occurs in the Okanogan Highlands and the Blue Mountains, is forecasted to remain in 2060. Importantly, by 2090, only 12 to 57 percent of the current area is forecasted to have climates suitable to the biomes occurring there today, although the rate of decline is uncertain. Of course we do not know how extensive the geographic shift in biomes will eventually be, because there are many complex ecological interactions that will play out over time, and ecophysiological modeling is in its infancy. Current models give us an indication of how dramatic the changes could be. Nonetheless, some areas currently occupied by subalpine forest in the Cascades, for example, will likely become suitable as mixed-conifer forests now found at mid elevations. Climate in the Northeast Cascades of Washington becomes suitable for the Coastal Hemlock Biome type. Forest areas in the Okanogan Highlands and Blue Mountains are largely replaced by climates suitable for the Great Basin Shrub-Grassland type.

Forest productivity is also projected to change under future climates. Productivity is forecasted to increase in what are currently subalpine and alpine zones across the region and to decline in the drier forests, which are largely at the lower forest ecotone in the East Cascades, Okanogan Highlands, and Blue Mountains (Latta et al. 2010). Concomitantly with warmer temperatures, forests may respond to increased atmospheric CO_2 concentrations through increased water use efficiency. However, forest growth response to rising CO_2 is less clear than it appears it will be for temperature, perhaps because soil moisture availability is expected to decline (Peñuelas et al. 2011). Warming may allow some insect species (e.g., some bark beetles) to complete extra generations per year, and adult emergence and flight activity could occur earlier and last longer. Cold-induced mortality of insects during winter may also decrease. For example, model simulations indicate that the climatic suitability for mountain pine beetle will increase during the next several decades in eastern Oregon and Washington (Bentz et al. 2010, Preisler et al. 2012),

and when combined with current forest conditions (Fettig et al. 2007, Hicke and Jenkins 2008), higher levels of tree mortality are expected.

Conversely, there could be some reductions in insect-induced tree mortality when warming increases susceptibility to predators, parasitoids, or pathogens. Preliminary evidence suggests that warmer conditions might shorten the incubation period (time between infection and mortality) of the baculovirus that limits Douglas-fir tussock moth populations (see footnote 2). Given projected warming in winter and decreases in precipitation in summer, the impact of western spruce budworm will likely decrease in the future relative to the current distributions of susceptible forest types in this region (Williams and Liebhold 1995). The insect hibernates in winter, and elevated temperatures during this period reduce survival. Warming may also change the timing and synchrony of bud break in Douglas-fir, which in turn may influence outbreak frequency and severity. Projected climate change impacts to MMC forests in the region are likely to be manifest through ENSO and other oscillations such as the PDO. Moreover, the multiscale (broad-scale and fine topographic) nature by which climate change is likely to manifest across the landscape necessitates a multiscale hierarchy such as the one we have outlined in previous sections of this synthesis (CIG 2009, IPCC 2013, Mote et al. 2005):

- El Niño/Southern Oscillation remains the most important coupled ocean-atmosphere phenomenon to cause climate variability on seasonal to interannual time scales in the Pacific Northwest.
- Projected changes in climate will be manifest at both highly localized and broad regional scales for moist mixed-conifer forests.
- Necessitating the need for multiscale, hierarchical approach to address future climate change impacts.

Changes in Vegetation

Changes in the structure and composition of forests since Euro-American settlement are well documented (Hessburg and Agee 2003). For example, forests are now typically several times denser in most locations than under native fire regimes (Camp 1999, Hagmann et al. 2013, Merschel 2012, Perry et al. 2004) (table 5). However, one recent study (Baker 2012) has indicated that these forests were "generally dense" (100 trees per acre [275 trees per hectare]) in the late 1800s and suggested that the amount of change in the structure of these forests and the need for density reduction has been overstated. It is unclear how density estimates from the Baker study apply to MMC forests, which are a subset of the ponderosa, dry mixed-conifer, and lodgepole pine stands that he sampled, as less than 1 percent of the trees were identified as white or grand fir. This suggests that either his records

Table 5—Historical and current tree density (trees per hectare, TPH) estimates in dry and moist mixed-conifer forests

Region	Forest description	Historical density	Current density	Source	Notes
		Mean ± standard deviation (range) and time period			
Eastern slope of the Cascade Range, southern Oregon	Mixed-dry	64 ± 22 (14–156) 1914–1922	286 ± 130 (109–572) 1997–2006	Hagmann et al. 2013	Historical density is reported for trees >15.2 cm diameter at breast height (d.b.h.) based on timber inventory transects that covered 10 to 20 percent (6646 ha) of a 38 641 ha study area of ponderosa pine and dry and moist mixed-conifer forest. Current density is reported for trees >15 cm d.b.h. and is based on 24 current vegetation survey plots within the sample area. Inventory plots were assigned to habitat types using mapped potential vegetation types (ILAP).
	Mixed-moist	78 ± 37 (0–296) 1914–1922	233 ± 90 (104–378) 1997–2006		
Warm Springs Indian Reservation, eastern slope of the Cascade Range, Oregon	Mixed-dry	65 ± 25 (6–188) 1922–1925	NA	Hagmann, unpublished data, 2013[a]	Historical density is reported for trees >15.2 cm d.b.h. based on timber inventory transects that covered 20 percent (32 293 ha) of a 158 354 ha study area of dry and moist mixed-conifer forest. Inventory plots were assigned to habitat types using mapped potential vegetation types (ILAP).
	Mixed-moist	70 ± 32 (0–289) 1922–1925	NA		
Austin-Whitney Tract in the Blue Mountains of northeast Oregon	Mixed-dry	120 1910	NA	Munger 1912 (summarized by David Powell)	Density is reported for trees >10 cm d.b.h. Munger specifically inventoried "well stocked" stands.
Crawford Creek Tract in the Blue Mountains near Unity, Oregon	Mixed-dry	126 1912	NA		
Lookinglass Creek Tract in the Wallowa Mountains of northeast Oregon	Mixed-moist	162 1910	NA		
Eastern slope of the Cascade Range, central Oregon	Mixed-dry	136 1912	NA	Munger 1917	Density is reported for trees >10 cm d.b.h. Munger specifically inventoried "well stocked" stands.
Eastern slope of the Cascade Range, central Oregon	Mixed-conifer	275 Late 1800s	NA	Baker 2012	General land office survey records were used to estimate stand density. Estimates for a 398 346 ha area are based on 11 856 trees marking section and quarter-section corners. Four trees were used to estimate density at section corners, and two were used at quarter corners. This inventory area included lodgepole pine forests, which can have high stand densities.

Table 5—Historical and current tree density (trees per hectare, TPH) estimates in dry and moist mixed-conifer forests (continued)

Region	Forest description	Historical density	Current density	Source	Notes
		Mean ± standard deviation (range) and time period			
Eastern slope of the Cascade Range, central Oregon	Mixed-dry (Douglas-fir)	447 ± 186.8 (227–778) 14 sample sites 2009–2010	NA	Merschel et al. [N.d.]	Density is reported for trees >10 cm d.b.h. Sample sites (1.0 ha) were widely distributed in mature forest mapped in any of the mixed-conifer dry or mixed-conifer dry plant association groups. The number of sample sites used in each estimate is reported following the reported density.
	Mixed-dry (grand fir)	NA	536 ± 185 (113–825) 16 sample sites 2009–2010		
	Mixed-moist	NA	429 ± 200 (52–900) 24 sample sites 2009–2010		
Ochoco Mountains, central Oregon	Mixed-dry (Douglas-fir)	NA	274 ± 132 (95–533) 26 sample sites 2009–2010		
	Mixed-dry (grand fir)	NA	203 ± 102 (76–430) 19 sample sites 2009–2010		
	Mixed-moist	NA	312 ± 211 (67–799) 26 sample sites 2009–2010		
Eastern slope of the Cascade Range, central Oregon	Dry and moist mixed-conifer	40–80 in 8 stands,<30 in 5 stands. Refers to trees >150 years old.	868 (335–1415) ~2004	Perry et al. 2004	Age and size were sampled for live trees at thirteen 0.2-ha sites. Historical density refers to the number of trees per hectare >150 years in age. Current density refers to all trees >5 cm d.b.h.
Eastern slope of the Cascade Range, northern Washington	Mixed-conifer-dry	HDSG[b] —119 WDSH—168 WDTS—315 CDG—311 WMSH—113 1899	HDSG—218 WDSH—326 WDTS—293 CDG—376 WMSH—556 1999	Ohlson and Schellhaas 1999	Historical density was estimated using 52 one-tenth-acre plots. Authors suggest that changes in fire regime and associated changes in structure began in the 1860s and that maximum density was reached in the mid-20th century. Historical reconstructed densities and current densities are reported for all trees >12.7 cm d.b.h., and are stratified by different Douglas-fir potential vegetation types ranked from most xeric to most mesic. WMSH would correspond to moist mixed-conifer potential vegetation types. It had a fire return interval of <19 years. The relatively high historical density in WDTS, a type related to a mixed severity fire that occurred in 1886.

Table 5—Historical and current tree density (trees per hectare, TPH) estimates in dry and moist mixed-conifer forests (continued)

Region	Forest description	Historical density	Current density	Source	Notes
		Mean ± standard deviation (range) and time period			
Eastern slope of the Cascades Range and foothills, Oregon and Washington	Mixed-dry	NA	470 ± 267 (n = 512) 1994–2004	M. Reilly, unpublished data[c]	Density is reported for trees >10 cm d.b.h. Density is based on forest current vegetation survey (CVS) plots distributed on a 2.5 by 2.5 km grid (5 km in wilderness areas) throughout national forests of Oregon and Washington. Sample sites include developmental stages ranging from early seral in recently disturbed areas (logging, wildfire, etc.) to mature old-growth forest. The number of CVS plots used to calculate density is reported in parentheses. CVS plots were assigned to PVTs based on ILAP map.

Note: Dry mixed-conifer forests are included because several studies indicate that historical and current disturbance regimes and stand densities of the two sites overlap to a large degree (see table 2). Diameter thresholds, methods of estimation, and spatial coverage used to develop estimates varies among authors.

did not sample much MMC forest or that there were few individuals of these *Abies* species present in the late 1800s. Hagmann et al. (2013) examined stand inventory records from the 1920s in landscapes that overlap areas sampled by Baker (2012) and found much lower tree densities for the same areas. Munger (1917) reported a density of 55 large trees per acre for ponderosa pine forest, and 61 in dry mixed-conifer forests in the eastern Cascades in the early 20th century. That study characterized dry mixed-conifer stands as open with widely spaced trees, but noted that the forests consisted of open stands of mature trees interrupted by treeless areas and denser patches of young trees.

Although total stand densities have increased several fold, the densities of large trees (>50 cm [~20 in]) have declined in many areas within older mixed-conifer forest areas (excluding clearcut areas) by as much as 50 percent based on a few studies (table 3). The decline has been observed in both Oregon and Washington and is likely a result of selective logging of large pines and Douglas-firs during the 20th century. One study from Washington reported increases in the density of large trees.[3]

Heyerdahl showed that fire occurrence in several pine and mixed-conifer forest patches in central Oregon strongly declined after 1880, and grand fir establishment started to increase in the 1880s and 1890s (Heyerdahl et al. 2001 and unpublished data; Merschel 2012). If we assume that the presettlement density of trees in mixed-conifer patches was 50 to 100 trees per hectare (20 to 40 trees per acre), then current densities for mixed-conifer forests may be two to six times the historical densities of some patches. For example, several recent studies have estimated current mixed conifer densities at about 200 to more than 300 trees per hectare (80 to more than 120 trees per acre) (Camp 1999, Merschel 2012, Perry et al. 2004). Under the recent disturbance regime of fire suppression and logging of old trees, MMC forests often consist of scattered remnants of medium- to large-sized shade-intolerant dominant trees, with medium-sized shade-tolerant co-dominant trees, and often several dense layers of intermediate and overtopped or suppressed shade-tolerant trees (Oliver and Larsen 1996). Thus, land use and fire regime changes have shifted successional pathways from dynamic fine scale mosaics driven by low- to mixed-severity fire to coarser grained, more homogenous patch types driven by high-severity fire.

Seed availability, either the absence of seeds of a species or the presence of nearby seed sources (e.g., a kind of "mass effects" in which a high rate of

[3] Ohlson, P.; Schellhaas, R. 1999. Historical and current stand structure in Douglas-fir and ponderosa pine forests. Unpublished report. Portland, OR: U.S. Department of Agriculture, Forest Service, Okanogan and Wenatchee National Forests.

propagule input maintains species on sites that are not well suited for reproduction or long-term survival) (Shmida and Wilson 1985), can have a strong influence on community development, and is often overlooked as a factor in succession. For example, fire suppression has led to an increase of grand or white fir in many forest environments, which has converted many acres of open ponderosa pine forests to dense mixed-conifer forests (Everett et al. 1994, 1997; Hann et al. 1997; Hessburg et al. 1999a, 2000a). In many cases, the true firs and Douglas-fir may be establishing on sites that are less optimal for their growth only because there are massive amounts of seeds in the local landscape (these species dominate the seed rain) that swamp out some of the environmental and ecological controls over species distributions within a community. The densification of these stands could inhibit regeneration of early-seral species such as ponderosa pine and western larch, which are an important component of the overstory, and require relatively open conditions and frequent disturbance for establishment. In many areas, high-grade logging over the 20th century has reduced the densities of these large young forest dominants (Harrod et al. 1999), and they will not return to these sites without disturbances that open the canopy, reduce the overall seed rain of the shade-tolerant species, and reduce stem densities.

Old-growth forests are one of the most ecologically and socially valuable successional stages in the Pacific Northwest (Spies and Duncan 2009), but they are also quite variable in structure and dynamics, especially between the west and east sides of the Cascade Range. The classic old-growth forests of the coastal portion of the Pacific Northwest—fire-infrequent forests that contain large, emergent, long-lived conifers (e.g., Douglas-fir) and dense multilayered mid- and understories of shade-tolerant trees (e.g., western hemlock)—have analogs on the east side of the Cascades. Fire-infrequent old growth on the east side establishes through different pathways and exists under differing conditions. Much of what developed prior to the onset of the timber utilization era, beginning in the later part of the 1800s, consisted of large old ponderosa pine and Douglas-fir in the upper canopy, with occasional western larch and shade-tolerant white/grand fir in the upper canopy and white/grand fir filling lower canopy layers (Merschel 2012). However, this old-forest type would have been uncommon in the drier, fire-prone landscapes, occupying moist, less fire-prone sites. For example, Agee (2003) estimated that only 10 to 17 percent of MMC forest sites would have supported dense old forests under the native fire regime, although some individual watersheds may have had as much as 20 to 35 percent (Hessburg et al. 1999a, 2000a).

The composition of patches of old-growth trees on the east side also depended very much on topographic position. Solar insolation and soil moisture retention,

The composition of patches of old-growth trees on the east side depends very much on topographic position. Solar insolation and soil moisture retention, key factors in determining growing potential and relative drought stress, are considerably different depending on slope aspect and slope position.

key factors in determining growing potential and relative drought stress, are considerably different depending on slope aspect and slope position. Thus the species composition and structure of patches of old forest are quite different at the bottom of a drainage, where soil moisture and shade enable the growth of mixed species of denser, multilayered patches compared with patches on a south-facing midslope, which tend to be single layers of more sparse groups of predominantly large pines.

Another important difference between older, structurally diverse, interior MMC forest stands is that they do not persist for long periods as westside old growth does. It is important to continually recruit forest stands into this older, structurally diverse condition because forests on the east side do not stay in that condition. The transience of old forest conditions in interior MMC forest is a consequence of the unique assemblage of primary disturbances (e.g., fire, insects, and diseases) found in these drier landscapes. The dense, multilayered old forests that have developed under extended periods of fire exclusion are vulnerable to a host of disturbance factors and are unlikely to persist except where local topography, soils, and microclimate are suitable (e.g., sufficient soil moisture). By contrast, the sparser, single-layered old forests, dominated by large pines, are capable of persisting for as long as 500 years.

Historically, the most common expression of old growth would have been a "fire climax" (Perry et al. 2008) or old single-story, park-like forest (sensu O'Hara 1996), where various combinations of large, old, fire-resistant ponderosa pine, Douglas-fir, and western larch would occur in the canopy over a relatively open but variable and ephemeral understory of pines or shade-tolerant tree species depending on the fire frequency at the site. On sites with longer fire return intervals (>25 years) dominated by mixed-severity fire regimes, the canopies of the fire-dependent old growth would include patches (fractions of an acre to several acres) formed by small mixed-severity disturbances from fire or insects and disease. In many landscapes, streamside environments would have longer fire return intervals (>50 years), and support old growth stands with larger components of fir in the understories and sometimes in the overstories.

Young forest communities may have been altered as well, but we have less information about the amounts and patterns of open plant communities maintained by high-severity fire, which was a variable component within the mixed-severity regime of the mixed-conifer forest. Of special interest, clonal aspen patches, often imbedded within mixed-conifer forests, have been heavily affected by fire exclusion owing to their relatively short life expectancy (stands begin to deteriorate at 55 to 60 years of age and are pathologically old and decadent at 90 to 110 years; Bartos

2000). Wildfires normally revitalized aspen clones, with some patches sprouting 10,000 to 20,000 stems per hectare (24,710 to 49,421 stems per acre) in early life stages after fires. Ungulate browsing, both wild and domestic, and a host of stem cankers, foliar diseases, and insect defoliators naturally thin aspen clones to a few hundred stems per hectare after several decades.

Changes in Disturbance Factors: Insects and Disease

The frequency, severity, and scale of insect outbreaks in MMC forests of eastern Oregon and Washington vary considerably (table 5), even by species. In short, effects on vegetation range from short-term reductions in crown cover (e.g., larch casebearer), to modest increases in background levels of tree mortality (e.g., balsam wooly adelgid [*Adelges piceae*]), to regional-scale outbreaks resulting in extensive amounts of tree mortality under some circumstances (e.g., Douglas-fir tussock moth and western spruce budworm). Of more recent concern is the impact of mountain pine beetle outbreaks in the region (see "Animals of the Moist Mixed-Conifer Ecosystem"). Wickman (1992) noted that historically the impacts of insects on mixed-conifer forests were typically of shorter duration and lower severity than was observed in recent decades. A heterogeneous landscape is thought to be more resilient to insect- and disease-caused disturbances (Fettig et al. 2007, Filip et al. 2010). Although it is difficult to isolate the confounding effects of recent management practices and climatic changes, a more heterogeneous landscape likely ensured that most disturbances in MMC forests were more brief and spatially confined in the past (Hessburg et al. 1994). This has been well documented for dry mixed-conifer forests in the region, and it is likely a similar trend existed for MMC forests as they are interconnected with dry mixed-conifer forests that are now substantially modified by fire exclusion and selective harvesting (Hessburg et al. 1994, Lehmkuhl et al. 1994).

Outbreaks of forest diseases caused by native and introduced pathogens are generally thought to become more frequent and severe as a result of climate change (Sturrock et al. 2011). However, diseases caused by pathogens directly affected by climate (e.g., needle blights) are predicted to have a reduced impact under warmer and drier conditions. For thorough reviews on the expected effects of climatic change on forest pathogens, see Dale et al. (2001) and Sturrock et al. (2011).

Effects of Altered Disturbance Regimes, Land Use, and Climate Change on Animal Populations and Habitats

There have been significant changes to fish and wildlife populations associated with MMC forests during the last 150 years. The effects of human land uses and altered disturbance regimes discussed in previous sections of this report have

had a significant impact on fish and wildlife populations across this entire area. Additionally, climate change has already produced observable changes in animal communities in the Pacific Northwest (Hixon et al. 2010), and those changes are likely to intensify in the future (Dalton et al. 2013).

Regional landscape assessments over the past 20 years have documented the profound effects of historical human use and forest management on mixed-conifer and other wildlife habitats of eastern Oregon and Washington (Everett et al. 1994; Hann et al. 1997; Hessburg et al. 1999a, 2000a; Lehmkuhl et al. 1994; USDA FS 1996). The area and condition of grasslands, shrublands, and old forest multistory and late-seral single-story forests, and the forest backbone of large residual trees, have declined markedly (Hessburg and Agee 2003, Hessburg et al. 2005) (fig. 42). At the same time, the area occupied by invasive species, roads, intermediate-aged forest, and insect, disease, and fire susceptibility (as indicated by changes in forest structure, fuel loading, and crown fire potential) have increased. Habitat trends reported in recent wildlife habitat assessments reflect a widespread reduction in habitat values relative to historical conditions for wildlife associated with early-seral, open forest, and postfire habitats (Gaines et al., in press; Suring et al. 2011; Wales et al. 2011; Wisdom et al. 2000). Old forest habitat conditions show less decline at a regional scale, but patterns are variable across sub-basins.

For example, Wisdom et al. (2000) found that habitat for species associated with low-elevation old forest, which includes single-story ponderosa pine forest and single- and multistory mixed-conifer forest, has declined in most of eastern Oregon and Washington (table 6). The habitat trend for species associated with old forest (i.e., forests with multistory stands and large old trees), which spans the elevation gradient from low to high, varies across the region from markedly declining in the northeastern Cascade Range, to neutral in the southeastern Cascades and Blue Mountains, to increasing in the Klamath province. The habitat trend for generalist forest mosaic species, which use a broad range of forest cover types and structural stages, has been neutral or positive. The habitat trend for young forest species varies from highly or moderately negative in the Klamath and Blue Mountain provinces, respectively, to positive to neutral in the Cascade Range province (Wisdom et al. 2000).

Habitat assessments in support of national forest plan revision activities in eastern Washington and Oregon have produced results similar to those of Wisdom et al. (2000). In their assessment of wildlife habitat and population viability in national forests of eastern Washington (the Okanogan-Wenatchee and Colville National Forests), Gaines et al. (in press) found that the species whose viability had declined most relative to historical conditions were those species sensitive to

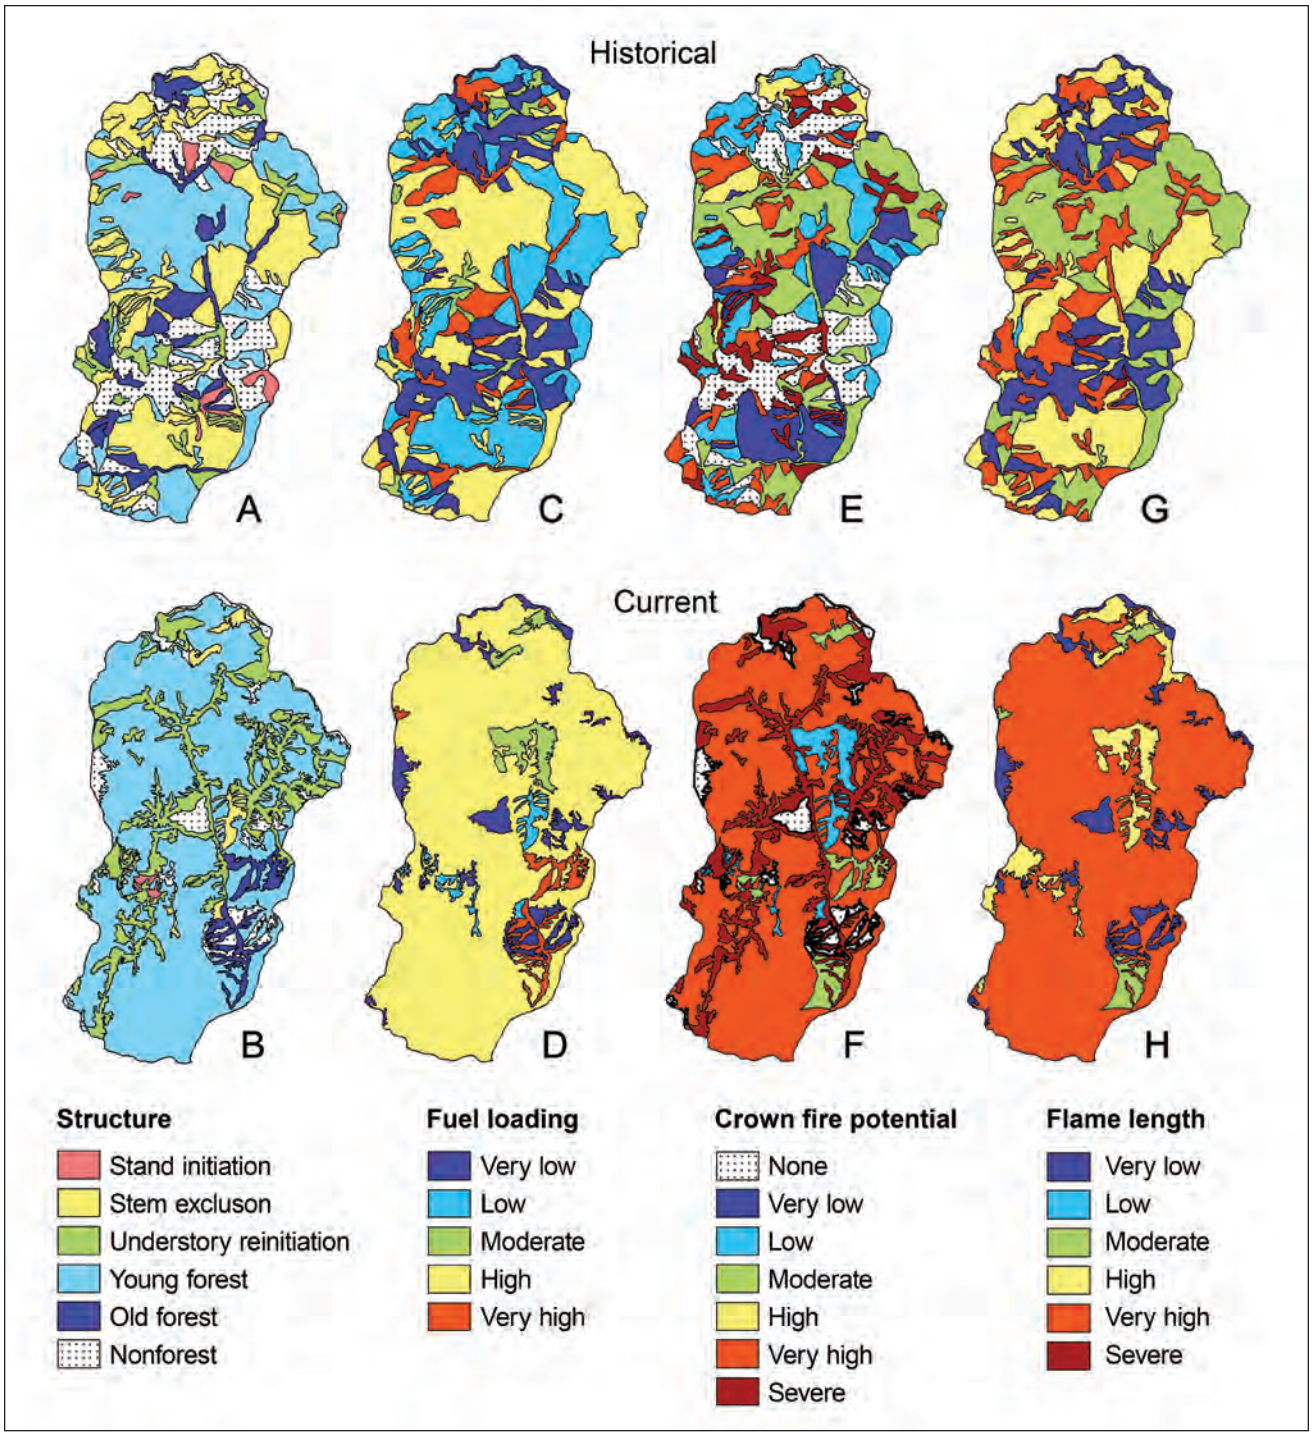

Figure 42—Comparison of an example watershed from the early (ca. 1900, historical) and late (1990s, current) 20th century. Note how spatial patterns of fuel loading, crown fire potential, and flame length closely track forest structural conditions: i.e., process followed pattern. Maps are of the Peavine Creek drainage, a dry forest subwatershed of Lower Grande Ronde subbasin in the Blue Mountains Province displaying historical and current structural classes (A and B), fuel loading (C and D), crown fire potential (E and F), and flame length during wildfire (G and H). Fuel loading classes are very low <22.5 Mg/ha; low = 22.5 to 44.9 Mg/ha; moderate = 45 to 56.1 Mg/ha; high = 56.2 to 67.3 Mg/ha; very high >67.3 Mg/ha. Crown fire potential classes were a relativized index. Flame length classes were very low <0.6 m; low = 0.7 to 1.2 m; moderate = 1.3 to 1.8 m; high = 1.9 to 2.4 m; very high = 2.5 to 3.4 m; severe >3.4 m (Hessburg and Agee 2003, Hessburg et al. 2005).

Table 6—Source forest-habitat trends (1800s to 1995) for families of focal wildlife species in 6th hydrologic unit code (HUC) subwatersheds of the interior Columbia River basin in eastern Oregon and Washington

		Percentage of 6th-code watersheds			
Province	**Family name**	**Decreasing**	**Neutral**	**Increasing**	**Trend**
Blue Mountains	Low-elevation old forest	67	20	13	–
	Broad-elevation old forest	47	17	36	0
	Forest mosaic	7	15	78	+
	Early-seral montane and lower montane forest	53	4	42	–
	Average	43.5	14.0	42.3	0
Northern Cascades	Low-elevation old forest	69	24	7	–
	Broad-elevation old forest	74	13	13	–
	Forest mosaic	17	45	37	0
	Early-seral montane and lower montane forest	30	8	63	+
	Average	47.5	22.5	30.0	0
Southern Cascades	Low-elevation old forest	56	22	22	–
	Broad-elevation old forest	37	15	47	0
	Forest mosaic	0	20	80	+
	Early-seral montane and lower montane forest	45	13	42	0
	Average	34.5	17.5	47.8	0
Upper Klamath	Low-elevation old forest	33	19	48	0
	Broad-elevation old forest	7	5	88	+
	Forest mosaic	5	7	88	+
	Early-seral montane and lower montane forest	98	0	2	–
	Average	35.75	7.75	56.50	0

Note: Trend was determined by >50 percent of subwatersheds decreasing (–) or increasing (+); otherwise, trend was neutral.

human disturbances or grazing, and associated with shrub-steppe, early-seral, or postfire habitats (e.g., fox sparrow, white-headed woodpecker, western bluebird, and sage thrasher [*Oreoscoptes montanus*]). Species associated with older forest conditions (including northern goshawk, pileated woodpecker, and American marten) also experienced declines in viability relative to historical conditions, but those declines were not as substantial as experienced by the shrub-steppe, early seral, or postfire species.

In their assessment of wildlife habitat values in three national forests in northeastern Oregon (the Umatilla, Wallowa Whitman, and Malheur National Forests), Wales et al. (2011) found that focal species representative of old forest conditions (including goshawk and pileated woodpecker) had current habitat values that were generally consistent with historical conditions at a regional scale, while species associated with open, large tree forests and early-seral or postfire habitats (including Cassin's finch [*Carpodacus cassinii*], white-headed woodpecker, western bluebird, fox sparrow, black-backed woodpecker [*Picoides arcticus*], and Lewis's

woodpecker) generally had experienced declines in habitat values relative to historical conditions. Species sensitive to human disturbances (including wolverine and American marten) also experienced declines in habitat values relative to historical conditions. Both Gaines et al. (in press) and Wales et al. (2011) noted that the area of postfire habitat in eastern Washington and Oregon has increased since 1980, but most of it is concentrated in a few watersheds that have experienced large-scale, high-intensity wildfire, producing patterns that did not contribute to population viability for postfire species at a regional scale as effectively as the patterns produced by historical mixed-severity fire regimes.

Two broad factors contributing to reductions in wildlife population viability were highlighted in these assessments: (1) changes in amount and distribution of old forest, deciduous, early-seral, shrub-steppe, and postfire habitats, and (2) impacts of human activities associated with grazing, roads, and recreation. These habitat trends give a general sense of the regional and provincial status of those habitats, but there is much variability in the trends among subwatersheds within provinces. As with stand and landscape management, the variability in conditions is perhaps more important to understand and manage for than the average. Hence, managers need to assess the trends in their local subwatersheds for an accurate assessment of habitat trends and management needs. For example, the trend in broad-elevation old forest habitat was neutral in two of the four provinces; but within those neutral provinces old forest habitat decreased in 47 percent of the subwatersheds in the Blue Mountains and 37 percent of the subwatersheds in the southeastern Cascades (Wisdom et al. 2000).

Human land uses have important effects on animal populations at several scales. At the broadest regional scale, residential, agricultural, and transportation network development has resulted in habitat loss and fragmentation throughout western North America (Theobald et al. 2011). In eastern Oregon and Washington, broad-scale habitat connectivity patterns for species associated with MMC forests are determined by major landform features and associated ecotonal boundaries, in combination with human development patterns (Singleton et al. 2002, WHCWG 2010). Major natural barriers for species associated with MMC forest habitats in the Pacific Northwest include the shrub-steppe landscapes of central Washington and Oregon, and dramatic landforms like the Columbia Gorge, Lake Chelan, the Okanogan Valley (U.S.), and Hells Canyon (Singleton et al. 2002, WHCWG 2010). Major anthropogenic barriers include high-volume highways (e.g., Interstate 90, Interstate 84, portions of U.S. Highway 97, and Canada Highway 3), as well as areas of agricultural, residential, and industrial development. One area of dramatic recent rapid development has been in southern British Columbia, through the Okanogan

Valley and portions of the Highway 3 corridor between Osoyoos and Castelgar (Singleton et al. 2002, WHCWG 2010). These linkage patterns are particularly important for species associated with MMC forests in Washington because populations in Washington are often southern extensions of populations centered in Canada (Singleton et al. 2002, WHCWG 2010).

At a finer scale, forest roads and trails and associated recreational activities can have substantial impacts on wildlife populations associated with MMC habitats (reviewed by Gaines et al. 2003). Common responses of animals to roads and trails include displacement and avoidance, which can contribute to disruption of nesting, breeding, or wintering areas and reduced population density (Benitez-Lopez et al. 2010, Gaines et al. 2003). For example, Naylor et al. (2009) quantified elk behavioral responses to off-road recreational activities including ATVs, mountain biking, hiking, and horseback riding in the Blue Mountains. They found that feeding time decreased and travel time increased in response to these activities. Road access for firewood gatherers can also contribute to loss of large snags and logs in many areas (Hollenbeck et al. 2013). Ecological effects of domestic livestock grazing are reviewed in "Grazing" on page 99.

Altered disturbance regimes and historical land management practices have contributed to substantial changes in the amount and distribution of forest habitats relative to historical conditions, but management activities focused on restoration of historical habitat patterns and stand structure conditions can also have a variety of effects on wildlife populations. These effects can differ substantially across species (reviewed by Kennedy and Fontaine 2009, and Pilliod et al. 2006). At a stand scale, restoration treatments tend to favor those species associated with more open conditions and increased understory vegetation diversity, and have the potential to reduce abundance of species associated with closed canopy, old forest conditions (e.g., Converse et al. 2006, Gaines et al. 2010). However, responses can be quite variable depending on the intensity of the treatment, and although the abundance of individual species can change, restoration treatments generally do not cause substantial changes in species diversity (e.g., Gaines et al. 2010, Lyons et al. 2008, Russell et al. 2009).

Retention of large, old trees, snags, and logs can help maintain the old forest functions of many stands when smaller trees are removed for fuel reduction or forest restoration objectives.

Retention of large, old trees, snags, and logs can help maintain the old forest functions of many stands when smaller trees are removed for fuel reduction or forest restoration objectives. For example, Bull et al. (1995) found that a MMC stand in the Blue Mountains continued to function as old growth for pileated woodpecker and Vaux's swift (*Chaetura vauxi*) when large trees and logs were retained after treatment to remove small trees killed by western spruce budworm. Most research

on the effects of forest restoration or fuel reduction treatments on wildlife have focused on responses soon after treatment (<5 years post-treatment; Kennedy and Fontaine 2009). Longer-term (>10 year post-treatment) effects of forest restoration treatments on animal populations have yet to be well documented. This will be a fertile area for future research as recently treated areas mature and provide opportunities for monitoring the effects of those restoration-oriented treatments.

Old forest habitats are of particular conservation concern because they provide a variety of ecological and social values (reviewed in Spies and Duncan 2009), and old forest characteristics take a long time to regenerate when they are lost as a consequence of high-intensity disturbance or intensive management. In the following section we present information on habitat dynamics and conservation of the NSO. We recognize that much of the area being addressed by this document is outside of the range of the NSO, but we present this information to highlight the lessons from spotted owl conservation that are also important for conservation of other old forest species associated with MMC forests across eastern Washington and Oregon.

The old growth forests of the east Cascades are diverse, dynamic, and shaped by the complex behavior of multiple disturbance factors including fire. The historical structure and function of these forests have been extensively altered by fire exclusion, logging, and other activities (Buchanan et al. 1995, Spies et al. 2006, USFWS 2011). The implications of these changes and the current and future conditions of east Cascades forests for NSO recovery are complex. Habitat conditions for spotted owls in this region are significantly different today than 150 years ago. Although much habitat has been degraded, particularly with the chronic loss of suitable structures for nesting and roosting sites (i.e., selective removal of large trees, removal of snags and damaged live trees) there has also been an increase in dense forest across portions of the landscape (Everett et al. 1997, Hessburg et al. 2005). These changes present multiple challenges for land managers. Where and how much of these dense stands should managers strive to retain? How is retention of dense forest reconciled with meeting restoration goals that necessarily consider the resiliency of a forest in light of impending disturbance factors and climate change?

The recent recovery plan for the NSO (USFWS 2011) stated that the recovery strategy requires action in the face of uncertainty. The plan cites Carey (2007) in advocating "active management for ecological values that will trade short-term negative effects for long-term gains. Collaborative management must be willing to accept short-term impacts and short-term risks to achieve long-term benefits and long-term risk reduction." The recovery plan described the difficulties in defining conservation objectives for habitat of NSO in these drier forests of the east side:

> Changing climate conditions, dynamic ecological processes, and a variety of past and current management practices render broad management generalizations impractical. Recommendations for spotted owl recovery in this area also need to be considered alongside other land management goals—sometimes competing, sometimes complementary—such as fuels management and invasive species control. In some cases, failure to intervene or restore forest conditions may lead to dense stands heavy with fuels and in danger of stand-replacing fires and insect and disease outbreaks (USFWS 2011: III-20).

In general, dynamic, disturbance-prone forests of the eastern Cascades, California Cascades, and Klamath Provinces could be actively managed in a way that reconciles the overlapping goals of spotted owl conservation, responding to climate change, and restoring dry forest ecological structure, composition and processes, including wildfire and other disturbances

As stewards of NSO habitat, land managers are endeavoring to provide the full complement of habitat requirements. Strong evidence exists suggesting that nesting and roosting habitat, the array of structures in trees that provide a platform, cover, or both, have been largely removed from many areas through decades of selective cutting and sanitation treatments (USFWS 2011). Managers are advised to pay special attention to this habitat management issue when assessing and planning projects, and to make special efforts to retain and restore these habitat elements to the landscape. However, less certainty exists regarding the relationship between owls and habitat used for foraging across the broader landscape. Evidence suggests that owls tend to forage in the moderate- to higher canopy-closure forests and by the same token tend to avoid open stands (reviewed by Courtney et al. 2004).

Northern spotted owl numbers may continue to decline as a consequence of competition with barred owls, but retention and recruitment of habitat continues to be important because reductions in habitat availability are likely to increase competition between the species and will limit opportunities for spotted owls to adapt to the presence of barred owls (Dugger et al. 2011, Forsman et al. 2011, Singleton 2013). Risk and uncertainty are inescapable with management of these forests. Employing a landscape view of assessment and management can help us understand these risks and uncertainties more clearly.

Spotted owls are different from other old forest species associated with MMC forest. For example, northern goshawks and pileated woodpeckers have a broader distribution throughout the Interior West and are associated with a broader range of forest conditions including drier, more open mixed-conifer stands than those used by NSOs, but there are some lessons from spotted owl management that are worth

considering for conservation of these other old forest species. In particular, loss of old forest structures to large-scale, high-intensity wildfire is a concern for all old forest species. Landscape conditions that provide for mixed-severity fire patterns and that are resilient to intermittent disturbances will be most likely to provide a shifting mosaic of old forest habitat conditions for all old forest species over time. Managing for patterns that continually bring stands into old forest conditions is also important because we cannot rely on existing old forest stands to remain in that condition over long time periods. This approach of maintaining a shifting mosaic of old forest conditions is likely to be an increasingly important concept for old forest wildlife conservation under future disturbance regimes that are anticipated under many climate change scenarios.

Conservation of unique forest structures (particularly big old trees) is important, but it will be most effective if it is done in the context of sustainable landscape patterns. Big old trees, both vertical and horizontal, living and dead, are important across all stages of stand development (Bull et al. 1997). Where big old trees are absent from a landscape, retaining the largest trees, even of undesirable species, may be appropriate for retaining and developing stand structure. Retaining legacy structures can also provide conditions that facilitate more rapid development of multistory canopy conditions in younger forests.

Another fundamental challenge is that overly aggressive stand sanitization can contribute to a loss of structural diversity. This is a key issue in balancing silvicultural and wildlife habitat objectives at the stand scale. For example, past forest management practices often focused on reducing pathogens like mistletoe and root-rot to enhance fiber production through vigorous tree growth. At moderate levels, these pathogens can enhance spatial and structural complexity within forest stands. Mistletoe can contribute to tree mortality, but it also provides important structures for forest wildlife, particularly in harvested or young stands devoid of snags where mistletoe can create large clumps that function much like cavities to provide nesting and roosting opportunities for a variety of bird and mammal species, including spotted owls and their prey (Parks et al. 1999, Sovern et al. 2011, Watson 2001) (fig. 43). Endemic levels of insects and disease can contribute to stand and spatial heterogeneity important to wildlife, but epidemic levels can be detrimental. We acknowledge that retention of these endemic insect and disease processes involves a delicate balance between tree growth and wildlife habitat objectives, and it entails a certain degree of risk.

Climate change has the potential to strongly influence wildlife populations and habitats (Dalton et al. 2013, Hixon et al. 2013). At the broadest level, changes in the area and location of major habitat types influence wildlife. The habitat types

Peter Singleton

Figure 43—Fine-scale structural diversity associated with dwarf mistletoe clumps and other tree defects provide important habitat components for many wildlife species. This Douglas-fir tree is severely infested with dwarf mistletoe.

that are projected to change in the near future may be of highest concern. Within Oregon and Washington, Rocky Mountain and Cascade subalpine systems are forecast to decline most rapidly (Rehfeldt et al. 2012). Several Forest Service-designated sensitive species are associated with subalpine habitats including wolverine, grizzly bear (*Ursus arctos*), lynx (*Lynx canadensis*), and American marten (Gaines et al. 2000). The wolverine, for example, is thought to be restricted to places with late spring snow pack (Aubry et al. 2010). McKelvey et al. (2011) modeled change in the distribution of such areas in the Western United States under projected future climates. Based on a downscaled ensemble model, they projected that 67 percent of

predicted spring snow cover will persist within the study area through 2030–2059, and 37 percent through 2070–2099. Areas with spring snow are currently relatively limited in eastern Oregon and Washington.

Nearly all of these areas except the Eagle Cap Wilderness are projected to entirely lose spring snow by mid-century, which will likely substantially reduce viability of the wolverine populations in those areas (McKelvey et al. 2011). Substantial reductions in the Rocky Mountain montane conifer habitats that cover much of the Okanogan Highland and Blue Mountains are of concern for lynx and the old-forest specialists mentioned above (Aubry et al. 2000). There are many other wildlife species that are likely to be affected by phenological changes resulting from climate change. We are already observing earlier onset of spring and longer, dry summer periods that will increase drought stress (Hixon et al. 2011). These changes will have significant ramifications for the entire biological community (Rosenzweig at al. 2008, Walther et al. 2002).

Maintaining broad-scale landscape patterns that allow species to move in response to changes in climatic and habitat conditions may be particularly important for conservation of sensitive species (Heller and Zavaleta 2009, Nuñez et al. 2013). Climate change also has the potential to alter connectivity for some species. Initial studies have estimated reductions in habitat connectivity under future climate change for wolverine (McKelvey et al. 2011) and American marten (Wasserman et al. 2012). However, we are not aware of studies that have estimated the combined effects of climate and land use change on connectivity in the Northwestern United States.

The effects of climate change are also manifest within the landscape and stand scales most familiar to forest managers. Many wildlife species require access to two or more habitat types in close proximity, such as use of grasslands and forest by elk. Over the past century, ecotones between habitat types have shifted within landscapes owing to changes in climate, livestock grazing, and fire exclusion. In many portions of eastern Oregon and Washington, conifer forests have encroached into grasslands and shrublands (e.g., Hessburg and Agee 2003; Hessburg et al. 2000b, 2005). In the last decade, the frequency of severe fire in the lower forest ecotone has increased (Perry et al. 2011), sometimes leading to a retraction of the forest ecotone. Under future climate and land use, habitat mosaics across landscapes are likely to be even more dynamic. Within forest stands, structural complexity also varies with climate, land use, and disturbance. Fire exclusion can lead to increased density of stems and higher canopy closure; insect outbreaks can result in losses of live large trees and major increases in snags and coarse woody debris. In sum, interactions among climate, land use, and disturbance are expected to bring wide swings in

habitat composition within landscape, developmental stage distribution, and within-stand structure. These conditions will challenge forest managers to maintain the stand, landscape, and regional habitat components required by many native species.

Altered snowmelt run-off regimes in the mixed-conifer forests will affect downstream fish-bearing reaches. Discharge patterns affect water depth; thus, earlier low flows downstream may reduce habitat availability for fish dependent on deeper, slower flowing habitats (Luce et al. 2013, Tague and Grant 2009). Cutthroat trout and bull trout are the most sensitive species likely to be present in mixed-conifer zones. Bull trout occupy the coldest freshwater habitats of all salmon and trout species and these habitats are predicted to be severely affected by climate change in coming decades (Isaak et al. 2010, Rieman et al. 2007, Wenger et al.

Sensitive Species of Moist Mixed-Conifer Forests

A variety of terrestrial wildlife species is associated with the moist mixed-conifer (MMC) forests and surrounding landscapes in the Pacific Northwest, including one endangered species (gray wolf [*Canis lupus*], recently delisted in part of its range), three federally listed threatened species (NSO, grizzly bear, and lynx), and three federal candidate species (Oregon spotted frog [*Rana pretiosa*], fisher [*Martes pennanti*], and wolverine). In addition, several other wildlife species of concern recognized by state or federal agencies inhabit these forests (table 7). Many of the species that are at risk in the region are associated with particular stand structure conditions, vegetation community types, and landscape configurations. For example, NSOs are found in MMC forests on the east slope of the Cascades from the Canadian border into northern California (USFWS 2011). They are associated with structurally diverse, large tree, moderate- to closed-canopy conditions generally found in older forests that do not have a recent history of fire, much of which has been altered by both logging and more recently large fires in the last 50 to 100 years. A small population of grizzly bears inhabits MMC forest in the Pacific Northwest. Distribution of this population is limited to a few areas along the Canadian border in the North Cascades and Kettle Mountain/Wedge areas of northeast Washington (Gaines et al. 2010, USFWS 1997). Grizzly bear habitat associations in the Cascades and northeast Washington include moist forests, particularly areas of those forests that are interspersed with moist meadows or avalanche chutes where food plants are abundant (Gaines et al. 2000). Oregon spotted frogs were once found near moving water through much of the Cascades in Oregon and Washington (Cushman and Pearl 2007, McAllister and Leonard 1997). More recently, populations have been documented in Washington's southeast Cascades (near Trout Lake and Conboy in Klickitat County) and in Oregon's south-central Cascades. The historical range of fishers encompasses mesic interior forests in the Oregon and Washington Cascades, northeast Washington, and Blue Mountains (Lewis and Stinson 1998). Fishers were extirpated from most of that range as a result of fur trapping. A small population is present in Oregon's southern Cascades but at present they are largely absent from interior forests in Oregon and Washington.

Table 7—Sensitive wildlife species found in interior mesic forests, including species broadly associated with interior moist forest and ecotones; many of these species are associated with specific forest structure or seral stages found within the interior mesic forest zone

Common name	Scientific name	Class	Status[a]	Comments
Western toad	*Anaxyrus boreas*	Amphibian	FCo	
Rocky Mountain tailed frog	*Ascaphus montanus*	Amphibian	FCo	
Oregon slender salamander	*Batrachoseps wrighti*	Amphibian	FCo	Eastern Oregon Cascade Range
Larch mountain salamander	*Plethodon larselli*	Amphibian	FCo	Southeast Washington Cascade Range
Columbia spotted frog	*Rana luteiventris*	Amphibian	SC	
Northern leopard frog	*Rana pipiens*	Amphibian	FCo	
Oregon spotted frog	*Rana pretiosa*	Amphibian	FC	
Northern goshawk	*Accipiter gentilis*	Bird	FCo	
Upland sandpiper	*Bartramia longicauda*	Bird	SE	
Vaux's swift	*Chaetura vauxi*	Bird	SC	
Olive-sided flycatcher	*Contopus cooperi*	Bird	FCo	
Black swift	*Cypseloides niger*	Bird	FCo	Associated with waterfalls and wet cliffs
Pileated woodpecker	*Dryocopus pileatus*	Bird	SC	
Peregrine falcon	*Falco peregrinus*	Bird	FCo	
Harlequin duck	*Histrionicus histrionicus*	Bird	FCo	
Lewis' woodpecker	*Melanerpes lewis*	Bird	SC	
Flammulated owl	*Otus flammeolus*	Bird	SC	Associated more with dry forest
White-headed woodpecker	*Picoides albolarvatus*	Bird	FCo	Associated more with dry forest
Black-backed woodpecker	*Picoides arcticus*	Bird	SC	
Northern spotted owl	*Strix occidentalis*	Bird	FT	
Silver-bordered fritillary	*Boloria selene atrocostalis*	Insect	SC	
Manns mollusk-eating ground beetle	*Scaphinotus mannii*	Insect	SC	
Gray wolf	*Canis lupus*	Mammal	FE[b]	
Townsend's big-eared bat	*Corynorhinus townsendii*	Mammal	FCo	
Spotted bat	*Euderma maculatum*	Mammal	FCo	
Wolverine	*Gulo gulo*	Mammal	FC	
Silver-haired bat	*Lasionycteris noctivagans*	Mammal	FCo	
Lynx	*Lynx canadensis*	Mammal	FT	
Fisher	*Martes pennanti*	Mammal	FC	Northeast Washington, east of Okanogan River
Long-eared myotis bat	*Myotis evotis*	Mammal	FCo	
Long-legged myotis bat	*Myotis volans*	Mammal	FCo	
Woodland caribou	*Rangifer tarandus caribou*	Mammal	FE	Selkirk Mountain population in northeast Washington
Preble's shrew	*Sorex preblei*	Mammal	FCo	
Grizzly bear	*Ursus arctos*	Mammal	FT	
Poplar Oregonian	*Cryptomastix populi*	Mollusk	SC	
Dalle's sideband	*Monadenia fidelis minor*	Mollusk	SC	
Western pond turtle	*Actinemys marmorata*	Reptile	SC	
Sharptail snake	*Contia tenuis*	Reptile	FCo	Local in eastern slope of the Cascade Range

[a] Status codes are FE = federal endangered, FT = federal threatened, FC = federal candidate, FCo = federal species of concern, SE = state endangered, SC = state species of concern.

[b] Recently delisted east of U.S. Highway 97.

2011). Changing precipitation and fire regimes are expected to compound the effects of warming trends by shifting hydrologic patterns and those of sediment transport and solar radiation (Dunham et al. 2007, Isaak et al. 2010).

Bull trout life histories include migratory forms that spawn and rear in cold streams close to headwaters, then migrate downstream to larger rivers where they live as adults prior to spawning ("migratory") or migrate to lakes following rearing ("adfluvial"). Fragmentation of cold water habitats by stream warming can increase physiological stress to bull trout and decrease interconnectivity of adequate spawning and rearing aggregations. In the "resident" life history form, bull trout remain in cold headwater streams for spawning, rearing, and as adults. Thus, they are subject to these physiological stressors at all life stages.

Cutthroat trout are also common to upland streams in mixed-conifer forests of the eastern Cascades. In small streams within mixed-conifer watersheds of the Wenatchee River sub-basin, cutthroat trout density and total biomass are limited by higher flows (fig. 36) (see footnote 1). Thus, changing flow regimes as a result of precipitation and snowmelt-timing shifts can potentially have consequences for the persistence of populations of this species.

Current Socioeconomic Context

When this science synthesis was initiated, the decision was made to focus on the biophysical science associated with managing MMC forests. However, management of these forests takes place within the broader socioeconomic context of eastern Oregon and Washington, which both influences and is influenced by forest management.[4] In addition, some concepts of resilience include interactions between social and ecological subsystems (see "The Concept of Resilience" on page 18). Thus, some important socioeconomic issues relevant to forest management in the region are briefly reviewed here, recognizing that the topics covered are not all-inclusive. We focus on issues most relevant to accomplishing forest restoration on eastside forests by creating a more enabling social and economic environment. Two such topics—collaboration and the social acceptability of forest restoration treatments—are addressed in chapter 6. The key issues of focus in this section are wood products infrastructure and business capacity to support forest restoration, opportunities for biomass utilization, and some of the tribal concerns associated with forest restoration in the region. Also highlighted are the potential impacts of restoration treatments on recreation. Germane management implications are included in each sub-section. It is important to note that the literature addressing

[4] For purposes of this section, eastern Oregon and Washington refer to all of the counties that lie east of the Cascade crest in Oregon and Washington.

the socioeconomic context of forest management in eastern Oregon and Washington is rarely specific to the MMC forest type; is more extensive for eastern Oregon than for eastern Washington; is largely gray literature (as opposed to peer-reviewed literature); and consists mainly of assessment work rather than scholarly research.

The region is dominated by rural counties where natural resources have historically played an important role in contributing to local economies through agriculture, ranching, forestry, and more recently, recreation.

The region is dominated by rural counties where natural resources have historically played an important role in contributing to local economies through agriculture, ranching, forestry, and more recently, recreation. Many of eastern Oregon's counties exhibit high levels of poverty and unemployment however (Davis et al. 2010), and many eastern Washington counties have been characterized as having relatively low socioeconomic resilience (Daniels 2004). Social and economic assessments of interior Columbia River basin communities carried out as part of the Interior Columbia Basin Ecosystem Management Project (Harris et al. 2000, Reyna 1998) found that small population size, geographic isolation, low economic diversity, heavy dependence on one or a few employment sectors, low level of money coming in from the outside, poorly developed infrastructure, and less active leadership all contribute to low community resilience in the region.[5] Conducting forest restoration can potentially increase community resilience by sustaining existing and creating new and future job opportunities, diversifying the local employment base, retaining existing jobs and stimulating new infrastructure development, and spurring innovations and investments to create new business and employment opportunities—all of which contribute to community resilience (Berkes and Ross 2013, Davidson 2010, Magis 2010, Walker and Salt 2006).

The Forest Service 2012 Planning Rule provides direction to contribute to social and economic sustainability through forest management to help support vibrant communities and rural job opportunities. In addition to employment, other economic benefits resulting from fire hazard reduction through forest restoration may include reduced fire suppression costs over the longer term, increased production of wood products, higher state tax revenues, reduced unemployment payments, and lower expenditures on social services (State of Oregon 2012). Forest restoration to improve forest health can also benefit other ecosystem services associated with national forest lands, including clean water, fish and wildlife habitat, and recreation activities (State of Oregon 2012). Frameworks for identifying the ecosystem services from national forests that are important to stakeholders, and for evaluating the social and ecological tradeoffs between services that are associated with different forest management actions, have been developed by Asah et al. (2012), Kline (2004), Kline and Mazotta (2012), and Smith et al. (2011).

[5] Community resilience is defined here as the ability of a community to successfully cope with, adapt to, and shape change and still retain its basic function and structure.

Forest restoration to reduce hazardous fuels also reduces the risk of wildland fire to communities located in the wildland-urban interface.

Wood Processing Infrastructure and Business Capacity for Forest Restoration

Decreased timber harvesting on federal lands in Oregon and Washington (and elsewhere in the West) since the late 1980s, together with changing technology and markets, industry restructuring, and the recession of 2007–2009 have led to dramatic declines in the production of wood products and mill infrastructure throughout these states (Charnley et al. 2008, Keegan et al. 2006, OFRI 2012). In Oregon and Washington, most of the remaining mills are on the west side of the Cascades (Keegan et al. 2006, Nielsen-Pincus et al. 2012). The increase in severe, large-scale fires that has occurred during the 2000s points to the need for hazardous fuels reduction, in which treatments to remove trees of different sizes play an important role (Keegan et al. 2006). Such removals may include trees having commercial value, as well as trees with smaller diameters than what have traditionally been considered merchantable. Important questions are how to retain what remains of the wood processing infrastructure, whether existing mills can process trees of different size classes (Keegan et al. 2006), and how to develop a new and more diversified infrastructure.

In eastern Oregon, the primary wood processing infrastructure that exists today represents about 20 percent of what it was in the 1980s (Swan et al. 2012). Associated milling capacity has also declined (OFRI 2012). In 2012, there were 45 major primary wood processing facilities and operations in eastern Oregon, including 11 open and three closed sawmills, two open plywood plants, and a number of chipping facilities and operations, post and pole mills, species-specific specialty mills, firewood processors, and whole log shaving operations (Swan et al. 2012). Together, these wood processing facilities employed an estimated 1,730 people (at minimum). Although this diversified mill infrastructure provides opportunities for producing a range of products from logs of different sizes and types, existing mills are not operating at full capacity. Sawmills and chip mills currently operate at about 50 percent of capacity, and whole log mills at 40 percent. Increasing the capacity of their operations could potentially increase employment at eastern Oregon's wood processing facilities by 35 percent (Swan et al. 2012). Doing so would require an increased and sustained supply of logs and fiber of the appropriate sizes and species, favorable market conditions, adequate financing, and a reliable, experienced workforce (OFRI 2012, Swan et al. 2012).

With regard to production from MMC forests to help meet supply needs, eastern Oregon mills that produce lumber graded for strength prefer interior Douglas-fir

and white fir, but also use Engelmann spruce, lodgepole pine, and subalpine fir (Swan et al. 2012). Mills that produce lumber graded for appearance prefer ponderosa pine but also use high-quality white fir. Pulp and paper mills that consume wood products from eastern Oregon, located mainly along the Columbia and Snake Rivers, prefer lodgepole pine and white fir, but accept other tree species. Size preferences typically range from 31 to 41 cm (12 to 16 in) diameter for large logs (though some mills take up to 56 cm [22 in] logs), and 10 to 15 cm (4 to 6 in) to 25 to 30 cm (10 to 12 in) for small logs (Swan et al. 2012).

Ownership of eastern Oregon's timberlands is 67 percent Forest Service and 29.2 percent private (OFRI 2012). However, 75 percent of the current supply of wood products for industry in eastern Oregon comes from nonfederal lands, and 25 percent from federal lands (nearly all Forest Service) (Swan et al. 2012). Eastern Oregon sawmills obtain an average of 63 percent of their supply from nonfederal (almost all private) lands (Swan et al. 2012).

Assessments have found that in eastern Oregon, private lands will not be able to support pre-economic recession (2007) harvest levels in a sustainable way, implying that increased wood supplies will need to come largely from federal lands (OFRI 2012). Harvests from federal lands in eastern Oregon are currently estimated at 7 percent of annual growth (OFRI 2012).

The nature of the supply from Forest Service lands has also shifted significantly since the 1980s from predominantly sawlogs greater than 31 cm (12 in) in diameter, to mostly non-saw logs (biomass). Thus, to significantly increase forest restoration treatments in eastside forests, new investment in mill facilities designed to process smaller-diameter material will likely be needed, which in turn will hinge on public support and a reliable supply of raw material over a 10-year time horizon at a minimum (OFRI 2012). The State of Oregon (2012) provided a number of recommendations for how to increase the scale of restoration on Forest Service lands in eastern Oregon.

There is also a need in eastern Oregon to recruit more people into the logging workforce and to increase access to capital to support investments in new equipment (OFRI 2012). One consequence of the loss of forest products industry infrastructure has been a loss of people having the skills and knowledge to work in eastern Oregon's forestry sector (OFRI 2012). The business capacity to engage in forestry support work (e.g., activities in support of timber production, firefighting, and reforestation) has been growing in eastern Oregon over the past decade (Davis et al. 2010). Retaining and increasing the local infrastructure, workforce, equipment, and businesses needed to engage in forest management is critical for carrying out landscape-scale forest restoration to improve the ecological integrity and resilience of forest ecosystems (Kelly and Bliss 2009, State of Oregon 2012).

Another consequence of reduced forestry infrastructure has been that the average distance between mills is often greater than 161 km (100 mi) in eastern Oregon, increasing log haul distances and associated transportation costs (Swan et al. 2012). This leads to reduced competition for logs—driving down stumpage prices—and higher transportation costs to get logs to more distant mills, which together can result in uneconomical timber sales, making it more difficult and costly to engage in forest restoration and hazardous fuels reduction. Nielsen-Pincus et al. (2012) found that national forest ranger districts that are close to sawmills and biomass facilities treated more overall hectares for hazardous fuels reduction, and more hectares in the WUI, than those farther away, and that there was a threshold distance (hauling time) for this effect in Oregon and Washington of 40 minutes. A lack of local wood processing infrastructure constrains the management options available to forest managers and, in turn, affects managers' capacity to address declining forest health and increasing fire risk (Eastin et al. 2009).

In Washington state, there was a steady decline in the number of wood processing facilities between 1991 and the 2000s, with several mills closing along the east side of the Cascades, and the remaining industry shifting from rural to urban areas to be nearer to major transportation corridors (WA DNR 2007). In 2010, there were 14 mills in central and eastern Washington, half of them sawmills (Smith 2012). Three pulp mills, one veneer and plywood mill, and three roundwood chipping mills comprise the remainder of the infrastructure. Few new mills have replaced the mills that closed, though the remaining mills tend to be larger and more efficient (Smith 2012). The distance between mills is greater than 322 km (200 mi) in some parts of eastern Washington however, meaning high transportation costs for what are often low-value, small-diameter logs, and less competitive prices (WA DNR 2007).

The dominant log species consumed by eastern Washington mills in 2010 were Douglas-fir (38 percent), ponderosa pine (25 percent), true firs (18 percent), and lodgepole pine (9 percent) (Smith 2012). Of these logs, 48 percent came from private lands, 21 percent from tribal lands, 17 percent from state lands, and 11 percent from national forest lands. The dominant size classes harvested were 13 to 25 cm (5 to 10 in) (40 percent) and 25 to 51 cm (10 to 20 in) (36 percent) (Smith 2012).

Studies have found that in order to achieve forest restoration goals in eastern Washington, new investments in wood processing infrastructure will be needed (WA DNR 2007). Again, having a stable and adequate supply of wood is critical for stimulating such investments. Increasing harvests from state and private lands to meet supply needs is unlikely to be sustainable however, implying an important role for federal land harvests. Other factors that would help would be government

incentives for investing in wood processing facilities, diversification of processing infrastructure (as has occurred in eastern Oregon), establishing markets for carbon and biodiversity, and reducing local regulatory constraints to mill construction and forest products manufacturing (WA DNR 2007).

Ensuring a reliable supply of wood of all size classes from federal lands in eastern Oregon and Washington is critical for maintaining existing and establishing new wood processing infrastructure (Keegan et al. 2006). To stay in business, mills also need to remain competitive by investing in improvements such as increasing the efficiency of log conversion, producing higher value products and a more diverse product mix, or constructing drying kilns on site (Dramm 1999). Stewardship contracting, where appropriate, is one tool that can help in this regard because it allows the Forest Service to enter into contracts of up to 10 years in duration and to provide a reliable supply of wood. The Collaborative Forest Landscape Restoration Program is another mechanism that should encourage a more reliable supply of small-diameter wood to support industry investments in infrastructure in participating landscapes (which currently include four areas of eastern Oregon and Washington, plus one affiliate in Washington). This program aims not only to encourage national forests to commit to carrying out restoration projects by providing a source of funding for up to 10 years, but to incentivize restoration treatments on other ownerships within the same landscapes by leveraging funding from other sources (Schultz et al. 2012). Doing so may help increase the supply from other ownerships. The program also requires projects to make use of existing or proposed processing infrastructure to support jobs and local economies (Schultz et al. 2012).

Ensuring a reliable supply of wood of all size classes from federal lands in eastern Oregon and Washington is critical for maintaining existing and establishing new wood processing infrastructure.

Developing biomass utilization opportunities is also important for retaining and increasing the number of sawmills. Sawmills produce a large volume of residual material associated with log processing that can be used for many biomass utilization applications, as well as for producing pulp and paper and other wood products (Davis et al. 2010). Unless they can market these residuals, sawmills may not be able to operate economically (Swan et al. 2012). The next section addresses this topic.

Biomass Utilization

The development of woody biomass utilization opportunities has received much attention over the past decade because (1) biomass is a domestic source of renewable energy; (2) biomass utilization can help to partially offset the cost of needed hazardous fuels reduction treatments on public lands and contribute to economic development opportunities in forest communities (Aguilar and Garrett 2009, Morgan et al. 2011, Nechodom et al. 2008); and (3) biomass utilization reduces the need for onsite burning of piled material produced by fuels treatments, and associated

environmental effects (Daugherty and Fried 2007, Springsteen et al. 2011). To date, biomass utilization infrastructure remains underdeveloped in eastern Oregon and Washington. As of 2012, there was only one stand-alone biomass energy cogeneration plant in eastern Oregon, which was temporarily closed because it could not obtain a favorable power sales agreement (Swan et al. 2012). When market conditions are good, biomass from eastern Oregon may be transported to western Oregon or to mills along the Columbia and Snake Rivers for use, but markets are highly variable. There were no stand-alone biomass energy facilities in eastern Washington in 2010 (Smith 2012), posing a challenge for forest restoration there (WA DNR 2007). Davis et al. (2010) provide an overview of status and trends in woody biomass utilization, including challenges and opportunities, across many eastern Oregon counties.

A number of economic issues constrain the development of viable biomass utilization facilities. To attract investors, there must be an adequate and predictable supply of biomass, a concern in places where federal land is the main potential source of supply (Becker et al. 2011, Hjerpe et al. 2009). The supply problem could be addressed by diversifying sources of raw material, through the use of stewardship contracts, or by addressing internal institutional barriers to biomass utilization within the Forest Service (Becker et al. 2011, Hjerpe et al. 2009, Morgan et al. 2011). Supporting remaining wood products industry infrastructure to prevent its further loss can also help provide opportunities for biomass removal and utilization. For a number of reasons, the presence of wood products industry infrastructure has been found to enhance the development or expansion of biomass utilization, which is difficult to develop as a stand-alone enterprise (Becker et al. 2011).

The cost of harvesting and transporting biomass is another key constraint (Aguilar and Garrett 2009, Becker et al. 2009, Pan et al. 2008). Becker et al. (2009) found that the cost of transporting biomass from the harvest site to the market outlet is the single greatest cost associated with biomass utilization, and that decreasing the travel distance between markets and harvest sites is the only strategy that offsets this cost in a meaningful way. Strategies for addressing the cost issue include establishing a network of decentralized processing facilities of an appropriate size and type closer to the source where biomass is removed (Aguilar and Garrett 2009, Nielsen-Pincus et al. 2012); developing utilization options that focus on higher value products; bundling biomass removal with the removal of larger trees that produce higher value products (e.g., lumber) (Barbour et al. 2008); developing transportation subsidies, which Oregon has done (though these can be problematic) (Becker et al. 2011, Nicholls et al. 2008); and implementing financial incentives such as cost sharing and grant programs for facility development and equipment purchases, and

tax incentives for facility development and harvesting and transporting biomass (Sundstrom et al. 2012).

Because biomass produced as a byproduct of forest restoration tends to be of low value, strategies associated with national forest management are likely to focus on establishing smaller processing facilities closer to public lands (Becker et al. 2011). Small and mid-sized facilities that focus on electricity generation, firewood, animal bedding, commercial heating, or combined heat and power systems are likely to be more feasible than large processing facilities because they tend to be less controversial and require a smaller supply of biomass to operate (making it easier to obtain in a reliable manner) (Becker et al. 2011).

Markets are another major constraint on increasing biomass utilization. Key to increasing biomass utilization east of the Cascades is stimulating market demand and opportunities. The abundance of hydropower in the Pacific Northwest limits market opportunities for biomass electricity (Stidham and Simon-Brown 2011). Although low natural gas prices may also threaten the viability of biomass energy projects (OFRI 2012), eastern Oregon has large areas that lack access to natural gas, and woody biomass is more economical for heating than propane or heating oil (Swan et al. 2012).

The main constraints on developing stand-alone, industrial-scale biomass energy plants in eastern Oregon currently are low prices for electricity under power purchase agreements, and uncertain pricing in the California market, making construction of such plants unlikely in the near future (Swan et al. 2012).

Although the supply of biomass for manufacturing value-added products is greater than market demand (Stidham and Simon-Brown 2011), promising opportunities for biomass utilization lie in developing a broader range of products and applications such as pellets, bricks, small-scale institutional thermal applications (such as space and water heating), onsite electricity generation, transportation fuels, and bio-char (Davis et al. 2010, OFRI 2012, Swan et al. 2012). More diversified and integrated biomass utilization projects have been developing in eastern Oregon in recent years (Davis et al. 2010), signaling progress that may enhance forest restoration efforts there.

Tribal Concerns

Tribal concerns associated with the management of MMC forests on federal lands in eastern Oregon and Washington include protecting tribal lands from fire, insects, and disease; creating job opportunities for tribe members in forest restoration; management to address the potential impacts of climate change on forest resources that are important to tribes; and incorporating tribe members and their traditional ecological knowledge into forest restoration decisionmaking and implementation.

The 2004 Tribal Forest Protection Act (TFPA) was passed to protect tribal lands, resources, and rights from fire, insects, disease, and other threats (ITC 2013). The Act allows tribes to propose fire mitigation and environmental restoration activities on Forest Service and Bureau of Land Management lands adjacent to or bordering tribal trust lands and resources. The agencies may enter into contracts or agreements with tribes for this purpose. Despite the potential that TFPA authorities offer for fulfilling federal trust responsibilities, enhancing forest restoration activities, and creating job opportunities for tribe members in fuels reduction and postfire rehabilitation, only a handful of projects have been implemented. Reasons for this lack are described in ITC 2013. Ways that federal forest managers in eastern Oregon and Washington can take greater advantage of the opportunities provided by the Act include strengthening partnerships with tribes through formal agreements, promoting the use of the TPFA authorities internally, and conducting training and outreach to increase understanding and utilization of the TPFA (ITC 2013).

Regarding job opportunities, a survey of 31 of the 42 federally recognized tribes in Oregon, Washington, and Idaho found that tribes had a strong interest in obtaining jobs in fire management, such as work on wildland fire suppression crews and hazardous fuels reduction work (Rasmussen et al. 2007). A number of strategies for promoting tribal economic development through fire management can be found in the Tribal Wildfire Resource Guide (Intertribal Timber Council and Resource Innovations 2006). Obstacles that limit the capacity of tribes to engage in this work include the seasonality of the work, the training required for employees and contractors, the cost of investing in equipment, a lack of financial capital with which to start businesses, and supportive tribal leadership to help form partnerships with public agencies (Rasmussen et al. 2007). Different communication and operating styles and Forest Service bureaucratic processes can also create barriers (Charnley et al. 2007). To the extent that the Forest Service can assist tribes in addressing some of these obstacles, it can help build the capacity of tribal communities to engage in fire management and forest restoration activities.

The environmental impacts of climate change are expected to be disproportionately felt by American Indian and Alaska Native tribes relative to nonnative communities because of their unique rights, economies, and cultures that are linked to the natural environment.

The environmental impacts of climate change are expected to be disproportionately felt by American Indian and Alaska Native tribes relative to nonnative communities because of their unique rights, economies, and cultures that are linked to the natural environment (Lynn et al. 2011). In eastern Oregon and Washington, climate change impacts on forests that may affect tribes include the potential for increased frequency and intensity of wildland fire; increases in invasive species, insects, and disease; and shifts in the quantity, quality, and distribution of culturally important forest resources (plants, animals, fungi, water, and minerals) (Voggesser et al. 2013). As a result, climate impacts on forests may threaten tribal subsistence,

culture, and economies. The traditional ecological knowledge held by tribe members can play an important role in helping federal forest managers identify species having social, cultural, and economic importance to tribes in the MMC zone, and in helping to inform management strategies for these species in the context of climate change. Strong federal-tribal relationships around forest management may also help to mitigate climate change impacts on species important to tribes, and assist tribes in developing adaptation strategies (Voggesser et al. 2013). Resources and research to support federal forest management in a manner that is responsive to the climate change-related concerns of tribes in the Pacific Northwest can be found at http://tribalclimate.uoregon.edu/.

The relationship that exists between federally recognized tribes and the United States means that federal agencies are required to consult with tribes when they engage in policy making or undertake actions that affect tribal interests and resources. Consultation processes also promote collaboration between tribes and federal agencies in protecting and managing tribal resources on and off reservation lands (Whyte 2013). Working toward effective consultation processes will help ensure that restoration activities on national forests east of the Cascades address tribal concerns. Traditional ecological knowledge may also make an important contribution to forest restoration on national forest lands and can be fostered through federal-tribal consultation and partnerships and by directly engaging traditional knowledge holders in planning and implementing restoration activities (Vinyeta and Lynn 2013). A number of models for doing this are reviewed in Charnley et al. (2007), Donoghue et al. (2010), Vinyeta and Lynn (2013), and Voggesser et al. (2013).

Recreation

Moist mixed-conifer forests have high recreation value. The status of and trends in recreation activities on national forests in eastern Oregon and Washington can be found in the National Visitor Use Monitoring survey reports for these forests (http://www.fs.fed.us/recreation/programs/nvum/). Assessment information about recreation activities, trends, and issues in eastern Oregon and Washington can also be found in the Statewide Comprehensive Outdoor Recreation Plan (SCORP) reports for these states (http://www.oregon.gov/oprd/PLANS/pages/scrop08_12.aspx; http://www.rco.wa.gov/documents/rec_trends/SCORP_2008.pdf), and in Hall et al. (2009). National forest recreation in MMC forests is likely to be affected by forest restoration treatments, which could be a source of contention. Exactly how recreation values may be affected by restoration treatments is difficult to predict, however, in the absence of site-specific research.

A number of studies have been carried out in the Intermountain West to evaluate the effects of prescribed fire treatments and crown fires on recreation visitation and associated economic benefits. These studies have found that crown fires generally have a negative effect on recreation visitation and economic values over time, although there may be an initial, short-term positive response by some types of visitors (Englin et al. 2001; Hesseln et al. 2003, 2004; Loomis et al. 2001). Hikers, for example, may be drawn to see wildfire effects and wildflower blooms following a crown fire (Englin et al. 2001, Loomis et al. 2001). Longer term declines in recreation visitation may result from the negative aesthetic effects of the fire, reduced access for certain activities, or damage to recreation facilities and infrastructure (Kline 2004). Areas that have substantially recovered from a crown fire may experience a rebound in visitation, however (Englin et al. 2001). In contrast, a study from Oregon's Mount Jefferson Wilderness found that the B&B Fires of 2003 did not dramatically affect recreation in the first few years following the fire (Brown et al. 2008).

Prescribed fires have been found to have either no effect or a positive effect on recreation visitation and associated economic benefits over time in some places (Hesseln et al. 2004, Loomis et al. 2001). These effects can vary by recreation activity (e.g., hiking versus mountain biking) (Loomis et al. 2001). Elsewhere, prescribed fires have been found to have a negative effect on recreation visitation by hikers and mountain bikers and associated economic values, with visitation decreasing as the percent of a burn visible from the trail increased (Hesseln et al. 2003).

These findings have a number of management implications. Because crown fires can be detrimental to recreation visitation and values, fuels reduction treatments may be one way of mitigating the negative social and economic impacts of crown fires on recreation (Hesseln et al. 2004). In some places, mechanical treatments may be more effective at mitigating these impacts than prescribed fire, and have fewer overall social and economic costs, because prescribed fire may also have a negative impact on recreation visitation and values (Hesseln et al. 2003). If prescribed fire is used, minimizing the area of the prescribed burn visible from popular recreation trails may reduce its negative effects. It is important to note, however, that some wildfires, such as fires that take place in areas dominated by shrubs, may have positive effects on recreation by creating more open forest conditions (Kline 2004). The ways in which wildfire and fuels treatments affect recreation vary by recreation activity, geographic location, type of wildfire and fuels treatment, forest characteristics, and over time (Kline 2004). Thus, the best way forward for identifying how different types of recreation activities may be affected by restoration treatments, and the most appropriate approach to forest restoration in

places where recreation values are high, is likely to be through place-based research and collaborative processes (Hesseln et al. 2003, Kline 2004).

This brief overview of socioeconomic issues associated with forest restoration in eastern Oregon and Washington is not intended to be all-inclusive. Important issues not addressed include community wildfire protection, the effects of restoration treatments on other ecosystem services provided by national forests, the challenge of forest restoration at the landscape scale across ownership boundaries, and institutional barriers to forest restoration within federal agencies. This overview aims to touch on some of the key socioeconomic issues managers may face in trying to restore MMC forests, and provides some guidance about how to address these issues so that managers can evaluate both ecological and socioeconomic considerations when making decisions about forest restoration. Remaining research gaps with regard to the socioeconomic dimensions of managing MMC forests make it difficult to develop a robust framework for evaluating the social and economic tradeoffs entailed in management decisionmaking.

Summary of Key Scientific Findings and Concepts

The previous sections synthesize scientific findings most relevant to forest managers. We encourage the reader to investigate more thoroughly any of the topics discussed using the extensive reference section (about 400 citations) provided.

Our key scientific findings and concepts are as follows:

Landscapes

- **Broad-scale (top-down), meso-scale (within landscape), and fine-scale (bottom-up) spatial controls (aka, drivers or forcing factors) combine to control ecosystem behavior and ecological outcomes.** Examples of top-down drivers are broad-scale patterns of the regional climate, geology, land surface forms, and broad patterns of biota—lifeforms and land cover types. Meso-scale or within landscape spatial controls are natural and human disturbances, topography, patterns of structure, composition, fuelbeds, and patch size distributions. Examples of fine-scale drivers are patterns of local topography, microsite, soils, plant communities and plant life history and life cycle differences, patterns of micro-climate, and the like. Some patterns at each of the three scales are not likely to be stationary in time or space, while others (geology, topography, geomorphic processes) are relatively more stationary. Any given landscape today is on a trajectory to a future condition that will be a result of these combined forces.

- **Regional landscapes can be viewed as a multi-level hierarchy of mosaics** for landscape planning and management purposes; patches exist within local landscapes, which provide the patchiness and variability of the regional landscape. Patchiness also exists within patches (clumped tree distributions and gaps of various sizes) and this forms the variability of the local landscape.
- **Steep, topographically driven precipitation and temperature gradients have a significant influence** on the vegetation east of the Cascade Range divide; the most significant effect is the rain shadow created by the high divide.
- **Forest productivity and disturbance regimes are highly influenced by these gradients.** Position on the landscape combined with local weather conditions (precipitation and temperature), surface lithologies (parent materials and the soils that are derived from them), and land surface forms contribute to a complex mosaic of patches supporting a diverse array of vegetation. **On any given landscape, dry, moist, and wet mixed-conifer forests occur within a large ecological gradient.** As a consequence it is difficult to neatly disentangle these forest types for management purposes.
- **Landscapes exhibit varying degrees of inertia.** The degree of change over the 20th century in forest structure, tree species composition, and disturbance regimes has given landscapes an inertia (which can be thought of also as ecological momentum or resistance to change) that will be difficult to alter through restoration-based management. For example, field observations suggest that after recent wildfires, instead of regenerating to ponderosa pine or western larch, some areas now quickly regenerate to Douglas-fir and white, grand, or subalpine fir, or lodgepole pine, despite intentional efforts (which often fail unless done well) to reestablish ponderosa pine or larch. The presence of abundant seed from shade-tolerant tree species (e.g., firs) provides this inertia. Likewise, high contagion of surface and canopy fuels creates large homogeneous patches that reinforce the occurrence of a higher than normal number of large and very large fires, and higher than normal fire severity.
- **The historical range of variability (HRV) that created pre-Euro-American forest landscapes has been changing and returning to it is no longer feasible or practical** in some places. The pattern and processes of forest ecosystems in a landscape are functions of the range of variability in disturbances, climate, and species movements that has occurred over a long period of time. The range of variability in these processes in the future

will determine how the current patterns and processes of ecosystems and species will develop. Managers can influence the future range of variability to achieve desired future ecosystem conditions for a landscape. The HRV can serve as a guide but not a target.

- **Depending upon the biogeoclimatic setting and physiographic region, historical and future ranges of conditions may be either strongly or weakly overlapping.** Future climate projections suggest that large differences between the past and the future tend to be associated with the extreme ends of ecological gradients, and ecotones may be particularly sensitive areas. For example, at forest and shrubland ecotone margins, and at subalpine-alpine ecotones, digital global vegetation models suggest significant changes, where life forms and plant community composition may suddenly shift after disturbances. Within the MMC forest, which falls within mid-montane and valley bottom environments, there may be only small differences in environments when comparing past and future range of variability, but the degree of difference will vary with topography and ecoregion.

Disturbances

- **Significantly altered disturbance regimes exist as a result of 150 years of Euro-American land use, altering the manner in which systems behave.** In general, mixed-conifer forests are on a trajectory leading to further divergence from a resilient condition.
- **Wildfires, along with insect, pathogen, and weather disturbances, historically did the bulk of the work to continuously restructure and recompose the historical landscape,** providing sustainable patterns of terrestrial and aquatic habitats, and supporting processes. Several forest insects (e.g., bark beetles and defoliators) and pathogens (e.g., dwarf mistletoe and root diseases) are notable disturbances in this region today and they are imparting influences at uncharacteristically high levels.
- **The disturbance ecology and resulting vegetation of the mixed-conifer type is influenced by the dominant disturbance regimes of the local landscape.** Historical fire regimes in dry and MMC forests differed across a broad range of spatial and temporal scales in response to local and regional variation in climate and weather, topography, soils, and fuels. Where dry mixed-conifer forests are a dominant feature within a landscape, the MMC forest often is influenced by more frequent fire. The converse is also true.

- **Small and medium sized fires (<1000 ha in size [2,471 ac]) were most numerous,** comprising 85 to 95 percent of the fires, but representing no more than 5 to 15 percent of the total area burned. **Larger fires (>2000 ha in size [4,942 ac]) were least abundant, but accounted for the majority of area burned.**
- **Low-, mixed-, and high-severity fires all occurred in dry and MMC forest but the relative portion of these fires varied across ecoregions.** Surface fire effects coming from low- and mixed-severity fires tended to dominate in dry forests, and local topography was especially influential during common events. Patches of high-severity fire resulted from rare or extreme weather and climatic events. Low-severity fires within MMC forest may have been more common in drier warmer ecoregions with less topographic relief. High-severity fires within MMC forests appear to be more common in cooler and wetter ecoregions and areas with stronger topographic relief. Low-severity fires occurred commonly in moist forests where they were intermixed with dry forests; high-severity fires in moist forests may have been more common where moist forests were intermixed with wet and subalpine forests.
- **We are in the early stages of anthropogenically induced climate warming in eastern Oregon and Washington, and we anticipate significant vegetation and disturbance impacts to dry and MMC forests during this century.** Over the 21st century, climate change impacts will increase in magnitude and extent, transforming some forests. Impacts to terrestrial ecosystems will include increased fire frequency, severity, and burned area, increased susceptibility to insects and diseases, and increased presence of invasive plant and animal species. Climate change will likely reduce or eliminate some subalpine habitats and snow cover that are essential to the survival of some wildlife species.

Vegetation

- **Fire exclusion, silvicultural practices, agriculture, livestock grazing, intensive road and rail development, and introductions of alien plant species** have significantly influenced the structure, composition, and disturbance regimes of many forests.
- **Dry and MMC forests represent a broad range of potential vegetation types** and include the grand fir, white fir, and Douglas-fir series. MMC forest falls within a gradient between the dry ponderosa pine and dry mixed-conifer forest and woodland types at the lowest end of the moisture gradient and subalpine and wet conifer forests at the upper end of the gradient. MMC forests are

often intermixed with dry mixed-conifer forests on the lower end and wet (e.g., western hemlock, western redcedar [*Thuja plicata* Donn ex D. Don], Pacific silver fir), or subalpine forests at the upper end of the gradient. The neighborhood a forest type lives in can influence the nature and extent of processes that are influential. We do not provide a precise definition of the mixed-conifer plant associations for different ecoregions or national forests. Agency ecologists are best suited to make the final decisions on MMC types occurring on each national forest.

- **A large number of successional pathways and old forest conditions historically existed** in the MMC forests of eastern Oregon and Washington as a result of the environmental complexity and disturbances that shaped them. Some old forests were the result of repeated low-intensity fire that maintained multicohort single-stratum condition of fire-tolerant species, while others developed to complex, multiple-strata structures that occasionally experienced mixed- or high-severity disturbances. Managers have options to shape the trajectories of vegetation patches and landscapes along these different pathways. However, targeting a single developmental stage as a management objective does not fit with variability of the mixed-conifer forest.
- **Fire- and drought-tolerant trees of medium diameter (about 41 to 64 cm [16 to 24.9 in]) and large diameter (more than about 64 cm [25 in]) are the backbone of wildfire- and climate-tolerant landscapes, and are an essential component of wildlife habitat.** The occurrence of older trees and older forests currently is far below the historical range of variability, despite their ecological importance.
- **Areas of ecologically diverse, early-seral grass, shrub, and seedling- or sapling-dominated forest patches are in short supply in some landscapes.** Historically, these areas would have been created and often maintained by mixed- and high-severity fires, complete with fire-killed snags and down logs. The largest fire-killed snags and down logs would have lasted a long time and provided needed plant and animal habitat. Grassland and shrubland patches were historically quite abundant on forested PVT settings, owing to variability in wildfire regimes and frequently reburned areas. It is likely, according to climate change projections, that grassland and shrubland conditions will be more common in forested PVT settings.
- **The assumption that plant association groups** (e.g., moist and dry mixed conifer) **can be used to infer historical disturbance regimes is only moderately true.** Limited studies suggest considerable variability in

Fire- and drought-tolerant trees of medium and large diameter are the backbone of wildfire- and climate-tolerant landscapes, and are an essential component of wildlife habitat.

disturbance regimes within and between moist and dry mixed-conifer types. They both contain components of the mixed-severity regime, which is a highly variable disturbance regime. Managers need a variety of information sources (e.g., known history, landscape context) in addition to plant association types when assessing the historical and future range of variability for a landscape.

- **In many areas of the mixed-conifer type, the density of large fire-tolerant trees has declined from historical levels largely because of past logging and recent high-severity fire.** The density of mid-sized trees may have increased; most of these are shade-tolerant species that reduce resiliency of the MMC forest.

Wildlife and Fish

- **The diversity and juxtaposition of patch types of differing composition and structure that were produced by historical mixed-severity fire regimes provided a variety of habitat resources to resident wildlife.** A key concept for understanding animal distribution and abundance in MMC forests is that animals need to acquire a variety of resources to meet their life-history needs, and most animals use a variety of different habitats and structural features to acquire those resources. The mosaic of conditions provided under historical mixed-severity fire regimes provided a rich variety of habitat features for native wildlife.
- **Different stand development stages provide different habitat structures and resources for wildlife:** Recently disturbed patches tend to support high plant productivity, and often exhibit a particularly high diversity of plant and animal species, including many specialist species.

  Even-age young forest patches generally support less diverse and abundant animal communities than are found in other stand development stages, but can provide important ecological functions, depending on specific habitat conditions and landscape context.

  Older forests with a diversity of tree ages and sizes (including large old trees) provide many unique ecological functions. Big old trees, living and dead, standing and down, provide unique and important habitat structures within old forest stands. The multilayer canopies found in older stands contribute to unique thermal characteristics within stands and provide structural complexity important many species.
- **Natural disturbance processes play a key role in the development of stand structure conditions and landscape patterns that determine habitat values for animals.** Endemic levels of disturbance and pathogens (including

dwarf mistletoe) can contribute to stand and landscape heterogeneity, while large-scale, high-intensity disturbances can reduce stand and landscape heterogeneity. Balancing the risk of long-term loss of stand structure and landscape heterogeneity with the retention of current ecological values often associated with the presence of forest pathogens and local high fuel loads is a fundamental challenge for land managers.

- **Biological legacies (including big old trees, snags, and logs) provide important habitat structures across all stages of stand development.** Within-stand structural diversity is generally much greater in stands with a variety of tree age and size classes, even if those stands are recently disturbed or dominated by younger trees. Big trees and logs are often a legacy of previous stand conditions that have been retained after some disturbance event, like fire or harvest. The variety of extremely valuable habitat structures provided by these large old trees include cavities, large branches, broken tops, brooms, and platforms.
- **Recent wildlife habitat assessments have reported a widespread reduction in habitat values relative to historical conditions for wildlife associated with early-seral, open forest, and postfire habitats.** Old forest habitat conditions show less decline at a regional scale, but patterns are variable across sub-basins. Owing to the variation in habitat trends across the interior Pacific Northwest, managers need to assess the trends in their local subwatersheds for appropriate guidance on wildlife habitat management needs.
- **Management activities focused on restoration of historical habitat patterns and stand structure conditions can have a variety of effects on wildlife populations.** At a stand scale, restoration treatments tend to favor those species associated with more open conditions and increased understory vegetation diversity, and have the potential to reduce abundance of species associated with closed-canopy, old-forest conditions. However, responses can be quite variable depending on the intensity of the treatment, and although the abundance of individual species can change, restoration treatments have generally not been shown to cause substantial changes in species diversity.
- **Loss of old-forest structures to large-scale, high-intensity wildfire is a concern for all old-forest species, including northern spotted owls.** Landscape conditions that are resilient to intermittent disturbances will be most likely to provide a shifting mosaic of old forest habitat conditions for all old forest species over time. Managing for patterns that continually bring stands into old forest conditions is also important because we cannot rely on existing old forest stands to remain in that condition over long time periods. This approach

of maintaining a shifting mosaic of old forest conditions is likely to be an increasingly important concept for old-forest wildlife conservation under future disturbance regimes that are anticipated under many climate change scenarios. Conservation of unique forest structures (particularly big old trees) is important, but it will be most effective if it is done in the context of sustainable landscape patterns.

Management Applications in the Field

- Ecological restoration has become a principle objective that drives current management on national forest system lands in the Western United States. It is defined as "the process of assisting the recovery of an ecosystem that has been degraded, damaged, or destroyed. Ecological restoration focuses on **re-establishing the composition, structure, pattern, and ecological processes necessary to facilitate terrestrial and aquatic ecosystem sustainability, resilience, and health under current and future conditions.**" The scientific thinking on restoration has evolved as we learn more about land use change effects, climate change, paleoecology, and socioecological interactions (Hobbs et al. 2011). In using the term "restoration," our intended meaning is that restoration involves restoring degraded ecosystems to a desired state considering historical and future ranges of conditions. Where the historical conditions strongly resemble the predicted future range of variability, they will be quite relevant. Where they do not, the focus will be on the future ranges. For example, the concept of socioecological resilience focuses on the adaptive capacity of species, ecosystems, and institutions rather than restoring or recovering a condition. In this report, we define restoration as the applied practice of renewing degraded and damaged landscapes, habitats and ecosystems with active human intervention.
- Rates of environmental change vary across eastern Oregon and Washington, and as a consequence some ecosystems have attributes that may still be similar to their HRV. In other ecosystems, however, **attributes and entire ecosystems are clearly out of their HRV**. For purposes of understanding and prioritization, it is important to assess the degree of landscape departure from the HRV. However, there is obvious importance for considering the future range of variability (FRV) and how that will influence vegetation. It is important to consider the dynamics of ecosystems that are possible as a result of climate change, changing land uses, and evolving social values. Projections or scenarios of FRV recognize the important implications of climate change on forests (Fettig et al. 2013).

Chapter 5—Management Considerations

In the midst of complicated social and political forces, forest managers make decisions that require the application of complex scientific concepts to case-specific project conditions. Decisions often must balance risks (e.g., elimination of fuels hazards vs. preservation of old-forest conditions) while acknowledging and allowing for uncertainties. Decisionmakers also must weigh tradeoffs associated with alternative courses of action to obtain multiple-use policy and land management objectives. We acknowledge this difficult task and the concurrent need to have and thoughtfully apply thoroughly the body of available scientific information.

It is not the role of the research community to direct management decisions, but it is appropriate to synthesize research and its core findings, and underscore key management implications of that research in specific management contexts. It is also the role of researchers to work alongside managers and seek to learn from their successes and failures. Here we provide considerations for management and emphasize that their application to local and regional landscapes requires the skill and knowledge of local practitioners to determine how best to apply them to each local situation they encounter, and its particular management history. Legacy effects matter and one size does not fit all.

One of the roles of researchers is to work alongside managers and seek to learn from their successes and failures.

In the following section we synthesize the principle scientific findings that have been gleaned from the body of scientific literature (summarized in chapter 4) as it pertains to management of moist mixed-conifer (MMC) forests. These constitute the "take home" messages that are intended to assist land managers.

Key Concepts to Consider in Management of MMC Forests

- **Resilience at regional scales is fostered by heterogeneity in patterns of local landscapes**, but not just any heterogeneity will do. Heterogeneity that is useful to maintaining resilience is that which is supported by the inherent variability of the local climate, geology, and disturbance regimes of each subregional locale. The variability of the regional landscape mosaic should be represented in unique patterns of local landscapes. Management for resilience at broad scales can promote this variability.

Resilience at regional scales is fostered by heterogeneity in patterns of local landscapes.

- **Overlap in the historical range of variability (HRV) and future range of variability (FRV) may be useful to defining desired local landscape patterns** (fig. 44). If landscapes reflect these overlapping envelopes of an eco-region, they are likely to be more resilient and conserve more future options for management. If all local landscapes look the same, the regional landscape will have been simplified. We make this suggestion because of high uncertainty about the use of the FRV alone.

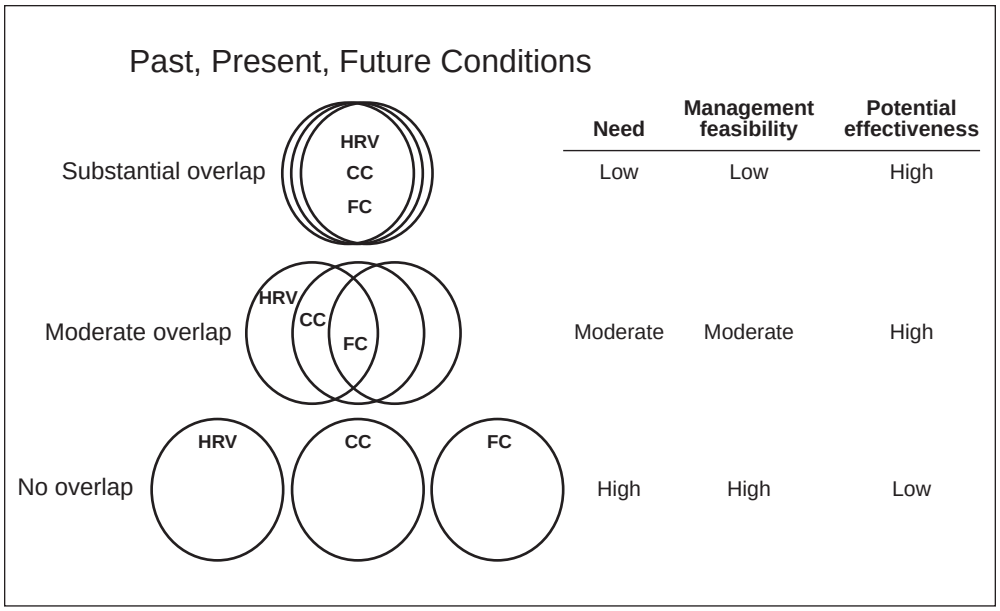

Figure 44—Conceptual illustration of the extent to which current ecosystem conditions (CC) in a place differ from the historical range of variability (HRV) in conditions and from projected future conditions (FC).

- **Managing for resilient landscapes that have patterns consistent with the range of variation under current and expected future disturbance regimes provides a conceptual starting point for capturing the habitat needs of native wildlife.** Native animals evolved in the context of historical disturbance regimes and resultant landscape patterns. Landscape resilience is also important to animal populations because it represents the tendency of a post-disturbance landscape to return to conditions to which the native animal community is adapted. Landscapes that are not resilient may shift into novel environmental conditions that can contribute to substantial changes in the animal community and loss of or change in biodiversity.
- **Some native wildlife species have been affected by threats not related to habitat amount and distribution,** including ecological interactions with invasive species and sensitivity to effects of specific human activities (e.g., livestock grazing or residential, highway, or forest road development). Conservation of these species often requires specific strategies that address habitat in combination with the specific risks to which they are sensitive.
- **Well-connected patterns of habitats across regional landscapes are important to sustaining diversity of native species.** A regional goal is to maintain interconnected networks of habitats that link ecoregions and subregions that would normally provide suitable habitats. Understanding how patterns on the

natural landscape (including vegetation communities and landforms) interact with human-created features (e.g., major highways and residential developments) to influence animal movement and population functions is also important for maintaining landscapes that can sustain populations of wide-ranging species over time.

- **When restoring within-patch heterogeneity, consider varying the tree clump and gap size distribution among patches.** If patches within local landscapes have the same structural characteristics, patch heterogeneity will have been simplified. Consider adapting methods like those developed by Larson and Churchill (2012) and Churchill et al. (2013) to the management of MMC forests. To do that, additional ecoregion-specific datasets will be helpful in fine-tuning innovative silvicultural and forest management strategies.
- **Second-growth 60- to 100-year-old forests offer substantial opportunities for restorative management.** Consider an emphasis on restoring patterns of successional stages that better match the variability of the inherent disturbance regimes. A large acreage of highly productive MMC forest, managed via regeneration and partial harvests during the 20th century, is in this general age class. Resulting forests are intermediate-aged and contribute to simplified landscape patterns.
- **Consider restructuring large areas of the dry and MMC forest on the landscape to return to more resilient forest conditions.** After more than a century of forest and fire management, the current mixed-conifer landscape has developed more than a century's worth of successional inertia (compositional and structural change) and fuel accumulation. Wildfires and insect outbreaks are resetting conditions on the landscape; spatial allocation is driven by ignitions, fire weather, and fuels; changes are occurring suddenly; and the window of treatment opportunity for restoration is growing shorter. Consider identifying patches in key geographic, topographic, and edaphic locations that because of soils, aspect, elevation, and site climate are not likely to sustain these dense, drought- and disturbance-intolerant conditions. Likewise consider reestablishing the inherent landscape heterogeneity, using topography as the underlying template. Where early-seral species would naturally dominate (ponderosa pine [*Pinus ponderosa* Lawson & C. Lawson], western larch [*Larix occidentalis* Nutt.], and western white pine [*Pinus monticola* Douglas ex D. Don]) and natural regeneration is improbable (i.e., grand fir [*Abies grandis* (Douglas ex D. Don) Lindl.], white fir [*Abies concolor* (Gord. & Glend.) Lindl. ex Hildebr.)],

Second-growth 60- to 100-year-old forests offer substantial opportunities for restorative management.

and Douglas-fir [*Pseudotsuga menziesii* (Mirb.) Franco] will likely dominate for a long time), consider regenerating these areas, as is appropriate to the topo-edaphic conditions.

- **To the extent practicable, consider reestablishing the inherent resilience capacities of ecological systems.** This can be done by restoring ecological processes as the foundation of ecosystem resilience. A keystone priority may be to reestablish the central role of the natural or inherent fire regime as the source of reinitiation, development, and maintenance of a heterogeneous landscape mosaic. Where feasible and socially acceptable, create management conditions that enable natural processes to do important work on the ground that is otherwise expensive and less effective to emulate with direct management. Doing this will be economically beneficial, contribute to fire and climate resiliency, and improve diversity of wildlife habitat conditions. Repeated treatments over time will be required to achieve such goals given the century's worth of successional inertia and fuel accumulation that has occurred in many areas.

Expect surprises and consider maintaining a broad range of management options. Expect rare events; they have always influenced the majority of the landscape.

- **Expect surprises and consider maintaining a broad range of management options. Expect rare events; they have always influenced the majority of the landscape.** Twenty-first century climatic changes will result in conditions that differ from the pre-management era, and differ from those we are currently experiencing. Managers and scientists will work to constantly improve the accuracy of future projections, but it may remain prudent to expect the unexpected. There is much uncertainty in the complex interactions between a changing climate, environments, disturbance regimes, and the diversity of organisms and communities in our ecosystems.
- **Consider providing a full complement of vegetation cover types and successional stages within mixed-conifer landscapes.** Patterns and variability of cover types and successional stages consistent with the inherent fire regimes may be desired. Managers can reduce the need for a more highly engineered and costly resilience (that is also more uncertain as to ecological and spatial outcomes) through managing to create or recreate a landscape pattern that would be formed by the patterns and variability of native disturbance regimes.
- **Manage with entire landscapes, all ownerships, and all vegetation types in mind.** Mixed-conifer and other forest types do not exist in isolation and are not confined to ownership boundaries. Disturbance regimes and habitat conditions of neighboring types are interconnected and interrelated, and are best addressed by working together with adjacent landowners.

- **Consider maintaining a backbone of large and old early-seral trees as a primary and persistent structure of all mixed-conifer forests.** If they have been removed by timber harvest, regrow them. This can be a key to restoring climate and wildfire resilience and reestablishing many core wildlife habitat values. Consider favoring ponderosa pine in the dry mixed-conifer forests, and western larch, western white pine, sugar pine (*Pinus lambertiana*), and Douglas-fir in MMC, consistent with local conditions.
- **Consider maintaining a backbone of large standing dead and down trees, and live deformed trees** (those with broken tops and limbs, cavities, and structures for nesting and denning sites) to provide structures for wildlife use. As a result of past timber harvest and "sanitation" treatments, these fine-scale structures are in short supply in most areas. Typically, it takes decades to centuries for a once healthy tree to develop the proper characteristics of such a "wildlife" tree, but techniques are available to create and accelerate their development. Information for both snag and down wood management in green and dead stands can be found in the Decayed Wood Advisor (DecAid) (http://www.fs.fed.us/r6/nr/wildlife/decaid/). Manage these structures as needed (i.e., remove if necessary) in developed recreation areas, such as campgrounds and trailheads, where they could pose a threat to human safety.
- **Old-forest refugia located in suitable locations may be important to retain.** Dense, multilayered mixed-conifer old forest patches are typically not sustainable in many landscapes of eastern Oregon and Washington unless they reside in environmental settings (e.g., valley bottoms and north-facing slopes) that enable them to persist (i.e., suitable topo-edaphic, climatic, and disturbance contexts) by escaping common disturbances. Likewise, focus restoration efforts on developing future old-forest patches in these areas, especially where old forest exists in short supply.
- **Consider reducing the density and layering in the neighborhood surrounding old-forest refugia, and favoring fire-tolerant species to help reduce the risk of loss of multilayered old and otherwise structurally complex forest patches to high-severity fires.** Loss of some existing complex structural patches is an inevitable but reasonable tradeoff for maintaining old forests in fire-prone environments.
- **Restoring the natural variability of wildfire regimes may be a key to restoring the physical processes that create productive aquatic habitats in streams.** Anadromous and cold water fish are fire-adapted species. The natural frequency, severity, and extent of historical fires governed the pulse of erosional

events that carried wood, rocks, and soil to streams. Native fish habitat can be greatly improved through restoration of the natural fire regime.

- **Consider encouraging the natural fire regime within the riparian zones of high-gradient (steep) stream reaches.** With the exception of low-gradient (<5 percent slope) often fish-bearing valley bottom reaches, riparian ecosystems adjacent to high-gradient streams commonly exhibited the fire regime of the adjacent upslope environments. Low-gradient (flatter) reaches are routinely distinguished as flood plain depositional areas whose riparian vegetation is dominated by hardwood tree and shrub vegetation and hydrologic disturbances, whereas the riparian vegetation of higher gradient streams is remarkably similar to the upslope vegetation.

Consider focusing restoration on large, functional landscapes rather than on individual landscape attributes, goals, or risks, such as fuels reduction, timber production, or owl conservation.

- **Consider focusing restoration on large, functional landscapes rather than on individual landscape attributes, goals, or risks,** such as fuels reduction, timber production, or owl conservation. Although we acknowledge the need for short-term measures to protect key habitats, species, and resources that are currently at risk, management emphases with singular resource objectives generally marginalize other important values and eventually fail because they lack this larger focus.
- **Give adaptive management serious consideration.** It simply formalizes learning from successes and failures. The new Forest Service Planning Rule offers yet another opportunity to implement adaptive management. We realize that many prior attempts to conduct adaptive management have failed, but it still represents a rich opportunity for learning, and it is how people learn, through structured trial and experience. Flexible management approaches employing evidence-based, scientifically credible methods promote learning.
- **Consider managing forests in the context of current and potential climate change.** Rates of climate change in the past century and projected for the remainder of this century differ spatially across eastern Oregon and Washington. In some geographic settings, changes in climate in recent decades have altered fire regimes, increased insect infestations, and resulted in high levels of tree mortality. Such changes linked to climate are likely to expand to larger portions of the region in coming decades. Consider identifying rates of change in climate and ecological response over the past century and those projected for future decades and setting management goals and treatments accordingly.

Example of Landscape Management: Okanogan-Wenatchee Landscape Evaluation Decision Support Tool

In eastern Washington, scientists at the Pacific Northwest Research Station Forestry Sciences Laboratory in Wenatchee and on the Okanogan-Wenatchee National Forest have developed and implemented a landscape evaluation and decision support tool (DST) that directly aids managers with implementing a comprehensive landscape restoration strategy. The landscape restoration strategy and the DST have been fully adopted on this national forest and are being implemented on all districts for projects that undertake restoration.

We acknowledge that this particular evaluation and decision support tool represents only one example of how landscape management can be executed. In this instance the forest had access to extensive data sets and skill levels not common on national forests. This example is offered to illustrate what is possible when the necessary resources and expertise are available.

The DST is an outgrowth of a long-standing joint research and management partnership, and a peer-reviewed, forestwide restoration strategy (OWNF 2012). Under the strategy, the objectives of landscape evaluations are to:

- Transparently display how projects move landscapes toward resilience to drought, wildfire, and climate;
- Define and spatially allocate desired ecological outcomes (e.g., adequate habitat networks for listed and focal wildlife species [Gaines et al., in press] and disturbance regimes consistent with major vegetation types);
- Logically and transparently identify potential landscape treatment areas (PLTAs), treatment patches, and the associated rationale; and
- Spatially allocate desired ecological outcomes from landscape prescriptions, and estimate outputs from implemented projects.

Landscape evaluations under the strategy assemble and examine information in five topic areas: (1) current patterns and departures of vegetation structure and composition from historical and climate change reference conditions; (2) spread potential for wildfires, insect outbreaks, and disease pandemics across stands and landscapes given local weather, existing fuel and host conditions; (3) damaging interactions among road, trail, and stream networks; (4) wildlife habitat abundance, distribution, and sustainability; and (5) minimum roads analysis (i.e., which of the existing system roads are essential and affordable, and which are not) (fig. 45).

(continued on next page)

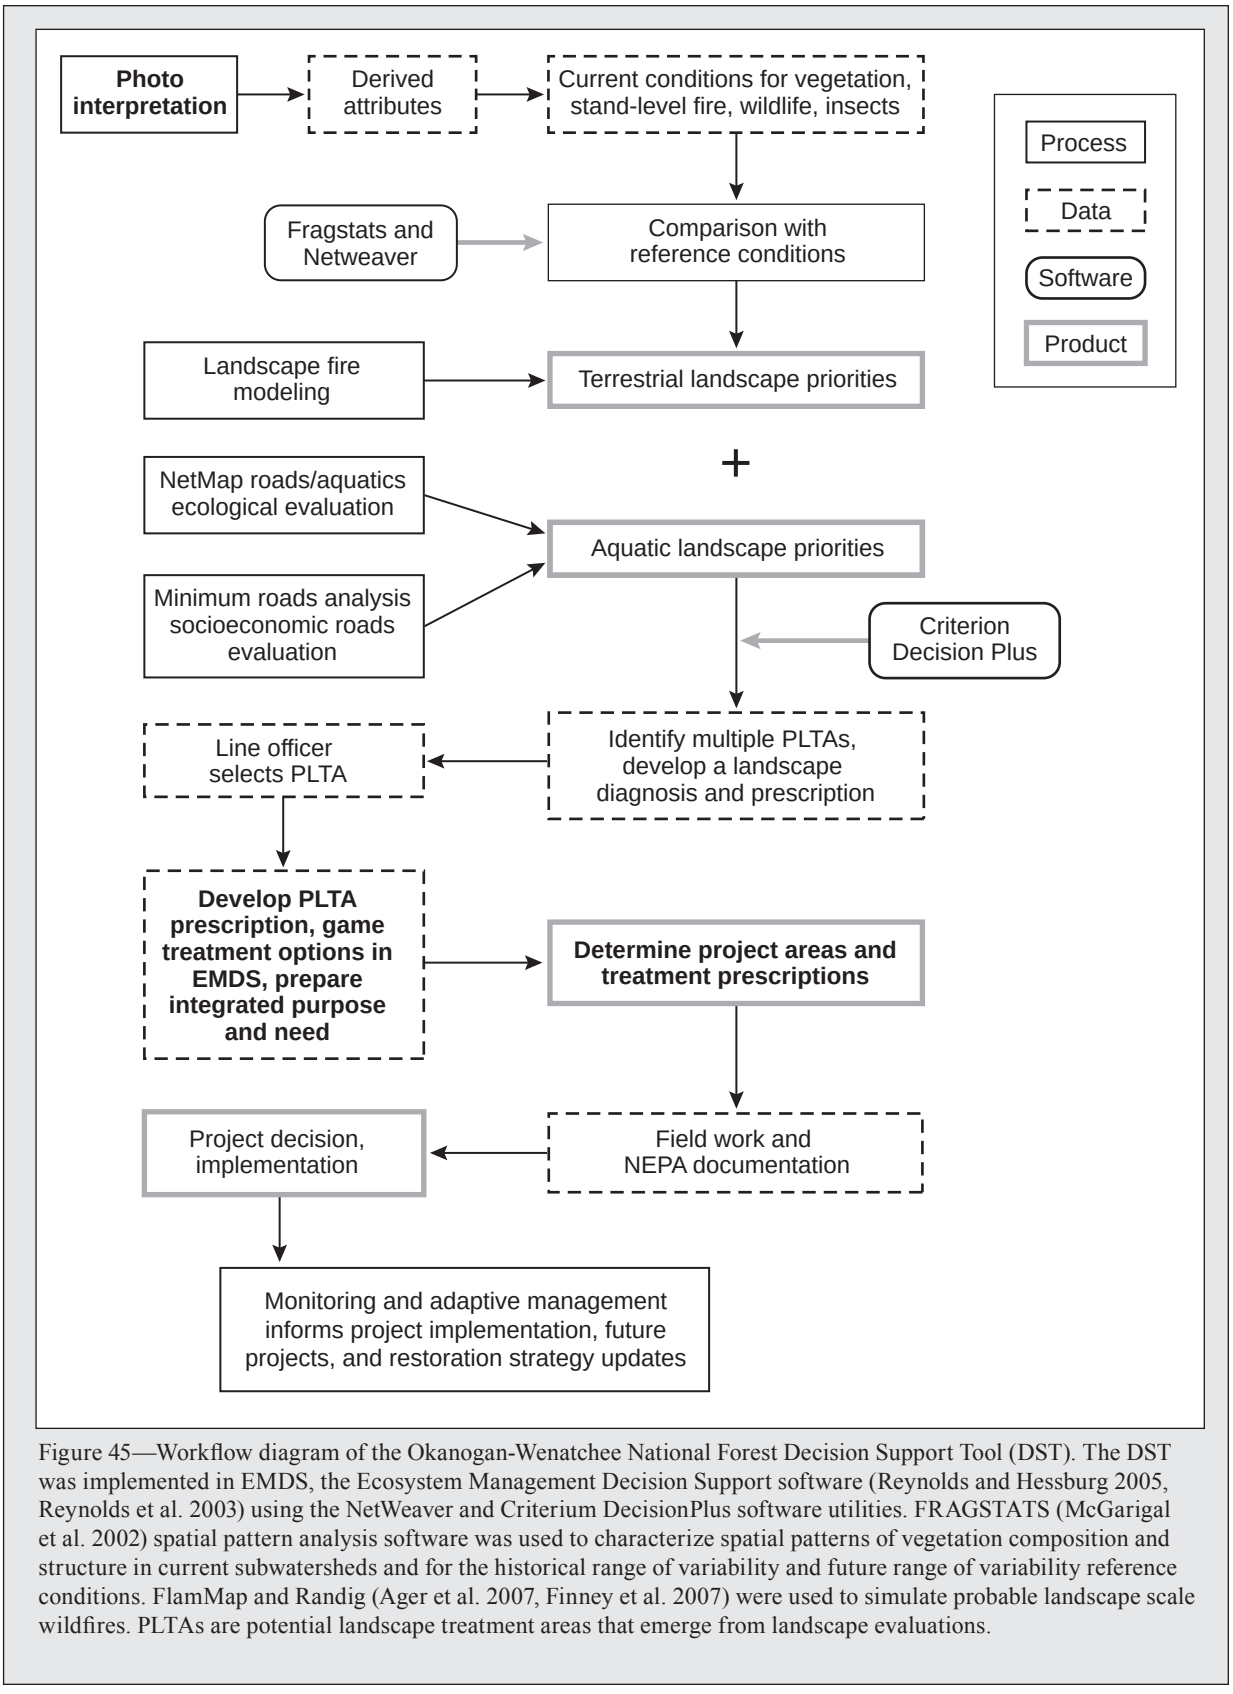

Figure 45—Workflow diagram of the Okanogan-Wenatchee National Forest Decision Support Tool (DST). The DST was implemented in EMDS, the Ecosystem Management Decision Support software (Reynolds and Hessburg 2005, Reynolds et al. 2003) using the NetWeaver and Criterium DecisionPlus software utilities. FRAGSTATS (McGarigal et al. 2002) spatial pattern analysis software was used to characterize spatial patterns of vegetation composition and structure in current subwatersheds and for the historical range of variability and future range of variability reference conditions. FlamMap and Randig (Ager et al. 2007, Finney et al. 2007) were used to simulate probable landscape scale wildfires. PLTAs are potential landscape treatment areas that emerge from landscape evaluations.

The restoration strategy is a living document, which is updated and expanded to include new relevant science and technology. Likewise, with each implemented project, new utilities are added to the decision support tool. Landscape evaluations in the DST examined current vegetation spatial pattern conditions and quantitatively compared them with both historical (past 1900s-era climate, the HRV) and future, mid-21st century climate reference conditions (the FRV), which represent plausible ranges of pattern variability for these periods. Current vegetation conditions were established via interpretation of stereo pairs of aerial photos using standard aerial photogrammetry techniques. The samples for each of the reference conditions were developed using the same vegetation attributes and these same photogrammetry techniques. Evaluated areas were typically small groupings (two or more) of modern-era subwatersheds (12-digit HUCs).

Once current vegetation conditions were interpreted and field verified, the most significant departures of local landscape pattern conditions from reconstructed early 20th century reference conditions (the HRV) were evaluated in the DST. These reconstructed conditions were obtained from the Interior Columbia Basin Ecosystem Management Project (ICBEMP) mid-scale assessment dataset (Hessburg et al. 1999a, 2000a). Since that project, these reconstructed conditions have been summarized for each of the major ecological subregions (Hessburg et al. 2000a) on the two national forests. After the initial departure analysis, departure from a second set of future warmer and drier climate change conditions (FRV) was evaluated. The FRV conditions were represented using historically reconstructed conditions of an ecological subregion whose climatic conditions best match those predicted under warming. This approach used what are often referred to as "climate change analogue conditions" and was intended to show the range of patterns that would emerge with climatic warming and the associated biotic conditions and disturbance regimes. The results of the two departure analyses were used together with equal weighting to determine the most significant changes in forest vegetation structure and composition in the evaluated subwatersheds (Hessburg et al. 2013). Equal weighting was used when considering the HRV and FRV conditions to maximize management options in future landscapes because of the scientific uncertainty surrounding predicted climate change predictions.

Reference conditions were developed for each unique ecological subregion to reflect the range in patch sizes and successional pattern conditions that are

(continued on next page)

(from page 155)

typical for the biota, climate, geology, and disturbance regimes of a physiographic region (Hessburg et al. 2000a), whether they occurred before the advent of management, or they occur at some time in the future. Results of departure analyses were reported by potential vegetation type (PVT) to provide managers with a mechanism for establishing on-the-ground treatments in response to departure analysis. Departure analysis results can inform development of landscape-level restoration prescriptions that are designed to specifically address the most significant departures. Resulting prescriptions can help restore landscape vegetation conditions that are better adapted to wildfires, native insects, pathogens, and predicted climatic warming.

In addition to the vegetation departure analysis, departure analyses were implemented for habitats of regionally listed and focal wildlife species (Gaines et al., in press), and for patch scale fire behavior attributes under a 90th percentile wildfire burn scenario (Hessburg et al. 1999a). Departure analyses were also completed that reflect landscape changes in vulnerability to a variety of major insects and pathogens using models developed for the ICBEMP project (Hessburg et al. 1999a, 1999b, 2000a).

A landscape-scale wildfire analysis was also completed and programmed into the DST, which characterizes the most probable wildfire flow across the large ecoregional landscape when typical wildfire season wind direction, wind intensity, terrain routing of wind and wildfire, and thousands of randomized ignitions are considered. The landscape-scale wildfire analysis provided concrete map depictions of the anticipated flow of large wildfires across the landscape. Managers can use these maps to determine where wildfire flow may be interrupted via strategically placed fuels treatments to reduce the likelihood of large events (Hessburg et al. 2013). Local landscape evaluations can also incorporate these insights into their landscape-level prescriptions.

New in 2013–14, aquatic landscape evaluation utilities are being added to the DST. Under construction are the addition of a minimum roads analysis subroutine, stream crossing and culvert subroutines (currently handled external to the DST), and a module designed in NetMap (Benda et al. 2007) or similar software that identifies road segments that constrain stream channel migration and natural connection with the historical flood plain, separate existing channels from off-channel features, and contribute the most to instream sediment. For additional details about the entire landscape evaluation process, see Gaines et al. (in press) and Hessburg et al. (2013).

Stand Management—Silvicultural Tools and Their Role in Landscape Management

Achieving landscape-level management objectives will require making explicit connections between patch- or stand-level and landscape-level assessments, especially among patch interactions within landscapes. We use the term "stand" to conform to the familiar nomenclature of silviculture. The term "patch" is a similar term used by some to describe a group of trees (O'Hara and Nagel 2013). The planning and operations conducted by land managers will achieve the broader objectives when making this kind of nested spatial relationship explicit in their entire planning process. Stand-level management is therefore the operational level to meet landscape objectives. Creating stand structures that meet these large-scale objectives will be a central concept to management of eastside mixed-conifer forest and riparian ecosystems. Silviculture represents the operational process and offers a matrix of options to achieve these broad-scale objectives.

Stand-level management is the operational level to meet landscape objectives. Creating stand structures that meet these large-scale objectives will be a central concept to management of eastside mixed-conifer forest and riparian ecosystems.

Reducing stand density, altering species composition, and enhancing stand and landscape complexity, where appropriate, will be the central silvicultural objectives in many eastside landscapes based on our findings and conclusions. Stand densities are too high in most locations and ecological resilience is generally lacking owing to past management. For example, logging removed a disproportionate number of large early-seral dominant trees and favored simpler stand structures where dense stands of shade-tolerant trees homogenized both stands and landscapes. Land managers are advised to evaluate the fire risks of both current conditions and what might have developed under active fire when considering how to reconstruct forest structure. Most of the ponderosa pine, and the dry and MMC forested landscapes of eastern Oregon and Washington, had a relatively open stand structure under the influence of active fire (for more information, see "Wildfire" and table 5 in chapter 2). Nonetheless, stands had a particular horizontal and vertical complexity that was characterized by a dominant matrix of relatively open canopies with tall fire-tolerant trees, canopy gaps with patches of tree regeneration or shrubs, and dense patches or scattered individuals of shade-tolerant trees. The relative proportion of these fine-scale stand and landscape elements varied with environment and disturbance regimes.

In dry ponderosa pine and dry mixed-conifer types, stands on southerly aspects were relatively open with a few dense patches of shade-tolerant Douglas-fir and grand fir. Tree regeneration and cohort development coincided with wildfires, but frequent fires killed the majority of the regenerating pines, such that relatively few survived from fire to fire, thereby yielding the appearance of many cohorts through time. In wetter areas, valley bottoms, and north aspects with longer fire

return intervals, the MMC mosaic would have had more dense patches with shade-tolerant understories or larger canopy gaps created by active or passive crown fire associated with mixed- or high-severity fire.

Restoration goals that achieve both landscape and stand objectives can be met by directing landscape units toward the species composition and diversity in age class structure, and complexity in vertical and horizontal stand structure, that are resilient in the face of fire, insects, disease, and climate change. In many cases, promoting the kind of horizontal heterogeneity of stands that occurred prior to Euro-American settlement will greatly increase resiliency to large-scale disturbances such as insect outbreaks (Fettig et al. 2007, Franklin et al. 2013, Hessburg et al. 1994, O'Hara and Ramage 2013). For many landscapes, development of a multiscale mosaic of age and size structures of fire and drought-tolerant species will be the objectives.

Another key objective, particularly in some stands where fire risk is acute, includes reducing fuels and associated potential for large-scale fires. This involves simplifying some stand structures to reduce ladder fuels or to modify understory vegetation and other fuels. Finally, some stand structures can be modified to restore old-forest single-stratum structures (e.g., O'Hara et al. 1996) where scattered overstory trees dominate and other vegetation is relatively scarce. This condition would have been common in many dry pine and dry mixed-conifer forests but also some MMC forests prior to settlement and management. These old-forest structures may be considered simple compared to contemporary stands where historical fire suppression has favored development of multiple strata, but these simple structures also exhibited a fine-scale heterogeneity of size, age, and occurrence, in clumps of varying size, and among gaps with varying size, which made these patches far more resilient to fire, insects, and drought. The result is that over the entire eastside mixed-conifer zone, and even in individual watersheds, some area (patches, stands, or small landscapes) may be directed on trajectories toward complex structures (e.g., a mosaic of open canopies and dense canopies characterized by multi-storied shade-tolerant tree species that are needed for some objectives such as northern spotted owl habitat) while the majority of others may be directed toward more open structures with a subtle but distinctive spatial, compositional, and age heterogeneity. Landscape-level planning will provide the guidance for these decisions.

Silviculture can encompass both passive and active approaches. A variety of treatment options are available to manage stands so that they develop toward desired structures. A central management objective is implementing silvicultural activities (including both mechanical treatments and prescribed burning) that

prepare areas for expected wildfire, to restore stand structures, or alter structures. Treatment options contain a wide range of methods including those that lie between traditional even-aged methods and uneven-aged methods (O'Hara 1998). Desired stand structures may be highly variable across different forest types and the treatments to direct stands toward these structures should also be variable. Implementing forest and riparian management strategies that promote the needed heterogeneity of mixed-conifer forests (dry, moist, and wet) across the landscape will require willingness to innovate on the part of land managers. There may be periods during stand development when the treated forest may not meet, or appear to meet, longer term objectives.

Stand management will often involve social or ecological tradeoffs. Some restored stand structures may not be popular with some stakeholder interests when they result in dramatic reductions in trees or cover. Additionally, many stands may have reached a state where they are prone to wind damage and cannot be manipulated with partial harvest or light thinning treatments, in which case more intensive harvest may be needed to "reset" the ecological trajectory. In other cases, prescribed burning cannot be used without substantial alterations of existing fuels. In these situations, silvicultural treatments can facilitate subsequent prescribed burning treatments. The combination of extensive areas needing treatment, air quality constraints, and work-force requirements presents enormous challenges to land managers, especially at the landscape scale (North 2012, North et al. 2012). Managers are encouraged to view their work as a series of incremental steps intended to move systems in the direction of restoring resilience of mixed-conifer forests to fire and other disturbances. Restoration will require more steps in some places than others.

Managers are encouraged to view their work as a series of incremental steps intended to move systems in the direction of restoring resilience of mixed-conifer forests to fire and other disturbances. Restoration will require more steps in some places than others.

There are opportunities for silviculture to be more cost efficient by recognizing the potential for passive treatments to achieve objectives under certain circumstances. Passive silviculture relies on natural processes including wildfire and regeneration to achieve target stand structures. For example, mixtures of tree species with differential growth rates can result in complex, stratified stand structures even though the stands are even-aged. The rapid growth of western larch and lodgepole pine (*Pinus contorta* Douglas ex Loudon) in comparison to grand fir, evident in many mixed-conifer areas in eastern Oregon and Washington, is one example (e.g., see Cobb et al. 1993).

Another cost-saving strategy involves offsetting expenses of active treatments through commercial activities that help maintain local industries. Active components of silviculture include mechanical removal of low- and mid-story vegetation

to restore a stand dominated by the largest early-seral trees. These restoration treatments will often involve treatments that result in removal of some commercially valuable trees. To meet the ecological objectives, the commercial volume could come from larger diameter, shade-tolerant species. Ideally, the byproduct of landscape restoration is wood fiber from ecologically undesirable components of stands that can help offset treatment costs, which can sometimes be quite high.

Silvicultural treatments of stands will be more effective when directly tied to a landscape analysis and prescription, and tailored to resolve many concurrent issues. Both single- and multi-aged stand structures are naturally part of eastside forest landscapes. Single cohort structures often result from stand-replacement fires, which can be structurally mimicked by several types of silvicultural techniques, if a significant large dead wood component is provided. However, there is no direct substitute for fire and its effects (McIver et al. 2012, Stephens et al. 2012). Fine-scale multi-aged conditions, on the other hand, were much more common in dry ponderosa pine, dry mixed conifer, and MMC forests, especially where surface fire effects dominated, and fires were relatively frequent. Multi-aged stand management at a variety of scales offers a means to create complex structures and emulate the structural complexity found in forests subject to mixed-severity fire regimes. However, traditional uneven-aged management methods are generally inappropriate to achieve these ends. These tools focus on achieving certain diameter frequency distributions rather than meaningful structural characteristics such as numbers of canopy strata, crown coverage, or light penetration for regeneration (O'Hara 1996, 1998; O'Hara and Valappil 1999). These tools also tend to encourage stand structures that are constant from one location to the next and over time.

Instead, managers can focus on retaining meaningful structures that build on existing structural features that vary from site to site and where patchiness of cohorts within stands may vary from fine (groups of trees) to rather coarse (acres to parts of acres) grains. For example, some large and old ponderosa pine and other large young forest dominants would ideally be retained on sites where they are scarce, regardless of the effect on a diameter distribution curve. Simpler two-aged stands offer the opportunity to form structures that fit historical disturbance regimes, retain some cover at all times, and provide structural diversity within stands and across landscapes. The multi-aged approaches in eastside forests may therefore not resemble traditional uneven-aged silviculture (e.g., O'Hara and Gersonde 2004). Instead, guides with a high level of flexibility will be needed to encompass a wide range of stand structural features. Examples of flexible prescriptions and stand structures are available for ponderosa pine (O'Hara et al. 2003) and lodgepole pine (O'Hara and Kollenberg 2003).

In some MMC forests where native disturbance regimes previously created patches of high-severity fire and, in turn, patches of early-seral grass, shrubs, or forest, the wildlife habitat associated with early-seral conditions may be lacking. This may be due to a lack of stand-replacement disturbance or because recent timber harvest has consisted of partial removal treatments that consistently left some of the more dominant trees. In situations where early-seral structure is clearly underrepresented, treatments targeted at creating early-seral grass, shrub, seedling, sapling, and pole-sized tree patches within the forest may be needed, complete with large snags and down logs, as appropriate. Variable retention systems that leave residual trees after harvest (e.g., Beese et al. 2003, Mitchell and Beese 2002) are one way to develop these stand structures.

Existing stands without desired variability in stand structure may be managed to enhance stand-level variation with variable-density thinning (VDT) and other similar methods. VDT is used to enhance variability in homogeneous stands by thinning to a range of densities within a single stand (Carey 2003, O'Hara et al. 2012). This general concept can be applied to any stand to any degree where increased variability is an objective (e.g., see Harrod et al. 1999). However, generalized VDT protocols do not exist because these protocols are usually not transferable from one stand to another, so prescriptions will be needed for individual stands.

Systematically achieving variability in managed forest landscapes is a major change from past practices because traditional silviculture emphasized homogeneity rather than heterogeneity.

Systematically achieving variability in managed forest landscapes is a major change from past practices because traditional silviculture emphasized homogeneity rather than heterogeneity. The challenge will be finding ways to systematically integrate variability into stand management. Recent efforts are making meaningful progress toward development of operational marking rules and procedures for implementing VDT in a variety of vegetation types (O'Hara et al. 2012). Larson and Churchill (2012) cautioned that typical global pattern analysis ignores within-pattern variation that is often the key feature of forest restoration. They recommended maintaining mosaic structures within patches that often exist at quite small spatial scales (<0.4 ha [1 ac]) and developing marking guidelines that focus on creating or maintaining individuals, clumps, and openings (ICO) as key structural elements (Churchill et al. 2013, Larson and Churchill 2012) (fig. 46). This approach has been employed recently and demonstrates the innovation that is emerging in forest management to achieve these varied landscape objectives (Churchill et al. 2013, Franklin et al. 2013, Stine and Conway 2012). More extensive datasets are needed from additional physiographic regions and potential vegetation type settings to better understand the variability in within-patch clumpiness that can inform marking guidelines and silvicultural prescriptions throughout the mixed-conifer forest.

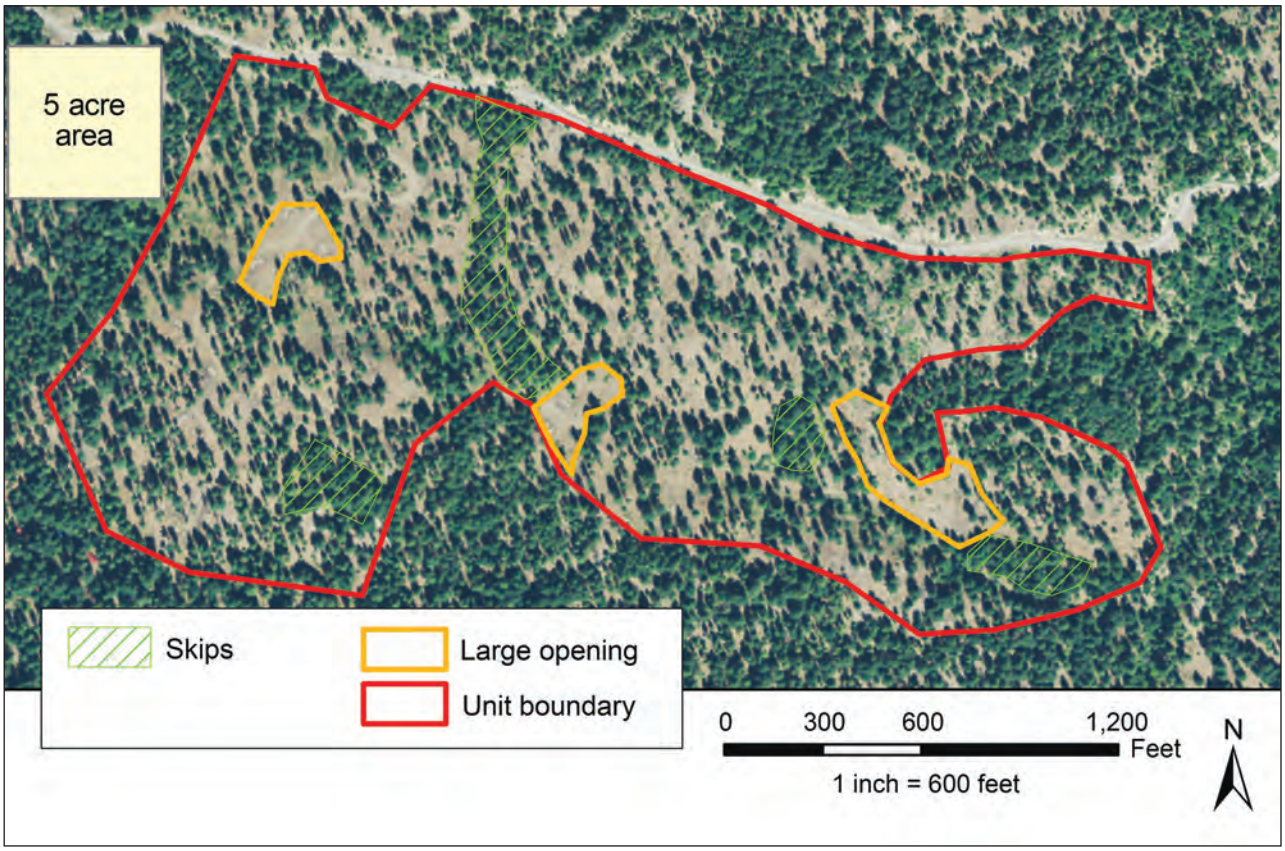

Figure 46—Example of a 32-ha (80-ac) ponderosa pine and Douglas-fir treatment from the Okanogan-Wenatchee National Forest. The treatment was designed to restore a pattern of individual trees, clumps, and openings consistent with prefire exclusion conditions. The prescription included specific guidelines for retentions of clumps of different sizes, as well as openings (Churchill et al. 2013). Large openings were flagged out during layout and were often sinuous in shape. Smaller openings occurred as a result of leaving clumps. Large skips (0.2 to 1.2 ha [0.5 to 3 ac]) were included to protect a riparian buffer in the middle of the unit and other biological hotspots such as large Douglas-fir with dwarf mistletoe, concentrations of downed logs, and multistory patches. Note how the unit boundaries were used to create an additional "finger" skip that extends into the stand. A 2-ha (5-ac) square area is shown to indicate the approximate size of an area that should contain a skip or large clump to break up siting distances. For more details on this approach, see http://www.cfc.umt.edu/forestecology/files/ICO_Manager_Guide_V2.pdf.

In the case of the diverse mixed-conifer forests of eastern Oregon and Washington (dry, moist, wet) the ICO method identifies important components of heterogeneity at fine spatial scales that should be considered in any silviculture prescription. Knowledge about the landscape context, disturbance history, environment, and other management goals will need to inform how the ICO goals are set. For example, in MMC where grand-fir invasion has created large areas of dense canopies, a stand-level silvicultural prescription may be focused first on creating relatively open conditions by removal of most grand fir stems (subject to other management objectives) and second on the spatial patterning of individuals, clumps, and openings in the remaining early-seral species-dominated stand. These considerations may be sequenced or concurrent, depending upon the particular vegetation conditions, and other relevant contexts.

Offsite or nonlocal seed sources were commonly used to replant many plantations in previous decades. These stands frequently exhibit poor survival and growth. Individual trees that are clearly maladapted to a site can be removed, but the presence of these trees should not necessitate special operations to remove them. Often such trees are not producing either pollen or seed and their presence may be of limited ecological importance.

Salvage treatments are an option to produce some timber from stands where trees have been killed by fire, insects, or pathogens. In addition to potentially providing wood resources to local communities, salvage treatments can mitigate future damages from wildfires, especially if salvage removes the smaller trees and associated fine fuels. However, there is typically little ecological justification for salvage of dead trees (Lindenmayer et al. 2008, Spies et al. 2012). Treatments to remove fire- or insect-killed trees are best focused on first achieving residual stand structural goals determined through landscape analysis including retention of snags and downed logs for wildlife habitat considerations (O'Hara and Ramage 2013). Additionally, salvage treatments can be a necessary safety measure in developed recreation areas, near communities, and along roads to reduce hazards.

Upper diameter limit restrictions on tree harvesting have been implemented to improve retention of larger trees on some public lands (e.g., OWNF 2012). Conservation of remaining large and old trees makes sense in many ecological settings where these structures are in short supply, especially where remaining old trees are fire-tolerant, shade-intolerant species. However, strict application of this restriction can prevent managers from having flexibility to achieve ecological objectives. For example, Abella and Covington (2006) found that in Southwestern ponderosa pine forests, upper diameter limits hindered abilities to achieve ecosystem goals and instead served primarily as an economic constraint. Likewise, in some forest patches, large and old trees may be more susceptible to supporting and sustaining bark beetle infestations (Fettig et al. 2007), so some discretion is needed.

Similar constraints exist in eastside forests where these arbitrary limits on harvested tree diameters lead to an unsustainable abundance of large, shade-tolerant trees that actually impede regeneration of shade-intolerant and fire-tolerant trees. This happens on relatively productive sites where shade-tolerant trees, established after the advent of fire exclusion, have grown to relatively large diameters that exceed these arbitrary limits. The presence of such trees may also prevent restoration of openings or a patchy heterogeneity in stand structure. Many of the post-harvest stands contain large (more than about 53 cm [21 in] diameter at breast height) young trees with species compositions and stand structures that

are not representative of the native forests that we might expect to be resilient to drought stress, beetle infestation, changing climate, and other ecosystem stressors. In those situations, active management that may include the harvest of some medium- and large-size trees may produce ecologically enhanced stand structure and species compositions. Management options in these young, productive stands should take into account historical stand structure and species composition, using a landscape-scale context to help ensure that project implementation fits into overall restoration and desired future conditions. That said, large and old trees, particularly of shade-intolerant and fire-tolerant species, are essential elements to include in any eastside landscape. However, strict age or size limits on tree harvest that are not sensitive to site conditions, disturbance history, and topo-edaphic settings can hinder some restoration efforts and may reduce resiliency. Rules of thumb provide helpful guidelines but departures from these may be allowed with well-reasoned explanations.

Chapter 6—Social Agreement and Institutional Capacity for Restoring Moist Mixed-Conifer Forests

The social agreement and institutional capacity for restoring moist mixed-conifer (MMC) forests is every bit as important as the scientific foundation for doing so. The ability to institute the kinds of management changes managers will consider is directly a function of the capacity of the entire affected community to form working partnerships and a common vision. Thus, this section focuses on (1) the social acceptability of different types of restoration treatments among the general public; (2) collaboration as a means for developing, broadening, and sustaining social agreement around specific restoration projects among local stakeholders; and (3) some ideas for how the Forest Service and its partners could approach restoration on national forests that would enhance the agency's institutional capacity to implement the kinds of management strategies discussed in this synthesis document.

The social agreement and institutional capacity for restoring moist mixed-conifer forests is every bit as important as the scientific foundation for doing so.

Social Acceptability of Restoration Treatments Among Members of the Public

Public acceptance is a critical factor influencing whether or not an agency like the Forest Service can carry out its forest management goals (Shindler 2007). It is generally not enough for decisions about forest management to be scientifically sound and economically feasible; they must also be socially acceptable (Shindler 2007). Scientific evidence clearly attests to the need for forest restoration, as this science synthesis demonstrates, and most people living in the wildland-urban interface express a high level of support for reducing fuels on public lands that exhibit high fire risk (McCaffrey et al. 2013). Research from Oregon and Washington also finds that many members of the public recognize the need for restoration treatments on federal lands because of poor forest health and high fire risk (Abrams et al. 2005, Brunson and Shindler 2004, Shindler and Toman 2003). Nevertheless, there is often social disagreement about the methods used to accomplish these treatments, and the locations where they should be carried out. Furthermore, public acceptance of fuels reduction treatments can vary by both geography and social group (Raish et al. 2007, Shindler 2007). For example, a study of nine different stakeholder groups in Oregon found that they were much more supportive of active management of lower elevation ponderosa pine (*Pinus ponderosa* Lawson & C. Lawson) forests than of upper elevation mixed-conifer forests, where the perceived need for treatments was controversial (Stidham and Simon-Brown 2011). This finding suggests that science-based planning—in which the ecological need for fuels reduction is demonstrated by a solid foundation of scientific evidence—is important for improving the social acceptability of restoration treatments in the mixed-conifer zone (Stidham and Simon-Brown 2011).

Social acceptability of forest restoration activities is greatest when the perceived risk of wildfire is high, forest health is believed to be poor, and proposed treatments are perceived as being cost effective and successful at achieving desired outcomes (Bright et al. 2007, Brunson and Shindler 2004, Winter et al. 2002). There is less support for management actions that are perceived as being costly, producing long-duration smoke, posing a risk of escaped or catastrophic fire, or reducing the aesthetic qualities of the landscape (Brunson and Shindler 2004, Winter et al. 2002). Moreover, when citizens believe that forest restoration and fuels treatments are likely to have positive outcomes—economic, ecological, or social—they are more likely to be supportive of them (Shindler 2007).

This science synthesis suggests that both mechanical thinning and the use of prescribed fire will be needed to restore the resilience of MMC forests. In general, there is social support for both types of treatments, though prescribed fire has been found to be less socially acceptable than mechanical thinning in some places (Abrams et al. 2005, Brunson and Shindler 2004). Regarding mechanical treatments, one survey of Oregon and Washington residents (Abrams et al. 2005) found that 88 percent of respondents supported the selective thinning of overstocked forests, and 50 percent supported selective thinning of healthy forests. There was virtually no support for clearcutting. Another study of public acceptance of mechanical fuels reduction treatments from Oregon and Utah (Toman et al. 2011) found a high level of support for mechanical thinning among survey respondents (83 percent), followed by mowing understory vegetation (68 percent).

The social acceptability of prescribed fire use appears to increase when there is confidence in those carrying out the treatments; when it is conducted in remote areas away from development; when it is implemented in a reasonably sized area and resources are present to assure its control; when people are knowledgeable about fire and fuels management and prescribed fire treatments; when people believe it will be effective in producing desired outcomes; when it is cost effective; when mitigation measures are taken to reduce negative air quality and aesthetic impacts; and when stakeholders are involved in planning and preparing the treatments (Bright et al. 2007, Brunson and Shindler 2004, Nelson et al. 2004, Ostergren et al. 2008, Shindler and Toman 2003, Toman et al. 2011, Winter et al. 2002). Ideological perspectives may also inform opinions about the use of fire as a restoration treatment. A study from Montana found that landowners who valued forests as working landscapes that produced economic value disapproved of wildland fire use and prescribed fire because they result in “wasted” timber resources (Cacciapaglia et al. 2012). These landowners also saw fire as a detrimental or unnatural force that

needed to be suppressed. They tended to view mechanical thinning in a positive light, however. In contrast, almost all of the landowners who valued land for its naturalness and ecological values supported wildland fire use (in wilderness) as well as prescribed burning, as appropriate, citing the regenerative properties of fire.

Trust and communication are key components of social acceptability. Researchers have found that the greater the trust in an agency to implement fuels treatments, the more supportive people are of their use (Olsen et al. 2012, Toman et al. 2011, Winter et al. 2002). In addition, the more informed people are about fuels management practices, the more supportive they are (Brunson and Schindler 2004). Activities that build trust between agencies and the public and increase communication and knowledge about fuels treatments are important. Communication and outreach efforts that emphasize the benefits of mechanical thinning and prescribed fire treatments for improving forest health and reducing fire risk to local residents are more likely to increase public acceptance of these treatments (Ascher et al. 2013). Highlighting the amount of control forest managers have over prescribed fire may also help increase support for it. Creating pilot demonstration projects in the places and forest types where restoration activities would be located is another approach to increasing support for them (Stidham and Simon-Brown 2011). Finally, developing fuels reduction and restoration activities through collaborative processes that include stakeholders in planning, decisionmaking, and partnerships (discussed below) is an important approach for overcoming social disagreement and lack of trust (Becker et al. 2011, Hjerpe et al. 2009, Stidham and Simon-Brown 2011, Sundstrom et al. 2012).

Shindler (2007) identified five strategies that forest managers can pursue in order to increase public acceptance of forest management activities: (1) view public acceptance as a process that evolves through building understanding, exchanging and discussing ideas, and evaluating alternatives; (2) develop agency capacity to respond to public concerns; (3) recognize trust building as the goal of public communication and outreach; (4) be sensitive to the local social and community context in which fire management activities are to be carried out, and how these activities may affect communities and forest users; and (5) encourage stable leadership so that shared understanding of forest conditions and fire management practices can develop, and so that strong agency leadership is evident in agency interactions with the public. It is important to remember, however, that social acceptability is dynamic in nature, and can change as people learn more, or when external variables shift (Shindler 2007). Thus, it is important for managers to pay continual attention to public values associated with forest restoration.

Collaboration

Decisionmaking processes play an important role in influencing public acceptance of fire and fuels management activities (Shindler 2007). One of the major constraints to increasing the rate and scale of forest restoration on national forest lands in eastern Oregon is the capacity to reach social agreement about how to achieve it (Economic Assessment Team 2012). The same is likely true in eastern Washington. The Forest Service has emphasized collaboration as a means for developing the social agreement needed among diverse stakeholder groups to carry out forest restoration projects, as demonstrated by recent investments in the Collaborative Forest Landscape Restoration Program and language in the 2012 Forest Service planning rule. Collaboration can be defined as "an approach to solving complex environmental problems in which a diverse group of autonomous stakeholders deliberates to build consensus and develop networks for translating consensus into results" (Margerum 2011: 6). Consensus can range from a simple majority to unanimous agreement regarding a decision, but usually means reaching a decision that everyone can live with. Collaboration in identifying approaches to forest restoration in MMC forests is particularly important because these forests have relatively high economic value in addition to high recreation value, and the methods needed to restore them may be complex and controversial.

There are many models for collaboration associated with forest and fire management on national forest lands (reviewed in Charnley et al. 2013); the best model will depend on local context and the nature of the issues. A number of community-based collaborative groups have formed around eastside national forests to address the ecological and economic issues associated with forest restoration, and to help implement solutions. In eastern Oregon, these include Blue Mountains Forest Partners, Umatilla Forest Collaborative Group, Wallowa-Whitman Forest Collaborative, Harney County Restoration Collaborative, and Ochoco Forest Restoration Collaborative. In eastern Washington, they include the Tapash Sustainable Forest Collaborative and the Northeast Washington Forestry Coalition.

Research has addressed what is needed for successful community-based collaborative processes. For example, McDermott et al. (2011) identified three sets of features that contribute to successful collaboration. The first factor is external sources of support. This includes the support and involvement of elected officials, agency leaders, and key decisionmakers; enabling laws and policies; and active community involvement. The second factor involves having access to sufficient resources to enable meaningful engagement of the many entities, such as funding, staffing, and information. The third factor involves the capacity to perform, which depends on effective leadership, trust, and social capital.

Bartlett (2012) laid out a logical and promising pathway for collaboration based on the collaborative process used to reach stakeholder agreement about hazardous fuels reduction projects at Dinkey Creek, on the Sierra National Forest in California. Successful collaboration there was based on a process that included five main stages: assessment, organization, education, negotiation, and implementation (see Bartlett 2012 for a description of these stages). Her experiences from California provide some key insights about what promotes effective collaboration:

- Include a broad range of participants;
- Establish a common conceptual framework, purpose and need, and long-term desired condition;
- Include scientific experts who serve as technical resources during meetings;
- Move some intractable issues forward without complete consensus if necessary;
- Include site visits to support decisionmaking and reach agreements; and
- Have an impartial mediator to promote trust and problem solving.

Other suggestions that seem to have a positive effect on collaboration include timely engagement, building trust, and developing patience with the process.

The organizational capacity of collaborative groups is critical for sustaining effective collaborative processes. Cheng and Sturtevant (2012) provide a framework for assessing the collaborative capacity of community-based collaboratives to engage in federal forest management. They identify six arenas of collaborative action: organizing, learning, deciding, acting, evaluating, and legitimizing. Within each of these arenas there are different kinds of capacities associated with individuals, the collaborative group itself, and other organizations that the group engages with. Their framework can be used to evaluate what capacities exist within local collaboratives, and what capacities could be enhanced, so that investments in building and sustaining these groups can be targeted.

Davis et al. (2012) examined the organizational capacity of community-based collaborative groups in Oregon that are engaged in natural resource management issues on public as well as private lands. They found that many of these groups have limited financial capacity and insecure funding. They also have small numbers of staff who are expected to carry out a broad range of activities, and are heavily dependent on volunteers. Most accomplish their work through partnerships, often with federal agencies. They make a valuable contribution to local-level natural resource management and community economic well-being. Finding ways to successfully engage, support, and help build the capacity of local community-based collaboratives east of the Cascades in Oregon and Washington is an important

strategy for building social agreement around the management of MMC forests, and for implementing forest restoration activities there.

Management of public lands today is as much a social experiment as it is an ecological experiment, especially when viewed through the lens of social-ecological resilience.

Management of public lands today is as much a social experiment as it is an ecological experiment, especially when viewed through the lens of social-ecological resilience. The public wants to be involved. The best efforts to engage them in this work are not only well advised but critical to the success of restoration programs. It will be prudent to engage expertise in the areas of public involvement, social science, and economics in the cadre of players who help guide these national forest planning and management efforts.

Institutional Capacity

Land managers operate within established policy, constraints, and limitations as well as in accordance with established practices and conventions. However, some of the potential changes in forest management evoked within this document represent a departure from "business as usual." Land managers will decide how to proceed, and this will depend in large part on budget, policy, local circumstances, and, ultimately, the judgment of line officers. However, there are some ideas and observations from past work, both research and management, that suggest some prudent adjustments in management approach.

Create Landscape Management Demonstration Areas

We suggest that the identified approach to project and forest planning described above dovetails quite seamlessly with the intentions and expectations of the 2012 Forest Service planning rule (36 CFR Part 219) and has value for all forms of ownership. In that vein, perhaps the findings and conclusions contained herein can be implemented both formally within the planning rule context as well as informally for current project planning on public and private lands. On public lands, Forest Service staff (or other public land managers) can identify the appropriate landscapes, sometimes including mixed ownerships, and treat them as "landscape laboratories" or landscape demonstration areas. Although the geographic scope of these "learning" landscapes is yet to be fully defined, we are generally referring to large drainage basins on the order of tens to hundreds of thousands of hectares (1 ha = about 2.5 ac).

These large landscapes can provide the context in which we evaluate past, current, and potential future conditions and then develop project plans and desired future conditions for stands, watersheds, and the entire landscape (i.e., a nested hierarchical spatial organization of a landscape) accordingly. In this way, the project and forest planners can include the crucial perspective of broader spatial and

temporal scales as they consider what to do on any given project area. It is prudent to put local project evaluations within this context of a nested landscape that can effectively consider the broader scales where the full implications of ecosystem drivers (e.g., fire, insects, and disease) and the periodicity of their occurrences can be accurately assessed.

National Forest System (NSF) staff, in collaboration with Research and Development (R&D) staff, and a variety of potential partners and collaborators will likely work together to develop this approach. Information from a wide variety of sources (e.g., experimental forests and ranges situated in the landscapes, other research results, NFS legacy data) can be used to develop better management options for public land managers and private landowners. This will also enable implementation of ecosystem restoration activities across the landscape, as well as the Department of Agriculture's guidance to consider "all lands" in our planning and management activities. Within these "landscape laboratories," Forest Service R&D, universities, and other partners with relevant information will be able to contribute long-term data records. This approach is a significant administrative and scientific challenge but it represents an important learning opportunity. The Forest Service has already made some strides in developing this concept through the relatively new Collaborative Forest Landscape Restoration Program (CFLRP). The purpose of the CFLRP is to encourage the collaborative, science-based ecosystem restoration of priority forest landscapes. Twenty projects have been established across the United States since 2010 to implement this concept. Perhaps this effort can expand to encompass larger experimental areas and a more robust role for the assistance from the scientific community.

Incorporate the "All-Lands" Initiative

The Department of Agriculture's 2010–2015 Strategic Plan contains a goal that strives to "ensure our national forests and private working lands are conserved, restored, and made more resilient to climate change, while enhancing our water resources." There are many facets to this ambitious goal and one new initiative in support of this goal involves use of a collaborative, "all lands" approach to bring public and private owners together across landscapes and ecosystems.

An all-lands approach would move landscape-level assessment and planning beyond the limits of the MMC forest type to other forest types, other land designations, and other ownerships that are often intermingled on logical landscape-level planning units. Managers can strive to involve all owners and management agencies and include all lands, even wilderness, in this kind of landscape planning. Additionally, these all-lands assessment efforts may indicate the need to treat areas such

as wilderness-designated areas with controlled ignitions and burning to achieve landscape-level goals such as fuels reduction and achieving target future ranges of variation.

Revisit Current Management Constraints; Eastside Screens

In August 1993, the Pacific Northwest Region regional forester issued a letter providing interim direction to eastside national forests on retaining old-growth attributes at the local scale and moving toward the historical range of variability (HRV) across the landscape. These became known as the "eastside screens." A subsequent decision notice in May 1994 amended all eastside forest plans to include these standards. These provisions involved a three-stage process for screening projects to evaluate effects:

- Riparian Screen. Defers timber harvest in riparian areas.
- Ecosystem Screen. Compares the acres of old forest stages in a watershed with the HRV for that structural stage.
- Wildlife Screen. Maintains options for future wildlife habitat requirements for old growth-dependent species.

Eastside screens for large trees (>21 in [about 53 cm] in diameter) were intended to be an 18-month interim measure to screen out projects that could potentially harvest significant amounts of old forest and of remnant medium- and large-size trees. Managers were advised to avoid removal of trees above a certain diameter limit for a variety of reasons. The eastside forest health assessment in eastern Oregon and Washington had shown that remnant large trees and old-forest patches had been heavily targeted for timber harvest, and were seriously depleted (Everett et al. 1994). Public concern for loss of large and old trees also became significant beginning in the late 1980s and has continued to the present. Forest managers had to rapidly "screen" timber sales and then exclude parcels from those sales that included these large trees. Tree diameter was also used as a rapid and conservative but crude surrogate for old growth to limit removal of larger and older trees—because analyses had not been completed to characterize old forests and old trees—across the variety of forest types and productivities.

The team that developed the large tree screen designed it to be replaced by more in-depth landscape evaluations that considered the key departures in forest structural and compositional patterns from HRV. In fact, in 1994 the regional forester stated that "projects need to be designed according to the principles of landscape ecology and conservation biology." Nonetheless, these screens have been employed for 20 years now. We are not aware of how much variation in these

procedures has been exercised since the screens were instituted, but the screens are still being used. Restoration of patterns that support natural processes and terrestrial species habitat arrangements is better achieved through evaluations that lead to landscape prescriptions. We know of no research that has evaluated the effects of the screens since they were implemented. However, other research on the ecology and history of pine and mixed-conifer forest (Hessburg et al. 1999a, 2005; Merschel 2012; Perry et al. 2004) indicates that many shade-tolerant trees more than 51 cm (20 in) in diameter were established after fire exclusion in the early 1900s. Consequently, restoration guided by size alone will not remove all of the individuals of species and ages of trees that are products of the altered disturbance regimes of these forests.

Furthermore, a recent report on climate change impacts on Western forests indicates that increased fire frequency and severity, insect outbreaks, and drought stress will challenge managers with novel conditions that fall outside what was identified from the 500+ years prior to Euro-American settlement (Fettig et al. 2013). To develop adaptation strategies, including ones that allow for new species composition and changes in forest structure across the landscape, managers will need more flexibility than is provided under one-size-fits-all rules for silviculture, such as those imparted by the eastside screens. Local variability coupled with an uncertain climate future requires an ability to adjust to site conditions and be nimble, as better and more complete information becomes available.

Rather than simple rules based only on stand structure, managers can be guided by multi-scale evaluations that include landscape and site-level criteria.

Rather than simple rules based only on stand structure, managers can be guided by multi-scale evaluations that include landscape and site-level criteria. Such approaches would consider and remedy the key departures in forest structural and compositional patterns relative to their HRV and future range of variability (FRV), the latter of which incorporates climate change. This integration of historical and potential future conditions is likely to conserve more desired components of ecosystems than would occur under the use of HRV or the FRV alone. The departure analyses using the HRV and the FRV are not meant as a recipe, but as guidance about the nature of pre-management-era patterns that supported native species habitats and disturbance regimes. With climate warming we use the FRV in the same way as HRV—as guidance about the nature of the patterns that may emerge as species distributions and disturbance regimes (e.g., ecological envelopes) shift as climate interacts with land use to create novel environmental conditions and behaviors. As we are seeing in eastern Washington ecoregions, these envelopes of HRV and FRV can actually overlap quite a bit, but are clearly being deformed by warmer and drier conditions.

As managers reevaluate their planning approaches using the concepts and findings contained in this report, they might also consider phasing out these interim directions. As mentioned, these screens were a short-term solution to prevent harvesting of larger trees. The diameter limits were intended as a crude and conservative filter to avoid harvesting old trees, pending the development of more precise definitions and tools. These limits are arbitrary with respect to meeting any ecological objectives because they applied to all sites regardless of the number or species of large trees present, or the potential of these areas to grow large trees. The limits on removing any tree larger than about 53 cm (21 in) whatsoever, regardless of geographic context, or age, or species, or relative abundance, or other considerations (e.g., forest health) within a patch can inhibit regeneration in some stands, lack any real landscape objectives, and impede landscape-level management and restoration.

The concepts presented in this report address the underlying ecological objectives of the eastside screens. As these concepts are explored and implemented by managers, the ecological goals intended by the eastside screens can be met. Some individual features (i.e., nesting, roosting, and resting sites for wildlife) may continue to merit short-term conservation measures. However, employing a landscape approach to assessment, planning, and execution of forest management will improve our ability to effectively restructure forests to a more resilient condition and cope with impending change. Moving landscapes toward these desired conditions will be expensive, thus some flexibility in treatment options is needed. Treatments designed based on the considerations herein are capable of generating some revenue that will offset a portion of the costs of achieving landscape-level objectives. Flexibility will also help managers address long-term socio-political and operational issues related to eastside screens.

Chapter 7—Conclusions

Active management of vegetation in moist mixed-conifer (MMC) forests in eastern Oregon and Washington has declined over the last two decades because of uncertainties about management. During this time, shade-tolerant and fire-intolerant trees have regenerated, grown, and densified forests in many locations. Consequently much of the landscape of ponderosa pine and dry and MMC forests of eastern Oregon and Washington is in a non-resilient condition. Some of the MMC landscape would benefit from active vegetation and fire management to restore or create vegetation conditions and landscape patterns that are better adapted to fire, drought, insects and disease, and climate change than conditions and patterns managed passively. Although managers have a scientific foundation and some amount of social license to conduct active restoration in pine and dry mixed-conifer types, there is far less consensus on what should be done in MMC types. This report offers scientific findings and management considerations to help managers take informed steps toward restoring resilience to MMC forests.

This report offers scientific findings and management considerations to help managers take informed steps toward restoring resilience to moist mixed-conifer forests.

Dry, moist, and wet mixed-conifer forests coexist in landscape mosaics that have been altered by settlement and land use activities. On balance, the array of changes over the last 100 to 150 years make these forests and landscapes subject to high-severity and sometimes large fires (with varying degrees of mixed- and low-severity components), insect outbreaks, and drought-related tree mortality that negatively affect many ecological and social values. During the presettlement era, the dry **and** MMC forest landscapes were sculpted by low-, mixed-, and high-severity wildfires (tables 8 through 13 in app. 3) that maintained relatively open canopies and understories. Landscapes were mosaics, dominated by a mix of tree species, sizes, and ages (tables 8 through 13 in app. 3). Some ecoregions exhibited more mixed- and high-severity fire than others.

Environments and vegetation patterns are diverse and complex in the MMC forest (e.g., historical disturbance regimes differ within potential vegetation types as a result of topography and landscape context). We lack uniform vegetation classifications, maps, and disturbance regime information that can be applied at local landscape scales. This information is sorely needed. Despite these challenges, we were able to identify and develop a working definition of the MMC types (potential vegetation types, disturbance regimes, ecoregions) within the broader mixed-conifer mosaic, where structure, composition, and processes have been significantly altered by Euro-American activities.

In many respects the impacts of postsettlement activity on forests and implications to restoration are the same in MMC forests as those in the ponderosa pine and dry mixed-conifer forests. The disturbance regimes were similar in the dry and moist environments, but in the productive MMC forest environments the large

increases in understory density were composed of shade-tolerant species like grand fir or Douglas-fir rather than ponderosa pine. We identify that in the wettest mixed-conifer types, restoration of resilient vegetation patterns is much less needed or inappropriate given their low frequency disturbance regimes.

Given the stated restoration goals of the Forest Service, we identify a set of objectives and actions at stand and landscape levels that would move forests and landscapes on a trajectory toward resilience in the face of fire, insects, disease, and climate change. These include creating diverse, fire-resilient vegetation types over a large portion of the MMC landscape, creating seral-stage diversity and patterns at stand and landscape scales, using topography as a guide, maintaining habitats for key wildlife species, including those that need landscapes with patches of dense mixed-conifer forests, and maintaining ecological and physical processes that favorably reconnect terrestrial and aquatic ecosystems and support habitat for fish.

Stands (patches) and local landscapes, conjoined with regional landscape-scale perspectives, are needed to achieve restoration goals. Although we address all three scales in this report, we have emphasized local landscape perspectives because they are newer and the theory and practice is rapidly developing through research and innovative management. For those seeking more detail on the latest stand-level considerations for mixed-conifer forests, other resources exist (e.g., Franklin et al. 2013). The geographic scope and context of forest restoration dictates an "all lands" approach to address the challenges of the 21st century. Vegetation succession and disturbance dynamics emerging from wildfires, insect and disease outbreaks, exotic species invasions, and multiple ownerships and management directions—set against a backdrop of climate change—do not observe local forest patch boundaries, land lines, or administrative boundaries. More effective land management can be realized through action grounded in collaboration and a landscape perspective.

A list of management considerations is provided for planners and managers when managing for restoration and resilience at landscape scales (see app. 1). The list includes guidance on development and use of historical reference conditions (historical range variation is a useful guide), addressing climate change (using potential future range of variation in designing landscapes), and a workflow plan. Several eastside national forests and other forest landowners in this region now actively employ some principles of restoration management at a landscape scale. The example provided from the Okanogan-Wenatchee National Forest is one of a number of bottom-up initiatives that explore innovative approaches to forest management. Many of the concepts presented in this report may be known to land

managers, but they are not yet in common practice. Understandably, new innovations and scientific insights take time and often require experimentation to integrate into standard operations.

It makes sense for both the management and research communities to work together to learn about restoration and collectively stop every few years and take stock of where we are and what we have learned in implementing these ideas. This is, in essence, the conceptual core of adaptive management, and we encourage such flexible management approaches that promote learning and sharing. It also makes sense to build stronger day-to-day ties between management and research to enhance the real-time flow of information, improve researcher insights about ongoing and newly emergent problems, and to improve management by experimentation and adaptation. Regional land management, with all of its uncertainties and risks, and the significant and growing public scrutiny, is an enterprise that could benefit from increased adaptive management and enhanced science-management collaboration.

Land management activities necessarily integrate many policy and societal considerations, while utilizing the best available science. Managers can rely on well-tested, dependable methods and approaches of our respective professions, but can also continually avail themselves of developing innovations and technologies to better enable decisions and implementation. That, we believe, is evident in the synthesis presented in this report. We have presented a synopsis of the best available science, old and new, combined with an array of management concepts and principles that have yet to become common practice. We have also assessed the best of both traditional scientific and management approaches with some recent innovations that substantially improve our ability to understand how complex forest ecosystems function and how management influences those processes.

Finally, when viewed through the lens of socioecological resilience, creating ecologically resilient landscapes cannot occur without support and consideration of the institutions and socioeconomic components. Restoration and renewal of resiliency in eastside forest landscapes requires economic support, forest management infrastructure, and social license and partnerships between management agencies and various publics. Human activities over the last 150 years have reduced the resilience of mixed-conifer forests across millions of acres of federal lands. This problem, a long time building and currently widespread, will require a sustained, comprehensive, and collaborative approach to remedy.

Restoration and renewal of resiliency in eastside forest landscapes requires economic support, forest management infrastructure, and social license and partnerships between management agencies and various publics.

Acknowledgments

In the preparation of this report, many more people contributed to the final product than simply the listed authors. Accordingly, we thank the following for their meaningful efforts: Becky Gravenmier for helping coordinate our efforts in so many ways; Keith Routman for considerable expertise in editing and formatting the document for final publication; Tom DeMeo, Rod Clausnitzer, Sabine Mellmann-Brown, Dave Powell, and Mike Simpson for their input into developing table 2 and suggestions for text related to potential vegetation types; Ayn Shlisky for reviewing portions of earlier drafts and preparing some graphics; the Umatilla National Forest staff, particularly Dave Powell, who hosted our August 2012 workshop and field tour and helped with arrangements for the December 2013 workshop in Pendleton; the peer reviewers; and many others who offered comments on earlier drafts.

Appendix 1—List of Practical Considerations for Landscape Evaluation and Restoration Planning

This list of management considerations is intended to provide an example of the kinds of key steps that could be taken in achieving restoration and resilience goals. The list does not establish a rigid process nor required steps in project planning; rather, these are reminders of the types of planning actions that can enable managers to achieve a broad range of landscape restoration objectives. Their application to a specific project is at the discretion of the responsible official, depending on the purpose of the action. The six major elements of this example process are presented first, followed by a more detailed discussion of the kinds of activities that can contribute knowledge through this process:

- **Local landscapes can be prioritized within ecoregions for restoration.** Local landscapes might be individual or groups of subwatersheds or watersheds. Local landscape domains should represent land units that are useful to terrestrial and aquatic system evaluations. Broad-scale assessment methodology can be used to base prioritization on the degree of vegetation departure from historical and future climate change reference conditions (including exotic plant invasions); vulnerability to large-scale, high-severity fire, drought, insect, and pathogen-caused tree mortality events; and priorities for terrestrial and aquatic habitat restoration and regional linkages, especially as they relate to listed and focal species. Other criteria may also be important.
- **Consider engaging in stakeholder processes early and as often as is practical.**
- **Characterization of the current vegetation conditions of high-priority local landscapes is recommended.** Using a meso-scale assessment methodology, estimate and spatially allocate the departure of current conditions from historical and climate change reference conditions; landscape vulnerability to large-scale, high-severity fire, drought, insect, and pathogen-caused tree mortality events; noxious and nonnative plant and animal invasions; and priorities for listed and focal species (terrestrial and aquatic) habitat restoration and improved connectivity.
- **For local landscapes, we recommend developing target frequency and patch size histograms (distributions) of desired vegetation conditions,** including physiognomic types, cover types, structural classes, canopy cover classes, density and age classes, and other related conditions, considering the potential vegetation type, the topographic setting, local soils, historical

disturbance regimes and range of variability, expected climate change and future range of variability, special legacy wildlife concerns, and other ecological, operational, or socioeconomic factors as needed.

- **Consider developing a method to spatially allocate and distribute these patch size distributions to local landscapes.** Fine tune target distributions based on landscape context and special legacy considerations.
- **Consider developing Proposed Landscape Treatment Areas (PLTAs) in local landscapes based on ecological and socioeconomic criteria**, including stakeholder input.

The following more detailed steps may be considered for local landscape evaluations where appropriate to the purpose of the project or planning action:

- **Characterizing and mapping the current vegetation conditions of entire local landscapes; include all potential vegetation types (PVTs) is recommended.** Motivating questions are:
  - What are the current patterns of physiognomic types, cover types, structural stages or successional classes, stand density, and basal area classes?
  - What is the density and distribution of large, old, fire-tolerant/intolerant trees, and the density and basal area of shade-tolerant trees?
  - What are current surface and canopy fuel conditions?
  - What is the vulnerability of the current vegetation to major insect and pathogen disturbances?
  - What is the vulnerability of the current vegetation and fuelbeds to wildfires?
- **For each ecoregion, we suggest characterizing historical reference conditions (ca. 1880–1900) for all PVTs.** Motivating questions are:
  - What were the historical patterns of physiognomic types, cover types, structural stages or successional classes, stand density, and basal area classes?
  - What was the historical pattern and distribution of large, old, fire-tolerant trees?
  - What was the historical pattern and distribution of shade-tolerant trees? How did their basal area and density vary? How were these patterns distributed with respect to topography, PVTs, and dominant processes?
  - What is a set of guiding reference conditions (potential restoration and resilience targets) based on historical patterns of structure and composition?

  - What is a desired set of class and landscape pattern metrics to characterize these reference conditions?

  Develop reference conditions that enable a direct comparison of the current conditions with the historical reference conditions.

- **Consider comparing current vegetation with reference conditions** (structure, composition, disturbance regimes). Motivating questions are:
  - Where within the local landscapes have disturbance regimes and vegetation structure and composition have been significantly altered by Euro-American activities?
  - How does this departure vary by topography, soils, and PVT setting, and by disturbance regime?
- **To strengthen understanding of sustainable landscape-scale ecological condition, future climate change reference conditions (ca. 2010–2050) for all PVTs can be characterized for each ecoregion.** Motivating questions are:
  - What do climate change models predict to be the most likely climate change scenarios for each ecoregion? Identify one or two most likely climate change scenarios for each ecoregion; use existing information from models or expert opinion.
  - What are predicted future patterns of physiognomic types, cover types, structural stages or successional classes, stand density, and basal area classes?
  - What is a set of guiding reference conditions (potential restoration and resilience targets) based on future patterns of structure and composition?
  - What is a desired set of class and landscape pattern metrics to characterize these reference conditions?

  Develop reference conditions that enable a direct comparison of the current conditions with the future climate change reference conditions.

- **Assessment of the risk of high-severity fire under current fuel conditions is suggested.**
  - Tools such as FlamMap, a fire behavior mapping and analysis program, are currently being used for this.
  - Terrain-routed wind flow projections can be obtained from Wind Ninja, Wind Wizard, or similar simulation tools.
  - To initialize wind speeds and directions, use meteorological data from nearby weather stations where available, or expert advice as needed.

- Determine the mapped distribution of burn probability, probable flame length, fireline intensity, rate of spread, crown fire ignition, and spread potential.
- Note the hotspots on the landscape for high-probability flame length and fireline intensity.
- Note the corridors on the landscape that most strongly tend to spread fire.

- **Assessment of the departures from historical and climate change reference conditions in patch-scale fire behavior attributes.** Motivating questions are:
  - How have spatial patterns of surface and canopy fuels changed with respect to these references?
  - How will changes translate to changes in expected fire behavior?
  - What are the key changes by PVT setting?
  - How are changes in expected fire behavior spatially distributed?

- **Evaluating the wildlife habitat conditions (distribution, abundance, and connectivity of different habitat types) and assessing current conditions. The following steps have been used for regional-scale wildlife habitat assessment (Suring et al. 2011), but can be adjusted to address planning at other scales:**
  - Identify species of conservation concern.
  - Describe habitats and other important factors (e.g., sensitivity to activities associated with roads or residential developments).
  - Group species according to habitat associations and other threats.
    - Select species for assessment. Appropriate assessment target species could include threatened, endangered, or sensitive species, or focal species selected based on their association with specific habitat conditions and particular threats associated with human activities.
    - Develop assessment models for each focal species.
    - Develop conservation strategies that address management of habitat and other risks.
    - Design monitoring and adaptive management plans.

- **A terrestrial landscape diagnosis of habitat retention and vegetation restoration needs can be developed by considering items above.**
  - Evaluation of the road network associated with the current landscape is recommended.
  - Identify all roads crossing streams, culverts, and other fish passage barriers.
  - Identify road segments that confine stream channels, reduce access to off-channel features, and contribute the most sediment.

  - Identify portions of the road network that most reduce subsurface water flow and accelerate runoff.
  - Identify the portions of the road network that are most essential for access.

- **Evaluation of the stream network of the current landscape is recommended.**
  - Identify and map existing anadromous and cold water fish habitats, especially for listed or focal species.
  - Identify and map habitats with inherent potential for these same species.
  - Identify and map the cold water upwelling areas within the stream network and the extent of their influence on water temperature.

- **Evaluation of the surface erosion and mass failure potential within the landscape is recommended.**
  - Identify anadromous and cold water fish habitats that are prone to erosion, especially those of regionally listed or focal species.
  - Identify habitats with inherent potential for these same species that are especially prone to erosion effects.

- **An aquatic landscape diagnosis of habitat restoration needs can be derived by considering items above.**

- **Terrestrial and aquatic landscape and road restoration needs can be diagnosed using considerations items above.**

- **Using integrated risk and vulnerability assessments and socioeconomic opportunity factors can be effective in spatially allocating treatment priorities and identifying proposed landscape treatment areas (PLTAs)** (fig. 47). Spatial decision support tools can help users jointly consider the spatial allocation of treatment priorities across a multitude of factors.
  - Assess and map current land use and land designations and whatever constraints, challenges, or opportunities this suggests.
  - Develop and identify PLTAs that restore key concerns identified in analysis.
  - Among the PLTAs, vary the emphasis among the concerns to provide a wide variety of management alternatives to consider.
  - Array and compare the social and economic benefits and costs of each alternative.
  - Identify transitioning issues: How do we transition from a tenuous current condition to a more desirable and resilient future? How do we provide specific attention to species at risk and the elements of the landscape that need conservation in the near term while transitioning to the future?

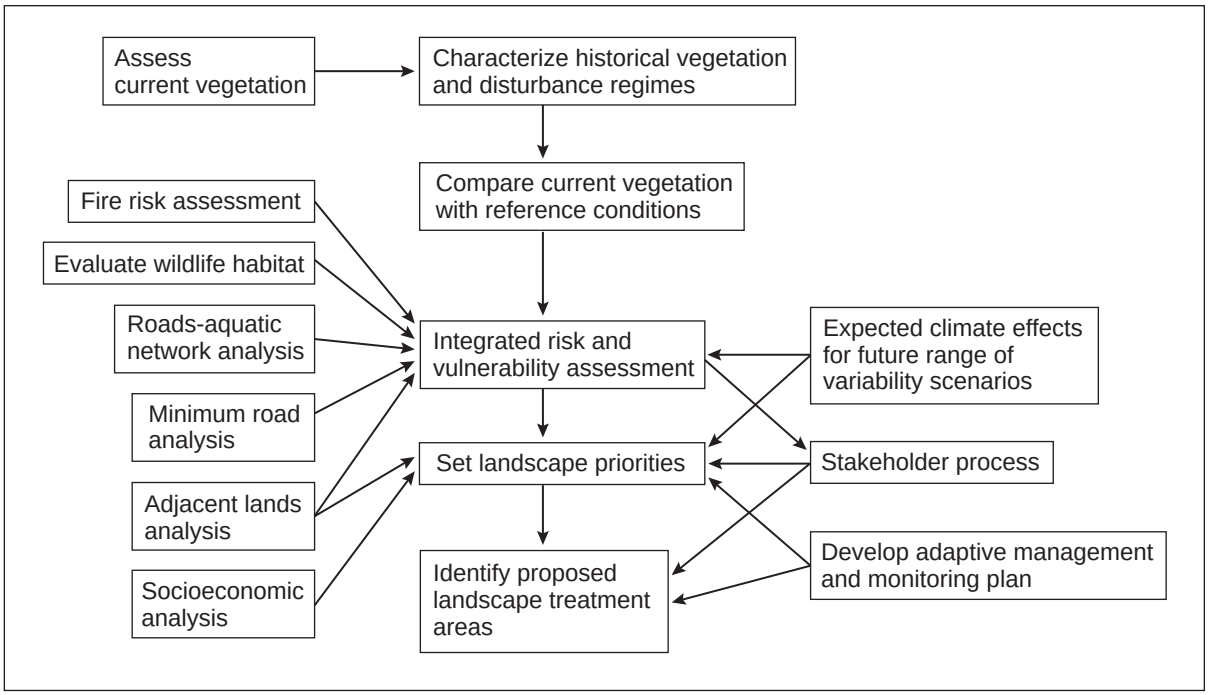

Figure 47—Schematic diagram of a suggested landscape evaluation workflow.

- Develop a landscape diagnosis and prescription for the best subset of alternatives based on stakeholder inputs and the condition of the resources.
- Assess potential effects of proposed work on adjoining lands and possible effects of ongoing activities on adjacent lands.

- **Develop a plan for monitoring implementation and effectiveness of the proposed treatments.** Monitoring programs take many different forms depending on specific objectives and available resources. Careful planning of a monitoring strategy is important to enable scientifically effective and reliable data collection and analysis for the intended purposes. The Forest Service planning rule provides detailed guidance for Forest Plan monitoring (36 CFR 219.12) including both a broad and local-scale approach. This plan also includes the option for jointly developed (i.e., more than one forest) plans that will effectively address broader-scale needs.

- **Regularly assess new scientific findings and adjust plans accordingly.**

Disclaimer: As stated above, the preceding elements are provided for the consideration of managers in conducting landscape evaluations to achieve sustainable land management objectives. These specific elements are not meant to suggest strict requirements; rather they are examples of the kinds of considerations that enable managers to obtain the best available scientific information for project planning.

Appendix 2—Regional-Scale Fire Regimes Group Classification for Oregon and Washington[1]

Most Moist Mixed-Conifer (MMC) Fire Regimes Fall Within Types I and III a and b.

0 to 35 years, low severity—
Typical climax plant communities include ponderosa pine, eastside/dry Douglas-fir, pine-oak woodlands, Jeffrey pine on serpentine soils, oak woodlands, and very dry white fir. Large stand-replacing fire can occur under certain weather conditions, but are rare events (i.e., every 200+ years).

0 to 35 years, mixed and high severity—
Includes true grasslands (Columbia basin, Palouse, etc.) and savannahs with typical return intervals of less than 10 years; mesic sagebrush communities with typical return intervals of 25 to 35 years and occasionally up to 50 years, and mountain shrub communities (bitterbrush, snowberry, ninebark, ceanothus, Oregon chaparral, etc.) with typical return intervals of 10 to 25 years. Certain specific communities include mountain big sagebrush and low sagebrush-fescue communities. Grasslands and mountain shrub communities are not completely killed, but usually only top-killed and resprout.

35 to 100+ years, mixed severity—
This regime usually results in heterogeneous landscapes. Large, high-severity fires may occur but are usually rare events. Such high-severity fires may "reset" large areas (10,000 to 100,000 ac [4050 to 40 500 ha]) but subsequent mixed-severity fires are important for creating landscape heterogeneity. Within these landscapes a mix of stand ages and size classes are important characteristics; generally, the landscape is not dominated by one or two age classes. In southeastern Oregon, this regime also includes aspen, riparian communities, most meadows, and wetlands.

<50 years, mixed severity—
Typical potential plant communities include mixed conifer, very dry westside Douglas-fir, and dry grand fir. Lower severity fire tends to predominate in many events.

---

[1] Evers, L. 2002. Fire regimes of Oregon and Washington. Unpublished report. Portland, OR: U.S. Department of Agriculture, Forest Service, Pacific Northwest Region. 3 p.

50 to 100 years, mixed severity—
Typical climax plant communities include well drained western hemlock; warm, mesic grand fir, particularly east of the Cascade crest; and eastside western redcedar. The relative amounts of lower and higher severity patches within a given event are intermediate between IIIa and IIIc.

100 to 200 years, mixed severity—
Typical potential plant communities include western hemlock, Pacific silver fir, and whitebark pine at or below 45° N latitude and cool, mesic grand fir and Douglas-fir. Higher-severity fire tends to dominate in many events.

35 to 100+ years, high severity—
Seral forest communities that arise from or are maintained by high-severity fires, such as lodgepole pine, aspen, western larch, and western white pine, often are important components in this fire regime. Dry sagebrush and mountain mahogany communities also fall within this fire regime. Natural ignitions within this regime that result in large fires may be relatively rare, particularly in the Cascades north of 45° N latitude.

35 to 100+ years, high severity, juxtaposed—
Typified by what would normally be considered a long-interval regime that lies immediately above a shorter interval or lower severity fire regime. Most often the fire originates lower on the slope and burns uphill into regime IVa. In southeastern Oregon, this subregime includes Wyoming big sagebrush communities on deeper soils below 5,000 ft elevation. Forest examples include lodgepole pine immediately above ponderosa pine in the eastside Washington Cascades and aspen imbedded within dry grand fir in the Blue Mountains. This regime is often found in lower elevations or drier sites than is considered typical for regime IV.

100+ years, high severity, patchy arrangement—
Typical potential forest communities include subalpine fir and mountain hemlock parkland and whitebark pine north of 45° N latitude.

Other community types include mixed Wyoming big sagebrush and low sagebrush on low productivity sites such as scablands, stiff sagebrush, and true old growth juniper savannah (<10 percent canopy closure). Some forbs are present, such as Sandberg's bluegrass, and the availability of many of these areas for burning depends on wet years that result in much greater grass production than is typical. Typical fire return interval in these communities is 100 to 150 years.

100 to 200 years, high severity—
Typical forest plant communities include subalpine mixed conifer (spruce-fir), western larch, and western white pine. Important potential forest plant communities include mountain hemlock in the Cascades and Pacific silver fir north of 45° N latitude.

Other plant communities include the intergrade between Wyoming big sagebrush and greasewood, shadscale on non-alkali soils, spiny hopsage, and alpine grasslands and heath in southeastern Oregon.

> 200 years, high severity—
This fire regime occurs at the environmental extremes where natural ignitions are very rare or virtually nonexistent, or environmental conditions rarely result in large fires. Sites tend to be very cold, very hot, very wet, very dry, or some combination of these conditions.

Typical plant communities include black sagebrush, salt desert scrub, greasewood on dunes, true old-growth juniper with at least 10 percent canopy closure and mountain-mahogany in rocky areas, and alpine communities and subalpine heath in the Blue Mountains and Cascades. Most species tend to be small and low-growing. Bare ground is common.

200 to 400 years, high severity—
Forest plant communities are at least somewhat fire-adapted. Typical plant communities include Douglas-fir, noble fir, and mountain hemlock on drier sites in parts of western Washington.

400+ years, high severity—
Forest plant communities are weakly fire-adapted or not fire-adapted. Typical plant communities include Douglas-fir, Pacific silver fir, western hemlock, western redcedar, and mountain hemlock on moister sites in western Washington.

No fire—
This regime includes forest plant communities with no evidence of fire for 500 years or more. Stands often have extremely deep duff layers on poorly developed soils. Typical plant communities include Sitka spruce and Pacific silver fir along the Oregon and Washington coast and very wet western redcedar sites.

Appendix 3—Reconstructed Historical Vegetation Conditions Within Sampled Areas of the Blue Mountains Province

This appendix is provided to highlight vegetation conditions that existed early in the 20th century in the Blue Mountains. The data are sorted by potential vegetation type (PVT); this sorting gives the reader the capacity to contrast overstory and understory size class, canopy cover, cover type, and structural class conditions for the major potential vegetation types. These insights are a companion to the body of this synthesis and are meant to amplify our observations about disturbance regimes and the sorts of patterns resulting from them. The data are adapted from Hessburg et al. (1999b, 2000a) and are available upon request. We provide these data to help the reader develop a mental picture of how the Blue Mountains landscape looked and likely functioned before forest management was in full swing (fig. 48). The vegetation conditions do not reflect a pristine condition and instead reflect some influence of early livestock grazing, timber harvest, and wildfire exclusion. Nonetheless, they are the best data we have and are based on the earliest available black-and-white, stereo-aerial photography, which was usually taken in anticipation of major future harvest activities. We found the earliest aerial photography to be an extensive reconnaissance of mostly nonharvested forest reserves. From characterizations like these, it is possible to visualize the primary directions and magnitudes of changes that occurred to the present day as a consequence of the first century of forest management.

Key to abbreviations in the tables that follow:

Potential vegetation types (PVT):

PIPO = ponderosa pine
WD PSME/ABGR = warm/dry—Douglas-fir/grand fir
CM PSME/ABGR = cool/moist—Douglas-fir/grand fir
WD ABLA2/PIEN = warm/dry—subalpine fir/Engelmann spruce
CM ALBA2/PIEN = cool/moist—subalpine fir/Engelmann spruce

Cover types:

PIPO = ponderosa pine
PSME = interior Douglas-fir
LAOC = western larch
ABGR = grand fir or white fir
Other = forest cover types not in PIPO, PSME, LAOC, or ABGR
NF = herbland, shrubland, and nonforest/nonrange types

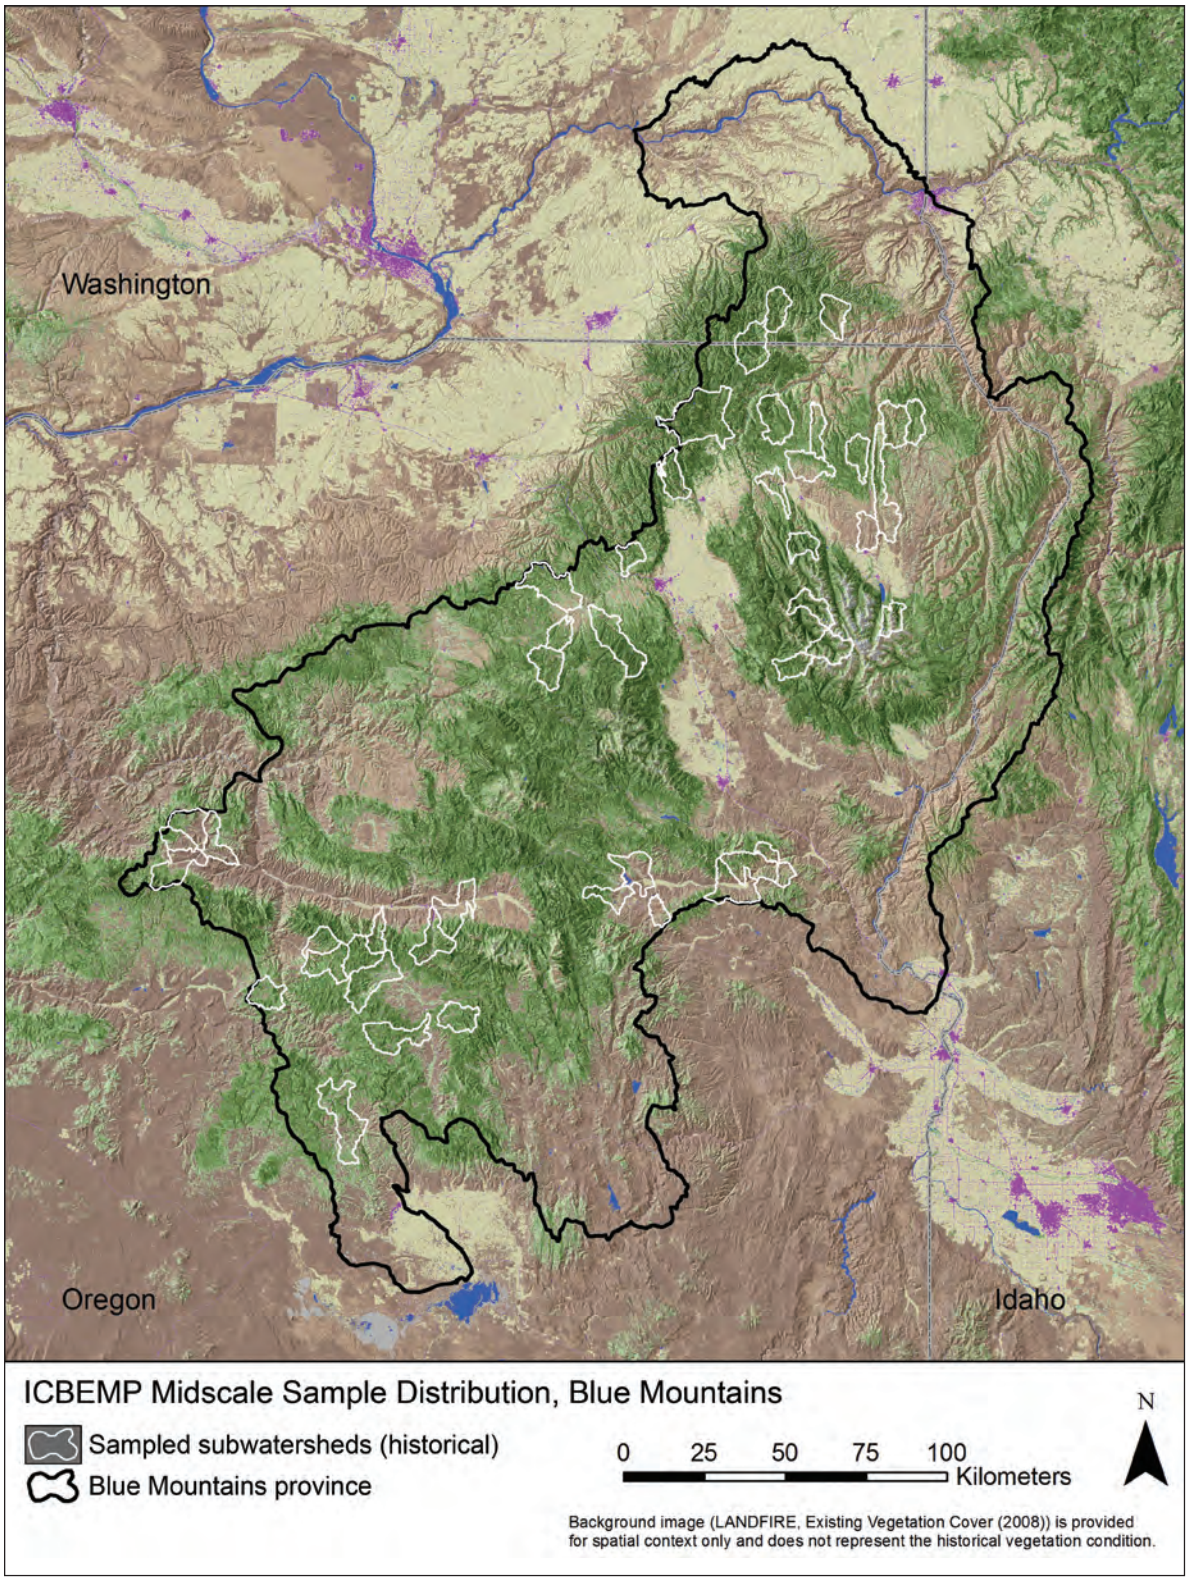

Figure 48—Subwatersheds sampled in the Blue Mountains ecological reporting unit during Interior Columbia Basin Ecosystem Management Project (ICBEMP) (Hann et al. 1997; Hessburg et al. 1999a, 2000c). The black outline delimits the sampled Blue Mountains area; the white lines delineate the reconstructed subwatersheds.

Structure class:

si = stand initiation
seoc = stem exclusion, open canopy
secc = stem exclusion, closed canopy
ur = understory reinitiation
yfms = young forest, multistory
ofms = old forest, multistory
ofss = old forest, single story
wood = woodland structures (all woodland structural classes combined)
herb = herbland (all herbland structural classes combined)
shrub = shrubland (all shrubland structural classes combined)
other = nonforest/nonrange and other anthropomorphic types

Tree size (overstory "OS," understory "US," and "Size"):

SS = seedlings and saplings (< 5.0 in diameter at breast height [d.b.h.])
PT = pole-size trees (5.1 to 8.9 in d.b.h.)
SmT = small trees (9.0 to 15.9 in d.b.h.)
MedT = medium trees (16.0 to 25.0 in d.b.h.)
LgT = large trees (>25.0 in d.b.h.)
Single story (no US) = forested patches without a visible understory
Nonforest = herbland, shrubland, and nonforest/nonrange types

Canopy cover (CC):

10–100 = percentage forest canopy cover class: 10–30, 40–60, 70–100
Single story (no US) = forested patches without a visible understory ("US_CC" tables only)
Nonforest = herbland, shrubland, and nonforest/nonrange types

Table 8 shows a total sampled area of about 415 000 ha, or more than 1 million ac. In the Blue Mountains, about 4 percent of that area resided in the dry PIPO PVT, about 10 percent in the dry mixed conifer (WD Douglas-fir/grand fir), 46 percent in the moist mixed conifer (CM Douglas-fir/grand fir) PVT, 4 percent in the dry spruce-fir PVT (WD subalpine fir/Engelmann spruce), and 8 percent in the moist and cool to cold spruce-fir PVT (CM subalpine fir/Engelmann spruce). The remainder of the area (28 percent) was occupied by early-seral forest conditions (grass, shrub, bare ground), woodlands, and other forested PVTs.

Table 8—Percentage of sampled area in the Blue Mountains ecological reporting unit (ERU) by potential vegetation type

Potential vegetation type	Area	PCT_ERU
	Hectares	*Percent*
Ponderosa pine	15 624.56	3.77
Warm/dry Douglas-fir/grand fir	40 208.19	9.70
Cool/moist Douglas-fir/grand fir	191 632.00	46.22
Warm/dry subalpine fir/Engelmann spruce	16 903.80	4.08
Cool/moist subalpine fir/Engelmann spruce	33 475.22	8.07
Total	297 843.76	71.83

Table 9 examines the distribution of overstory tree size classes (OS) combined with canopy cover class (CC) for each of the five major PVTs. The canopy cover classes are 0 (nonforest), 10 to 30 percent, 40 to 60 percent, and 70 to 100 percent. Canopy cover was originally interpreted in decile classes but reclassified here for simplicity. The size classes are given in the key that precedes these tables. Note the amount of each PVT that was occupied by early-seral nonforest conditions. One quarter of the area in the PIPO PVT was not forested, but in grass, shrub, or bare ground condition at any one time. This was also true of about 10 to 20 percent of the area of the other PVTs. Also observe that there was a relatively small area in SS in any CC class in the PIPO PVT, but this area increased among the other PVTs. When considered along with the nonforest area by PVT, this gives some insight into the amount of stand-replacing disturbance (in grass, shrub, or forested patches that was going on at any time. Note also that regardless of PVT setting, most of the area in any OS size class falls within the lower canopy cover classes. Note as well that the area with MedT or LgT in the overstory consistently ranges from 40 to 60 percent of the PVT area (PIPO = 42.7 percent, WD PSME/ABGR = 55.6 percent, CM PSME/ABGR = 59.75 percent, WD ABLA2/PIEN = 38.2 percent, and CM ABLA2/PIEN = 44.42 percent), and most of that area is in the lower CC classes. Finally, note that each PVT shows a considerable area in PT and SmT trees (PIPO = 31.5 percent, WD PSME/ABGR = 36.1 percent, CM PSME/ABGR = 31.1 percent, WD ABLA2/PIEN = 37.1 percent, and CM ABLA2/PIEN = 46.3 percent), suggesting that mixed- and high-severity fire occurrence has to be a part of the fire history story.

Table 9—Percentage of the sampled area in the Blue Mountains province by historical potential vegetation type, overstory size class, and canopy cover class combination

	Potential vegetation type

Nonforest	25.75	7.69	8.85	18.85	7.59
Total	100.00	100.00	100.00	100.00	100.00

CC = canopy cover; PIPO = ponderosa pine; WD PSME/ABGR = warm/dry Douglas-fir/grand fir; CM PSME/ABGR = cool/moist Douglas-fir/grand fir; WD ABLA2/PIEN = warm/dry subalpine fir/Engelmann spruce; CM ALBA2/PIEN = cool/moist subalpine fir/Engelmann spruce; SS = seedlings and saplings; PT = pole-size trees; SmT = small trees; MedT = medium trees; LgT = large trees.

Table 10 examines the distribution of understory tree size classes (US) combined with canopy cover class (CC) for each of the five major PVTs. It is a companion to the previous table and provides insights about the understories of the forested PVTs, when that is the focal point. The canopy cover classes are 0 (nonforest), 10 to 30 percent, 40 to 60 percent, and 70 to 90 percent; obviously 100 percent US CC cannot exist for it to remain a US rather than an OS layer. Canopy cover was originally interpreted in decile classes but reclassified here for simplicity. The size classes are given in the key that precedes these tables. Note that as in table 9, regardless of PVT most of the area showing any US size class or CC occurs in the lowest 10 to 30 percent CC class (PIPO = 46.9 percent, WD PSME/ABGR = 51.9 percent, CM PSME/ABGR = 50.6 percent, WD ABLA2/PIEN = 38.5 percent, and CM ABLA2/PIEN = 49.1 percent). A much smaller sized area existed in any PVT in the 40 to 60 or 70 to 90 percent CC classes (PIPO = 7.6 percent, WD PSME/ABGR = 18.6 percent, CM PSME/ABGR = 24.3 percent, WD ABLA2/PIEN = 13.6 percent, and CM ABLA2/PIEN = 17.1 percent). Note also that in all PVTs, 16 to 29 percent of the patch area shows no evidence of US trees of any size class. Taken together, these results suggest that, for each of the five PVTs, most patch area

did not have dense understories, suggesting a strong influence of fire, perhaps in overlapping reburns, and from adjacent drier PVTs (e.g., those surrounding the WD and CM ABLA2/PIEN PVTs) that typically displayed more frequent fire return (the PIPO and WD and CM PSME/ABGR PVTs).

Table 10—Percentage of the sampled area in the Blue Mountains ecological reporting unit (ERU) by historical potential vegetation type, understory size class, and canopy cover class combination

CC = canopy cover; PIPO = ponderosa pine; WD PSME/ABGR = warm/dry Douglas-fir/grand fir; CM PSME/ABGR = cool/moist Douglas-fir/grand fir; WD ABLA2/PIEN = warm/dry subalpine fir/Engelmann spruce; CM ALBA2/PIEN = cool/moist subalpine fir/Engelmann spruce; SS = seedlings and saplings; PT = pole-size trees; SmT = small trees; MedT = medium trees; LgT = large trees.

Table 11 examines the areal distribution of cover types (CT) for each of the five major PVTs. For an expanded description of the cover types see Hessburg et al. 1999a (table 7: 48–49). Note that the PIPO cover type existed in all PVTs. It was dominant in the PIPO (65.5 percent), WD PSME/ABGR (79.42 percent), and CM PSME/ABGR (44.08 percent) PVTs, and occurred in trace amounts in the ABLA2/PIEN types. Surprisingly, more area in the PIPO CT occurred in the WD PSME/ABGR than in the PIPO PVT. This was driven by the large area (about 26 percent) in patches in a nonforest physiognomy (grass and shrub cover) in the PIPO PVT. Looking across all PVTs, it appears that grass and shrub vegetation patches were integral to the forest patchwork; many patches occurred in all forested PVT settings that were otherwise capable of supporting the growth of forest cover. Undoubtedly, some of these patches were alternative stable states that experienced relatively

frequent fires and experienced difficulty establishing a dominant cover of trees. In contrast with the PIPO and WD PSME/ABGR PVTs, CT conditions in the CM PSME/ABGR PVT are increasingly complex, with 47 percent of the patch area in PSME, LAOC, ABGR, and other forest cover types. Nearly one-quarter of the CM PSME/ABGR PVT area was dominated by the ABGR (ABCO) CT, second only to the PIPO CT. A similar area in the ABGR CT occurred in the WD and CM ABLA2/PIEN PVTs, but the greatest difference was that the other forest CTs dominated the latter PVTs. These observations coupled with those from the preceding three tables suggest that several findings are plausible: (1) surface fires associated with low- and mixed-severity fires likely dominated the fire regime in the PIPO and WD PSME/ABGR PVTs; however, replacement-severity fires also occurred and they provided a nontrivial contribution; (2) low-, mixed- and high-severity fires likely occurred in the CM PSME/ABGR PVT owing to variability in fire frequency and topo-edaphic conditions, and surface fire effects from low- and mixed-severity fires were likely on par with crown fire effects from mixed- and high-severity fires; and (3) crown fire effects from mixed- and high-severity fires likely dominated in the ABLA2/PIEN PVTs.

PIPO = ponderosa pine; WD PSME/ABGR = warm/dry Douglas-fir/grand fir; CM PSME/ABGR = cool/moist Douglas-fir/grand fir; WD ABLA2/PIEN = warm/dry subalpine fir/Engelmann spruce; CM ALBA2/PIEN = cool/moist subalpine fir/Engelmann spruce; PSME = Douglas-fir; LAOC = western larch; ABGR = grand fir.

Table 12 layers together in one location the relations existing in three of the four previous tables, excluding table 10. We integrate them all in table 13. From table 11 we saw that 65.5 percent of the PIPO PVT area supported the PIPO CT, and 26 percent of the area was nonforested. Of that 65.5 percent, 86 percent (56.3 percent of the PVT area) existed in two classes: the SmT and MedT_10 to 30 percent CC classes. Two aspects are noteworthy: canopy cover is low, in many cases less than full potential site occupancy and size class is dominated by small- and medium-sized, not large, and very large trees. In the photointerpretation, large trees were in evidence in a great many patches. To be identified as an overstory layer, LgT CC had to meet or exceed 10 percent of the CC, the lowest CC class. Where LgT cover did not meet the 10 percent CC threshold, the LgT cover was considered a remnant of a former patch and its CC was pooled with the dominant overstory size class. If, as the literature suggests, surface fires primarily thin from below but contribute <20 percent overstory mortality, then surface fire dominated regimes continuously regenerate patches affected by them, and they manifest at any point in time as multicohort, multi-aged, multisized patches. Put alternatively, if fires are occurring every 5 to 15 years in the PIPO and WD PSME/ABGR PVTs and they conservatively kill on average just 5 percent of the CC at each instance of fire, it is difficult to imagine finding many patches of PIPO CT with a high canopy cover of mostly LgT, and with many trees older than about 350 years of age. That is what is shown here. Notice the strong similarities between the PIPO and WD PSME/ABGR PVTs—but there are differences as well. In both PVTS one can see the powerful influence of surface fires in maintaining low canopy cover conditions; however, in the WD PSME/ABGR PVT, the story is less tidy; nearly 28 percent of the area is comprised of patches with a broader array of size classes, intermediate and higher canopy cover classes, and a broader range of cover types. It is apparent that fire frequency and fire severity are more variable in the WD PSME/ABGR than the PIPO PVT. This pattern continues into the CM PSME/ABGR PVT, where there is greater evidence of CT, size, CC, and hence fire regime variability.

CC = canopy cover; PIPO = ponderosa pine; WD PSME/ABGR = warm/dry Douglas-fir/grand fir; CM PSME/ABGR = cool/moist Douglas-fir/grand fir; WD ABLA2/PIEN = warm/dry subalpine fir/Engelmann spruce; CM ALBA2/PIEN = cool/moist subalpine fir/Engelmann spruce; PSME = Douglas-fir; LAOC = western larch; ABGR = grand fir; SS = seedlings and saplings; PT = pole-size trees; SmT = small trees; MedT = medium trees; LgT = large trees.

In table 13, we layer the information from all five of the preceding tables together using structural classes of O'Hara et al. (1996). Structural classes are used because they provide a sense of the relative abundance of components of each PVT landscape resulting from the combined influences of forest succession, stand dynamics, and disturbance processes. The structural classes take the continuum of conditions and bin them into key mileposts in succession and disturbance regimes. Toggling between tables 12 and 13 is useful for visualizing this point. In the PIPO PVT, we see that stem exclusion open canopy structures (seoc, 31.4 percent) dominated, occupying nearly one half of all PIPO cover (31.4/65.5). This was followed by stand initiation structure (si, 21.2 percent), grass and herb patches (herbland, 15.62 percent), shrubland patches (9.8 percent) woodland patches where tree cover (PIPO and JUOC, western juniper) was <30 percent CC (woodland), followed by young multistory forest (yfms), and understory reinitiation (ur, 3.32 percent) structures. It is plausible that PIPO_si cover occurred in patches after severe fires or that PIPO forest was reinvading a much larger area of grass, shrub, and woodland patches under the influence of livestock grazing, fire suppression, and fire exclusion. At the time of the photointerpretation, only 2.5 percent of the total area showed any evidence of prior timber harvest, and most of this was light selection cutting. Conditions were similar to the PIPO PVT in the WD PSME/ABGR PVT; however, more closed canopy conditions are present and structural conditions are spread across a broader range of CTs. From table 11, we note that nearly 80 percent of the area in the WD PSME/ABGR PVT displayed the PIPO CT. This was distributed across all structural classes, but not evenly so; 59 percent was comprised on PIPO_si, PIPO_seoc, and PIPO_yfms conditions, PIPO_ur contributed another 9 percent, and old single and multistory forests contributed another 10 percent. At the time of the photointerpretation, one third of the WD PSME/ABGR PVT area had experienced some noticeable selection cutting. We notice a much broader distribution of CT and structural class combinations when we observe the CM PSME/ABGR PVT. Here, 33 and 23 percent of the area is comprised of yfms and seoc structures, respectively, across all cover types. At the time of the photointerpretation, 15 percent of this PVT area had experienced light selection cutting, and there was little evidence of regeneration harvesting. In both the WD and CM ABLA2/PIEN PVTs, there was trace evidence of selection and regeneration harvests. In most cases, regardless of PVT, the selection cutting dominated the observed logging in the early photos, it was obvious and recent, and the largest and oldest remnant large and very large trees were the target of opportunity.

Glossary

Adaptive management—A system of management practices based on clearly identified outcomes and monitoring to determine if management actions are meeting desired outcomes, and if not, to facilitate management changes that will best ensure that outcomes are met or reevaluated. Adaptive management stems from the recognition that knowledge about natural resource systems is sometimes uncertain (36 CFR 219.16; FSM 1905).

Composition—The biological elements within the different levels of biological organizations, from genes and species to communities and ecosystems (FSM 2020).

Connectivity (or habitat connectivity)—The degree to which intervening landscape characteristics impede or facilitate the movement of organisms or ecological processes between patches. The concept of connectivity implies that some feature or patch in the landscape is spatially related to other, similar features, and that intervening landscape characteristics influence the ecological relationship between those features. Although somewhat counterintuitively, it is important to note that a landscape can be highly fragmented or patchy, as is commonly the case in landscapes with mixed-severity fire regimes, and still be highly connected for a variety of ecological processes.

Disturbance—A force that causes significant change to the structure, composition, or function of an ecosystem through natural events such as earthquake, fire, flood, insect and disease outbreaks, weather, or wind; or by human activities such as the harvest of forest products. Many or most disturbances of interest are integral parts of and important to ecosystem function and health.

Ecophysiological—Relating to the interrelationships between an organism's function and its physical environment.

Ecosystem services—Benefits people obtain from ecosystems (FSM 2020), including:

1. **Provisioning services** such as clean air and fresh water, as well as energy, fuel, forage, fiber, and minerals;
2. **Regulating services** such as long-term storage of carbon; climate regulation; water filtration, purification, and storage; soil stabilization; flood control; and disease regulation;
3. **Supporting services** such as pollination, seed dispersal, soil formation, and nutrient cycling;
4. **Cultural services** such as educational, aesthetic, spiritual and cultural heritage values, as well as recreational experiences and tourism opportunities.

Elasticity—The speed with which a system returns after disturbance.

ENSO—El Niño/Southern Oscillation, a band of anomalously warm ocean water temperatures that occasionally develops off the western coast of South America and can cause climatic changes across the Pacific Ocean. The extremes of this climate pattern's oscillations cause extreme weather (such as floods and droughts) in many regions of the world.

Epicormic—Literally, "of a shoot or branch," this term implies growing from a previously dormant bud on the trunk or a limb of a tree.

Fire intensity—The amount of energy or heat release during fire.

Fire regime—The characteristics of fire in a given ecosystem, such as the frequency, severity, extent, and seasonality of fire.

Fire severity—The scale at which vegetation and a site are altered or disrupted by fire, from low to high severity. It is a combination of the degree of fire effects on vegetation (amount of fire caused vegetation mortality) and on soil properties.

Fragmentation—A term that has various meanings depending on the context of its use. Here we define it in two related ways (also see "connectivity"):

> **Landscape fragmentation**—The breaking up of continuous habitats into patches, thereby generating habitat loss, isolation, and edge effects.
>
> **Wildlife habitat fragmentation**—The set of mechanisms leading to the discontinuity in the spatial distribution of resources and conditions present in an area at a given scale that affects occupancy, reproduction, and survival in a particular species.

Frequency distribution—A depiction, often appearing in the form of a curve or graph, of the frequency with which possible values of a variable have occurred. In this report, we speak of the frequency of wildfire patches of various sizes.

Function—Ecological processes, such as energy flow; nutrient cycling and retention; soil development and retention; predation and herbivory; and natural disturbances such as wind, fire, and floods that sustain composition and structure (FSM 2020).

Future range of variation (FRV)—The natural fluctuation of pattern components of healthy ecosystems that may occur in the future, primarily affected by climate change, human infrastructure, and invasive species.

Heterogeneity—Any factor that induces variation in individual demographic rates.

Hierarchy theory—Ecological hierarchy theory presupposes that nature is working at multiple scales and has different levels of organization which are part of a rate-structured, nested hierarchy.

Historical range of variation (HRV)—The natural fluctuation in pattern of components of ecosystems over time.

Inertia—The resistance of a system to disturbance.

Integrity—An ecosystem has integrity if it retains its complexity, intact biotic and abiotic processes, capacity for self-organization, and sufficient diversity, within its structures and functions, to maintain the ecosystem's self-organizing complexity through time.

Interdigitate—The interlocking of (in this case) different components of the landscape like the fingers of two clasped hands. This creates an intertwining or intermingling mosaic of different vegetation or habitat conditions.

Landscape—A large land area composed of interacting ecosystems that are repeated in terms of factors such as geology, soils, climate, and human impacts. Landscapes are often used for coarse grain analysis.

Landscape hierarchy—Landscapes are systems that can be divided or decomposed into a hierarchy of nested geographic (i.e., different sized) units. This organization provides a guide for defining the functional components of a system and defines ways components at different scales are related to one another.

One common way this is conceptualized is the following organization: region = millions of hectares; landscapes = tens of thousands of hectares; watersheds = hundreds to thousands of hectares; stands (patches) = one to tens of hectares; gaps = 0.01 to 0.1 ha.

Mosaic—The contiguous spatial arrangement of elements within an area. For regions this is typically the upland vegetation patches, large urban areas, large bodies of water, and large areas of barren ground or rock. However, regional mosaics can also be land ownership, habitat patches, land use patches, or other elements. For landscapes, this is typically the spatial arrangement.

Multi-aged stands—Stands having two or more age classes and including stands resulting from variable-retention systems or other traditionally even-aged systems that leave residual or reserve trees.

Nested hierarchy—The name given to the hierarchical structure of groups within groups or branches from a trunk used to classify organisms.

Orographic—The lift of an air mass when it is forced from a low elevation to a higher elevation as it is moves over rising terrain. As the air mass gains altitude, it cools, its relative humidity increases, and clouds and sometimes precipitation result.

Patch—An area of similar vegetation, in structure and composition. Patches may range in size from a portion of a hectare to thousands of hectares.

PDO—The Pacific Decadal Oscillation is often described as a long-lived El Niño-like pattern of Pacific climate variability. As seen with the better-known El Niño/Southern Oscillation (ENSO), extremes in the PDO pattern are marked by widespread variations in Pacific Basin and North American climate.

Plant association—Plant associations are a finer level of classification in the potential vegetation hierarchy. They are defined in terms of a climax dominant overstory tree species and an understory herb or shrub species that is typical of the environmental conditions of a distinctive community of plants.

Plant association group (PAG)—A group of potential vegetation types that have similar environmental conditions and are dominated by similar types of plants (e.g., the dry shrub PVG). They are often grouped by similar types of life forms.

Potential vegetation type (PVT)—A potential vegetation type is a kind of physical and biological environment that produces a kind of vegetation, such as the dry Douglas-fir (*Pseudotsuga menziesii* (Mirb.) Franco) type. Potential vegetation types are identified by indicator species of similar environmental conditions. For example, Douglas-fir indicates a cooler and moister environment than ponderosa pine (*Pinus ponderosa* Lawson & C. Lawson). Because of growth, mortality, and disturbance of the vegetation, many other kinds of vegetation will occur on this type through time. In many cases the indicator species will not be present, due to disturbance. Douglas-fir is simply an indicator, and name, for the kind of physical and biological environment stratification that is used for prediction of response.

Resilience—The capacity of a system to absorb disturbance and reorganize while undergoing change so as to still retain essentially the same function, structure, identity, and feedbacks (FSM Chapter 2020). Resilience can be further defined to mean the amount of disturbance that an ecosystem can withstand without changing functional states. In this context, while dominant floristics may vary, a forest remains a forest as exemplified by maintenance of certain characteristic biological composition and the ecological goods and services it produces. Resiliency is the inherent capacity of a landscape or ecosystem to maintain its basic structure, function, and organization in the face of disturbances, both common and rare.

Restoration—The Forest Service defines restoration (National Forest System Land Management Planning, 36 CFR 219.19) as the process of assisting the recovery of an ecosystem that has been degraded, damaged, or destroyed. Ecological restoration focuses on reestablishing the composition, structure, pattern, and ecological processes necessary to facilitate terrestrial and aquatic ecosystem sustainability, resilience, and health under current and future conditions.

Stand—A descriptor of a land management unit consisting of a contiguous group of trees sufficiently uniform in age-class distribution, composition and structure, and growing on a site of sufficiently uniform quality, to be a distinguishable unit.

Structure—The organization and physical arrangement of biological elements such as snags and down woody debris, vertical and horizontal distribution of vegetation, stream habitat complexity, landscape pattern, and connectivity (FSM 2020).

Sustainability—Meeting needs of the present generation without compromising the ability of future generations to meet their needs. Sustainability is composed of desirable social, economic, and ecological conditions or trends interacting at varying spatial and temporal scales, embodying the principles of multiple use and sustained yield (FSM 1905). Conditions that support native species, ecosystem services, and ecological processes are sustainable when influences on them have not resulted in significant depletion or permanent damage.

Topo-edaphic—Related to or caused by particular soil conditions, as of texture or drainage, rather than by physiographic or climatic factors within a defined region or area.

Variable density thinning—The method of thinning some sub-stand units to a different density than other sub-stand units.

Vegetation series (plant community)—An assembly of different species of plants growing together in a particular habitat; the floral component of an ecosystem. According to Powell et. al. (2007 page 12), a series is the highest level of a potential vegetation hierarchy and is defined by the dominant climax plant species.

Vegetation type—A plant community with distinguishable characteristics.

Re: Review and Comment on the "Forest Plans Amendment – Forest Management Direction for Large Diameter Trees in Eastern Oregon and Southeastern Washington Environmental Assessment" and the Consequences and Impacts to Fish Habitat and Native Fish Populations in Riparian Areas

Dear Mr. Stiefel,

I have reviewed the environmental documents issued by the US Forest Service, Region 6, in the limited National Environmental Policy Act (NEPA) Environmental Assessment (EA) process used to remove the standard from the "Eastside Screens" that formerly protected large mature trees over 21 inches for the past 25 years on six national forests (USDA 2021a) and other related research and literature (Appendix A, Literature Cited). The following are my comments regarding the future impacts and consequences of the removal of protection of trees over 21 inches in riparian areas, including those designated as "riparian habitat conservation areas" (RHCAs), on native fish species. In my letter, I will comment on the importance of large trees in riparian areas and the consequences to native fish habitats, and the lack of adequacy of the environmental documents to fully assess and account for impacts to native fish populations, particularly species listed under the Endangered Species Act (ESA).

I am a fisheries biologist with over 38 years of experience, including 30 years with the Oregon Department of Fish and Wildlife (ODFW) before retiring in February 2014. My work for ODFW included the lands within the Project area including the John Day and Deschutes basins. I was the lead author and co-lead author for research papers on bull trout and redband trout, and restoration of anadromous fish including spring chinook and steelhead in the Deschutes basin. Attached as Appendix B is my resume.

I. Introduction

From the 1960s to the early 1990s, there were few limits on federal land management agencies to control management actions on or near streams (Roper et al. 2019). There were no safeguards to balance the risks posed by increasing timber harvest and a lengthening road system (Hicks et al. 1991; Dose and Roper 1994). This led to simplified stream channels with less instream large woody debris, increased fine sediments in streambeds, and destabilized streambanks (Meehan 1991). This period followed decades (since the 1920s) when management actions such as the construction of valley bottom roads, channel straightening, and log drives had a great direct effect on stream channels (Burnett et al. 2007; Steel et al. 2016). Beschta et al. (1995) reported that "*Land management practices in the interior Columbia… have profoundly impacted forest, grassland, and aquatic ecosystems. Watersheds and forests have been degraded (e.g., ecosystems fragmented, habitats simplified or lost, disturbance regimes altered). At every level of biological organization -- within populations, within assemblages, within species, and across the landscape -- the integrity of biological systems has been severely degraded. This is best seen in the marked reduction in the biological diversity in the region*." The authors further stated that "*By narrowly concentrating on forest health (often a euphemism for tree health, recently referring to carbon cycling), federal land*

managers have embarked on an ambitious attempt to address forest management in ways that risk neglecting watershed health and the ecology of aquatic ecosystems."

One of the primary goals of amending planning documents in the 1990s was to implement new management practices that would support viable native salmonids (Ratner et al. 1997; McHugh et al. 2017). The primary method to improve stream conditions was to limit activities such as timber harvest, road construction, livestock grazing, and other activities near streams that had caused the degradation of streams and riparian areas (Boisjolie et al. 2017; Roper et al. 2018). In addition, there were new policy guidelines to minimize sediment runoff from roads, requirements to conduct watershed scale analysis, identify priority watersheds where aquatic species would have greater protection, and implement stream restoration projects. Concurrent with changes in management policies that were expected to improve streams and riparian areas was a 70% reduction in the quantity of timber harvested from public lands in the Pacific Northwest region (Adams et al. 2006).

The Eastside Screens were implemented in 1994 in order to preserve the relatively few remaining large and old trees, and to protect ecosystem values such as wildlife and stream habitats. Those protections were recently removed by the scientifically controversial decision that the Forest Service implemented when the Undersecretary of the Department of Agriculture signed the Environmental Assessment (EA) Decision Document to remove protections for trees over 21 inches on east side forests in Oregon. Those protections were not in place long enough to restore the large and old trees, and the crucial fish and wildlife habitat they provided for recovery from the past century of logging that had removed the largest and oldest trees in eastern Oregon. There remains a significant deficit of large live and dead trees on the landscape in eastern Oregon as well as a relatively low abundance of the fish and wildlife species that the Eastside Screens were designed to protect and maintain.

Large trees are the foundation of old growth and mature forests, and they have a crucial role in supporting biodiversity, native fish and wildlife including numerous sensitive and Endangered Species Act (ESA) listed species, and clean water (DellaSala and Baker 2020). It is important to retain ALL remaining large trees since they are scarce on a landscape that has experienced decades of high grading timber harvest for large old trees. Large, old trees are also important since they are much more resistant to surviving wildfires. There is a large body of science that shows that increased harvest of large trees results in long-term and irreparable harm to fish and wildlife, ecosystem processes, biodiversity, and water quality. Since the Eastside Screens were implemented in the mid-1990s, the ecological basis for the Screens has not changed.

Since the Eastside Screens were amended, all six eastside forests have proposed projects to cut trees over 21 inches, with some projects including large tree removal in riparian areas. These proposed projects range in size from 35,000 to over 110,000 acres. Thus far three projects, Morgan Nesbit on the Wallowa-Whitman, Ellis on the Umatilla, and South Warner on the Fremont-Winema forests have proposed cutting trees over 21 inches in Riparian Habitat Conservation Areas (RHCAs).

For example, the Ellis project proposes to thin trees up to 9 inches diameter breast height (dbh) in the first 100 feet of the RHCA along fish bearing streams (Category 1), but contains no restrictions on harvest for the next 200 feet to the edge of the RHCA. In Category 2 and 3 streams (perennial and non-fish bearing streams and ponds, lakes and wetlands), harvest is limited for the first 75 feet from the stream but not the remaining 75 feet to the outer edge of the RHCA. Category 4 intermittent streams have even less protection, with restricted harvest only in the first 50 feet from the edge of the stream and no limits to the edge of the RHCA. Another project, Cliff Knox,

proposes logging operations in RHCAs including roadwork and ground-based skidding, and the cutting of trees over 21 inches adjacent to RHCAs.

Even though riparian buffers were established in PACFISH and INFISH to protect riparian areas, streams, and wetlands, the Forest Service has increasingly pursued cutting in RHCAs. The Forest Service has been using silvicultural prescriptions and modifying buffers to eliminate protections for and allow the cutting of large trees that provide critical shade for the streams. The impact of cutting large, mature trees, particularly in mixed conifer forests, old growth, connectivity corridors, and especially in riparian areas, will significantly and directly impact many important functions that old trees provide. Large trees over 21" are important because they support a large variety of fish and wildlife species by providing a multi layered large structural habitat as well as habitat for snag dependent and old growth species, provide shading that preserves clear, cold water for native aquatic species and assists in the improvement of soil health.

II. Riparian areas provide countless benefits for aquatic species.

Riparian areas provide very important ecosystem functions for their associated aquatic environments. Riparian areas, wetlands, seeps, and springs are among the most critical fish and wildlife habitats. Riparian areas provide habitat for over 80% of the native fish and wildlife species in western landscapes. However, riparian areas typically comprise less than 5% and sometimes as little as 1-2% of National Forest lands.

Historically, river systems provided highly complex habitat conditions for a diversity of native salmonids including Chinook salmon, steelhead, bull trout, cutthroat trout, and redband trout populations. Mature forests covered almost 75% of the region's forest types (DellaSala and Baker 2020). Old growth and large mature forests buffered the river system and contributed large quantities of wood to stream channels, forming pools and creating hiding and feeding cover for adult and juvenile fish. Mature trees and streamside riparian vegetation shaded streams, provided connectivity between floodplains and stream channels, and kept water cool for fish production.

Large trees in riparian areas are particularly important, either live or dead, standing or fallen onto the forest floor or into the stream, and are critical to forest and watershed function. In streams, they are referred to as large woody debris (LWD). There is abundant literature on the importance of LWD to the structure, function, and biodiversity of forests and particularly in aquatic ecosystems.

Large trees in riparian areas provide stream-side shading and, when they fall into streams, hiding cover for aquatic species. Large mature trees accrue soil depth, cycle nutrients, mitigate pollution, purify water, release oxygen, and provide habitat for wildlife at levels far superior to logged forests (Mackey et al. 2013, Mackey 2014, Mackey et al. 2014, Brandt et al. 2014).

The bulk of the National Forest System roads were built in the last 50 years, and with a few exceptions, most were constructed for access to timber harvest, particularly along streams and in riparian areas. Given the depletion of large trees over the past century from high grading timber harvest practices, the remaining large trees in riparian areas are all the more important to retain. Large trees provide a far greater benefit than smaller trees since they are critical for forming and retaining high quality pools, they last longer than smaller trees, and are more effective at providing instream habitat and reducing bank erosion.

Forest Service research scientists have repeatedly acknowledged the importance of large old trees for aquatic ecosystems. Hessburg et al. (2020) reported that "*Larger stems with root wads are more effective at creating deep*

plunge pools and side channels than smaller wood pieces because they can deflect greater hydraulic power and they last longer in streams. Smaller stems are often removed by spring flood and other channel reorganizing events...Large trees play a vital role in creating instream structure by adding complexity to stream channels and providing shade, and they are essential to creating high-quality, durable fish habitats…Across a continuum of habitats from the headwaters to the mouth, large wood plays a functional role in the creation of complex habitats for native fish (Fauschet al. 2002, Vannote et al. 1986)." The authors further stated that "Highly complex habitat mosaics reflect a combination of dead trees, log and debris jams, sediment, varying hydraulic power, and stream width (fig. 24). In headwater areas, habitat is often characterized by high-gradient streams. In such environments, large wood moderates flow, providing cold water and micro refugia for fish, salamanders, and other aquatic species (Vannote et al. 1986). Farther downstream, large wood contributes to the complexity of floodplain habitats by slowing water, depositing sediment, and facilitating seasonal flooding. These floodplain environments are highly productive for native fish and are enhanced by the presence of embedded large wood (Jeffres et al. 2008). Large water-adjacent trees often contribute to the complexity of aquatic habitats (Reeves et al. 2018). Large wood slows water, resulting in the deposition of sediment that is then sorted into microhabitats by the water column (Montgomery and Buffington 1997). Instream cover provided by large wood offers critical refuge from predation, particularly for rearing juvenile fishes (Dolloff and Warren 2003). Large wood is also important to the life histories of dozens of species of fish that associate with large wood for cover, spawning, and feeding. Other aquatic organisms such as crayfish freshwater mussels, and turtles also use large wood during part of their life cycles (Dolloff and Warren 2003). Further, large wood with root wads tends to survive longer in the stream channel, providing cover and moderating sediment and flow dynamics more effectively than small wood, which tends to be washed downstream. Shading of stream channels by large riparian trees provides critical thermal regulation and cooling (Poole and Berman 2001), particularly for cold-water dependent fish such as bull trout (Salvelinus confluentus) (Dunham et al. 2011). As climate changes, anticipated thermal stress will further reduce habitat available to native coldwater fish (Falke et al. 2016, Isaak et al. 2017, Rieman et al. 2007). Large trees throughout the river network are important regulators of thermal condition."

Yet, despite these extensive observations on the importance of large old trees to aquatic ecosystems and their importance for fish and other aquatic species, the Eastside Screens amendment removes the protections for large trees in riparian areas.

III. Riparian logging impacts ESA-listed aquatic species—such as Chinook salmon, steelhead, bull trout—and other native fish and aquatic species in many ways, including by impacting nutrient loads, stream temperatures, sediment loads and LWD, all important components for habitat quality.

It is well established that timber harvest and thinning near streams and in riparian areas can harm water quality and fish habitat. An established and growing body of science has documented the negative effects associated with the removal of large, commercial-sized trees. While non-commercial thinning and prescribed burning of fine fuels may only cause a short-term loss of habitat (i.e. a few months or a few years), the impacts from removal of large trees and their canopies, snags and down wood can last decades or longer.

Effects on fish habitat from loss of riparian vegetation include increased stream temperature, loss of cover, increased erosion, a widening and shallowing of the stream channel, and reduction or loss of perennial flow. Degraded habitat is characterized by increased sediment, increased water temperatures, a decline in pool depth, quality and frequency, reduced LWD, increased cutbanks and bank instability, and high width/depth ratios. Water

quantity and quality problems, primarily flow reduction or loss, temperature, sedimentation, and turbidity, limit fish distribution and production (Bottom et al. 1985).

Studies have shown that logging, even selective logging, has increased instream fine sediments (Kreutzweiser et al. 2005, Miserendino and Masi 2010) and increased instream water temperatures (Guenther et al. 2012), and these changes in habitats are found decades after logging.

Most streams on National Forest lands in Eastern Oregon already have high stream temperatures and currently violate state water quality standards for temperature. These high temperatures are a serious and long-term threat to water quality and continue to be a problem due to both past and current land management practices of timber harvest, high road densities and livestock grazing. High stream temperatures, especially in violation of state and Forest Plan stream temperature standards, create chronic and acute lethal conditions for native fish and limit their productivity and survival in areas where they are already stressed by high loads of fine sediments. Even local increases of water temperatures and sediment at the subwatershed or reach scale can cause local extinctions which cannot be recovered (Frissell 2017).

Logging in riparian areas can increase nutrient loads, stream temperature, and sediment to the stream, compromising fish habitat and water quality. Any active management in stream corridors and riparian areas causes a risk of harm to stream ecosystems (Frissell 2017) via the release of nutrients and increases in sediment and stream temperatures.

A. Nutrients. One important function of riparian areas is nutrient filtering and retention from harvest activities up slope. Any vegetation disturbance from wildfires or timber harvest, but especially logging, frees phosphorus and nitrogen in soils and causes a spike of these elements in streams. Excess nitrogen causes increased growth of aquatic plants and algae and in excessive amounts it can use up dissolved oxygen and block light to deeper waters. Too much nitrogen and phosphorus in the water causes algae to grow quickly and beyond what riparian areas and streams can handle. Large increases in algae harms water quality and aquatic habitats and decreases oxygen that fish and other aquatic life need to survive. In large algal blooms, oxygen is depleted leading to toxicity and even death of large numbers of fish. Sweeney and Newbold (2014) reported that "*The most familiar aspect of streamside forest buffers is their role in creating sufficient space to intercept pollutants created by upland activity before they enter the stream. It is intuitive that wider buffers with more vegetation have greater potential for intercepting, sequestering, degrading, and processing pollutants*." The authors conducted modeling of nitrogen removal and, for a site with average water flux, predicted "*removal efficiency of 48% for a 30-m buffer, increasing to 90% for a 100-m buffer*."

Wetlands, like riparian areas, also serve important ecosystem functions, such as improving water quality by filtering sediments, and nutrients and contaminants from the water column (Environmental Protection Agency 2002). Wetlands are also critically essential habitats for a wide variety of plants and animals, including many federally threatened and endangered species.

B. Stream temperature. Timber harvest, particularly in streamside zones, increases water temperature that can become chronic or acutely lethal to native fish species especially salmonids that are adapted to cold water. Yonce et al. (2021) observed that "*The effects of timber harvest on the thermal regime of streams have been observed globally*". The authors stated that "*Reduction in baseflow, which can occur due to soil compaction during harvest, may also reduce the capacity to absorb increased thermal inputs. Preventing these adverse effects was a motivating*

factor in the development of riparian buffer management practices for forestry. Riparian buffers influence water temperature through shading that reduces direct insolation to streams, and secondary effects on microclimate (air temperature and wind) within the buffer are also important. Additional benefits of buffers include reducing peak storm runoff, maintaining stable baseflow, and potentially filtering out sediment, nutrients, and other pollutant loads from the surrounding area."

Stream temperatures are also increased by the interruption of hillslope drainage patterns. By intercepting surface and subsurface flow, and increasing the channels on the landscape, it alters the magnitude of peak flows and lowers base stream discharge (Furniss et al. 1991). Loss of riparian cover and shading from timber harvest is well known while a third mechanism is the conversion of groundwater to surface water (Williams 1999). When water is changed from subsurface to surface water, as streams degrade, it is exposed to solar heating (Fissekis and Hersh-Burdick 2007; Wonzell et al. 2009). The hyporheic zone is the area under or beside a stream channel or floodplain that contributes water to the stream and has been found to have a significant role in supporting cold water refugia for salmonid fish populations.

Stream temperature is also impacted by the density of the road network in watershed. Increases in stream temperature have been strongly correlated with roads constructed along valley bottoms and next to stream channels and from the associated loss of riparian vegetation and canopy cover adjacent to those roads. Higher stream temperature impacts aquatic species by raising stream temperatures above the tolerable range for rearing, and increases vulnerability to disease, reduces metabolic efficiency, shifts fish species assemblages, and inhibits upstream migration (Beschta et al. 1987; Hicks et al. 1991).

C. Sediment. It is well documented in many studies that elevated sediment occurs as a result of timber harvest and the increase of "temporary" roads that continue to have impacts on the landscape well after the project is completed. PACFISH and INFISH both expounded on the contribution of timber harvest and roads to the degradation of streams and listing of anadromous and inland fish species. Many scientists and reports have affirmed that 200-to-300-foot riparian buffers along streams are minimums to protect aquatic habitats. A review of numerous authors in INFISH reported that "*non-channelized sediment flow rarely travels more than 300 feet and that 200-to-300-foot riparian 'filter strips' are generally effective at protecting streams from sediment from non-channelized flow."* Beschta et al. (1995) reported that "*Analysis of sediment impacts, for example, that accept existing conditions as the baseline are highly inappropriate because these have been increased over natural background levels for 50-100 years in many cases. There is considerable evidence that current conditions are insufficient to maintain viable populations of many native species, including sensitive and declining trout, salmon, and other fishes*." The large influxes and biological impacts of sediment beyond those normally in a stream are well documented, and come from timber harvest, roads construction and grazing. Bowerman et al. (2014) reported that fine sediments reduced percolation of water through salmonid redds (fish nests) and impacted both egg and early life survival. The authors also reported that management actions that restore hydraulic complexity in the form of pool–riffle sequences, point bars, and large wood enhance hyporheic exchange and support higher salmonid survival. May and Lee (2004) also stated that "*increases in coarse sediment supply can be associated with sharp reductions in salmonid habitat and productivity*" and reported that streams with discontinuous flow caused by sediment increases reduced survival by crowding fish into smaller areas with reduced food availability. The additional bedload of both fine sediments and coarser sediment delivered to streams fills in the channel, losing pool depth, channel complexity, and changing the channel profile to a shallow, wide profile (Chin et al 2004; May and Lee 2004).

Increased sediment in streams connected with roads causes increased aggradation of stream beds, filling of pools, enlarged channel widths and widening width-to-depth ratios (Jackson and Beschta 1984; Lisle 1982). Lee et al. (1997) (referenced in Carnefix and Frissell 2009) reported as road density increases, there is a clear decline in pool frequency and frequency of large pools, both of which are essential requirements for high-quality fish habitat. Lee et al. (1997) reported that increasing road densities are correlated with declines in the four non-anadromous salmonid species including bull trout, Westslope cutthroat trout, Yellowstone cutthroat trout, and redband trout. All species are less likely to use streams in highly roaded areas for spawning and rearing, and if found are less likely to be at strong population levels. As pools are filled in by sediment, they support fewer fish, and they suffer higher mortality. Elevated levels of fine sediment also adversely affect salmonid embryo survival (Bjornn and Reiser 1991; Jensen et al. 2009) and have been linked to decreased fry emergence and juvenile densities, loss of winter carrying capacity, and increased predation (Chapman 1988; Everest et al. 1987; Scrivener and Brownlee 1989; Magee et al. 1996; Weaver and Fraley 1993; Young et al. 1991). Furthermore, higher fine sediment load reduces intragravel dissolved oxygen, increases metabolic waste concentrations, decreases intergravel space for aquatic life, and restricts movements of alevins (young fry) (Bjornn and Reiser 1991; Chapman 1988; Everest et al. 1987; Baird et al. 2012).

Sedimentation affects fish habitat quality by increasing the amount of fines and causing embeddedness of gravel and substrate. This in turn reduces spawning habitat by making gravel difficult to lift, oxygenation to incubating eggs, and cover for rearing fish. Turbidity affects fish production by reducing production of aquatic insects and plankton, and foraging efficiency of fish. Sediment fills interstitial spaces between rocks in the substrate, reduces habitable area in streams, and when it exceeds 20 percent of the total area on the substrate, can smother fish and frog eggs and increase mortality (Bjornn and Reiser 1991). Increased turbidity reduces the ability of fish to feed on aquatic insects and reduces aquatic insect and plant production. Many streams throughout eastern Oregon forests have documented sediment embeddedness of greater than 20% and in some cases has high as 45% (USDA Summit Off Highway Vehicle Trail (USDA, Ochoco National Forest SFEIS 2016)).

As another example, the US Fish and Wildlife Service (2010) describes the effects of sediment on ESA-listed bull trout: "*The introduction of sediment in excess of natural amounts can have multiple adverse effects on bull trout and their habitat (Rhodes et al. 1994, pp. 16-21; Berry, Rubinstein, Melzian, and Hill 2003, p. 7). The effect of sediment beyond natural background conditions can be fatal at high levels. Embryo survival and subsequent fry emergence success have been highly correlated to percentage of fine material within the streambed (Shepard et al. 1984, pp. 146, 152). Low levels of sediment may result in sublethal and behavioral effects such as increased activity, stress, and emigration rates; loss or reduction of foraging capability; reduced growth and resistance to disease; physical abrasion; clogging of gills; and interference with orientation in homing and migration (McLeay et al. 1987a, p. 671;Newcombe and MacDonald 1991, pp. 72, 76, 77; Barrett, Grossman, and Rosenfeld 1992, p. 437;Lake and Hinch 1999, p. 865;Bash et al. 2001n, p. 9;Watts et al. 2003, p. 551;Vondracek et al. 2003, p. 1005;Berry, Rubinstein, Melzian, and Hill 2003."*

D. Large Woody Debris. LWD is an important measure of habitat complexity and is important for sediment retention, pool formation and bank stability (Cordova 1995; Stuart et al. 2007). It is also an important feature in the physical and biological structure of a forested stream (McDade et al, 1990). In general, higher native salmonid densities are found in streams with more LWD. LWD adds to stream complexity and stability and provides habitat for a variety of species and age classes in aquatic communities (Lisle 2002). Most RHCAs on the managed portions of National

Forest lands are deficient in LWD from past and present timber harvest. Roper et al. (2019), comparing actively managed and reference (unmanaged) reaches of streams on national forests in eastern Oregon and Washington, and Idaho and Montana, reported that wood frequency, wood volume, and pool frequencies all increased as the percent of the riparian zone that was forested increased.

IV. Logging-associated roadbuilding and road use also causes degradation of water quality and adversely impacts ESA-listed and aquatic species.

The Eastside forests all have high road densities, a legacy of logging operations. Roads act like dry stream beds, and when rains come, they push significant amounts of sediments and polluted water into streams and rivers. This is true whether roads are functionally open, designated open or designated closed - the roads continue to have some of the greatest impacts contributing sediment to streams and aquatic habitats.

The ongoing existence of a dense road network has already stressed the system and is causing significant effects. The construction and use of new roads in riparian areas to facilitate timber harvest will only increase the significant impact that roads are having on riparian areas, wetlands, seeps, and springs and associated fish and wildlife species. The Forest Service is already proposing new road construction, the reopening of old roadbeds and new stream crossings to facilitate timber harvest. These actions will dramatically increase the impact of and the amount of sediment being pushed into the system. These are not minor, short-term impacts but large-scale, long-term impacts to aquatic systems that are already on the brink.

Most national forests have road density standards that were implemented as part of the 2005 Travel Management Rule (USDA 2005). The 2005 Travel Management Rule was adopted to address environmental harm resulting from unregulated motorized use across National Forest Service lands. For example, the Ochoco Forest has a road density standard of $\leq$ 3 mi/mi^2 in general forest (USDA, Forest Service 1989 Ochoco Forest Land and Resource Management Plan), yet in their own analysis of roads in 2003, road densities are as high as 12 mi/mi^2 (USDA Forest Service, Roads Analysis 2003). Another example is the Malheur National Forest where there are road density standards of 1.5 mi/mi^2 in big game summer range and 1 mi/mi2 in big game winter range (USDA Forest Service 2021b, Cliff Knox Project DEIS) yet the open road density in the project area is 3.98 mi/mi2 in the area planned for timber harvest. Since there are many closed and decommissioned roads that are either being driven or still present on the landscape in terms of their effects, the real road density is much higher.

In 2020 and 2021, volunteers with the Great Old Broads for Wilderness conducted surveys of "closed and decommissioned roads" in project areas of the Ochoco Forest. The Black Mountain Vegetation Management project DEIS stated that the existing road density was 2.66 mi/mi^2 only using ML 2-5 open roads (USDA, Forest Service 2018, Black Mountain DEIS). However, the Broads noted that counting ML 1 closed roads of which most were driven, the road density for M 1-5 roads was 3.66 mi/mi^2. The Forest Service failed to enumerate the real open road densities on the landscape. The surveys showed that the density was even higher as it found that 63% of the ML-1 "closed" roads, 33% of the decommissioned roads, and numerous user-created roads had unauthorized vehicular use. The surveys noted that 80-90% of the "closed" roads had little or no barriers to restrict access and most had been driven. In another area of the forest, the proposed Mill Creek project area (a project that proposes the removal of large trees greater than 21 inches), the survey crews found a similar level of closed and decommissioned roads actively driven by the public and many user-created roads.

Road density standards and meeting those standards are important because the effects of roads and motorized trails on the landscape concentrate flow and increase runoff and sediment to streams. The increased hydrologic connectivity of flow and sediment seriously degrades instream habitat for aquatic species including macroinvertebrates (aquatic insects), Columbia spotted frog, and a variety of salmonids including native fish such as Chinook salmon, steelhead, bull trout, and redband trout.

Many authors have reported on the consequences of forest management and the attendant proliferation of roads across the landscape. DellaSala et al. (2011) state that "*the roaded, intensively managed landscapes of the other national forest lands have been closely correlated with heavily sediment-laden streams and dramatic changes in flow regimes (Espinosa et al. 1997; Trombulak and Frissell 2000; Center for Biological Diversity et al. 2001; Coffin 2007; Frissell and Carnefix 2007).*"

Elliot et al. (2011) reported that sediment is the greatest pollutant of forest streams, and in the absence of wildfire, a forest road network is usually the main annual source of sediment in forest watersheds. A major factor that increases erosion is traffic. Roads with heavy traffic generate 4 to 5 times the sediment of roads compared to roads with light traffic (Elliot et al. 2010). Carnefix and Frissell (2009) found that there is not a truly "safe" threshold road density for aquatic species, but instead negative impacts begin with the first road segment in a watershed, and highly significant impacts began at road densities as low as 1 mi/mi^2. Motorized use of unpaved roads is a direct factor in sediment production (Furniss et al. 1991). While several research efforts have attempted to describe and quantify increased sediment production for use of roads, some studies have documented that heavily used roads increase sediment production by 130 times greater than abandoned roads (Reid and Dunne 1984). Other studies have documented that sediment production for roads with traffic deliver 2 to 30 times sediment production compared to unused roads (Luce and Black 2001). Foltz et al. (2009) reported that after Forest Service roads were reopened from being closed or decommissioned, sediment concentrations were significantly higher and were attributed to decreased vegetative cover. In addition, the authors found that 30 years of no traffic and vegetation regrowth was not sufficient to allow recovery of soil infiltration to values similar to an undisturbed forest. In other words, the years of compaction by vehicles effectively and permanently impacted runoff and sedimentation from lack of infiltration. Stream crossings along roads are also a major source of sediment to streams (Furniss et al. 1991).

The small roadless areas that have been left "unmanaged", with a lack of logging and roads, play a critical role in maintaining high-quality water and protecting aquatic ecosystems. The clean water from remnant roadless areas is important to maintain healthy coldwater salmonid fisheries, sustain viable aquatic ecosystems, and help protect threatened species and ecosystems (Abell et al. 2000; Trout Unlimited 2004). Roadless area are an important refugia for many salmon and trout populations, as well as for a diversity of endangered freshwater species (Henjum et al. 1994; Huntington 1998; Trombulak and Frissell 2000; Center for Biological Diversity et al. 2001; Strittholt and DellaSala 2001; Oechsli and Frissell 2002; Strittholt et al. 2004; Petersen 2005). DellaSala et al. (2011) state that "*restoration of salmon and trout fisheries in places with high road densities will likely fail without the pivotal role provided by roadless areas as fishery strongholds*." Further, they state that "*For many major drainages (entire watersheds of major rivers, such as the Columbia River Basin), roadless areas and other wilderness areas represent the last few percentages (typically 1% to 5%) of the landscape with a minimally disturbed, or near natural, hydrology*."

V. <u>The FS falsely relies on PACFISH and INFISH to protect streams and riparian areas. By failing to disclose all activities and consequences and relying on PACFISH and INFISH to protect riparian areas, the Forest Service disregards impacts to native fish habitat and fish populations.</u>

The Decision Notice and Finding of No Significant Impact (USDA 2021a) for removing the 21-inch rule of the Eastside Screens states that "*the direction of INFISH and PACFISH, which provide standards and guidelines to protect water quality, continue to apply*" while the Decision Summary states that *"all management will remain the same within Riparian Habitat Conservation Areas. PACFISH, INFISH, their objectives, goals, standards and guidelines direct management will still apply."* Based on this continued management direction, the FS brazenly concludes that the removal of protections for large trees across the Eastside Forests will have "no effect" on ESA-listed aquatic species.

PACFISH and INFISH were designated with the intent to recover highly degraded streams from past and present management activities of timber harvest, roading, mining, and livestock grazing. Timber management activities were only allowed if they were implemented with the intent to move Riparian Management Objectives (RMOs) to a better condition.

However, in the past decade, all forests east of the Cascades have increasingly pursued timber harvest in riparian areas, often under the guise of "restoration" or "wildfire resiliency." In some cases, forests have created arbitrary designations of a "streamside management zone", "an inner and outer RHCA zone" and a "limited activity buffer" that allow commercial harvest and other logging operations in a portion of the RHCA. In some cases, RHCA buffers themselves are too narrow to prevent impacts to aquatic ecosystems, and this further narrowing of buffers has introduced still more impacts. This has led to continued timber harvest, roading and livestock grazing and the failure to recover degraded streams and riparian areas.

Yet, the EA and Decision Notice for amending the Eastside Screens failed to provide any numerical data on stream conditions and parameters for meeting or violating RMOs from PACFISH and INFISH. All six forests that were covered under the EA to remove the 21-inch rule have highly degraded watershed function, streams and riparian conditions throughout all actively managed areas. The few areas that may meet RMOs are typically found in wilderness, roadless areas, and undeveloped lands. The EA and Decision Notice fail to look at baseline conditions and the cumulative effect of removing the protections for large trees across the broad landscape.

The EA and Decision document to amend the Eastside Screens (USDA 2021a) state that "*Aquatic and riparian species habitats are protected through the guidance of the PACFISH/INFISH strategies and will not change under this amendment" and "Project level analyses will be required to address any site-specific effects that projects may have on riparian and wetland associated species and their habitats*."

However, at the site-specific project level, the Forest Service fails to acknowledge that increased sediment from the large planning areas for timber sales will increase impacts on ESA-listed and sensitive aquatic species. For example, the Ellis Integrated Vegetation Management project on the Umatilla National Forest encompasses a planning area of over 114,000 acres for commercial timber harvest, thinning, and additional roads to conduct treatment activities. While the DEIS acknowledged that watersheds and streams were in very poor degraded conditions, the only data provided were that the expected sediment loads would increase from all action alternatives (USDA 2021c, Ellis DEIS and Ellis Hydrology Report). The projected sediment increases are alarmingly high, and in most of the subwatersheds, sediment is expected to increase anywhere from 100% to an astonishing almost 400% over the existing condition during treatment activities. Over 85 miles of streams in the project area are identified as designated critical habitat for ESA-listed Mid-Columbia River steelhead. The DEIS states that there are existing conditions of highly degraded watersheds and streams with elevated water temperatures and elevated sediment, and the project will result in increases of sediment from soil disturbance and loss of shade from the project. Then the DEIS asserts that "*Alternatives 2 and 5 [which will have the greatest amount of harvest and roads]*

would not hinder attainment of relevant properly functioning indicators pertaining to sediment and roads." In other words, the FS found that despite the huge sediment increases caused by the project's riparian logging and associated roadwork, the project is consistent with the PACFISH management direction.

As discussed above, sediment increases of this magnitude pose significant consequences for aquatic species. High sediment loads and water temperatures have already led to the severe decline of ESA-listed Mid-Columbia steelhead. Clearly in the case of the Ellis Integrated project and other projects, impacts to fish habitat and ESA-listed species will continue to occur, notwithstanding the PACFISH/INFISH management direction. Despite severely degraded riparian and stream habitat conditions and watersheds not in proper functioning condition, and the acknowledgement that timber harvest will dramatically increase sediment, the Forest Service continues to authorize riparian logging activities.

Another example is bull trout in the North Fork of the Malheur River that will be impacted by the Cliff Knox project (USDA 2021b). The Forest Service used a U.S. Fish and Wildlife Service process paper titled "A Framework to Assist in Making Endangered Species Act Determinations of Effect for Individual or Grouped Actions at the Bull Trout Subpopulation Watershed Scale" (USDI FWS 1998) to describe the environmental baseline for the project. The ESA-listed bull trout in this area has a subpopulation of less than 50 adults and are found in an 8-mile segment of designated critical habitat of the Malheur river and tributaries in the project area. The Cliff Knox DEIS cites that "*The Malheur River core area was estimated to have 50-250 individuals; however, the short-term trend was determined to be declining. The threat to the species was considered to be substantial, imminent and the population is at a high risk for extinction (USDI FWS 2008b)."* This high-risk bull trout subpopulation is characterized as in rapid decline or maintaining at alarmingly low numbers and under current management, the subpopulation will not improve with two generations (5 to 10 years). Yet, despite degraded habitat conditions with high water temperatures and sediment loads, the Forest Service downplays the impacts of increased sediment and loss of shade from the project and finds that the project is consistent with the INFISH management direction.

The impacts from riparian logging activities have the potential to increase significantly now that the Forest Service is permitted to cut large trees. As discussed previously, large trees are of outsized importance in terms of the benefits they provide to riparian areas, including provision of LWD, retention of fine sediment, and reductions of temperature. Removal of large trees will deplete already degraded systems. When roads are built in riparian areas and roads are constructed to remove large trees, the cumulative impacts from removing large trees will further aggravate seriously degraded conditions, leading to further declines in ESA-listed fish species. Since many of the ESA-listed fish are in dangerously low numbers, further timber harvest and roading will likely lead to local extinctions. Once gone, they cannot be recovered.

High quality forested riparian habitat for ESA-listed fish species is directly linked to the presence and abundance of large old trees. The combination of shade, soil and bank stability, nutrient cycling, and high-quality fish habitat is dependent on the continued existence of trees in riparian areas, particularly large trees since they have longer retention and durability. Bisson et al. (2003) reported that large trees are important to retain in areas with hydrologic connectivity to streams because they provide longer duration habitat structure in floodplains than small trees. Since large old trees have been depleted for over a century it is important to retain all remaining large trees. Continued removal under the guise of stand improvement is based on a silvicultural construct and not based on the habitat needs of ESA-listed species that are already jeopardized by past logging and roading practices.

In sum, the Forest Service's conclusion that the removal of protections for large trees will have "no effect" on ESA-listed aquatic species, based on the PACFISH/INFISH management direction, is insupportable. PACFISH and INFISH fail to prevent against logging-related impacts, and such impacts are likely to increase in magnitude with the removal of large trees. The continued entry into riparian areas via roads to harvest large trees will further compact and disturb soils, remove trees that are important for shade, sediment retention, nutrient cycling, and water quality, and further harm ESA-listed fish species. Yet the Forest Service is proposing to allow removal of large trees under the guise of restoration and wildfire resiliency contrary to the best available science and facts about large trees. One has only to look and compare wilderness and roadless areas to highly managed forested areas to see the last best chinook, steelhead and trout habitat is in the largely untrammeled areas. The quality of fish habitat and the abundance of ESA species are highly impacted by managed habitats due to the removal of large wood and extensive road systems to remove timber. In my opinion, the loss of the Eastside Screens' protections for large trees is another nail in the future coffin for ESA fish species and will likely lead to their extinction.

VI. Conclusion

Large trees in riparian areas are particularly important for a multitude of reasons. They are critical for a myriad of ecosystem services including filtering and providing clean water, shade to reduce water temperature, nutrient cycling, and future wood recruitment for LWD in streams. LWD provides important functions for sediment retention, hiding cover for aquatic species, a substrate for macroinvertebrates as food sources for fish, pool formation, and bank stability. These are important components for high quality habitat that support ESA-listed and sensitive fish species like Spring Chinook, steelhead, and bull, cutthroat and redband trout. Logging and associated roadbuilding activities adversely impact riparian areas in many ways, and such impacts have continued to occur in the last 25 years despite the PACFISH/INFISH management direction. Allowing the cutting of large trees in and around RHCAs—along with associated roadbuilding activities—will trigger increased impacts for riparian ecosystems and further jeopardize the future existence of ESA-listed fish species.

Sincerely,

Prineville, OR 97754
(541) 447-5448 amystuart63@gmail.com

Education:
M.S. 1980, Wildlife Management, Colorado State University, Ft Collins, CO.
B.S. 1977, Wildlife Biology & Management, Cornell University, Ithaca, NY.

PROFESSIONAL EXPERIENCE:

Oregon Department of Fish and Wildlife (ODFW), 9/2007 to 2/2014, Deschutes Watershed Manager

- Supervised 60 professional and technical staff.
- Managed expenditures of a combined budget of $9 million per biennium for 25 cost centers.
- Implemented fish, wildlife, research and habitat program goals, objectives and priorities.

ODFW 7/1997 to 8/2007, Hydro Power Program Biologist, High Desert Region

- Lead for the High Desert Region for re/licensing and compliance for state and federal FERC licensed hydro projects in the Klamath, Deschutes, Hood and Owyhee basins.
- Lead negotiator and/or technical lead for the Pelton Round Butte Settlement Agreement, Klamath Settlement Agreement, and Powerdale hydro project decommissioning.

ODFW, 1/1990 to 6/997, District Fish Biologist (DB), Supervisory FWB (3 1/2 years) and NRS 3 (4 years), Ochoco District, High Desert Region

- Fish program manager for the Ochoco District (7½ years). Hired, supervised, and conducted performance reviews of 1 permanent, several seasonal employees and 3 high school interns.
- Collected and analyzed fish population abundance and distribution, species composition, and harvest; evaluate hatchery stocking, harvest regulations; implement habitat protection/restoration.

ODFW, 2/1988 to 12/1989, Assistant District Fish Biologist II, Ochoco District, High Desert Region

- Implemented the fish management program. Sole fish biologist and assumed lead responsibility; ½ time Ochoco National Forest Fish Biologist: advised fish issues for timber sales and range allotments; conducted fish, habitat surveys and habitat projects. Authored bull trout plan at Lake Billy Chinook.

ODFW, January 1986 to January 1988, Fish Habitat Biologist II, BPA Program, John Day, NE Region

- Implemented habitat program using restoration techniques to improve fish and wildlife habitat: bank stabilization and habitat projects. Implemented contracts and landowner lease agreements. Prepared annual reports. Developed, supervised and administered budgets, personnel, equipment, and ODFW staff.

1977-1986. ODFW Ocean Salmon, US Forest Service, US Army Corps of Engineers, Colorado Mined Land Reclamation, and private timber cruiser.

Re: Review and evaluation of how the removal of trees greater than 21" dbh will significantly and persistently harm aquatic systems on USFS lands east of the Cascades.

Dear Mr. Stiefel,

I am a hydrologist with more than 35 years of experience, with a B.S. in hydrology from University of Arizona, a M.S. in hydrology and hydrogeology from University of Nevada-Reno and I finished all required academic work toward a Ph.D. in forest hydrology at the University of Washington. Since 2001, I worked as a consulting hydrologist for a variety of clients, including county and tribal governments in Oregon, Washington, and Idaho. Prior to that I worked for more than 12.5 years at the Columbia River Inter-Tribal Fish Commission (CRITFC), where I served as Senior Scientist-Hydrologist. My professional experience includes work with tribal, federal, state, county, and city governments, universities, and non-profit groups in eight western states. A copy of my curriculum vitae is attached.

Most of my work has focused on the effects of current and proposed uses of land and water on water quality, streams and habitats for native trout and salmon. I am quite familiar with the management direction in PACFISH and INFISH, including how the USFS has implemented activities on its lands in Eastern Oregon and Washington. Our work at the CRITFC provided much of the foundation of PACFISH. I am also quite familiar with riparian and stream conditions on these USFS lands.

I have co-authored numerous papers on the effects of logging (including thinning), roads, and other activities on watersheds and aquatic systems published in peer-reviewed scholarly

journals. I've served as a peer-reviewer for scholarly forestry and fishery journals, including the North American Journal of Fisheries and the Open Forest Science Journal, as well as the Proceedings of Forest-Fish Conference: Land Management Affecting Aquatic Ecosystems.

My evaluation of how the removal of trees greater than 21" dbh will significantly and persistently harm aquatic systems on USFS lands east of the Cascades is based on my education and experience. It is also based on my considerable experience with forest removal activities on those lands implemented under PACFISH, INFISH and other USFS management direction. **The allowance to log larger trees in Inland USFS lands will cause significant long-term harm to already highly degraded aquatic systems and imperiled fish.**

There are several reasons that aquatic systems and imperiled fish will be harmed by the allowance to remove larger trees. Most significantly, this loss of larger trees will contribute to the loss of downed large woody debris (LWD) in streams and riparian habitats. This will persistently degrade fish habitats and riparian functionality.

The allowance for removal of larger trees is likely to occur within Riparian Habitat Conservation Areas (RHCAs) established under PACFISH and INFISH, based on my reviews of numerous forest removal activities (hereinafter: "logging") implemented in the more than two decades since the adoption of PACFISH and INFISH on numerous inland National Forests. These projects have commonly involved logging within designated RHCAs, despite the guidelines and standards contained in PACFISH and INFISH.

A significant number of these larger trees in RHCAs, if left unmolested by the depredation from logging, would ultimately be recruited into streams via various means (windthrow, bank erosion, death from old age, etc), providing instream LWD. Larger trees within a given distance from streams in RHCAs are more likely to land in streams other factors being equal. Notably, larger trees are farther along the trajectory to age-related mortality, which is a significant LWD recruitment factor.

The loss of larger trees in and near RHCAs also contributes to long-term LWD losses from adjacent trees in RHCAs. This is because, when larger trees fall, they often knock down other trees that provide LWD to streams and riparian areas. Thus, logging of larger trees is likely to ultimately reduce instream LWD in perennial streams via several means.

The removal of larger trees outside of RHCAs on non-fish-bearing non-perennial streams will also reduce LWD levels in these streams. This is because the widths of RHCAs along these streams are not adequate to retain unimpaired levels of LWD recruitment, even if all trees in these RHCAs are retained. The full retention of all trees within one site potential tree height from streams is required to ultimately provide unimpaired levels of LWD recruitment (Rhodes et al., 1994), but RHCA widths on non-perennial streams without fish are much narrower than that under PACFISH and INFISH.

The loss of LWD in streams is extremely significant for several reasons. LWD is vital to the survival and production of imperiled salmonids and the functionality of riparian ecosystems.

As we noted in Karr et al., (2004): "…there is no debate about the key role that large trees play in aquatic systems…"

LWD is the primary pool-forming element in salmonid habitats (Buffington et al., 2002; Pollock and Beechie, 2014). Pools, particularly, large, deep pools, are essential to salmonid production and survival. They provide essential refugia and rearing and resting habitats (McIntosh et al., 2002). Instream LWD provides cover, a vital aspect of pool quality affecting salmonid production and survival (Pollock and Beechie, 2014). It also aids in moderating water temperature (Pollock and Beechie, 2014).

The largest pieces of LWD, which can only come from larger trees, are the most effective agent of pool formation. Larger LWD pieces serve as critical anchors for LWD jams which are important pool forming agents (Buffington et al., 2002) that are particularly important to aquatic systems due to multiple benefits they convey (Pollok and Beechie, 2014). The effectiveness of LWD in pool formation tends to increase with the size of LWD (Buffington et al., 2002). These larger pieces of LWD also have the greatest longevity in stream channels and provide longer duration of instream functionality. Larger trees are older, thus, the recovery time from LWD lost due to logging increases as the size of tree logged increases. The loss of LWD is an extremely persistent impact, lasting more than a century in areas where trees are able to grow back after removal (Rhodes et al., 1994; McIntosh et al., 2000).

Loss of LWD from large tree logging negatively impacts salmonids. Available data indicate that salmonid production increases as LWD increases (Rhodes et al., 1994).

LWD loss contributes to the loss of pool quality, volume, and frequency (McIntosh et al., 2000; Pollock and Beechie, 2014). Salmonid numbers tend to increase with pool volume, quality, and frequency (Rhodes et al., 1994). Pool loss reduces the production capability of salmonid habitat (Rhodes et al., 1994). Thus, the loss of LWD from larger trees incurs long-term significant impacts on salmonids and their habitats (McIntosh et al., 2004; Pollock and Beechie, 2014). The loss of salmonid survival and production caused by loss of larger LWD in streams is not reversible and is irretrievable.

LWD aids in reducing channel erosion and buffering sediment inputs by providing sediment storage in headwater streams (Rhodes et al., 1994). This is an important function even in non-perennial streams because these streams comprise the vast majority of the stream network and provide most of the sediment to salmonid habitats.

LWD provides important sources of organic matter and nutrients in soils, which are vital to the long-term maintenance and protection of soil productivity (USFS and USBLM, 1997a; Karr et al., 2004). Soil productivity is critical to forest vegetation and a host of forest functions.

LWD in riparian areas aids in limiting stream damage from livestock grazing. This is not trivial, because livestock grazing is a major source of damage to salmonid habitats in the affected area (USFS and USBLM, 1997a; b). LWD helps to limit this damage by impeding livestock access to streams. The largest pieces of downed LWD in riparian areas provide the most effective impediment to livestock access to streams.

Any loss of LWD is significant due to its importance to stream habitats and salmonids coupled with their existing conditions. Pool loss in salmonid habitats has been extensive and severe over the past several decades in logged and roaded watersheds draining USFS lands in the interior Columbia basin (USFS and USBLM, 1997a; McIntosh et al., 2000). LWD loss has been a major contributing cause of this pool loss. The loss of pools and LWD has been repeatedly implicated as a significant factor in the widespread decline in the range and numbers of salmonid populations (Rhodes et al., 1994; McIntosh et al., 2000; Pollock and Beechie, 2014). Past logging and roading has greatly depleted existing LWD sources in many riparian areas throughout the affected region. This is extremely significant because one of most important roles of riparian forests with respect to aquatic biodiversity is production of LWD from large trees big enough to anchor wood jams and form pools (Pollock and Beechie, 2014). Instream LWD levels are widely depleted, and the allowance to log larger trees will exacerbate this long-term aquatic affliction. Salmonid populations throughout the affected area are imperiled (USFS and USBLM, 1997a). Additional degradation due to LWD loss contributes to the likelihood of increased extirpation of these populations and is inimical to the recovery of these salmonid populations. The time needed to recover from the loss of LWD caused by large tree logging is on the order of century or more. For these combined reasons, the loss of any sources of LWD from larger trees is ecologically significant.

It is extremely unlikely that the removal of larger trees in riparian areas would convey any potential benefits to aquatic systems. Logging in riparian areas under the rubric of "thinning" has been shown to reduce LWD (Pollock and Beechie, 2014). Similarly, such logging has been repeatedly shown to be highly unlikely to alter fire behavior, because it is extremely unlikely that fire will encounter treated areas during the short period of time that fuels have been temporarily reduced by treatments aimed at fuel reduction (Rhodes and Baker, 2008; Price et al., 2015).

My decades of experience with forest management activities on lands implemented under PACFISH and INFISH amply demonstrate that riparian logging has often been approved under the guise of restoring forest structure and/or fire behavior. While PACFISH and INFISH contain subjective direction that projects are not to retard or prevent attainment of riparian management objectives, in practice, this has not meant that that riparian logging is prohibited, or that negative impacts from such logging have not occurred. Instead, riparian logging activities approved under PACFISH and INFISH have frequently impacted aquatic ecosystem functions. This trend will continue, based on the track record of the USFS over the more than two decades since the adoption of PACFISH and INFISH. In my professional opinion, based on abundant scientific information, these impacts will be more severe and long-lasting now that large tree logging is allowed.

Please don't hesitate to contact me with any questions or follow-up related to any aspect of this work.

Sincerely,

Jonathan J. Rhodes
Hydrologist

Curriculum Vitae: Jonathan J. Rhodes
Hydrologist

EDUCATION

1989: Doctoral candidacy degree in forest hydrology at the Univ. of Wash. Completed all requirements but dissertation.

1985: M.S. in Hydrology and Hydrogeology at the Univ. of Nev.-Reno. Thesis topic: The influence of seasonal stream runoff patterns on water quality.

1981: B.S. in Hydrology and Water Resources at the Univ. of Ariz.

PROFESSIONAL HISTORY

Sept. 2001 -- present. Principal Hydrologist, Planeto Azul Hydrology. Main duties: Analysis of water and land use effects on streams and aquatic resources, including native salmonids and their habitats; diagnosis of watershed and stream conditions; stream monitoring; development of programmatic and site-specific watershed and stream protection measures; project management. Some projects (and clients): Analysis of potential effects of groundwater pumping on streamflow (Conf. Tribes of the Umatilla Indian Reservation, OR); diagnosis of watershed and stream conditions in an urbanized watershed (West Multnomah Soil and Water Conservation District, OR); analysis of data on sediment effects on ESA-listed salmon in the South Fork Stillaguamish River, WA (Snohomish County, WA).

Aug. 1990 -- Sept. 2001. Consulting hydrologist for non-profit organizations. Past projects (and clients) include: hydrologic characterization of remnant marsh proposed as urban wildlife refuge/greenspace (Multnomah Co. Parks Dept, OR); review of aquatic effects of: quarry expansion (Friends of Forest Park, OR), urban construction (homeowners consortium, W. Linn, OR); forest manipulations on streamflow (Pacific Rivers Council).

Apr. 1989 -- Sept. 2001. Senior Fishery Scientist-Hydrologist, Columbia River Inter-Tribal Fish Commission. Main duties: Administration and implementation of projects monitoring channel change from land use; development of programmatic and site-specific land management plans to ensure protection of watershed integrity, water quality and aquatic resources; development of restoration plans for watersheds degraded by grazing, roads, logging, and mining; design of plans for monitoring watershed and stream erosion, sedimentation, water quality, and habitat conditions; review of land management plans for adequacy of protection of aquatic resources; field evaluation of watershed and channel conditions throughout the Columbia Basin; expert witness testimony; development of technical recommendations for policy staff for protection of natal habitat for anadromous fish; review of state and federal aquatic resource monitoring plans; report and proposal writing; and, participation in various state and federal technical work groups.

Aug. '84 -- Apr. '89. Research assistant, College of Forestry, Univ. of Wash. Main duties: analysis and interpretation of water quality-quantity data; technical report writing; design and maintenance of water chemistry and quantity monitoring network in a coastal forested watershed; training in data acquisition techniques; public presentation of findings.

July -- Oct. 1987 and May -- Oct. 1988. Consulting hydrologist, Tahoe Regional Planning Association, CA and NV. Main duties: field delineation and mapping of riparian zones, wetlands, and erosion-prone areas.

June -- Sept. 1985 and July 1986. Research assistant, Dept. of Geophysics, Univ of Wash. Main duties: operation of field station for glacier research on Mt. Olympus, Wash.; measurement of snow and glacier melt rates; mapping of supra- and extra- glacial streams contributing to basal sub-glacial flow rates on surging and non-surging glaciers in the Alaska Range, Alaska.

Jan. 1984. Consultant with C.M. Skau, Reno, NV. Main duties: field evaluation of logging roads for erosion potential and sedimentation risk; recommendations for placement of future roads to minimize erosion and sediment delivery to fish-bearing streams in coastal Northern California.

Oct. 1983 -- June 1984. Hydrologic Tech., USGS, Carson City, NV. Main duties: aid in development and calibration of predictive water quality model for the Truckee River; statistical analysis of water quality data; identification and quantification of non-point sources of nutrients to Truckee River, NV.

Aug. 1981 -- Sept. 1983. Research Assistant, Univ. of Nev.-Reno. Main duties: design and installation of instrument network to monitor water chemistry and quantity in a small, forested alpine watershed in the Sierra Nevada; water quality sampling; data interpretation and management; preparation of reports, grant proposals, and publications, computer programming for data reduction and storage; mapping of geology, soils and runoff-producing areas; and, training of field technicians.

Feb. -- May 1981. Water Quality Intern, Pima Assoc. of Gov'ts., Tucson, AZ. Main duties: water quality sampling of agricultural production wells; mapping of groundwater levels; and, coordination of sampling efforts.

PROFESSIONAL SERVICE

May 2009 – present. Peer Reviewer for the scholarly journal, Open Forest Science Journal, for papers related to hydrology and forest and watershed responses to disturbance.

Feb. 2010. Invited Guest Lecturer, Lewis and Clark School of Law course on public lands law:
"PACFISH and INFISH and Imperiled Salmonids on Public Lands" Portland, OR.

Apr. 1995. Invited speaker, Oregon State Univ. Dept of Fisheries and Wildlife Seminar, Corvallis, OR

Apr. 1995. Invited speaker, American Fisheries Society North Pacific International Chapter, Annual Meeting, Vancouver B.C., Can.

Mar. 1995. Invited speaker, American Fisheries Society Idaho Chapter Annual Meeting, Boise, ID.

Nov. 1994. Invited speaker, President's Council on Sustainable Development Workshop, Yakima, WA.

Sept. 1994. Invited speaker, Oregon Water Resources Research Institute Streambank Restoration Conference: "Biological Methods to Stabilize Streambanks--From Theory to Practice," Portland, OR.

Mar.-April, 1994. Peer-reviewer for Henjum et al., 1994. Interim Protection for Late Successional Forests, Fisheries, and Watersheds: National Forests East of The Cascade Crest, Oregon and Washington. The Wildlife Soc., Bethesda, MD.

Jan. 1993-Sept. 1995. Member, Oregon Department of Environmental Quality's (ODEQ) Technical Advisory Committee for Triennial Review of the State Water Temperature Standard.

Mar. 1993. Invited speaker, Northwest Scientific Association Symposium: "Cumulative Effects of Land

Management Practices on Anadromous Salmonids," La Grande, OR.

Aug. 1992 - Sept. 1992. Member, Ad Hoc Consultant Selection Committee for Portland Water Bureau Study of Future Water Supply Needs.

May 1992. Invited Speaker, US Forest Service, Pacific Northwest Region, Regional Workshop on Monitoring Soil and Water Resources, Bend, OR.

May 1992. Invited Speaker, Northern Arizona University, School of Forestry, Graduate Seminar Series, Flagstaff, AZ.

Jan. 1991 - Mar. 1995. Member, Technical Work Group: Upper Grande Ronde River Anadromous Fish Habitat Protection, Restoration and Monitoring Plan.

Aug. 1989 - Feb. 1990. Member, Technical Advisory Committee to ODEQ for development of definitions for level of beneficial use impairment by nonpoint sources.

May 1989 - Jan. 1991.Member, Nonpoint Source Technical Advisory Committee to Idaho Department of Environmental Quality: Coordinated Nonpoint Source Monitoring Program For Idaho.

PROJECT MANAGEMENT

1993-1996. Technical Assistance Contract with NMFS to produce technical guidance for ESA consultations for effects of land management on critical habitat for Columbia basin salmon. Main duties: Primary Investigator; primary author of peer-reviewed reports including proposed guidelines for salmon habitat effects assessment (Rhodes et al., 1994), evaluation of land management plans' protection of critical salmon habitat (Rhodes, 1995), and evaluation of models for estimating land management effects on salmon habitat (Rhodes, 1996); available scientific literature review; budget tracking; project coordination. Total budget: $230,000.

1998-2000. Watershed Evaluation and Aquatic Habitat Response to Recent Storms. Main duties: Primary Investigator; design and implementation of monitoring methods, coordination of technical staff in 10 watersheds with differing levels of grazing and logging in 3 subbasins in Idaho, Washington, and Oregon; technical training; data analysis; contract administration; proposal development; report preparation; budget development and tracking; coordination with grantor representatives. Total budget: $164,000.

1998-2000. Evaluation of Effects of Grazing on Rate of Salmon Habitat Recovery. Main duties: Primary Investigator; design and implementation of monitoring methods, training of field technician; data analysis and synthesis; proposal development; preparation of progress reports; budget development and tracking; coordination with grantor representatives. Total budget: $73,000.

1998-2001. Monitoring Fine Sediment Levels in Salmon Habitat in Grande Ronde and John Day Rivers. Main duties: Primary Investigator; design and implementation of methods for monitoring fine sediment levels in four rivers; field technician training; data analysis and synthesis; subcontract administration; proposal development; progress and technical report preparation; budget development and tracking; coordination with grantor representatives. Total budget: $128,000.

2001-2002. Western Native Trout Campaign, Aquatic Scientist and Coordinator. Main duties: Oversight and assurance of scientific integrity of all reports and work products; coordinate conservation efforts among campaign member organizations and other groups working to protect and restore trout habitats and populations; budget tracking; technical and progress report preparation.

HONORS AND AWARDS

1996. Leadership and Excellence. Col. River Inter-Tribal Fish Comm., Portland, OR

1991. Employee of the Year. Col. River Inter-Tribal Fish Comm., Portland, OR

1984. Academic Recruitment Scholarship for Outstanding Graduate Prospect. Univ. of Wash, Seattle, Wash.

1982. Maxey Award -- Outstanding Graduate Student Paper in Hydrology. Univ. of Nev.-Reno.

1980. Winslow and Myron Reuben Scholarship for Outstanding Undergraduate in the Earth Sciences. Univ. of Ariz., Tucson, Az.

ADDITIONAL TRAINING

1993. USFWS Water Temperature Modeling via SNTEMP

1991. USFWS Introduction to IFIM Investigations
